- ²⁴NJ: A physician who administers or supervises the administration of general anesthesia must complete at least 60 Category I hours of CME in anesthesia; regional and conscious sedation-8 hours. (upheld by NJ Supreme Court)
- ²⁵NJ: Physician who performs surgery should have hospital privileges or seek Board-approved privileges.
- ²⁶NJ: Report within 7 days death, transfer to hospital exceeding 24 hours., untoward event occurring within 48 hrs. of surgery.
- ²⁷NC: Level II or III should show substantial compliance with guidelines or obtain accreditation.
- ²⁸NC: MD should be credentialed by hospital, ASC or comply with Board criteria to perform surgical or special procedures that require administration of anesthesia.
- ²⁹NC: Should report complications.
- ³⁰NY: Effective July 14, 2009.
- ³¹NY: Effective January 14, 2008, licensees (physicians, physician assistants, and special assistants) must report adverse events to the Department of Health's Patient Safety Center within one business day of the occurrence.
- ³²OH: Required if using moderate sedation/analgesia or anesthesia services (deep sedation/analgesia, regional or general anesthesia)
- ³³OH: Moderate sedation/analgesia: Hold privileges to provide moderate sedation/analgesia from hospital or ASF or complete at least 5 hours of Category I CME; Deep sedation/analgesia, regional or general anesthesia; Hold privileges to provide anesthesia services from hospital or ASF; Completed a residency training program in anesthesia; or completed at least 20 hours of category I CME. Qualifications apply whether a CRNA or anesthesiologist administers anesthesia.
- ³⁴OH: Holding current privileges at hospital or ASF, among other qualifications, demonstrates sufficient certification, training, experience.
- ³⁵OR: Accreditation by a Board-recognized national or state organization. Facilities where office surgeries are already being performed, accreditation by August 1, 2009; new offices must be accredited within 1 year of the start date of the procedures being performed.
- ³⁶RI: Office shall apply within 9 months of initial licensure; attain within 24 months.
- ³⁷RI: Surgical procedures shall only be performed by physicians or podiatrists who have current surgical privileges for the same or similar class of procedures at a nearby hospital.
- ³⁸RI: Within 72 hrs. of receipt of information, notify of death within 30 days, transfer to ER, hospital admission within 72 hrs. of discharge, extension of surgical procedure beyond 4 hrs., unplanned readmission to office operative within 72 hrs., subjecting patient to procedure not offered or intended by physician, incidents reported to malpractice insurer.
- ³⁹SC: Level II, III
- ⁴⁰SC: Level I: Surgeon is encouraged to pursue CME in proper dosages, management of toxicity or hypersensitivity to local anesthetic and other drugs.
- ⁴¹SC: Surgeon must have staff privileges or document satisfactory completion of training such as Board certified or Board eligibility, or comparable background, formal training, experience.
- ⁴²SC: Report within 3 business days anesthetic or surgical mishaps requiring resuscitation, emergency transfer, or death.
- ⁴³TN: Level III by AAAHS, AAAASF, or JCAHO.
- ⁴⁴TN: Level III; Physician performing office procedure must have staff privileges to perform same procedure at hospital within reasonable proximity.
- ⁴⁵TN: Applies to Level II surgeries; report within 15 calendar days following physician's discovery of event.
- ⁴⁶TN: Level II: required if physician performing procedure does not have staff privileges at hospital withing reasonable proximity.
- ⁴⁷TX: Physicians shall follow ASA standards and guidelines.
- ⁴⁸TX: Offices accredited by AAAHC, JCAHO, and AAAASF and those that are part of a licensed hospital or ASC are exempt from the guidelines.
- ⁴⁹TX: Notify BME within 15 days if procedure resulted in unanticipated and unplanned transport to hospital for period exceeding 24 hrs., death intraoperatively or within 72 hrs. of procedure.
- ⁵⁰TX: If physician does not have hospital privileges must have written transfer agreement.
- ⁵¹VA: Report within 30 days incidents resulting in death within 72 hr. post-operative period or transport to hospital exceeding 24 hrs.

TABLE 35-4. Similarities and Differences Between Various Accreditation Organizations

Accreditation Body	AAAASF	AAAHc	TJC
Medicare deemed status	Yes	Yes	Yes
Requires board certification of surgeon	Yes	No	No
Requires physician supervision of anesthesia*	Yes	Yes	Yes
Additional educational requirements for nonanesthesiologists supervising	Yes	No	No
Accreditation cycle	3 Years	6 Months, 1 year, or 3 years	3 Years
Approximate base cost†	\$4265	\$3000-\$5000	\$6950
Corporate website	www.aaaasf.org/	www.aaahc.org/	www.jointcommission.org

From Accreditation Association for Ambulatory Health Care (AAAHc): *Summary of state activities on office-based surgery, August 2003 update*, accessed, September 29, 2003.

*This requirement may not apply in the event a state's governor has opted out of the physician supervision of nonanesthesiologist anesthesia providers requirement.

†Cost for an accreditation survey may be influenced by the number of offices to be accredited, the number of surgeons and surgical specialties, and whether a facility is asking for Medicare "deemed" status.

AAAASF, American Association for Accreditation of Ambulatory Surgical Facilities; AAAHC, American Association for Ambulatory Health Care; TJC, The Joint Commission.

(2003) reported no deaths in over 5000 cases. However, these authors noted that several patients required hospital admission for various medical problems.

Another dynamic that is and will continue to influence the push toward accreditation is the recognition by payers of the significant cost savings that can be realized in the office-based setting. Although the payers want to leverage these savings, they have to be reassured and be able to reassure their subscribers that they will only sanction care in a safe environment. Because the industry standards have been established by the accrediting bodies, it wouldn't be surprising if this fueled the push toward uniform requirement for accreditation more quickly than the state legislatures or the federal government.

CLINICAL ASPECTS

Particular attention must be paid to patient and case selection, preoperative preparation, special problems related to anesthetic administration, and postoperative care. Absence of a plan specifically related to these issues by the anesthesiologist caring for a child in the office can lead to a practice that is fraught with safety dilemmas and logistic and scheduling problems that negatively impact the success of an office-based anesthesia practice. Time constraints are the rule rather than the exception in office-based practice.

Patient and Procedure Selection

The decision process that occurs when determining which patients are appropriate to care for in the office-based setting does not differ greatly from that of caring for patients in the "free-standing" ambulatory surgery center. The factors that most commonly determine whether a child is an appropriate candidate for office-based anesthesia and surgery are patient age, associated medical illnesses and ASA physical status, type of surgery, potential for blood loss, potential for significant postoperative complications, and duration of surgery.

Because most office-based procedures for pediatric patients involve dental procedures, a majority of the children undergoing these procedures are older than 1 year of age. However, as the realm of office surgery for children expands (including tonsillectomies), and because there are no prospective studies as yet in the office-based anesthesia literature looking at outcomes and patient age for children undergoing office-based surgery, it seems that the present guidelines for other ambulatory surgery venues should be used (Gravningsbraten et al., 2009). When taking this latter point into consideration, the minimum age requirement (other parameters such as type of procedure not withstanding) for children undergoing office-based procedures can be determined by whether a child requires prolonged postoperative monitoring based on postconceptual age or the administration of opiate analgesics and other respiratory depressant agents (Welborn and Greenspun, 1994; Galinkin and Kurth, 1998). Although postanesthesia care unit (PACU) complications resulting from respiratory complications may be more common in neonates and infants, any other minimum age requirements are often arbitrary and may reflect the comfort level of the surgeon, office staff, and anesthesia personnel caring for the child (Westman, 1999; Ross and Eck, 2002; Murat et al., 2004). Adherence to policies and guidelines set forth for minimum age requirements for outpatient anesthesia in ambulatory surgery centers and hospital-based ambulatory surgery departments is critical.

Most children cared for in the office-based setting are ASA PS I and II patients. In some situations, it may be acceptable to provide anesthesia care for those children with stable comorbidities who are ASA PS III patients despite the fact that these patients in general may be more susceptible to adverse outcomes from anesthesia (Murray, 2002; Murat et al., 2004; Jimenez et al., 2007). Not surprisingly, getting consensus from pediatric anesthesiologists as to which comorbidities are appropriate for hospital-based or free-standing ambulatory surgery is difficult, but some of the pediatric comorbidities considered high risk for the office-based surgical suite are listed in [Box 35-2](#) (Abu-Shahwan, 2007).

In an early prospective study looking at prolonged recovery stay and unplanned hospital admission after ambulatory surgery in pediatric patients, the authors reported annual rates of approximately 4% and 2%, respectively. PONV and respiratory complications were the most common factors leading to prolonged recovery stay, whereas respiratory complications (32%) and surgical reasons (30%) were the factors most commonly responsible for unplanned hospital admission. These authors also found that higher ASA physical status had a direct relationship to unplanned hospital admission and adverse respiratory events (D'Errico et al., 1998).

Subsequently, Dornhoffer and Manning (2000), in a retrospective chart review, evaluated unplanned hospital admission

Box 35-2 Pediatric Comorbidities Considered High Risk for the Office-Based Surgical Suite

- Obstructive sleep apnea
- Labile asthma and other significant pulmonary disease
- Complex congenital heart disease
- Labile diabetes mellitus
- Significant neurologic and neuromuscular disorders
- Sickle cell disease
- Upper respiratory tract infection
- Increased body mass index

after four types of otologic procedures (not including myringotomy tube placement) in adult and pediatric outpatients. The unplanned hospital admission rates for children and adults were 5.7% and 2.3%, respectively. The most common reason for unplanned hospital admission was PONV. These findings are relatively consistent over time, and in a more recent study, Blacoe and others (2008) in Scotland found an overall unplanned admission rate of 1.8% in over 13,000 day-surgery cases. The combined percentage of admissions for two surgical complications (postoperative bleeding, 13.9%, and more extensive surgery than planned, 11.8%) exceeded that for the most common anesthesia-related cause for admission, PONV (23.5%).

Dornhoffer and Manning (2000) also noted that tympanomastoidectomy with ossicular reconstruction, procedures lasting longer than 2 hours, and asthma were risk factors predicting the need for postoperative admission. In contrast to this study, Mingus and others (1997) reported that surgical cases lasting as little as 1 hour may be associated with a higher rate of unplanned hospital admission.

In a study by Fortier and others (1998) involving over 15,000 patients, unplanned hospital admission after ambulatory surgery was related to longer duration of anesthesia and surgery, higher ASA PS (classes II and III), postoperative bleeding, excessive pain, and nausea and vomiting. Of note, and similar to the more recent study of Blacoe and others (2008), is that surgical reasons are identified to be more commonly responsible for hospital admission than are anesthesia-related issues (38% and 25%, respectively). The fact that the office-based setting is best suited for those children who are healthy without significant comorbidity and are undergoing minimally invasive procedures may inherently result in few postoperative complications.

Preoperative Preparation

Preanesthetic Interview

As is the case with ambulatory surgery in general, rarely is the preanesthetic interview for office-based surgery for pediatric patients conducted in person. For the anesthesiologist who works in a limited number of offices, preanesthetic interviews may be possible during the patient's presurgical office visit if the anesthesiologist should be attending that particular office on the same day. This is the exception rather than the rule when anesthesiologists provide itinerant care for a multitude of offices. Although some authors have advocated presurgical

evaluation in certain instances on the same day of surgery (Overdyk et al., 1999; Mangia et al., 2009), citing economic and logistic advantages for practitioners and patients, most preanesthetic interviews will be initiated by telephone before the day of surgery.

The preanesthetic interview for office-based procedures does not differ much from that described for other ambulatory settings (Ferrari, 2004; Polaner, 2006). However, there are caveats relative to the preanesthetic interview for an office-based procedure.

First, the anesthesiologist should make some initial contact with a child's parents or guardian before the day of surgery. Unlike the ambulatory surgery center or hospital-based ambulatory surgery department, the parents often cannot associate their child's scheduled procedure with the community-acquired reputation of a particular private or academic institution. An anesthesiologist's reputation in the office-based environment is based on the advocacy of the child's private physician, surgeon, or dentist and unfortunately is only as good as the anesthesiologist's last case (or self-advocacy literature). The initial telephone interview must be used as a way to instill confidence in his or her abilities and to alleviate parental anxiety by relating one's level of experience or training background or by discussing a cogent and acceptable anesthetic plan. These few "public relations" minutes are invaluable.

Second, the interview process must elicit enough of a history to determine whether a child is a candidate for the scheduled office-based procedure or whether the procedure needs to be delayed. The dreaded same-day cancellation leaves an undesirable block of open time for the anesthesiologist and the surgeon. Finally, in many instances, the preanesthetic telephone interview is used not only as the mechanism by which parents receive final preoperative instructions (e.g., NPO guidelines, medication instructions) but also to make final financial arrangements.

Preoperative Laboratory Testing

Because most children receiving office-based anesthesia services are healthy and are undergoing minimally invasive procedures, the necessity for preoperative laboratory testing is rare. As is advocated by other authors, any laboratory testing should be determined on an individual patient basis by clinical need after the preanesthetic interview (Meneghini et al., 1998; Friedberg, 2003; Maxwell, 2004; Polaner, 2006). Despite agreement on the lack of clinical utility and increased cost of routine preoperative laboratory screening among anesthesia professionals, an anesthesiologist providing office-based anesthesia services must be aware of any state and local government mandates for such testing. Additionally, each practitioner must establish a policy for determining the cost-to-benefit yield (especially in the office setting where cost savings are a key advantage) on more controversial laboratory testing such as pregnancy testing, especially in adolescents and teenagers (Wheeler and Coté, 1999; Hennrikus et al., 2001; Kahn et al., 2008; Bodin et al., 2010).

Preoperative Sedation

Despite the ostensibly less intimidating environment of the office, the anxiety that pediatric patients (and their parents) undergoing office-based procedures experience is probably no less than that in other surgical environments. The need

for preoperative sedation or some other useful mechanism by which the anesthesiologist can reduce preoperative anxiety is critical for a couple of reasons. First, parents are becoming more educated about the perioperative process via the Internet and the lay press, and second, the space-limited environment of many office practices and the close proximity to office waiting rooms and other patients may make preoperative sedation of children most at risk for preoperative anxiety even more important (Baldauf, 2009).

The group of children most likely to undergo a mask induction of anesthesia is also the age group of children most likely to experience preoperative anxiety (Kain et al., 1996, 2002; McCann et al., 2001; Watson and Visram, 2003). Most children receiving preoperative sedation receive midazolam (McCann et al., 2001; Rosenbaum et al., 2009). Although various routes of administration are advocated, including intranasal and rectal, oral administration of midazolam is the most common (Levine et al., 1993; Davis et al., 1995; Griffith et al., 1998; McGraw and Kendrick, 1998; Marhofer et al., 1999). Ease of administration as determined by acceptance by the child, in most instances, dictates the route of administration. Most often in practice, a dose of 0.5 to 1 mg/kg (maximum dose, 20 mg) orally is effective.

Although some have found that certain routes of administration of midazolam have no impact on discharge times (Davis et al., 1995; Kain et al., 2000), others find that there are significant delays in recovery or discharge times with the use of orally administered midazolam in combination with various anesthetic techniques (Viitanen et al., 1999).

Despite a report on the decreased efficacy in the levels of preoperative sedation using oral melatonin compared with oral midazolam, Kain and others (2009) did show a significant ($p < 0.05$) dose-related lower incidence of emergence agitation (another office undesirable) in those patients receiving melatonin. Furthermore, the use of combination preoperative sedation, such as intramuscular ketamine and midazolam, in uncooperative children may be inappropriate for the office-based setting because of prolonged discharge times (Verghese et al., 2003).

For children tolerating preoperative intravenous catheter placement (with or without application of local anesthetic cream), the use of midazolam may not be necessary. Small repeated doses (0.25 to 0.5 mg/kg) of intravenous propofol under constant monitoring provide excellent preoperative analgesia without respiratory depression and in most instances will provide excellent amnesia to the immediate preoperative period. This technique is especially advantageous in short surgical procedures. However, propofol is associated with pain on injection, and lidocaine may have to be added to the bolus syringe or infusion.

The benefit of parental presence in reducing preoperative anxiety remains questionable (to the child and parent), especially compared with other nonpharmacologic and pharmacologic approaches to preoperative anxiety reduction (McCann et al., 2001; Kain et al., 2003; Chundamala et al., 2009; Yip et al., 2009). Whatever a practitioner's personal preference, the office-based environment may provide an excellent opportunity for parental presence during induction of anesthesia, especially in cases where sterility concerns are minimal, such as for dental restoration or radiologic procedures.

When choosing parental presence as the sole method of anxiety reduction, it is important to consider the information available that may enhance the success of this approach. Some

authors report that specific patient behavior profiles, specific parent-child anxiety level combinations (e.g., calm parent and anxious child), and the presence of a child's mother as opposed to the father may have the most impact on reducing the anxiety level of the child (Messerli et al., 2004; Kain et al., 2006a; Chorney and Kain, 2009).

If the administration of a preoperative sedative is indicated, the anesthesiologist must take into consideration whether the benefit of sedation (to the patient, parents, waiting patients, and office staff) outweighs the chance that the sedative will delay discharge after anesthesia. This is particularly true in instances where a physician must be present until the patient is discharged to home.

Intraoperative Care

The intraoperative care of the pediatric patient in the office-based setting relative to induction and maintenance of anesthesia does not differ much from that in other ambulatory settings. Despite the minimal standards set forth by most states relative to office-based anesthesia, from the anesthesiologist's perspective, monitoring and equipment standards and guidelines must not be different for the office than for other surgical and anesthesia sites. The anesthesiologist should adhere to the *Standards for Basic Anesthetic Monitoring and Guidelines for Office-Based Anesthesia* (ASA, 2005, 2009b) (see Chapters 10 and 11, Equipment and Monitoring). With this in mind, anesthetic technique is limited only by the equipment, supplies, and resources of the physical plant that are available.

Most office-based surgical procedures using anesthesia require intravenous access and hydration. The child's fluid deficit is based on the fasting period and is replaced with lactated Ringer's solution.

Despite liberalizing the fasting period (clear liquids 2 to 3 hours before anesthesia), administration of intravenous fluids both during and after the surgical procedure is important. There is evidence in both adult and pediatric populations that aggressive intraoperative fluid management may in fact decrease the incidence of PONV (Holte et al., 2007; Goodarzi et al., 2009).

Anesthetic Technique

The concepts of "rapid onset, rapid recovery, and minimal side effects," used often to describe the important characteristics of an appropriate anesthetic technique in an ambulatory setting, is equally important for the office setting. Although all types of anesthesia, including regional anesthesia, can be used in the office setting, general anesthesia and varying levels of sedation are most often used in children (Hausman, 2008).

Even though anesthesiologists debate the clinical (safety and outcome) and cost efficacy of relatively newer anesthetic agents (e.g., sevoflurane, desflurane, remifentanyl, and propofol) compared with some of the older agents (e.g., halothane and isoflurane), these newer agents offer a distinct advantage as it relates to their predictability and perhaps their safety (Tang et al., 1999; Moore et al., 2002; Fishkin and Litman, 2003; Bhananker et al., 2007). All levels of the continuum of anesthesia (minimal sedation to general anesthesia) are used in the office setting. The type of anesthesia is determined by the age and cooperation level of the child, the type of procedure, the ease with which

local anesthetic can be administered, its efficacy in a particular surgical procedure, the specific routine of the anesthesiologist, and as stated previously, the available equipment.

General anesthesia can be accomplished by using a pure volatile technique, a total intravenous technique, or a combination of the two (volatile induction with intravenous maintenance) techniques. The first and latter obviously depend on the availability of an anesthesia machine and on whether a specific office can comply with OSHA requirements relative to appropriate gas scavenging. Some surgical offices, depending on surgical volume and cost efficacy, may provide the anesthesiologist with a standard anesthesia machine; in other instances, the anesthesiologist may transport a single-vaporizer-equipped portable anesthesia machine to each office (Barinholtz, personal communication, 2009).

All of the newer volatile agents are efficacious in pediatric ambulatory surgery (Moore et al., 2002; Polaner 2006). However, if the anesthesiologist is transporting a machine with single-vaporizer capability, then sevoflurane may be the agent of choice because of its efficacy in both induction and maintenance of anesthesia, as well as its rapid onset and offset characteristics. Although some advocate the use of desflurane for maintenance of anesthesia for ambulatory surgery because of its predictability relative to emergence, it is impractical as a complete office-based anesthetic agent in children because of its lack of efficacy for inhalation induction (Zwass et al., 1992; Olssen, 1995; Smiley, 1996; Fishkin and Litman, 2003). Similarly, the intravenous agents propofol and remifentanyl have been shown to be useful in the ambulatory setting (Hannallah et al., 1994; Davis et al., 1997, 2000; Pinsker and Carroll, 1999; Cohen et al., 2001).

Although remifentanyl can be used successfully in an ambulatory setting when the airway is secured with an endotracheal tube, evidence suggests this narcotic should be used cautiously when the airway is not secured. Litman (1999) evaluated the use of remifentanyl for moderate sedation in 17 patients (20 procedures) aged 2 to 12 years who were undergoing short, painful procedures. All patients received intravenous midazolam, 50 mcg/kg, in combination with remifentanyl 1 mcg/kg followed by an initial infusion of remifentanyl of 0.1 mcg/kg per minute. The remifentanyl infusion was then titrated every 5 minutes to provide adequate sedation and analgesia. The average appropriate dose of remifentanyl used was 0.4 mcg/kg per minute. Although the author reported successful use of this technique in 17 of 20 procedures, 1 child became unresponsive and required assisted ventilation, and hypoxemia was avoided in 10 of 13 children by continuous stimulation during the procedure.

In adults, the combination of a propofol infusion, titrated to bispectral analysis (BIS) number, and intermittent ketamine boluses has been reported (Friedberg and Sigl, 2000; Friedberg, 2003). In children undergoing dental restoration procedures, Barinholtz (2009) noted that combining propofol (100 to 200 mcg/kg per minute, titrated by BIS) with ketamine (0.5- to 1.0-mg/kg boluses) completely avoided the need for opiate analgesics. In contrast to these latter two reports, successful implementation of sevoflurane for maintenance of anesthesia for dental restorations has been reported by multiple authors (Abu-Shahwan and Chowdary, 2007; König et al., 2009).

Although it appears that any agent can be safely implemented in the office-based setting, it is imperative that the office-based anesthesiologist develop an anesthetic routine that allows for

an expeditious induction with appropriate maintenance levels of anesthesia while at the same time affording a rapid emergence. It is also essential that this anesthetic routine minimize the incidence of postoperative side effects such as nausea and vomiting.

Another critical aspect of intraoperative anesthesia care in the office-based setting is airway management. Although multiple factors determine the type of airway, any type of airway from a mask to laryngeal mask airway to an endotracheal tube may be appropriate. For some procedures, especially when using only sedation, airway intervention is usually minimal; on the other hand, deciding on the appropriate airway intervention may be difficult in other cases. This is particularly true when providing anesthesia for dental or other intraoral procedures.

Many dental cases are performed with oral sedation and nitrous oxide; however, longer dental restoration procedures may necessitate the use of an endotracheal tube (Saxen et al., 1999; Ross and Eck, 2002; Barinholtz, personal communication, October 2009). This is most prevalent in offices where the anesthesiologist may have limited access to the patient's airway because of positioning or cramped quarters. Subsequently, ventilation is controlled by hand or mechanical means or the patient is allowed to breathe spontaneously. The anesthesiologist must be judicious in the use of muscle relaxants to facilitate intubation. Prolonged effects of these agents may lead to delayed emergence and consequently delayed discharge and turnover for subsequent cases.

Another concern for the anesthesiologist practicing in an office-based setting is emergence agitation. The incidence of emergence agitation is reported to be approximately 12% to 18%, but Faulk and others (2010) report an incidence of approximately 30% in 400 patients undergoing dental procedures under general anesthesia with sevoflurane. The etiology of emergence agitation appears to be multifactorial and is associated with inadequate postoperative analgesia, high preoperative anxiety levels, rapid emergence, and the newer volatile agents, and it is reported to occur with both intravenous and volatile anesthetic techniques (Kain et al., 2006b; Vljakovic and Sindjelic, 2007; Kuratani and Oi, 2008; König et al., 2009).

There may be some benefits, although inconsistent, to preoperative sedation with various agents such as midazolam, clonidine, and melatonin in reducing the incidence of emergence agitation (Cox et al., 2006; Almenrader et al., 2007; Kain et al., 2009). The incidence of emergence agitation is also shown to be reduced by the intraoperative use of regional anesthesia, opiates, 5-HT₃ receptor antagonists and dexmedetomidine, as well as the administration of ketamine or propofol at emergence from sevoflurane anesthesia (Cohen et al., 2002; Ibacache et al., 2004; Weldon et al., 2004; Lankinen et al., 2006; Abu-Shahwan and Chowdary, 2007; Abu-Shahwan, 2008; Kim et al., 2009).

Depth of Anesthesia Monitoring

The central theme of office-based anesthesia is to accomplish excellent, safe, time-efficient, and cost-effective anesthesia. Hence, the anesthesiologist can look favorably on any technology that can possibly aid in achieving these goals simultaneously.

The BIS monitor (Aspect Medical; Newton, Massachusetts) was originally described as able to determine the level of sedation, predict the loss of consciousness, and thereby diminish

intraoperative awareness when used with various anesthetic agents (Glass et al., 1997). Although in some early reports BIS was shown to minimize awareness, decrease anesthetic use, or hasten recovery in adult patients, a more recent report of a prospective study of 2000 adult patients by Avidan and others (2008) describes no advantage to using accepted target values for BIS (40 to 60) over target values of end-tidal anesthetic concentrations in preventing anesthesia awareness or in reducing the administration of volatile agent (Glass et al., 1997; Song et al., 1997). Consequently, these authors did not recommend routine use of BIS monitoring during anesthesia.

The use of the BIS monitor is also controversial in pediatric anesthesia. A standard BIS number or range of numbers that precludes anesthesia awareness and simultaneously minimizes the amount of anesthesia delivered is difficult to establish, because subgroups of pediatric patients may have different baseline BIS numbers as is reported by Valkenburg and others (2009). In this report, intellectually challenged patients are found to have significantly lower BIS numbers while awake and while under anesthesia compared with patients in a controls group. This inconsistency is relevant, because care for intellectually challenged and special-needs children is commonplace in one of the higher volume areas using pediatric office-based anesthesia, the dental office. (Lalwani et al., 2007).

In a report on an electronic mail survey of members of the British and French pediatric anesthesia societies, over 60% of respondents feel that intraoperative awareness is an important issue in pediatric patients, whereas 10% of respondents report using BIS routinely (Engelhardt et al., 2007). Thus, the vast majority of respondents still continue to use clinical monitoring and end-tidal agent concentrations to assess depth of anesthesia.

There are also pediatric-anesthesia studies reporting advantages to BIS monitoring in patients receiving various types of anesthesia for a range of diagnostic and surgical procedures (Denman et al., 2000; Bannister et al., 2001; McCann et al., 2002; Religa et al., 2002; Messieha et al., 2005; Powers et al., 2005).

Denman and others (2000) found that in children ages 0 to 12 years who were anesthetized with sevoflurane, the BIS value correlated to the depth of anesthesia. Furthermore, this study also found that for a particular level of anesthesia (BIS = 50), children younger than 2 years had a significantly higher end-tidal concentration of sevoflurane than did children ages 2 to 12 years (1.55% vs. 1.25%, respectively). Bannister and others (2001) studied the effect of BIS on anesthetic use and recovery in 240 children. They noted that in patients aged 0 to 6 months the BIS had no effect on anesthetic emergence. However, in older children, BIS was associated with less anesthetic administration and an earlier emergence time.

Religa and others (2002) evaluated the association between BIS and level of consciousness in pediatric patients (aged to 6 years) undergoing dental procedures using a sedation protocol. These authors find that there is a significant association between behavioral responses and levels of sedation. However, the authors note that BIS offered no advantage over routine clinical monitoring and behavioral assessment in this setting.

Messieha and others (2005) report earlier times to extubation (5 ± 2 minutes sooner, $p = .04$) and PACU discharge (47 ± 17 vs. 63 ± 17 minutes, $p = .02$) in BIS-monitored patients receiving standardized doses of preoperative sedation with oral midazolam and sevoflurane for induction, with maintenance of anesthesia for dental procedures. Whereas these few “saved” minutes may

seem germane to the office-based setting, the cost effectiveness and clinical utility of level-of-consciousness monitoring across pediatric subpopulations still need to be elucidated.

Postanesthesia Care

As in any ambulatory setting, the patient undergoing office-based surgery must meet established criteria before discharge to home, with the goal being to discharge the patient as quickly and as safely as possible (Patel et al., 2001). Actual discharge criteria include an adequate level of consciousness, good pain control, good hydration, minimal to no nausea, and a defined period of time since the last emesis (Ross and Eck, 2002; Fishkin and Litman, 2003). Furthermore, the appropriate personnel (at the minimum that which is outlined by the *ASA Guidelines for Office-Based Anesthesia*, 2009b) must remain with the child until discharge-ready status is reached.

The causes for delayed discharge can be related to either anesthesia or surgery, but in the ambulatory setting two of the most common non-life-threatening causes are inadequate pain control and PONV. Unlike the typical ambulatory setting, where there exists the capability to care for patients with a prolonged recovery period, the office-based setting has little margin for error relative to these two problems.

Postoperative Pain Control

The undertreatment of pain in pediatric patients in traditional surgical and hospital settings continues to be an issue (Stamer et al., 2005; Segerdahl et al., 2008; Fortier et al., 2009). In fact, one study that compared oral ibuprofen (10 mg/kg) with oral acetaminophen with codeine (1 mg/kg per dose of the codeine component) for the emergency room treatment of acute arm fractures found that ibuprofen was more preferable to (because of its side-effect profile) and at least as effective (analgesia) as acetaminophen with codeine; however, the high incidence of treatment failure in both groups, 20.3% and 31.0%, respectively, although not statistically significant between the groups, is clinically relevant to the previous point of potential undertreatment of pain in pediatric patients (Drendal et al., 2009).

With this latter point in mind, the goals for postoperative pain control in the office setting are not dissimilar from the overall goals for office-based anesthesia and surgery. In situations where the use of local anesthesia is not possible or feasible, the anesthesiologist must attempt to use analgesic agents that are efficacious, have minimal side effects, and do not delay patient discharge.

Although various opiate analgesics are routinely used in pediatrics and can be administered via conventional (e.g., intravenously, intramuscularly while asleep, or orally) and less conventional (e.g., intranasally) routes in traditional ambulatory surgery settings, their use in the office setting is often minimized or eliminated to help avoid postoperative sedation and PONV that are specific to drugs, dose, and perhaps patients (Weinstein et al., 1994; Anderson et al., 2000; Galinkin et al., 2000; Finkel et al., 2001; Duedahl et al., 2007; Howard et al., 2008a, 2008b; Voronov et al., 2008). Furthermore, because a preponderance of complications leading to unplanned hospital admission after ambulatory surgery in infants is related to the respiratory system, opiate use, which can cause respiratory depression in this age group, could potentially increase these numbers (Westman, 1999).

Because most office-based procedures in children are minimally invasive (at least for now), standard use of nonopioid analgesics such as the nonsteroidal antiinflammatory drugs (NSAIDs) and acetaminophen, when not contraindicated, is advocated. Ketorolac is found to be useful with an excellent safety profile for postoperative analgesia in a variety of pediatric surgical procedures, and it can be administered intravenously in a dose of 0.5 to 0.8 mg/kg (maximum dose, 30 mg) (Lynn et al., 2007).

Relative to pediatric dental procedures, Needleman and others (2008) report that 95% of 90 children undergoing dental rehabilitation under a standardized general anesthesia regimen without local anesthetic infiltration experience postoperative pain. Increased postoperative pain was reported to be more likely in children who had dental extractions, those at least 4 years of age, and those who had experienced a greater number of procedures. It seems intuitive, then, that local anesthetic infiltration should be an excellent analgesic supplement for children undergoing dental rehabilitation. However, Townsend and others (2009) report that in children, 3 to 5½ years old, undergoing oral rehabilitation while under general anesthesia and receiving local anesthetic infiltration in addition to intravenous ketorolac did no better relative to postprocedural pain than those children receiving intravenous ketorolac alone. In fact, these authors report a greater (but not statistically significant) incidence of lip and cheek biting in those children receiving local anesthetic infiltration.

In some pediatric dental rehabilitation cases done under general anesthesia, patients receive 0.5 mg/kg of intravenous ketorolac with supplemental fentanyl (1 to 2 mcg/kg only when extractions are performed) after induction of anesthesia. More than 95% of patients qualify to bypass phase I recovery and rarely require supplemental analgesics before discharge. Those receiving intraoperative fentanyl receive prophylactic ondansetron, 0.15 mg/kg.

This experience with ketorolac is similar to those of Purday and others (1996) who found ketorolac, 0.75 mg/kg, 1.0 mg/kg, and 1.5 mg/kg to be as efficacious with statistically less PONV as 0.1 mg/kg of morphine sulfate in treating postoperative pain in patients aged 2 to 12 years undergoing dental restoration procedures. Similarly, Maunuksela and others (1992) noted ketorolac to be as efficacious as morphine after pediatric eye surgery. In contrast, Kim and others (2003) report that topical ketorolac is ineffective in treating the pain associated with strabismus surgery. Ibuprofen can also be used to treat postoperative pain, but reports on its effectiveness for some surgical procedures are mixed. Kokki and others (1994) showed that preoperative administration of rectal ibuprofen, 40 mg/kg, divided into four equal doses, was effective in the treatment of postoperative pain in children aged 1 to 4 years in that it reduced the need for supplemental morphine postoperatively. In contrast, Bennie and others (1997), in a double-blind, placebo-controlled study of children older than 6 months who were undergoing bilateral myringotomy and tube placement, found no benefit to the preoperative oral administration of ibuprofen (10 mg/kg) or acetaminophen (15 mg/kg) in the treatment of postoperative pain compared with a placebo group. Joshi and others (2003) reported success with preoperatively administered oral rofecoxib, a cyclooxygenase-2 NSAID, given in a dose of 1 mg/kg, in treating postoperative pain and reducing PONV in children (3 to 11 years old) undergoing tonsillectomy.

Acetaminophen administration is also effective for postoperative analgesia, especially in procedures resulting in mild or moderate pain (Tobias, 2000). Although high-dose acetaminophen (40 mg/kg) administered rectally has been shown to be effective and has opiate-sparing effects, the restrictive quarters of some offices may make this route of administration somewhat prohibitive (Korpela et al., 1999). Similarly, preoperative high-dose acetaminophen (40 mg/kg), administered orally in a one-time dose is shown to be effective in the treatment of postoperative pain after myringotomy and tube placement in children ages 17 months to 6 years, without reaching toxic plasma levels (Bolton et al., 2002). This is contrary to the aforementioned studies, where oral acetaminophen in standard doses (15 mg/kg) was shown to be ineffective (Bennie et al., 1997).

Although NSAIDs alone, or in combination with acetaminophen are opiate-sparing in certain types of surgical procedures, opiate analgesics are not totally precluded from office-based surgery and may in fact at times be necessary (Purday et al., 1996; Hiller et al., 2006; Riad and Moussa, 2007). When either NSAIDs or acetaminophen is inadequate in the treatment of postoperative pain, then traditional combination drugs such as acetaminophen with codeine (0.5 to 1.0 mg/kg of the codeine component) may be appropriate.

Whether interesting alternatives or adjuncts to traditional analgesia regimen, such as innovative nerve blocks and acupuncture, for specific surgical procedures can be time efficient and efficacious in the office setting warrants further study (Voronov et al., 2008; Lin et al., 2009).

Postoperative Nausea and Vomiting

The etiology of PONV is multifactorial, with perhaps a genetic component in some individuals, and remains a major cause of prolonged discharge time and unanticipated hospital admission after ambulatory surgery in children (Awad et al., 2004; Blacoe et al., 2008; Rueffert et al., 2009). Adequate treatment of this side effect may play a significant role in improving patient satisfaction with the perioperative experience (Eberhart et al., 2002). Furthermore, the incidence of postdischarge nausea and vomiting (PDNV) is also significant after ambulatory surgery and has risk factors that do not totally mirror those of PONV. In fact, PDNV occurs in a significant number of individuals who do not experience immediate postoperative vomiting before discharge (Wu et al., 2002; Kolodzie and Apfel, 2009). The optimal treatments of both PONV and PDNV, whether prophylactic or rescue, are essential because of the negative influence these entities can have on an office-based practice (Tang et al., 1999; Kolodzie and Apfel, 2009).

Prophylactic and rescue treatment of PONV and PDNV may not be completely effective, but Engelman and others (2008) show significant risk reduction in postoperative vomiting in a meta-analysis of 11 reports of the use of single- and multiple-drug pharmacologic prophylaxis regimens in children. With this in mind and in addition to the information previously provided on the low incidences of PONV and PDNV anecdotally reported in children and adults by those practitioners intimately involved in the practice of office-based anesthesia, several studies examining the incidence and treatment of PONV and PDNV in this setting are available.

Tang and others (2001) compared the use of propofol-N₂O anesthesia with the use of desflurane-N₂O anesthesia plus antiemetic prophylaxis on the incidence of PONV in patients

undergoing brief, superficial surgical procedures in an office setting. Patients in the propofol group received no PONV prophylaxis, whereas those in the desflurane group received ondansetron (4mg), droperidol (0.625mg), and metoclopramide (10mg) intravenously at the end of surgery. Neither group received opiate analgesics or muscle relaxants, and all patients received local anesthetic at the surgical site and ketorolac for postoperative pain management. The overall incidence of nausea and vomiting was very low in both groups (less than 10%) and did not differ statistically. Patient satisfaction in both groups was excellent.

In another office-based study, Tang and others (2003) compared the addition of 5-HT₃ receptor antagonists to a control regimen in patients receiving desflurane-N₂O maintenance anesthesia after propofol induction. All patients received droperidol (0.625 mg) and dexamethasone (4 mg) as baseline antiemetic prophylaxis. Subsequently, patients were randomly assigned to receive placebo, dolasetron (12.5 mg), or ondansetron (4 mg) intravenously before emergence from anesthesia. The results of this study show that the incidence of nausea and vomiting was the same in all groups.

It is obviously advantageous to the office-based practitioner to be able to predict which children are more likely to experience PONV and PDNV. A scoring system, included in management guidelines published by the Society for Ambulatory Anesthesia, predicting the risk of postoperative vomiting in children was presented several years ago and prospectively validated in another report (Eberhardt et al., 2004; Gan et al., 2007; Kranke et al., 2007). In this scoring system, the presence of one or more specific risk factors (surgery lasting longer than 30 minutes, strabismus surgery, age older than 3 years, and an immediate family with history of postoperative vomiting or PONV) increases the likelihood of postoperative vomiting.

Although the best regimen for the prophylaxis and rescue treatment of PONV/PDNV in children is not known, the approach to management is multimodal (Kovac, 2007). Treatment includes reducing baseline risk factors (e.g., regional vs. general anesthesia and avoiding opiates, nitrous oxide, volatile agents, and neostigmine) when possible (Gan et al., 2007). Other authors show that appropriate hydration and superhydration decrease the incidence of postoperative vomiting in certain surgeries (Scuderi et al., 2000; Goodarzi et al., 2009). On the other hand, interventions such as routine use of an intraoperative nasogastric tube and its inherent difficulties and routine postoperative fasting may not be effective (Kerger et al., 2009; Radke et al., 2009).

Pharmacologically, a multidrug approach to PONV prophylaxis in children is advocated, and medications from several drug classes are effective in prophylaxis and rescue treatment (Gan et al., 2007; Kovac, 2007). Dexamethasone is shown to be an excellent choice for various procedures in the pediatric and adult populations either by itself or in combination with 5-HT₃ receptor antagonists (Splinter, 2001; Subramaniam, 2001; Negri and Ivani, 2002; Sukhani et al., 2002; Liechti et al., 2007). Although the optimal dose for dexamethasone is unknown and reported to be from 0.1 mg/kg when used with ondansetron to 1.5 mg/kg when used alone, Kim and others (2007) report that a dose of 0.0625 mg/kg is as effective as 1 mg/kg (maximum dose, 24 mg) in the treatment of PONV in children undergoing tonsillectomy and adenoidectomy (Splinter and Rhine, 1998; Henzi et al., 2000). Although in a quantitative systematic review, Henzi and

others (2000) found the use of dexamethasone to be safe in otherwise healthy patients, a report by Czarnetzki and others (2008) shows that despite a dose-dependent decrease in PONV, there is an increased risk of bleeding in children receiving dexamethasone who undergo tonsillectomy and adenoidectomy.

Rescue treatment should focus on using agents from different classes of medications from those used for prophylaxis in a particular patient, and there is evidence that ondansetron in oral disintegrating tablets may be effective in preventing PONV and PDNV, specifically in those children who do not require rescue therapy before discharge (Wagner et al., 2007; Davis et al., 2008).

Whether prophylactic treatment of PONV and PDNV, either through a single-drug or multiple-drug approach, in low-risk patients undergoing office-based surgery and anesthesia is clinically and economically efficacious, as opposed to only treating patients who are at moderate and high risk, needs to be determined.

ESTABLISHING AN OFFICE-BASED PRACTICE

The individual or hospital-based surgery-center group must decide whether committing resources to this type of practice is a worthwhile endeavor. The initial investment for this type of practice in the United States can be prohibitive, because the cost may run as high as \$100,000 to \$200,000 (Barinholtz, personal communication, 2009). These costs include, but are not limited to, costs for equipment, supplies and drugs, professional accreditation as discussed earlier, legal services for incorporation of the group, malpractice coverage, professional staff (i.e., physician, nurses, biomedical technicians, and secretarial and billing staff), policy and procedure development, and marketing. Of course, an office to house all of these things is also a necessary expense.

It is also important to consider the type of office-based practice that should be initiated. The group or individual can be committed to one surgeon's office, depending on case volume, or to several surgeons, traveling to various office locations. From a logistic perspective, the former is easier because it allows for centralization of resources, the most important of which are equipment and medications. However, from a business perspective, if an individual or group is going to commit significant resources to establishing an office-based anesthesia practice, it makes sense to diversify among many different clients and across multiple specialties.

A group practice considering an office-based venture must decide whether it can designate a specific number of full-time equivalent staff to this site and still be able to provide sufficient clinical coverage to fulfill its contractual obligation to its home facility. If not, the group must then decide whether the cost of hiring new staff (e.g., physicians, recovery nurses, and technical staff) will be offset by the potential revenue generated by the new practice. As customer service is essential in office-based anesthesiology, the single biggest mistake large practices make when delving into an office-based practice is failure to give the client the personal attention required. For the solo practitioner who may be caught up in the excitement of a new practice, overcommitment to too many surgeons may result in scheduling nightmares and a failure to meet obligations.

The individual or group must also meet the challenge of being able to market against other physicians or physician groups, as

well as alternative and perhaps less expensive anesthesia providers in this competitive arena. Can the group provide a unique service, such as pediatric anesthesia coverage, that will make it more attractive to a particular surgeon or dentist?

Finally, and probably as important as any of the other issues related to establishing an office-based practice, the potential political fallout related to a new practice cannot be overemphasized. An anesthesia group with obligations to specific hospital or surgery center facilities must be ready to justify to administrators its practice of providing office-based anesthesia services to surgeons who typically operate in these administrators' facilities. This diversion of income-generating surgical procedures may be construed as a violation of a group's service agreement and consequently prompt administrators to solicit the services of a new group.

For a busy hospital or surgery center, however, there are now many procedures where the profit margin for the hospital or surgery center is narrow, and the ability to divert these cases from the overcrowded operating rooms to physicians' offices may be looked upon favorably by administrators. Furthermore, this could be an opportunity for a joint venture between the hospital (that owns the equipment) and physician group (that doesn't want to outlay capital dollars).

Equipment and Supplies

Essentially all of the standard anesthesia equipment that is required in hospital ambulatory facilities (operating room and off-site) and surgery centers is required for office-based practice. All monitoring standards must be met in the office-surgical suite. Monitoring equipment must have battery back-up capability, because some offices may not have emergency generator capabilities in the event of power failure. Working in one facility where the equipment is capitalized by the surgeon or capitalized by the anesthesiologist and stored in the surgeon's office is much easier to deal with than the more common alternative of the anesthesiologist bringing the anesthesia workroom from place to place. **Box 35-3** outlines general categories of supplies, standard and emergency, that must be transported to surgical sites by the office-based anesthesiologist. The array of portable equipment that exists these days is more than adequate to meet standards.

Box 35-3 General Categories of Required Supplies Transported by the Office-Based Anesthesiologist

- Anesthesia supply box
- Defibrillator (with appropriate-sized paddles)
- Recovery supply box
- Anesthesia drug box
- Pediatric supply box
- Recovery drug box
- Airway box
- Emergency airway equipment (e.g., LMAs, fiberoptic bronchoscope, and cricothyrotomy kits)
- Portable suction equipment
- Monitoring equipment with disposables
- Malignant hyperthermia tray
- Portable anesthesia machine with vaporizer
- Positive pressure ventilation system
- Oxygen "E" cylinders
- Miscellaneous (e.g., batteries, records, other helpful items)

Courtesy D. Barinholtz, Mobile Anesthesiologists, LLC, 2003.

For those practitioners who provide total intravenous anesthesia, an anesthesia machine is not necessary, but the presence of equipment capable of delivering positive-pressure ventilation with oxygen is mandatory. For those anesthesiologists providing care to pediatric patients, a vaporizer-equipped anesthesia machine is invaluable. Most anesthesia machines are moveable, but there are a few machines that are truly portable and available for care of pediatric and adult patients in the office setting. One such machine is the OBA-1 (OBAMED, Cardinal Medical Specialties; Louisville, Kentucky), which weighs approximately 35 pounds, is vaporizer equipped, and is compatible with magnetic resonance imaging (MRI) devices (**Fig. 35-3**). The OBA-1 allows only spontaneous or manually controlled ventilation, because it is not equipped with an internal ventilator. The Magellan-2200, Model 1/M (Oceanic Medical Products; Atchison, Kansas) and the Narkomed-Mobile (Draeger Medical; Telford, Pennsylvania) are also marketed for office anesthesia, and both contain an internal ventilator. The latter machine, despite its ability to be rolled, is a much heavier

■ **FIGURE 35-3.** Two types of portable anesthesia machines. **A**, The OBA-1 portable, MRI-compatible anesthesia machine. **B**, The DRE Integra portable anesthesia machine. (Courtesy Charles A. Smith, Vice-President of Operations, Research and Development, Cardinal Medical Specialties, Louisville, Ky.)

unit and may not be practical for the anesthesiologist who is changing office venues on a daily basis.

Regardless of the type of machine one chooses to use, caution must be used during transport; maintaining the machine's vaporizer in an upright position is essential to avoid spillage and the administration of an inappropriately high concentration of volatile agent. Often, draining the vaporizer before transport minimizes this risk. Furthermore, familiarity with state and federal safety guidelines relative to the transportation of medical gases is critical.

Whenever a volatile agent or succinylcholine is to be used, one must be prepared to treat malignant hyperthermia. A stock supply of dantrolene must be available, and it is the responsibility of the anesthesiologist or a representative of the practice to proactively educate the surgeon and the surgeon's office personnel on appropriate protocol in the event of a malignant hyperthermia episode (see Chapter 37, Malignant Hyperthermia).

Finally, the office-based anesthesiologist must become aware of and be in compliance with the rules and regulations (federal and state-specific) relative to the delivery, transport, clerical requirements (e.g., related to dispensing and wastage), and storage of opiates and other controlled substances that are used in the office setting.

Staffing

In the United States, the providers of office-based anesthesia services presently fall into one of three major categories (exclusive of the operator-anesthetist scenario): physician anesthesiologists, dentist anesthesiologists (two years of anesthesia training after completion of dental school), and CRNAs. The conditions under which each of these three groups can practice are determined by state regulations regarding the administration of anesthesia in dental and surgical offices. Consequently, the composition of office-based anesthesia groups may vary by geographic location and can be comprised of and owned by all physicians, all dentist anesthesiologists, CRNA groups with and without collaborating physician medical directors, or various combinations of these individuals.

Beyond the anesthesia providers, however, are the ancillary personnel who are necessary to make a busy office-based practice successful. The individuals who are often required include nursing staff, biomedical and technical staff, credentialing personnel, and billing and clerical staff. The number of anesthesia sites a practice covers simultaneously and the volume of cases usually determine the staffing for a particular organization.

In some practices, an anesthesiologist or a CRNA may travel alone to a site. In this instance, the anesthesia provider is responsible for preoperative, intraoperative, and postanesthesia care of the child and requires the assistance of the surgical nursing staff. When multiple cases are performed at a single site, then a surgical office nurse is responsible for monitoring a patient during recovery.

In anesthesiologist-only practices, the preferred scenario is to have a staff nurse, employed by the group, available to assist with induction of anesthesia and to be responsible for monitoring the postanesthesia care of the child. Nurses with critical care or PACU experience, who are certified in advanced cardiac life support and pediatric advanced life support (ACLS-PALS), are best suited for this type of position. Anesthesia practices are

sometimes able to procure reimbursement for the professional services rendered by these nurses for the care of patients in the PACU.

Having such personnel relieves the surgical ancillary staff from any anesthesia-related patient care responsibility and facilitates timely turnover when multiple cases are being performed in a single office. Experienced nurses may also be used to initiate telephone screening to provide patients with their preoperative anesthesia and surgical instructions, coordinate anesthesia scheduling, assist in purchasing supplies and equipment, and educate surgical staff on the specifics of the anesthesia process.

Reimbursement

Mentioned earlier is the potential for cost savings by moving surgical cases from hospital outpatient or ambulatory surgical facilities to the office. Unfortunately, in some arenas, anesthesia-requiring office procedures are the rule because of the lack of insurance coverage for these procedures. This is especially true in pediatric dentistry. With few exceptions in the United States, dental and medical insurance policies traditionally fail to cover the cost of anesthesia or hospitalization for children requiring dental procedures (Saxen et al., 1999; Yagiela, 1999; White et al., 2008). This has forced dentists to minimize costs for these children and their families by performing procedures in the office with or without the aid of an anesthesia provider.

However, the American Dental Association reports that there are at least 31 states that have passed laws since 1995 (Medically Necessary Care or Special Needs Legislation) requiring that medical insurance plans pay for hospital and connected medical expenses (e.g., general anesthesia services) when the dental treatment occurs in the hospital, ambulatory surgery center, or dental office (Box 35-4) (O'Connor, personal communication, January 2010).

Some of the elements of these state laws are similar and often determine which children are eligible to receive coverage based on minimum and maximum age and medical or behavioral conditions. Many of these laws, despite mandating coverage, also outline that any provisions of the existing policy, such as meeting prior authorization requirements by showing medical necessity or payable deductibles, still hold true.

Some states also determine the acceptable facilities where the procedure can be performed by mandating insurance coverage only for procedures performed in the hospital or surgery center. Some laws also exempt dental-only insurance plans from their provisions. The number of states requiring coverage for the anesthesia portion of dental care may continue to increase, resulting in increased access to care for those children having the greatest need, regardless of qualified surgical site.

Reimbursement and collections for anesthesia and surgery in offices are somewhat complex and often work differently for the surgical provider and the anesthesia provider (Koch et al., 2003). Fee-for-service reimbursement can be lucrative for the anesthesiologist in a high-volume cosmetic surgeon's office. However, because patients undergoing cosmetic surgery are often charged a set global fee for a specific procedure, some surgeons may look toward a lower-cost anesthesia provider, so the surgeon may recover a greater amount of the preset fee. This may intensify competition among anesthesia providers for these types of procedures.

Box 35-4 States (Some) Adopting Associated Medical Cost Laws Requiring Medical Plans to Pay for Hospitalization/General Anesthesia When Dental Treatment Must Be Performed in the Hospital or Medical Expenses Incurred When Treatment Is in the Dental Office

Arkansas (2005)	Louisiana (1997)	North Carolina (1999)

Reimbursement from third-party payers is at negotiated rates that usually vary by geographic location and payer. Despite the fact that some payers reimburse anesthesia practices for professional fees and supplies or equipment, there are those that invoke the CMS policy that a facility be licensed by the state in order to bill for the latter. Consequently, this may mean a greater cost burden to the patient (Barinholtz, personal communication, 2003). Koch and others (2003) point out that office-based anesthesia practices may become even more ubiquitous and successful by duplicating cost-recovery strategies of

surgeons—namely, better collection of facility fees and site-of-service differentials that provide for greater reimbursement for procedures performed in offices.

The reimbursement landscape for office-based surgery and anesthesia is improving significantly over the past several years. Payers are recognizing the significant cost savings that can be realized in the office compared with hospitals and surgery centers. Anthem in Virginia recently launched a program that pays facility fees in offices for over 2000 outpatient procedures. Blue Cross of Illinois is going to launch a similar program in 2010. The caveat to collecting these facility fees is that the facility must be accredited by the AAAHC, AAAASF, or The Joint Commission.

SUMMARY

Anesthesiologists are heavily involved in the practice of office-based anesthesia and surgery. Consequently, anesthesiologists must be proactive in ensuring that patient safety is the principal concern for all professionals providing anesthesia services in the office setting. Although there is some progress in this arena, it seems unlikely that the various professional societies, whose memberships are actively involved in office anesthesia and surgery, will agree on a specific set of anesthesia-delivery guidelines. Consistency between states in the regulation of this practice, perhaps in the form of accreditation of both office-based facilities and anesthesia practices, is imperative and may be the only viable alternative in helping to ensure that “the standard of care is the standard of care.” This standard should be applicable regardless of surgical setting or patient age. Only further study will assist in determining whether the safety and cost profiles for office-based anesthesia are comparable with those of other ambulatory settings and ultimately whether office-based anesthesia will continue to be a worthwhile venture.

Among patients who present special problems for anesthesiologists are children whose underlying conditions complicate anesthetic management and may be associated with an increased risk of morbidity. The number of rare diseases that may be encountered in infants and children is great, although only a few are mentioned here. Chosen for discussion are the diseases most commonly seen, those carrying an increased risk related to anesthetic management, and a few of unusual interest. Modifications to the understanding of mechanisms of coagulation are included, along with consideration of coagulopathic states, and there is a comprehensive review of the anesthetic implications of pediatric syndromes associated with genetic, metabolic, and dysmorphic features (Baum and O'Flaherty, 2006). A partial list of syndromes with possible anesthetic implications is included in Appendix D, which can be accessed online at www.expertconsult.com

ENDOCRINE DISORDERS

Diabetes Mellitus

The endocrine condition most commonly dealt with in the perioperative period is the management of glucose homeostasis in children with diabetes mellitus. The prevalence of type 1 (insulin-dependent) diabetes in the United States has remained stable for the past 15 years at 1 in 400 to 600 school-aged children, whereas the incidence of type 2 diabetes is increasing, especially among American Indian, Black, and Hispanic children and adolescents (CDC, 2007c). Diabetes mellitus is the result of an absolute or functional deficiency of insulin production by the pancreas. In type 1 diabetes, this deficiency is caused by an autoimmune pathophysiologic process. Insulin deficiency results in abnormalities of glucose transport and storage and of lipid and protein synthesis. Over time, these metabolic derangements result in the vascular pathology that leads to end-stage complications of renal, cardiac, and eye disease—diseases that typically do not occur before adulthood. The anesthetic implications of type 1 diabetes in children differ from those in adults with the same disease, for whom the primary concern is the type and severity of end-organ disease.

Children with type 1 diabetes may be treated with various types of insulin on a daily basis to maintain tight glucose control with the aid of frequent blood-glucose monitoring. Since 1982, most newly approved insulin preparations have been produced using recombinant DNA technology with laboratory-cultivated bacteria or yeast. This process allows the bacteria or yeast cells to produce complete human insulin. Recombinant human insulin has mostly replaced animal-derived insulin (e.g., pork and beef insulin) in diabetes management (Plotnick and Henderson, 1998). Insulin products called *insulin analogues* are produced so that the structure differs slightly from human insulin (by one or two amino acids) to change onset and peak of action. An example of an analogue is human lispro, an ultra-short-acting insulin that is given only 15 minutes before a meal. Its peak and duration of action parallel the glucose rise that results from carbohydrate ingestion.

Another new insulin is glargine, which almost mimics an insulin pump, providing a continuous, 24-hour, low background

TABLE 36-1. Kinetics of Commonly Used Insulins

Insulin	Route	Onset (hr)	Peak (hr)	Effective Duration (hr)
Human				
Lispro (Humalog)	SC	0.25	0.5–1.5	3–4
Regular	IV/SC	0.5–1.0	2–3	3–6
NPH	SC	2–4	4–10	10–18
Glargine (Lantus)	SC	1	2–3	24

level of insulin. The kinetics of some of the insulin preparations most commonly used in children are listed in Table 36-1. Some children's diabetes may be managed with an external insulin pump, which provides a low, background, subcutaneous infusion of insulin and the ability to give small boluses before meals. Most children with diabetes administer insulin at least three times each day and check their blood sugar at least four times each day. Type 2 diabetes in children and adolescents may be controlled with diet and exercise, but these children also may be taking metformin. Metformin was recently shown to decrease gluconeogenesis by directly modulating copper-binding protein (CBP) in the liver much as insulin itself does, rather than by overcoming the liver's decreased sensitivity to insulin (He et al., 2009).

Because of the effects of surgical stress on glucose homeostasis, children with type 1 diabetes are at risk for significant perioperative difficulties, even when their preoperative glucose control is good. Brittle or noncompliant patients with diabetes have additional problems, including an increased risk of perioperative hypoglycemia or hyperglycemia, osmotic diuresis with resultant hypovolemia, and altered mental status. The physician must document the child's current insulin regimen, degree of compliance, preoperative glucose control, and risk of hypoglycemia from preoperative fast. Much of this information can be obtained from the patient's endocrinologist or by examination of the child's blood-glucose monitoring log. A recent growth history can indicate how well controlled the child's diabetes may be. Coordination and cooperation among the patient, parents, pediatrician, endocrinologist, and anesthesiologist are essential if the goal of optimal perioperative glucose homeostasis is to be achieved. The anesthesiologist must particularly heed the recommendations of the child's primary physician.

Insulin is an anabolic hormone that promotes glycogen and triglyceride storage and protein synthesis. Present in small amounts even in the fasting state, it decreases glycogenolysis, gluconeogenesis, and lipolysis, with resultant ketogenesis and protein breakdown. Its complete absence at the time of surgery puts the patient in a state of starvation, in which caloric intake is greatly restricted and substrate demands (e.g., for healing) are at their highest. The risk of a catabolic state is increased by the release of stress hormones, including catecholamines, cortisol, and glucagon. Perioperative insulin administration is essential to control glucose and to promote an anabolic state, which

is most conducive to speedy healing and metabolic homeostasis. Preoperative anesthesia evaluation for elective procedures, informed by contemporaneous endocrine assessment of adequacy of glucose control, should be completed 7 to 10 days before the scheduled date of surgery to allow adjustment of treatment regimen or delay of procedure if control is not optimal. Rhodes and colleagues (2005) published a comprehensive review of concerns and perioperative management of pediatric patients with diabetes; it features an extremely useful clinical practice guideline that incorporates both preoperative assessment and choice of preoperative insulin regimen.

Preoperative Evaluation

The preoperative evaluation should include measurements of the hematocrit, electrolyte levels, and glucose levels. A hemoglobin (Hb) A1c level (i.e., glycosylated Hb assay), although a useful index of long-term glucose control, is unlikely to affect the anesthetic plan and is not a necessary preoperative test (Nathan et al., 1984). If glycohemoglobin results are available, it is important to remember that different laboratories have different ranges for Hb A1c in normal subjects. Even in the same laboratory, the normal range may change from time to time. It is therefore important to know the laboratory's normal range to interpret results in patients with diabetes. The normal range of Hb A1c is 4.5% to 6.1%, but the normal range also varies with age (Rhodes et al., 2005; Custer and Rau, 2009).

Several systemic abnormalities may be present in the child with diabetes. Nineteen percent of children with diabetes have a vital capacity two standard deviations below the predicted mean value, suggesting the presence of restrictive lung disease (Buckingham et al., 1986). No apparent association exists between decreased vital capacity and duration of diabetes or presence of other diabetic complications. Abnormal lung elasticity and thickening of the alveolar basal laminae have been reported in children with diabetes (Schuyler et al., 1976; Vracko et al., 1980). Routine preoperative pulmonary function tests are not indicated in the asymptomatic child who has diabetes.

Decreased atlantooccipital joint mobility, resulting in difficult intubation, may be present in a subset of adolescents with a syndrome of diabetes mellitus, short stature, and tightness of small joints of the fingers, wrists, ankles, and elbows (Salzarulo and Taylor, 1986). Abnormal cross-linking of collagen by nonenzymatic glycosylation is the postulated cause of this syndrome (Chang et al., 1980).

Perioperative Management

Various regimens for managing insulin therapy perioperatively have been proposed, three of which are discussed in the following sections and in Table 36-2: a classic regimen, the subcutaneous infusion insulin pump, and intravenous (IV) insulin infusion. Essential to optimal management, regardless of regimen, is the scheduling of elective surgery for the child with diabetes as early as possible in the day (first case) to minimize time that the patient must fast. The fasting interval should be the same as that recommended for patients who do not have diabetes: no solid food or milk for 8 hours, and clear liquids are permissible until 2 hours before the scheduled time of surgery (Schreiner et al., 1990). Children with diabetes should be encouraged to continue taking clear liquids until 2 hours before surgery. If this is not possible, an

TABLE 36-2. Protocols for Perioperative Insulin Therapy

Regimen	Morning of Surgery Procedure
Classic regimen	Start IV infusion of 5% dextrose in 0.45% saline or Ringer's lactate solution at 1500 mL/m ² /day. Administer half of usual morning insulin dose as regular insulin. Check blood glucose before induction, during and after anesthesia
Continuous insulin infusion	Start IV infusion of 5% dextrose in 0.45% saline or Ringer's lactate solution at 1500 mL/m ² /day. Add 1-2 units of insulin per 100 mL of 5% dextrose Starting insulin dose = 0.02 units/kg/hr Check blood glucose before induction, and during and after anesthesia
Insulin- and glucose-free regimen (for operative procedures of short duration)	Withhold morning insulin dose If indicated for procedure, give glucose-free solution (e.g., Ringer's lactate) at maintenance rate. Check blood glucose before induction, and during and after anesthesia.

IV fluid infusion should be started (described later). As recommended in adult patients with type 2 diabetes, metformin should be stopped 48 hours before surgery, based on reports of lactic acidosis in patients who remain on the drug and are in a fasting state perioperatively. Other orally administered medications (e.g., thiazolidinediones or sulfonylureas) may be continued through the day before surgery.

Although some investigators have recommended the withholding of preoperative sedation from patients with diabetes to better monitor for signs of hypoglycemia, premedication is recommended in children. The use of agents such as benzodiazepines, opioids, or barbiturates does not alter glucose metabolism, and the failure to use such agents may elevate the blood sugar level as a result of anxiety, which causes a stress response with catecholamine release.

Based on the blood-glucose level determined on arrival to the preoperative facility and before implementation of the regimens discussed in the following sections, glucose or insulin should be administered according to the scheme outlined in Table 36-3.

TABLE 36-3. Preoperative Glucose and Insulin Management for Diabetic Patients

Blood Glucose Level	Management
<80 mg/dL	2 mL/kg D10W followed by glucose infusion
80-250 mg/dL	D5/0.45 NS or D10/0.45 NS solution at maintenance if insulin is to be administered; 0.9 NS if short case; no insulin
>250 mg/dL	Administer rapid-acting (lispro) or short-acting (regular) insulin SC to reduce blood sugar; use correction factor from patient's endocrine provider or 0.2 unit/kg SC
>350 mg/dL	Consider canceling or postponing surgery, especially if ketonuria

NS, Normal saline; SC, subcutaneously.

Classic Regimen

On the morning of surgery, one half of the usual dose of long-acting insulin (e.g., Neutral Protamine Hagedorn [NPH]) is administered subcutaneously after establishing an IV infusion of 5% glucose-containing solution at a rate of 100 mg/kg per hour of glucose (Table 36-2). Plasma-glucose concentrations should be maintained between 100 and 180 mg/dL. This target range is chosen because mild to moderate hyperglycemia (without ketosis) usually does not present a serious problem to the child, whereas hypoglycemia has devastating consequences. Hyperglycemia greater than 250 mg/dL should be avoided because of associated mental status changes, diuresis, and subsequent dehydration, which can occur because of the hyperosmolar state. Hyperglycemia has been associated with poorer outcomes in patients at risk for central nervous system (CNS) ischemia, including those undergoing cardiopulmonary bypass (Lanier et al., 1987; Lanier, 1991). Hyperglycemia has also been shown to impair wound healing and has adverse effects on neutrophil function in vitro. (Marhoffer et al., 1992; Delamair et al., 1997). When the classic regimen is employed, supplemental subcutaneous doses of short-acting insulin can be given on a sliding scale postoperatively to maintain the desired plasma glucose level. This regimen should be restricted to patients who are scheduled for short surgical procedures, after which they are expected to resume eating promptly.

Subcutaneous Infusion Insulin Pump

Increasing numbers of pediatric patients with type I diabetes are being managed with an external insulin pump that is capable of subcutaneous administration of both continuous and bolus doses of insulin. Such pumps afford excellent control, with changes in administration coordinated with eating, exercise, and stress. At this time, the proliferation of pumps from multiple manufacturers precludes the easy acquisition of knowledge and familiarity with their use in the perioperative setting. Some clinicians and institutions allow continued use of insulin pumps for short, uncomplicated procedures (e.g., less than 2 hours), whereas most recommend transition to a continuous insulin infusion, as described in the next section (Glister and Vigersky, 2003; Rhodes et al., 2005).

Intravenous Insulin Infusion

If a long procedure or a prolonged period of postoperative fasting is anticipated, the continuous IV infusion of glucose and insulin may provide the best control. On the morning of surgery, a glucose infusion is begun at a maintenance rate of 100 mg/kg per hour, with an insulin infusion of 0.02 to 0.05 unit/kg per hour “piggy-backed” into the glucose infusion. The glucose infusion can be D5 or D10 in half-normal saline with 10 to 20 mEq/L of potassium chloride. These infusions should be started 2 hours before surgery to minimize the duration of fasting and decrease the risk of the development of a catabolic state. Insulin is absorbed by IV bags and tubing. When the insulin solution is prepared, the first portion of the solution should be run through the tubing and discarded to saturate the sites in the tubing that bind insulin (Kaufman et al., 1996). Blood glucose levels should be checked hourly for the first few hours, and adjustments of 0.01 unit/kg per hour in the insulin rate should be made to keep the blood sugar in the acceptable

range of 100 to 180 mg/dL. This continuous-infusion regimen has been shown to yield better control of glucose concentrations than the regimen in which intermittent subcutaneous insulin is administered (Kaufman et al., 1996). The administration of intermittent large IV-insulin doses has no role, as it can result in large swings in glucose concentration (high and low) and a greater chance of lipolysis and ketogenesis. Patients with insulin pumps should have them turned off in the perioperative period, and pumps should be replaced by the continuous-infusion regimen, as most anesthesiologists are not familiar with the details of operation of such pumps. Fifty-percent dextrose solution should be available for administration in case of the development of hypoglycemia; 0.1 g/kg of dextrose raises the blood-glucose level by approximately 30 mg/dL.

The glucose and insulin should be infused through a dedicated IV cannula to enable it to be well regulated apart from the non-glucose-containing crystalloid solutions that are administered to replace blood or fluid losses—especially important if the maintenance glucose solution contains potassium. Many institutions avoid potassium-containing solutions to prevent their inadvertent rapid administration in the setting of rapid administration of fluid for blood or fluid replacement. Most investigators believe that lactated Ringer’s solution should not be used for blood and fluid replacement, because lactate is a glycogenic precursor and may result in higher blood-glucose levels.

Alternative Procedure (Insulin- and Glucose-free Regimen)

For extremely brief procedures, after which prompt resumption of oral intake is expected, an alternative protocol involves the administration of no insulin or glucose before or during surgery. When oral intake is established postoperatively, 40% to 60% of the usual daily insulin dose is given (Stevens and Roizen, 1987). Myringotomy with tube placement is an example of a procedure for which this regimen would be appropriate. The surgical procedure should be performed as the first case on the morning schedule to avoid prolonged fasting and excessive delay in insulin administration.

The most serious perioperative complication that can occur in the diabetic child is hypoglycemia. Common signs of low blood-glucose levels include tachycardia, tearing, diaphoresis, and hypertension. In the anesthetized patient, these signs may be misinterpreted as the result of inadequate anesthesia. Because the clinical signs of hypoglycemia are masked by sedation or anesthesia, frequent (every hour) measurement of the serum-glucose level is critical for the prevention of hypoglycemia, independent of the glucose-insulin regimen chosen. Glucose test strips, with or without the use of a reflectance photometer, provide quick, convenient, and reliable bedside blood-sugar measurements to guide therapy. Blood-glucose determinations performed with reflectance photometers provide results that are generally within 10% of clinical laboratory glucose determinations done on the same specimen (Chen et al., 2003). Visual evaluation of blood-glucose strips is less accurate (Arslanian et al., 1994). Postoperative insulin administration is determined by the time of resumption of oral or enteral feeding and by the postoperative blood-glucose concentration. The endocrinologist and surgeon should be active partners in the choice of an appropriate insulin regimen, because they are responsible for monitoring glucose homeostasis after the patient leaves the recovery room. For day-surgery patients, contingency planning

for insulin management and mechanisms for follow-up care and consultation should be clearly defined for members of the care team and family.

Anesthetic Management

Regional or general anesthesia is appropriate for the child with diabetes mellitus. If tolerated with minimal sedation, regional anesthesia might be argued to offer the advantage of allowing for observation of the level of consciousness as a monitor of hypoglycemia. Practically speaking, most children require general anesthesia, even when regional techniques are employed. The ease and availability of point-of-care glucose determination from venous or finger-stick specimens obviate the need for monitoring of cerebral function.

Perioperative Management of Diabetic Ketoacidosis

Occasionally, patients with diabetes require surgery for trauma or infection while they are in a state of ketoacidosis. Diabetic ketoacidosis includes hyperglycemia (plasma-glucose concentration greater than 300 mg/dL) with glucosuria, ketonemia (ketones strongly positive at greater than 1:2 dilution of serum), ketonuria, and acidemia (pH lower than 7.30, serum bicarbonate lower than 15 mEq/L, or both). It is common for intraabdominal catastrophes with infection (e.g., appendicitis) to precipitate ketoacidosis. Foster and McGarry (1983) have succinctly summarized the pathophysiology of diabetic ketoacidosis. The initiating event is usually cessation of insulin therapy or onset of stress that renders the usual dose of insulin inadequate. Glucagon, catecholamines, cortisol, and growth hormone levels increase. A catabolic state is produced as substrates are mobilized, resulting in hepatic production of glucose and ketone bodies, which causes hyperglycemia and ketoacidosis. Subclinical brain swelling nearly always occurs during diabetic ketoacidosis therapy, although most patients remain asymptomatic (Krane et al., 1985). Fatalities from cerebral edema do occur, and some studies suggest that high rates of fluid administration early in treatment (more than 50 mL/kg in the first 4 hours) greatly increase the risk of herniation (Mahoney et al., 1999). Studies using 4 L/m² for the first 24 hours followed by 1 to 1.5 times maintenance resulted in clearance of ketoacidosis equal to that in patients who were given more fluid, but a low but persistent incidence (0.35% to 0.5%) of symptomatic cerebral edema remained (Felner and White, 2001). The best methods to prevent the development of this devastating complication are administration of isotonic fluid only and frequent monitoring of serum osmolality (by direct measurement or calculation) to ensure that elevated osmolality is reduced gradually. Insulin therapy should be tailored to decrease the blood glucose concentration at a rate not greater than 100 mg/dL per hour. To prevent a more rapid decrease in blood glucose concentration, 5% dextrose and if necessary, 10% dextrose, should be added to the rehydration solution to slow the rate of fall, rather than decreasing the rate of insulin infusion (Arslanian et al., 1994). Fortunately, the anesthesiologist is rarely called on to administer anesthesia during this severe metabolic derangement. If an anesthetic is required during diabetic ketoacidosis, preoperative attention should be directed toward the correction of hypovolemia and hypokalemia, along with beginning an insulin infusion. Invasive hemodynamic monitoring may be indicated preoperatively to optimize the patient's fluid and

electrolyte balance and to monitor the patient's hemodynamic status accurately. Surgery should not be delayed inordinately because it may be impossible to correct the metabolic derangements before the underlying source of infection or organ dysfunction is corrected. For patients with signs of cerebral edema, monitoring of intracranial pressure may be necessary.

Diabetes Insipidus

Diabetes insipidus (DI) is a clinical syndrome of hypotonic polyuria in the face of elevated plasma osmolality that results from inadequate production of, or inadequate response to, antidiuretic hormone (ADH). Central DI results from inadequate production or release of ADH from the posterior pituitary gland. ADH is synonymous with arginine vasopressin. Nephrogenic DI (also referred to as *vasopressin-resistant DI*) is characterized by partial or complete renal tubular unresponsiveness to endogenous ADH or exogenously administered arginine vasopressin. Congenital nephrogenic DI is caused by mutations in either the vasopressin receptor or aquaporin-2 gene. Inheritance is X-linked in the former and autosomal recessive or dominant in the latter (Sasaki, 2004). A combination of hydrochlorothiazide and a nonsteroidal antiinflammatory drug (NSAID) has been effective for the treatment of nephrogenic DI. Both cyclooxygenase-1 (COX-1; i.e., tolmetin and indomethacin) and cyclooxygenase-2 (COX-2; i.e., rofecoxib) drugs have been effective (Jakobsson and Berg, 1994; Pattaragarn and Alon, 2003). Toxic drug effects may also lead to acquired nephrogenic DI. Anesthetic implications of nephrogenic DI have been reviewed by Cramolini (1993) and Malhotra and Roizen (1987).

The causes of DI are outlined in [Box 36-1](#). This discussion focuses on central DI and its clinical manifestations, which are

Box 36-1 Causes of Diabetes Insipidus

VASOPRESSIN DEFICIENCY (NEUROGENIC DI)

Acquired

- Idiopathic
- Traumatic (accidental, surgical)
- Neoplastic (craniopharyngioma, metastasis, lymphoma)
- Granulomatous (sarcoid, histiocytosis)
- Infectious (meningitis, encephalitis)
- Vascular (Sheehan syndrome, aneurysm)
- Familial (autosomal dominant)

EXCESSIVE WATER INTAKE (PRIMARY POLYDIPSIA)

Acquired

- Idiopathic (resetting of the osmostat)
- Psychogenic

VASOPRESSIN INSENSITIVITY (NEPHROGENIC DI)

Acquired

- Infectious (pyelonephritis)
- Postobstructive (urethral, ureteral)
- Vascular (sickle cell disease or trait)
- Infiltrative (amyloid)
- Cystic (polycystic disease)
- Metabolic (hypokalemia, hypercalcemia)
- Granulomatous (sarcoid)
- Toxic (lithium, demeclocycline)
- Solute overload (glucosuria, postobstructive)
- Familial (X-linked recessive)

DI, Diabetes insipidus.

polyuria and polydipsia. The urine is hypotonic relative to the plasma. The urine osmolality is usually less than 200 mOsm/L, and urine specific gravity is less than 1.005 (Custer and Rau, 2009). When the patient has had inadequate access to water, severe dehydration and hypernatremia ensue, because a large volume of dilute urine is continually produced.

Patients with preexisting DI may need incidental surgery. They are usually taking maintenance doses of vasopressin, which for relatively short, uncomplicated, elective procedures, should be continued through the perioperative period (Wise-Faberowski et al., 2004). Desmopressin (1-desamino-8-D-arginine vasopressin, or DDAVP), a longer-acting (8 to 20 hours) vasopressin analogue, has a decreased vasopressor effect relative to its antidiuretic effect (Hays, 1990). DDAVP is usually given intranasally (2.5 to 10 mcg once or twice daily) or orally (25 to 200 mcg once or twice daily) to prevent diuresis (Lee et al., 1976). DDAVP also may be given subcutaneously or intravenously (1 to 2 mcg twice daily). An algorithm for the management of DI, whether preexisting or developing intraoperatively or postoperatively, is presented in **Figure 36-1**.

The most common situation encountered by the anesthesiologist, however, is the new onset of DI intraoperatively or postoperatively in patients who are having surgery for pituitary or hypothalamic tumors, most commonly craniopharyngiomas; 70% to 90% of these patients develop DI (Lehrnbecher et al., 1998; Ghirardello et al., 2006). Perioperative DI may present in one of four ways:

1. Transient polyuria probably is related to the onset and resolution of transient cerebral edema rather than to injury to the pituitary stalk. It usually resolves in 24 to 36 hours.
2. A triphasic pattern with an interval of normal urine output reflects the release of stored vasopressin from the

posterior lobe or median eminence of the pituitary, followed by resumption of polyuria when the stored supply of vasopressin is exhausted.

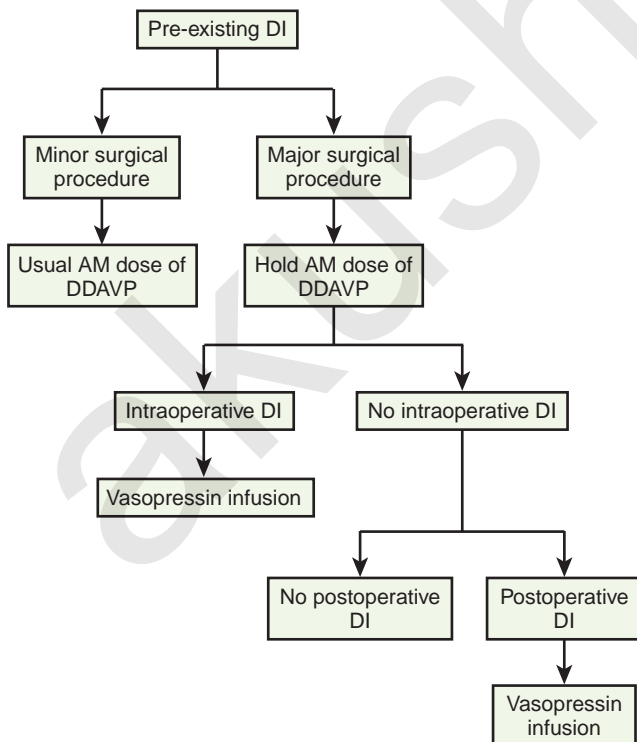

3. Mild polyuria reflects partial DI, which is exaggerated by local edema and corticosteroid administration.
4. Permanent DI is caused by destruction or removal of all cells capable of producing and storing vasopressin.

If any degree of DI is going to occur, the onset is most commonly within 18 hours after the operation. Recommendations for therapy are reviewed by Wise-Faberowski and colleagues (2004).

The goal of perioperative management of DI is to maintain normal fluid and electrolyte balance, urine output, and hemodynamic stability. Urine output may be prodigious (10 to 20 mL/kg per hour). Care must be taken to differentiate polyuria caused by DI (urine specific gravity of less than 1.005) from diuresis caused by mannitol administration, hyperglycemia (urine specific gravity that is usually greater than 1.015), or simple excessive administration of crystalloid (urine specific gravity of greater than 1.005). Patients with partial ADH deficiency usually do not require supplemental aqueous vasopressin perioperatively, because large quantities of ADH are produced in response to surgical stress (Malhotra and Roizen, 1987). However, serum osmolality should be measured often, and aqueous vasopressin should be given if the plasma osmolality exceeds 300 mOsm/L (Wise-Faberowski et al., 2004).

If central DI is present preoperatively and the planned surgery is prolonged, an infusion of aqueous vasopressin is begun preoperatively and continued intraoperatively. The recommendations for adults include a bolus of 100 milliunits of aqueous vasopressin followed by a continuous infusion of 100 to 200 mU/hr. This should be accompanied by the intraoperative administration of isotonic saline at two thirds of the maintenance rate, with additional fluid given for blood loss replacement and for maintaining hemodynamic stability (Malhotra and Roizen, 1987). Hypotonic fluids should be avoided, as hyponatremia may result. For the pediatric population, an infusion is begun at 0.5 mU/kg per hour and increased in 0.5 mU/kg per hour increments until a urine osmolality twice that of plasma and a urine output of less than 2 mL/kg per hour are achieved. It is rarely necessary to use more than 10 mU/kg per hour (Weigle, 1987). Side effects from vasopressin administration are minimal at doses used for antidiuresis; at larger doses, generalized vasoconstriction can occur and has resulted in tissue ischemia and myocardial infarction.

DDAVP, rather than aqueous vasopressin, may also be used for treatment of perioperative DI because of its potent antidiuretic effect with minimal pressor activity or other side effects. In the perioperative period, it may be given intravenously until intranasal administration can be started or resumed. The suggested IV dose is 0.5 to 4 mcg, with a single dose having a duration of action of 8 to 12 hours (Muglia and Majzoub, 2008). It is important to note that this dose of DDAVP is one fortieth to one fourth of that used to prevent bleeding in patients with von Willebrand's disease (vWD). The ease of intermittent dosing with DDAVP with low incidence of side effects must be balanced against the ability to titrate the continuous vasopressin infusion cited earlier. The long half-life of DDAVP (6 to 24 hours) in combination with intraoperative fluid administration may incur an increased chance of hyponatremia. In either case, careful monitoring of fluid balance is essential.

■ **FIGURE 36-1.** Perioperative management of patients with preexisting DI.

The anesthesiologist may occasionally encounter children who are receiving nightly nasal DDAVP for the treatment of enuresis. A review of its use reveals a negligible incidence of water intoxication (and no permanent effect on enuresis when treatment is stopped) (van Kerrebroeck, 2002). Given the known duration of action, DDAVP administered the night before outpatient surgery should not affect the urine output on the day of surgery.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Just as central DI is caused by ADH deficiency, syndrome of inappropriate ADH secretion (SIADH) is caused by an excess production of ADH that is inappropriate with respect to the state of the intravascular volume. The most common causes of SIADH are listed in [Box 36-2](#). The hallmark of SIADH is hyponatremia in the face of high urine osmolality and sodium levels. A comparison of the urine and serum electrolyte status seen in DI and SIADH is presented in [Table 36-4](#). The treatment for mild cases of SIADH is fluid restriction (50% to 60% of maintenance fluid requirement) or insensible loss (400 mL/m² per day), plus one half to three fourths of the urine output. If hyponatremia is severe enough to cause coma or seizures, treatment with hypertonic saline (3%) solution may be indicated, but caution should be employed because the administration of hypertonic saline may cause circulatory overload because the intravascular volume is already increased. A too-rapid rise of osmolality (more than 20 mOsm/kg or more than 10 mmol/L of sodium in 24 hours) carries a risk of central pontine myelinolysis, a condition that can result in death (Laureno and Karp, 1997). This syndrome is thought to be caused by the sudden shrinkage of brain cells in response to rapidly increasing extracellular osmolality.

Adrenal Insufficiency

Adrenal Insufficiency as a Result of Primary Abnormalities of the Hypothalamic-Pituitary-Adrenal Axis

Adrenal insufficiency is an uncommon disease in children, but when it occurs it is associated with significant implications for the anesthesiologist. The causes of adrenal insufficiency are listed in [Box 36-3](#). Adrenal insufficiency may include glucocorticoid deficiency with or without mineralocorticoid deficiency ([Box 36-4](#)). Isolated hypoaldosteronism is rare. In the perioperative period, children with congenital adrenal insufficiency require glucocorticoid and mineralocorticoid replacement.

Chronic deficits in adrenal function result in the classic findings of Addison disease, including hyperpigmentation, weakness, and hyponatremia. The hyperpigmentation results from high levels of adrenocorticotropic hormone (ACTH) and unopposed melanophore-stimulating hormone caused by cortisol insufficiency. The additional presence of aldosterone insufficiency may produce hyponatremia, hyperkalemia, hypotension, and a small cardiac silhouette that results from hypovolemia (Keon and Templeton, 1993).

Perioperative Steroid Management

The preoperative recognition of adrenal insufficiency and appropriate preoperative therapy minimize the likelihood of significant perioperative complications. Ninety percent of patients with congenital adrenal hyperplasia with adrenal insufficiency have 21-hydroxylase deficiency (Migeon and Donohoue, 1994). Virilization of the external genitalia occurs in female patients, and they often require surgical revision of their external genitalia. An abnormal genital pigmentation occurs in male patients, but this finding may be subtle. Infants with undiagnosed congenital adrenal hyperplasia may undergo exploratory laparotomy for acute abdomen because of nausea and vomiting. It is important to be attuned to the signs and symptoms in the history, physical examination, and laboratory evaluation that point to this diagnosis to prevent or treat shock, which may occur because of failure to administer steroid replacement.

Mineralocorticoid deficiency can be managed by administering saline solution and avoiding potassium in IV fluids. Mineralocorticoid secretion rates in children are similar to those in adults, and the replacement dose is independent of age and weight. Desoxycorticosterone acetate may be administered intramuscularly in a dose of 1 mg/day. The intramuscular injection may be replaced by a single daily oral dose of 9-fluorocortisol (Florinef, 0.05 to 0.1 mg) when it is clear that an oral medication can be tolerated and absorbed. When cortisol is administered perioperatively, it has sufficient mineralocorticoid activity to obviate the need for any other replacement; 20 mg of hydrocortisone has mineralocorticoid activity equivalent to 0.1 mg 9 α -fluorocortisol (Miller et al., 2008).

Glucocorticoid deficiency is treated with cortisol (hydrocortisone) replacement. The importance of cortisol replacement for patients with known adrenal insufficiency should not

be underestimated, although vastly excessive doses are unwarranted. In the normal individual, the adrenal gland secretes 12 ± 2 mg of cortisol per square meter of body surface area every 24 hours (Kenny and Preeyasombat, 1966). The normal replacement dose prescribed for unstressed children is 25 mg/m² per day; the dose is double the normal production because of factors of bioavailability and half-life (Migeon and Donohoue, 1994). In response to stress (e.g., fever, acute illness, surgery, and anesthesia), the normal adrenal gland secretes 3 to 15 times this amount. Consequently, in the past, the recommendations for “stress” steroid coverage in the perioperative period ranged from 36 to 180 mg/m² per day.

More important than just the dose of steroid to be given, consideration should be devoted to the type of glucocorticoid administered, its half-life, the route of administration, and the timing of doses. The equivalencies for steroid preparations in terms of their relative glucocorticoid and mineralocorticoid effects are presented in Table 36-5. The most commonly cited recommendation for perioperative steroid coverage is hydrocortisone hemisuccinate (Solu-Cortef), given intravenously as 2 mg/kg immediately preoperatively and every 6 hours on the day of surgery, with reductions in the postoperative period depending on the degree of stress. Some practitioners feel that the half-life of hydrocortisone is so short that a 6-hour dosing interval may lead to periods of inadequate “coverage.” These practitioners recommend a preinduction dose of 25 mg/m² of hydrocortisone given intravenously, followed by a continuous infusion of 50 mg/m² administered during the estimated period of anesthesia. Postoperatively, 50 mg/m² by continuous infusion is administered over the remainder of the first 24 hours. The total dose for the first 24 hours is 125 mg/m², or 10 times normal physiologic production (Migeon and Donohoue, 1994). The first bolus dose must be administered before induction of anesthesia rather than waiting for an IV cannula to be placed after inhalational induction because of the stress associated with anesthetic induction itself. In the postoperative period, the steroid dose is tapered to a level commensurate with the residual stress. It is replaced with the child’s usual oral preparation when the child clearly can tolerate and absorb oral medication.

Hypothalamic-Pituitary-Adrenal Axis Suppression Caused by Exogenous Steroid Therapy

In addition to the diseases discussed previously, suppression of the hypothalamic-pituitary-adrenal (HPA) axis can also occur after exogenous steroid usage, such as that administered for the treatment of inflammatory conditions (e.g., Crohn disease and asthma) or autoimmune disease (e.g., lupus and juvenile rheumatoid arthritis). Nearly 60 years ago, it was reported that two patients developed irreversible shock perioperatively after glucocorticoid administration was stopped preoperatively (Fraser et al., 1952; Lewis et al., 1953). Both patients were found to have adrenal atrophy and hemorrhage at autopsy. These two cases led to suggestions for “stress” steroid coverage in the perioperative period. HPA suppression places steroid-dependent children at increased risk for complications in the perioperative period, because they may be unable to respond to stress with an appropriate increase in the adrenal secretion of glucocorticoid. Dosages of cortisol or its equivalent that exceed 15 mg/m² per day for more than 2 to 4 weeks invariably produce HPA suppression. A study in children with relatively short-term exposure to

prednisolone or dexamethasone (5 and 3 weeks, respectively) for treatment of acute lymphoblastic leukemia showed that recovery of normal adrenal function (in response to ACTH stimulation) had a very wide range, occurring between 2 weeks and 8 months (Petersen et al., 2003).

Although high dosages, prolonged therapy, and short duration between discontinuance of therapy and the surgical procedure increase the likelihood of HPA suppression, no practical test is available that unequivocally identifies patients who will need intraoperative steroids. Metyrapone depresses the production of cortisol by the adrenal glands and can be used to test the capacity of the pituitary gland to respond to decreased plasma cortisol concentrations by increasing ACTH secretion (Haynes, 1990). However, this test takes 3 days, is expensive, and has the risk of inducing adrenal insufficiency. Similarly, an ACTH-stimulation test can be performed at great expense to test adrenal responsiveness. However, even if cost and time were not issues, a study has shown a poor correlation between tests that indicate normal HPA function and dose or duration of glucocorticoid therapy or basal cortisol levels (Schlaghecke et al., 1992). Clinically significant events rarely occur during the perioperative period in unsupplemented patients who were receiving steroid medications for diseases other than adrenal insufficiency. Nevertheless, the potential for symptomatic adrenal insufficiency, although rare, coupled with the low risk of steroid-induced complications for short-term administration, suggests that steroids should be given in uncertain cases. If steroid therapy has been discontinued within the previous year, Donohoue (2005) makes the following recommendations:

- If the dose of the glucocorticoid administered was less than replacement levels, independent of the duration of

administration, there will be no major HPA suppression and therefore no need for supplementation.

- If the dose of glucocorticoid administered was greater than replacement levels, HPA suppression will occur. If treatment lasted fewer than 2 weeks, suppression is transient, with prompt recovery (fewer than 2 weeks). If treatment lasted longer than 2 weeks, HPA suppression may persist for 1 week to 6 months, with 50% of patients recovering function within 6 weeks. This is the case even if the glucocorticoid was administered on an every-other-day basis.

HPA suppression also can result from modes of steroid administration other than oral, including topical, nasal spray, and inhalers. Although adrenal suppression is rarely symptomatic with these modes of administration, some drugs, especially fluticasone propionate, in high doses have been associated with growth failure and adrenal suppression (Duplantier et al., 1998). With surgical stress, patients with adrenal suppression may become symptomatic, as has been reported for other kinds of stress. The patients reported by Drake et al. (2002) all had been taking fluticasone and had hypoglycemia at times of stress from intercurrent illness. Numerous cases of acute adrenal crisis have been reported in children receiving inhaled corticosteroids (ICS) for prolonged periods (Randell et al., 2003). Anesthesiologists should have a high index of suspicion of adrenal suppression if an asthmatic child on inhaled steroids develops hypotension or hypoglycemia in the perioperative period.

For children who have been on prolonged courses of high-dose steroids (e.g., for asthma or treatment of acute lymphocytic leukemia), the glucocorticoid regimen should follow that described earlier for patients with adrenal insufficiency. The dose

given should be commensurate with the normal physiologic corticosteroid production in response to stress (as described) and does not need to be a multiple of the pharmacologic dose being administered for the underlying medical illness.

The dose administered should also be proportional to the perceived degree of surgical stress. For brief procedures, such as upper endoscopy, a single preoperative dose of steroids is suggested (50 mg/m² of hydrocortisone); for more complicated cases, such as appendectomy or major intraabdominal operations, 100 mg/m² is administered as a continuous infusion or divided into 4 doses per day. This dose is usually continued for 1 to 3 days after more complex surgical procedures (Krasner, 1999). The dose is tapered postoperatively and replaced with the patient's usual oral steroid preparation and dose when the child is able to tolerate oral medications. The dose that these patients commonly take for the underlying disease often exceeds even maximum "stress" doses described for congenitally adrenal insufficient patients, and treatment required for the underlying disease may limit further tapering of the steroid dose. A small study of adults comparing "stress steroids" with saline showed no adverse effects in patients who continued their usual steroid dose for their underlying disease (Glowniak and Loriaux, 1997).

Thyroid Disorders

Hypothyroidism

Hypothyroidism occurs because of abnormally low production of thyroid hormone. It may be caused by primary thyroid dysfunction or result from pituitary failure with decreased production of thyroid-stimulating hormone (TSH). Normal values for routinely performed thyroid function tests are presented in Table 36-6, and the interpretation of these test results with regard to diagnosis is presented in Table 36-7.

Primary thyroid dysfunction may be congenital or acquired. Congenital hypothyroidism usually appears in infancy. Classic features in the infant include large fontanels, wide sutures, large tongue, umbilical hernia, and decreased deep tendon reflexes. In the older child, manifestations include slow heart rate, narrow pulse pressure, growth failure, hypothermia, and cold intolerance. Severe hypothyroidism is rare but may be associated with coma, cardiovascular collapse, hyponatremia, hypothermia, and respiratory failure. Keon and Templeton (1993) reviewed the anesthetic management of patients with hypothyroidism and stressed the importance of correcting hypothyroidism gradually over a 2-week period. Sudden death has been reported in children with myxedematous heart disease 2 to 3 weeks into therapy (LaFranchi, 1979). It is suggested that these children receive one fourth of the maintenance dose of thyroid hormone (6 to 8 mcg/kg per day for an infant), with gradual incremental increases over 2 to 4 weeks until a maintenance dose is reached (Custer and Rau, 2009). Patients who are adequately treated will have normal thyroid hormone and TSH levels. Patients who do not respond to oral thyroid replacement may be given IV triiodothyronine (T₃; loading dose of 0.7 mcg/kg), followed by an infusion titrated to T₃ and TSH levels. Severe cardiac dysfunction in such a patient improved with T₃ therapy (Mason et al., 2001). Patients with incompletely restored thyroid hormone levels may require hemodynamic monitoring and support to maintain hemodynamic stability. Patients with severe hypothyroidism may have

associated adrenal insufficiency, and if so, they should receive stress steroid coverage as outlined earlier.

The anesthetic care of the symptomatic patient with hypothyroidism can be problematic and requires caution when any depressant medications are given. Prolonged effects may result

TABLE 36-8. Anesthetic Implications of Hypothyroidism

System	Anesthetic Considerations
Pharmacologic	Possible lower MAC value; prolonged recovery from opioid anesthesia
Cardiovascular	Decreased cardiac output, heart rate, and stroke volume; increased PVR and decreased intravascular volume; myocardial depression resulting from impaired cellular metabolism or myxedematous infiltration; baroreceptor dysfunction
Respiratory	Abnormal response to hypercapnia and hypoxia
Thermal regulation	Hypothermia resulting from reduced basal metabolic rate; reduced ability to increase core temperature
Endocrine	Increased incidence of adrenal insufficiency; consideration for stress steroid coverage
Metabolic	SIADH; hypoglycemia with prolonged fasting
Gastrointestinal	Delayed gastric emptying; consideration for full stomach precaution

MAC, Minimum alveolar concentration; PVR, peripheral vascular resistance; SIADH, syndrome of inappropriate antidiuretic hormone.

from decreased drug metabolism. Important considerations in the management of hypothyroidism as described by Keon and Templeton (1993) are outlined in Table 36-8. Invasive monitoring may be indicated when significant blood loss or fluid shifts occur. Care should be taken intraoperatively to minimize heat loss. Postoperative care should include monitoring of oxygen saturation, blood pressure, heart rate, and respiratory rate; postoperative ventilation may be necessary in the patient with delayed emergence from anesthesia.

Hyperthyroidism

Hyperthyroidism is a syndrome produced by excess levels of circulating thyroid hormone. The most common causes are congenital hyperthyroidism and Graves disease (i.e., toxic goiter). Less commonly, acute suppurative thyroiditis, hyperfunctioning thyroid carcinoma, thyrotoxicosis factitia (i.e., exogenous administration of thyroid hormone), and toxic uninodular goiter (i.e., Plummer disease) may produce this syndrome. McCune-Albright syndrome (i.e., precocious puberty with polyostotic fibrous dysplasia) is also commonly associated with hyperthyroidism (Jones, 1988).

Congenital Hyperthyroidism

Congenital hyperthyroidism is a transient phenomenon seen in newborns that results from the transplacental transfer of thyroid-stimulating antibody from mothers who commonly have a history of Graves disease. Most of these infants have a goiter and typically appear anxious and restless or irritable. Signs of hypermetabolism, including tachycardia, tachypnea, and elevated temperature, may be present. In the severely affected infant, symptoms may progress to weight loss, severe hypertension, and high-output cardiac failure with hepatomegaly (Smith et al., 2001). Appropriate medical therapy (methimazole) should be instituted early. Because maternal immunoglobulins have a short half-life in infants, the hyperthyroid state resolves in a few

weeks to a few months, and it sometimes may be followed by a period of hypothyroidism (Higuchi et al., 2001).

Graves Disease

Diffuse toxic goiter (Graves disease) is the most common cause of hyperthyroidism in children. Its peak incidence occurs during adolescence, and it is five times more common in girls than in boys. The clinical course is generally gradual, with symptoms developing over 6 to 12 months. Early signs include motor hyperactivity, emotional disturbances, and nervousness. Affected children are progressively more irritable and restless and may have increased sweating, increased appetite, palpitations, and tremors of their fingers. Most children have obvious exophthalmos and an enlarged palpable thyroid. The cardiopulmonary symptoms of hyperthyroidism include systolic hypertension, tachycardia, palpitations, dyspnea, and cardiac enlargement, which may progress to frank cardiac decompensation. On rare occasions, atrial fibrillation or mitral regurgitation may also be present.

Thyroid Storm

An acute onset of hyperthermia, severe tachycardia, and restlessness comprises the syndrome of acute uncompensated thyrotoxicosis, or “thyroid storm.” Without appropriate and timely therapy, the patient’s condition may deteriorate to delirium, coma, and death. Therapy includes treatment of hyperthermia by cooling, maintenance of intravascular volume with balanced salt solutions, and β -adrenergic blockers such as propranolol titrated to ameliorate the cardiovascular response. Specific thyroid suppression therapy with propylthiouracil should be instituted. The clinical presentation of thyroid storm may occur intraoperatively, and this hypermetabolic state may be mistaken for malignant hyperthermia (Peters et al., 1981). The use of dantrolene mitigated the clinical signs in a patient who turned out to have thyroid storm (Bennett and Wainwright, 1989). It is well known that perioperative surgical stress can trigger the development of thyroid storm in a patient with previously unrecognized thyrotoxicosis (Stevens, 1983). For this reason, patients with signs and symptoms that may indicate the presence of hyperthyroidism should be carefully evaluated. Patients should be rendered euthyroid before any elective surgery, even if it is minor.

Laboratory Evaluation

Serum levels of thyroxine (T4) and T3 are usually elevated in hyperthyroidism. TSH secretion is suppressed and may be unmeasurable. T3 toxicosis (elevated T3 level with normal amounts of T4) is more common in adult patients and rarely seen in children. For borderline cases, thyrotropin-releasing hormone (TRH) stimulation tests may be needed. Many patients with Graves disease of recent onset may have elevated levels of thyroid-stimulating immunoglobulin. Radionuclide scans can also be helpful in making a diagnosis. If a large goiter is present, neck radiographs, computed tomography (CT) scans, or magnetic resonance imaging (MRI) may be used to evaluate the degree of tracheal compression and deviation.

Treatment

The management of hyperthyroidism is aimed at controlling the cardiovascular effects. β -adrenergic receptor blockade, usually

with propranolol (1 to 2 mg/kg per day), is titrated to effect. Antithyroid medications include propylthiouracil and methimazole, both of which inhibit the incorporation of inorganic iodide into organic compounds. Propylthiouracil inhibits the conversion of T₄ to T₃. Although early studies suggested that these agents might inhibit the formation of thyroid antibodies, later studies that included careful histopathologic analysis have shown this to be false (Paschke et al., 1995). The Food and Drug Administration (FDA) has recently recommended that propylthiouracil not be administered to pediatric patients because of reports of liver failure associated with its use. Methimazole is the antithyroid medication recommended for use in infants, children, and adolescents (FDA, 2009). Saturated solutions of potassium iodide may be administered orally (1 drop every 8 hours) to suppress thyroid hormone secretion. The clinical response to therapy is evident in 1 to 3 weeks, and the patient may require up to 3 months for adequate control to be achieved. Patients must have appropriate, regular surveillance to ensure that the T₃ and T₄ levels are in the normal range and that TSH concentrations are normal. Clinically, the patient demonstrates a euthyroid state by return of the heart rate, blood pressure, and reflexes to normal.

Radioactive iodine is often used to treat hyperthyroidism in adults. However, such therapy is avoided in children because of side effects such as thyroid cancer, genetic damage to germ cells, and a higher incidence of hypothyroidism than occurs with pharmacologic therapy.

Anesthetic Management

Preoperatively, patients should be pharmacologically euthyroid. Any residual cardiovascular signs and symptoms should be well controlled through the use of a β -adrenergic receptor blocker. Esmolol is an excellent choice for intraoperative use. A large goiter may produce tracheal deviation or compression, and the possibility of airway compromise should be evaluated preoperatively with radiographic studies. Any commonly used sedative may be given for premedication. Atropine and other anticholinergics should be avoided or used with extreme caution, because they decrease sweating and may interfere with thermoregulation. Medications, including antithyroid drugs and β -adrenergic blockers, should be administered through the morning of surgery.

Intraoperative Management of Patients for Thyroidectomy

In children with large goiters who have a compromised airway, anesthesia should be managed with caution, as in any other child with upper airway obstruction. A sedated fiberoptic intubation may be chosen, or an inhalational induction performed, with maintenance of spontaneous ventilation until the airway is secured. If a large goiter has caused prolonged tracheal compression, a segment of tracheomalacia may exist, and an armored endotracheal tube (ETT) may be indicated.

For patients without issues of tracheal compression, anesthesia may be induced with thiopental or propofol. However, if the patient's laboratory evaluation indicates a continued hyperthyroid state, ketamine should be avoided because of its effect on catecholamine release. Mask inductions may be prolonged in these patients because of increased cardiac output, resulting in a slower rise in the alveolar concentration of the anesthetic if the ventilation is kept constant. Minute ventilation may be

reduced if significant airway obstruction resulting from goiter or tracheomalacia is present. Care should be taken to lubricate, pad, and appropriately protect the eyes, especially if they are protuberant because of Graves disease.

With respect to choice of drugs, muscle relaxants with few cardiovascular side effects, such as cisatracurium, vecuronium, or rocuronium, provide a potential benefit by minimizing the occurrence of tachycardia. Similarly, for the maintenance of general anesthesia, anesthetics that have sympathomimetic effects should be avoided. If the child is in a hypermetabolic state, drug biotransformation may be accelerated; therefore, agents such as halothane, which has toxic metabolic products, are potentially more hazardous. Another reason to avoid halothane is its sensitization of the myocardium to catecholamines. If the patient is in a hypermetabolic state, controlled ventilation should be employed during the surgical procedure to minimize the development of hypercapnia, which can contribute to further sympathetic stimulation.

Anesthetic management at the conclusion of surgery may include deep extubation, with direct or fiberoptic laryngoscopy performed to evaluate the presence or absence of vocal cord paralysis, which may result from surgical trauma to the recurrent laryngeal nerve (traction or transection). Care should be taken after extubation to observe for signs of airway obstruction as a result of residual tracheomalacia. The decision to evaluate the airway prospectively at the time of extubation should be made jointly by the anesthesiologist and surgeon and should be based on the likelihood of residual tracheal obstruction caused by tracheomalacia or of vocal cord paralysis because the surgeon thinks that surgical trauma is likely.

Postoperative Care

Children who have undergone thyroidectomy require close observation in the postoperative period (Fewins et al., 2003). They may develop postextubation croup or upper airway obstruction as a result of paralysis of the vocal cords, tetany (hypocalcemia), residual tracheomalacia, or tracheal compression resulting from a hematoma. Patients with postextubation croup may respond to supportive measures, including humidified supplemental oxygen, nebulized racemic epinephrine, and possibly, continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP). Occasionally, these patients require brief reintubation before they can be successfully extubated. Unilateral vocal cord paralysis may go unnoticed or be associated with only mild stridor. Bilateral vocal cord paralysis, on the other hand, may manifest as severe stridor and upper airway obstruction. The child with bilateral vocal cord paralysis requires reintubation for airway support. A muscle relaxant such as rocuronium should be used to facilitate reintubation to avoid damage to the abducted cords. If the paralysis is prolonged, the child may subsequently require tracheostomy. Compression of the trachea by a hematoma may occur immediately after the operation or over the course of several hours. The child requires reintubation and surgical evacuation of the hematoma to relieve tracheal compression. Opening the wound in the recovery room may be necessary and lifesaving. After the extrinsic obstruction has been relieved and the incision closed again (if necessary), the child may be safely extubated.

Inadvertent resection of the parathyroid glands during thyroidectomy may result in acute hypoparathyroidism after surgery. Clinical signs of hypocalcemia may become manifest

within the first postoperative day or take as long as 72 hours to develop. A low serum-ionized calcium level and a low concentration of parathyroid hormone are diagnostic. Clinical hypocalcemia, including tetany, is treated with IV calcium therapy. Surgical manipulation of the trachea and neck tissues can also lead to subcutaneous emphysema and the more serious possibility of pneumomediastinum or pneumothorax. Postoperative evaluation should include radiologic examination of the chest if respiratory distress occurs.

Pheochromocytoma

Pheochromocytoma is a catecholamine-secreting tumor of chromaffin cells that most commonly arises in the adrenal medulla (DiGeorge, 1987). It may be found anywhere along the abdominal sympathetic chain, but it is most commonly near the aorta at the inferior mesenteric artery or the aortic bifurcation. Other sites include the neck, the mediastinum, and the walls of the bladder or ureters. Pheochromocytoma is a rare neoplasm in the pediatric population. Fewer than 5% of reported cases occur in children. The tumors may occur bilaterally or at multiple sites. This condition can be inherited as an autosomal-dominant trait (most often in association with von Hippel–Lindau syndrome) or as part of a multiple endocrine neoplasia (MEN) type II or III (Table 36-9).

The abnormally high plasma levels of epinephrine and norepinephrine produce a clinical syndrome with signs and symptoms related directly to the level of each hormone present in the patient. Hypertension is common and often leads to hypertensive encephalopathy and seizures. In particular, paroxysmal hypertension is most suggestive of pheochromocytoma. The patient may also complain of headaches and palpitations, pallor, sweating, and vomiting. In severe cases, patients develop chest pain that radiates to the arms, pulmonary edema, and cardiac decompensation. The catecholamine-induced hypermetabolism also can cause patients to have a voracious appetite but still lose weight and become cachectic. Polyuria, polydipsia, and abdominal pain may occur and be confused with diabetes mellitus.

Diagnosis

It is extremely important to establish the diagnosis of pheochromocytoma before induction of anesthesia and start of surgery. The significant cardiovascular effects of excess catecholamines

can pose difficulties for the anesthesiologist and endanger the patient during the perioperative period if an appropriate diagnosis is not made preoperatively. These tumors can produce paroxysms of hypertension and other symptoms. Between paroxysms, the patient may be totally asymptomatic, making diagnosis extremely difficult. The demonstration of increased levels of catecholamines is the most specific diagnostic test. Although pheochromocytomas can produce norepinephrine and epinephrine, the predominant catecholamine produced in children is norepinephrine, which leads to chronic hypertension. Urine catecholamine concentrations are directly proportional to circulating levels, and determination of 24-hour urinary excretion of the primary catecholamines and their metabolites (i.e., 3-methoxy 4-hydroxy vanillyl-mandelic acid [VMA] and metanephrine) used to be the primary means of establishing the diagnosis. The plasma free metanephrine determination has better sensitivity (100%) and specificity (94%). Because normal values differ with age, it is important to use age-specific norms when interpreting results (Weise et al., 2002).

The differential diagnosis includes renal vascular disease, hyperthyroidism, Cushing syndrome, coarctation of the aorta, adrenal cortical tumors, and essential hypertension. Cerebral disorders, diabetes mellitus, and DI may produce similar symptoms. Neoplasms of neural origin (e.g., neuroblastoma or ganglioneuroma) may also secrete catecholamines.

Before any contemplated anesthesia and surgery, the patient must undergo a complete evaluation to localize the tumor, including CT and MRI scans. Magnetic resonance angiography (MRA) and venography (MRV) may be used to identify vascular supply. A radionuclide (I-131 metaiodobenzylguanidine [MIBG]) scan may also help to localize the tumor. Differential venous catheterization may be needed to obtain blood from various sites for catecholamine levels if multiple tumors are suspected. Sedation or anesthesia may be required to perform these studies in infants and children. Before sedation for these diagnostic studies, hemodynamic abnormalities must be normalized. Drugs that induce catecholamine secretion or histamine release should be avoided. General anesthesia for the diagnostic procedures must be conducted with the same extreme caution one would exercise for resection of the tumor itself.

Preoperative Preparation and Evaluation

Preoperative evaluation should include the measurement of serum electrolytes, determination of renal function, and fasting blood glucose. Excessive serum epinephrine levels may be associated with hyperglycemia and hypokalemia. An electrocardiogram and echocardiogram are important to evaluate cardiac rhythm, size, and function. Some patients with pheochromocytoma have a catecholamine-induced cardiomyopathy with decreased left ventricular contractility. The patient should be evaluated for associated endocrinopathies that may be present as part of MEN type II or III.

Symptomatic treatment includes the administration of phenoxybenzamine over a period of several days to weeks before surgery. Phenoxybenzamine is a long-acting, orally administered α -adrenergic blocking agent that attenuates the effects of catecholamines on the peripheral circulation by blocking excessive vasoconstriction (Hoffman and Lefkowitz, 1990). The starting dose of phenoxybenzamine is 0.2 mg/kg once daily (maximum adult dose, 10 mg) (Taketomo et al., 2008). Then both dose and frequency are gradually increased (up to 3 times a day)

TABLE 36-9. Multiple Endocrine Neoplasia Syndromes

MEN, Multiple endocrine neoplasia.

until a clinical effect is obtained; that is, the patient's hematocrit decreases (because of vasodilation and increased blood volume), and the patient develops orthostatic changes in vital signs. Long-standing vasoconstriction produced by chronically high catecholamine levels causes decreased intravascular volume. Although the use of phenoxybenzamine restores vascular capacity to normal, increased oral fluid intake should accompany administration of phenoxybenzamine to avoid severe orthostatic changes. In some children, β -adrenergic blocking drugs such as propranolol may be needed to control heart rate and blood pressure. However, β -blocking agents should never be used without concurrent α -blockade therapy because of the deleterious effects of unopposed α -agonism, which may result in cardiac failure as a result of increased afterload. Labetalol may have a role in the management of pheochromocytoma, because it has α - and β -adrenergic blocking properties (Blom et al., 1987). It can be useful in minimizing the cardiovascular effects of excess catecholamines during the perioperative period, but it is not as potent an α -blocker as is phenoxybenzamine for preoperative treatment.

In addition to pharmacologic preparation, children with pheochromocytoma benefit from preoperative sedation to reduce the release of catecholamines caused by anxiety. Oral or IV midazolam alone or in combination with an opioid provides a good level of sedation.

Anesthetic Induction

Induction of anesthesia is accomplished with IV anesthetics. Ketamine is specifically contraindicated, because it induces catecholamine release. Halothane should be avoided, because it may sensitize the myocardium to catecholamines and produce dysrhythmias. Mask induction with sevoflurane is well tolerated if hemodynamic parameters are well controlled, and IV cannula placement can be deferred until after induction. Intubation may proceed in the usual fashion, facilitated by a hemodynamically neutral nondepolarizing muscle relaxant such as vecuronium. Pancuronium, which causes muscarinic blockade and tachycardia, should be avoided. Despite the fact that atracurium causes histamine release and vasodilation, it has been used safely in adult patients with pheochromocytoma (Prys-Roberts, 2000). Before intubation, IV lidocaine (1 mg/kg), fentanyl (2 to 5 mcg/kg), or both are effective in minimizing the hemodynamic response to intubation.

Intraoperative Management

After induction of anesthesia, an intraarterial catheter is placed to monitor the blood pressure continuously. Before induction, a reliable automated blood pressure device can provide frequent, accurate blood pressure measurements. A central venous catheter provides direct and reliable access for the assessment of intravascular volume and for infusions of fluids and emergency medications.

Anesthesia may be maintained with isoflurane or sevoflurane, air, and oxygen. Both anesthetic agents have been used without exacerbation of hypertension, despite the fact that they do not blunt the production of norepinephrine in response to surgical stimulation (Suzukawa et al., 1983). Desflurane should be avoided because of its tendency to cause tachycardia and hypertension. The addition of moderately large doses of fentanyl (10 mcg/kg) or remifentanyl (0.3 to 1 mcg/kg per

minute) minimizes the stress response and provides stable hemodynamics. If remifentanyl is chosen, it is important to give a longer-acting opioid before the end of surgery to avoid hypertension as a result of pain on awakening. Adjunctive use of epidural anesthesia (i.e., local anesthetic with or without a small dose of fentanyl) is an excellent method of reducing the stress response and catecholamine release caused by usual surgical stimulation. However, none of these anesthetic strategies blocks catecholamine release that results from direct surgical manipulation of tumor tissue.

Historically, controlling blood pressure during the induction and maintenance of anesthesia has been accomplished by an infusion of sodium nitroprusside or phentolamine. However, resection is increasingly being performed using a laparoscopic technique, and either nicardipine or magnesium sulfate infusions are used to maintain vasodilation and normotension during this type of surgery (Pretorius et al., 1998; Minami et al., 2002). In addition to propranolol use preoperatively, esmolol has been effective as a continuous infusion titrated to the level of surgical stimulation (Nicholas et al., 1988). Infusions of only short-acting vasodilators are recommended for control of hypertension before tumor resection, because with removal of the tumor, vasodilation caused by a persistent blockade and loss of excess catecholamines may lead to precipitous hypotension. Phenoxybenzamine has a long half-life; therefore, some physicians recommend discontinuing it 24 hours before surgery to decrease the likelihood that persistent vasodilation caused by a blockade will cause severe hypotension after the tumor is removed because of withdrawal of the catecholamines of tumor origin (Prys-Roberts, 2000). Hypotension is best treated with discontinuation of vasodilator infusions, titration of anesthetic agents, and administration of crystalloid or colloid and blood products, if it is indicated by the magnitude of blood loss. If these measures are ineffective, vasopressors may be necessary, but the patient may be relatively resistant to α -agonists as a result of persistent α -blockade. If this occurs, judicious use of small doses of more potent, direct-acting vasoconstrictors (e.g., norepinephrine or epinephrine) may be necessary. Recently, vasopressin infusion has been effective in this situation (Deutsch and Tobias, 2006).

During surgery, arterial blood gases, serum glucose, urine output, and body temperature should be closely monitored. Hyperglycemia may occur in response to high catecholamine levels. Hypoglycemia may occur when the tumor is removed and catecholamine levels decrease. Because of the potential for dysrhythmias, the electrocardiogram should also be vigilantly observed. At the end of surgery, the muscle paralysis is reversed. Extubation can be accomplished when the patient meets all normal extubation criteria.

Postoperative Care

Postoperatively, the patient should be observed in an intensive care unit, with continuous monitoring of the arterial blood pressure and electrocardiogram. Hypertension usually resolves within 24 to 48 hours after surgery. If symptoms persist beyond this period, further investigation for residual pheochromocytoma is warranted. Good postoperative analgesia is provided with epidural infusion (if an open procedure was performed) or IV patient- (parent- or nurse-) controlled analgesia.

RESPIRATORY DISORDERS

Upper Respiratory Tract Infection

Viral upper respiratory tract infections (URIs) are mild processes that do not preclude school attendance and other routine activities. However, URIs hold much greater significance for anesthesiologists. For many anesthesiologists, it is standard practice to avoid general anesthesia for elective surgery in children with URIs because of the respiratory complications during and after anesthesia reported in multiple small case series (McGill et al., 1979; Cohen and Cameron, 1991; Konarzewski et al., 1992; Williams et al., 1992). Unfortunately, the vexing problem of runny noses in children is accentuated by the difficulty in differentiating URIs from other causes, such as allergic rhinitis, which does not increase the risk of complications.

Pathophysiology of Upper Tract Respiratory Infection

Many investigators suggest that complications, including bronchospasm, intraoperative hypoxemia with an increased alveolar-arterial oxygen gradient, and postoperative hypoxemia, occur more often in children who undergo anesthesia while they have URIs (McGill et al., 1979; Olsson, 1987; DeSoto et al., 1988). The proclivity for these complications may be related to peripheral airway abnormalities, which have been demonstrated experimentally in adult humans and animals infected with viral respiratory pathogens (Johanson et al., 1969; Fridy et al., 1974; Dueck et al., 1991). These abnormalities include decreased diffusing capacity and increased closing volume—factors that can predispose patients to intrapulmonary shunting and hypoxemia, especially when they are combined with the effect of general anesthesia on lung volumes (decreased functional residual capacity) (see Chapter 3, Respiratory Physiology in Infants and Children) (Murat et al., 1985). These studies were done in adults who had infections involving their entire respiratory tracts rather than isolated URIs, and their results may support separation of treatment of patients with truly isolated URIs from those with any symptoms of more global airway or pulmonary parenchymal involvement (lower respiratory tract infection). Although the mechanisms by which viral respiratory infections lead to alterations in airway function are unclear, these experimental studies support the clinical impression that increased risk of perioperative hypoxemia occurs in patients with recent viral respiratory infection.

Empey et al. (1976) demonstrated in adult patients that acute viral respiratory tract infection (influenza) produced marked bronchial reactivity to experimental bronchoconstrictor challenge that may persist for 6 weeks. Mechanisms by which viral infections lead to increased airway reactivity include the release of immunologic and inflammatory mediators such as leukotrienes, bradykinin, and histamine, which cause bronchoconstriction. Vagal-mediated mechanisms may be involved, because viral infections have been associated with changes in muscarinic receptors on airway smooth muscle (Fryer et al., 1990). Tissue concentrations of important enzymes such as neutral endopeptidase, which break down the neuropeptides that cause bronchoconstriction, are also decreased in viral infections (Jacoby et al., 1988; Dusser et al., 1989). However, these patients and animals cannot be said to have only URIs, because the airways below the larynx are also clearly affected. Patients whose infections are truly uncomplicated URIs or those with noninfectious

causes of runny nose should be differentiated from those who have evidence of lower respiratory involvement.

Perioperative Risk

Many case reports in the literature document that in the perioperative period children with URIs have respiratory complications, including bronchospasm, stridor caused by subglottic edema, hypoxia, and atelectasis (McGill et al., 1979; Konarzewski et al., 1992; Williams et al., 1992). Three prospective studies have shown that patients with an active or recent URI had a 2- to 10-fold higher risk of bronchospasm or laryngospasm (Olsson and Hallen, 1984; Olsson, 1987; Cohen and Cameron, 1991). The incidence was higher among younger children, especially those younger than 2 years and those whose tracheas were intubated (Cohen and Cameron, 1991). Retrospective studies of much larger numbers of patients show a higher risk of respiratory complications may actually exist in asymptomatic children with history of URI within the 2 to 4 weeks preceding surgery than in those with acute URI (Tait and Knight, 1987b; Tait et al., 2001). Other studies found that the factors that increase the risk of adverse events were history of prematurity or reactive airways disease (RAD), parental smoking, copious secretions, nasal congestion intubation, and airway surgery (Tait et al., 2000, 2001). Despite this increased risk of adverse events, complications usually were easily treated and were not associated with any significant prolonged morbidity (Rolf and Cote, 1992; Tait et al., 2000, 2001). However, some patients in one study developed atelectasis severe enough to require bronchoscopy and prolonged postoperative mechanical ventilation. Although most of these studies evaluated children undergoing relatively minor elective surgery, another study reported that children with URI symptoms at the time of cardiac surgery also had increased risks for respiratory and other complications, including nonrespiratory infection (Malviya et al., 2003). Despite these findings, patients' hospital stays were not prolonged, and the incidence of long-term sequelae was not increased.

One study found that children with URIs who undergo mask halothane-nitrous oxide-oxygen anesthesia for myringotomy surgery had reduced severity and duration of URI symptoms in the postoperative period (Tait and Knight, 1987a). However, this reduction in symptoms may have resulted from the drainage and removal of infectious foci by the surgical procedure rather than from the beneficial effects of general anesthetics. Other investigators have reported no significant respiratory complications when children with URI were anesthetized (Hinkle, 1989; Jacoby and Hirshman, 1991). It is extraordinarily difficult to integrate the contradictory conclusions of these various series of patients to develop a logical algorithm for dealing with the child with a URI.

Anesthetic Decision Making

It is apparent that no consensus has been reached in the literature or in the general anesthesia community with regard to the wisdom and safety of anesthetizing children with active or recent URIs. The bulk of the literature, clinical and experimental, suggests that recent viral infection increases the perioperative risk for respiratory complications, albeit mild and treatable, when the surgical and anesthetic plans require intubation. In children with underlying RAD, the risk for pulmonary complications immediately after acute URI is much greater than in

the normal patient population, making intraoperative bronchospasm much more likely. The threshold for postponing surgery in the asthmatic child with a recent URI who requires intubation is much lower. These risks must be weighed against the physiologic, psychological, and financial implications of delaying surgery.

The most conservative approach to the child with a URI or recent URI is to postpone elective procedures for 1 to 2 weeks for uncomplicated rhinorrhea, congestion, and nonproductive cough and for 4 to 6 weeks for patients with lower-airway involvement (e.g., wheezing or productive cough). However, this may be an overly cautious and somewhat unrealistic recommendation. Children without other health conditions have an average of 3 to 8 colds per year, and children whose mothers smoke, who live in crowded conditions, and who attend daycare centers have a 61% incidence of URIs over a 2-week period (Fig. 36-2) (Fleming et al., 1987). It may be nearly impossible to find a time when the child does not have a URI or is not recovering from one. The needs of the family must be considered. Often, parents have traveled significant distances, taken time off from work, and made alternative childcare arrangements for their other children. Because the available data do not clearly indicate a single best approach to these patients, each anesthesiologist should develop a consistent approach appropriate to the individual practice.

The following is a summary of an approach to the child with symptoms of URI. First, many children undergo operations directed at ameliorating their chronic upper respiratory tract symptoms. In cases such as myringotomy with tube placement, tonsillectomy, adenoidectomy, and cleft palate repair, the procedures are not automatically canceled or postponed unless the child's signs and symptoms are clearly "different from baseline" or clearly involve more than the upper respiratory tract. Children who undergo the procedures just listed have a high incidence of upper respiratory tract symptoms and may always have manifestations consistent with URI. Most parents can advise whether their child is more congested than usual.

FIGURE 36-2. Probability of upper respiratory tract infection according to age, crowding, maternal smoking, and daycare status. (From Fleming DW, et al.: *Childhood upper respiratory tract infections: to what degree is incidence affected by daycare attendance?* Pediatrics 79:55, 1987.)

Box 36-5 Signs and Symptoms of Upper Respiratory Infection

1. Mild sore or scratchy throat
2. Mild malaise
3. Sneezing
4. Rhinorrhea
5. Nasal congestion or stuffiness
6. Nonproductive cough
7. Fever higher than 101° F (38° C)
8. Laryngitis

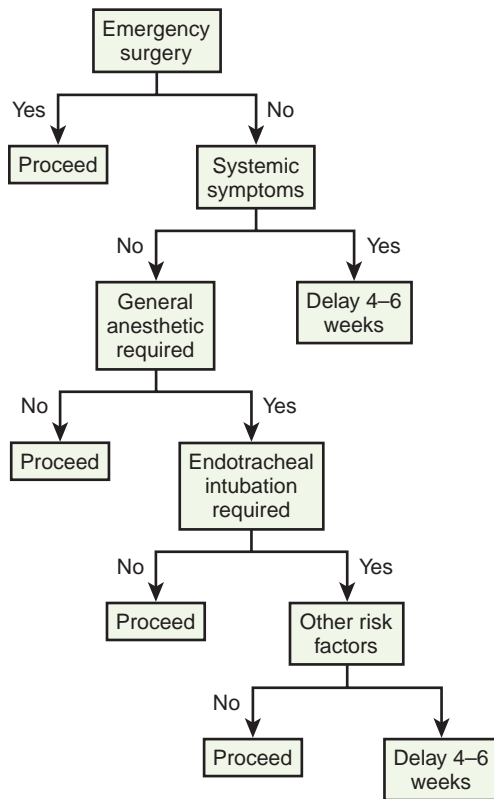

To make a diagnosis of URI, two of any of the above signs or symptoms are required. If 1 and 2, 3 and 4, or 5 and 6 are combined, one additional sign or symptom is required.

Modified from Tait AR, Knight PR: The effects of general anesthesia on upper respiratory tract infections in children, *Anesthesiology* 67:930, 1987a.

Elective surgeries other than those cited previously are postponed if any of the following are present: "croupy" cough; rectal temperature higher than 38.3° C associated with any URI sign or symptom; malaise or decreased appetite; and any evidence or recent history of lower respiratory tract involvement such as rales, wheezes, productive cough, or abnormal chest radiograph (Box 36-5). Laboratory and radiographic tests are usually not helpful in the decision-making process, although some investigators recommend obtaining a chest radiograph and a white blood cell count to evaluate the child with a URI. The white blood cell count is neither sensitive nor specific in identifying a URI, and chest radiography associated with a normal auscultative examination is unlikely to identify abnormalities (Brill et al., 1973). The presence of rales or wheezes should lead to postponement of elective surgery, regardless of findings on the chest radiograph. A suggested algorithm for making decisions about proceeding with surgery is presented in Figure 36-3.

Anesthetic Management

Several major principles of anesthetic management can be suggested for dealing with children with acute or recent URIs (Tait and Malviya, 2005). These are especially important in anesthetizing children when surgery is urgent and cannot be delayed. In elective situations, it is best to avoid intubation if possible (if the surgical procedure allows), instead using regional anesthesia or general anesthesia by mask or laryngeal mask airway (LMA). A randomized, prospective study demonstrated a much lower incidence of bronchospasm in children with URI managed with LMA rather than ETT (0% vs. 12.2%) (Tait et al., 1998). The incidence of all respiratory complications was reduced by 50% for the LMA group (19% vs. 35%). LMA may be an excellent alternative for airway management for patients with URI if the planned surgical procedure and fasting status are compatible with its use. If intubation is indicated, it should be accomplished when the patient is at a deep plane of anesthesia using an ETT at least 1 size (0.5 cm) smaller than age would determine. Any IV induction agent is acceptable, with the most important guiding principle being that enough should be given to achieve a deep level of anesthesia. An alternative is mask induction of inhalation anesthesia with sevoflurane, with or without nitrous oxide, and oxygen. If the procedure is expected to be prolonged,

■ **FIGURE 36-3.** Algorithm for clinical decision making for a patient with upper respiratory tract infection. (From Martin LD: *Anesthetic implications of an upper respiratory tract infection in children*, *Pediatr Clin North Am* 41:121, 1994.)

heated humidification should be used, because use of dry gas may lead to inspissation of secretions.

Adjunctive agents, such as IV lidocaine (1 mg/kg), an opioid, or both, decrease airway reflexes (Hirshman, 1983). The preoperative use of anticholinergic agents (i.e., atropine and glycopyrrolate) theoretically may block muscarinic receptors, thereby interrupting the airway reflex arc (Jacoby and Hirshman, 1991). Their properties as antisialogogues may be helpful; however, these agents have not been shown to be beneficial in prospective studies (Tait et al., 2007). The use of glucocorticoids experimentally has decreased viral-associated, tachykinin-induced airway edema formation, although glucocorticoids are not routinely prescribed in this clinical situation—in contrast to their use in the patient with RAD (Piedimonte et al., 1990). Dexamethasone, however, has been used in an effort to prevent postextubation croup, but these studies have been performed in critically ill children who had undergone prolonged intubation and mechanical ventilation in the intensive care unit, rather than in children with respiratory infections who are undergoing surgery. In this high-risk population, dexamethasone may be effective (Markovitz and Randolph 2002; Lukkassen et al., 2006). If intubation is necessary, tracheal suction of URI-associated secretions after intubation and before extubation may decrease the chance of atelectasis and mucus plugging, although this hypothesis has not been studied.

Management of children with URI requires a logical approach. When this issue arises in the preoperative period, the patient, parents, surgeon, and anesthesiologist must participate in an

informed fashion in the decision-making process; however, “in the final analysis, the name of the game is clinical judgment and a degree of good fortune” (Berry, 1990).

Reactive Airways Disease (Asthma)

RAD, or asthma, the most common chronic disease of childhood in industrialized countries, has received wide public attention in recent years because of increases in morbidity and mortality. Asthma is the major cause of restricted activity, absence from school, and hospital admission in children, and it is responsible for significant health care costs in the United States (Newacheck and Halfon, 2000). The prevalence of asthma among children is greater than among adults, and it has increased by an average of 4.3% each year between 1980 and 1996 (Akinbami and Schoendorf, 2002). Beginning in 1997, the survey questions used to determine the prevalence of asthma were changed, which resulted in a slightly lower prevalence than in previous years, but the increasing trend has remained constant (MMWR, 2000).

Etiologic Factors and Pathophysiology

Asthma is a chronic inflammatory disorder of medium and small airways in which many cell types play a role, including mast cells and eosinophils. These cells release mediators of inflammation that, in susceptible individuals, cause symptoms associated with variable airway obstruction and airway hyperreactivity that is partially or completely reversible spontaneously or with appropriate treatment. Understanding the important role of inflammation in the immunopathogenesis of asthma in recent years has changed the focus to a newer therapeutic approach using antiinflammatory agents. Among the immune regulatory pathways involved in the pathogenesis of asthma, 2 cytokines—interleukin-4 and interferon- γ —appear to be important in controlling immunoglobulin E (IgE) production, which is critical in the allergic inflammatory process. In individuals with asthma, mast cells and eosinophils are attracted to airways and release cytokines and lipid mediators that cause inflammation (Goldstein et al., 1994). The interplay of allergens and irritants, mast cells, eosinophils and their mediators, and the end effects on pulmonary vessels and airways is depicted in Figure 36-4. These mediators include histamines, leukotrienes, prostaglandins, kinins, and cytokines. Airway obstruction in asthma results from a combination of several factors, including airway smooth muscle spasm, airway mucosal edema, hypersecretion, and mucus plugging of small bronchi and bronchioles (Djukanovic et al., 1990). These changes result in airway obstruction, increased work of breathing, uneven distribution of ventilation, and in severe disease, air trapping, hyperinflation, and ventilation-perfusion imbalance, which leads to hypoxemia, diaphragmatic fatigue, hypercapnia, and respiratory failure. In longstanding RAD, mast cells infiltrate airway smooth muscle and in combination with chronic inflammation may result in airway remodeling, potentiating bronchoconstriction and airway hyperreactivity (Brightling et al., 2002).

A strong association exists between asthma and allergy. Up to 90% of children with recurrent wheezing respond positively to bronchoconstrictor challenge, especially when associated with atopy (Clough et al., 1991). An increased prevalence of asthma is reported among first-degree relatives of asthmatic

■ **FIGURE 36-4.** Pathophysiology of asthma.

subjects; over two thirds of children with asthma appear to have a familial predisposition (Clifford et al., 1989). Various environmental factors precipitate airway hyperreactivity and trigger asthma. Recent evidence has shown that obesity is associated with a proinflammatory state and is an independent risk factor for the development of asthma (Visser et al., 2001; Guerra et al., 2004).

The onset of asthmatic symptoms is often associated with viral infection of the lower respiratory tract, particularly respiratory syncytial virus (RSV) infection in infants and children (Rooney and Williams, 1971). Severe viral bronchiolitis in infancy is significantly associated with the subsequent development of airway hyperreactivity and asthma, although familial factors cannot be ruled out (Gurwitz et al., 1981; Gern et al., 2005; Lemanske et al., 2005). The development of IgE antibody to RSV may have an important role in inducing an allergic response to the virus (Welliver et al., 1989; Rakes et al., 1999). Children who experience respiratory failure and mechanical ventilation during infancy and early childhood, such as those with bronchopulmonary dysplasia (BPD), neonatal repair of congenital diaphragmatic hernia, or severe viral bronchiolitis, develop and sustain airway hyperreactivity even without a family history of asthma (Mallory et al., 1989; Nakayama et al., 1991). Prematurity alone may be associated with a higher incidence of asthma in preadolescent children (von Mutius et al.,

1993). The primary site of airway obstruction and hyperreactivity in children with a history of neonatal respiratory failure appears to be in relatively small airways—in contrast to relatively large central airway obstruction and hyperreactivity in those with typical allergic (i.e., IgE antibody-mediated) asthma (Mallory et al., 1991). In these patients, airway spasm is characterized by a rapid drop in oxygen saturation of Hb (SpO_2) without audible wheezing by auscultation.

In children with RAD, parental smoking (passive smoking) increases the severity of symptoms and exacerbates airway hyperreactivity (Soussan et al., 2003). Intrauterine exposure to maternal smoking also increases the incidence of airway hyperresponsiveness in infants (Singh et al., 2003). Infants with gastroesophageal reflux and chronic esophagitis often develop airway hyperresponsiveness with or without chronic aspiration and resultant tracheobronchial inflammation (Sheikh et al., 1999). Contributing factors responsible for the development of airway hyperreactivity and asthma are listed in [Figure 36-5](#).

Precipitating Factors for Reactive Airways Disease

Viral lower respiratory infections, particularly those caused by RSV and influenza, sensitize airways and provoke airway hyperreactivity even in individuals who are nonasthmatic and non-allergic for as long as 6 weeks (Empey et al., 1976). Exposure

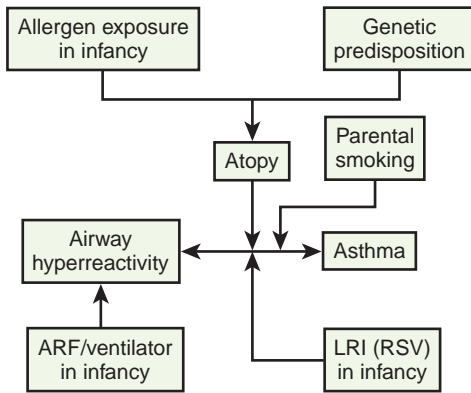

FIGURE 36-5. Contributing factors to the development of RAD. ARF, Acute renal failure; LRI, lower respiratory tract infection; RSV, respiratory syncytial virus.

to dry, cold air can precipitate tracheobronchial constriction in subjects with asthma, presumably in response to reduced tracheal temperature caused by evaporative heat loss (Gilbert et al., 1988). The same mechanism appears to be responsible for exercise-induced bronchospasm and precipitation of asthma with excitement, anxiety, and hyperventilation (McFadden and Gilbert, 1994).

The time before and during the induction of anesthesia is uniquely suited to trigger bronchospasm in susceptible individuals because of the patient's emotional stress, fear, and excitement. Hyperventilation results, with mouth breathing of dry anesthetic gas mixtures, airway irritation by volatile anesthetics, and mechanical stimulation of the pharyngeal and laryngeal mucosa by laryngoscopy and endotracheal intubation (Box 36-6).

Pharmacologic Agents for Asthma

The pharmacologic management of asthma consists of bronchodilators and antiinflammatory drugs and includes six different classes of drugs: corticosteroids, leukotriene inhibitors, β -adrenergic agonists, theophylline, cromolyn (or nedocromil), and anticholinergics. Recently published guidelines for treatment of asthma in children include a useful algorithm (Fig. 36-6) (Bacharier et al., 2008). Initial treatment for asthma most commonly consists of inhaled corticosteroids (ICSs) and leukotriene-receptor antagonists, with ICSs usually being the first-line drugs. Montelukast has been used widely in children. Other first-line alternatives are cromolyn

ALGORITHM FOR PHARMACOLOGIC TREATMENT OF REACTIVE AIRWAYS DISEASE

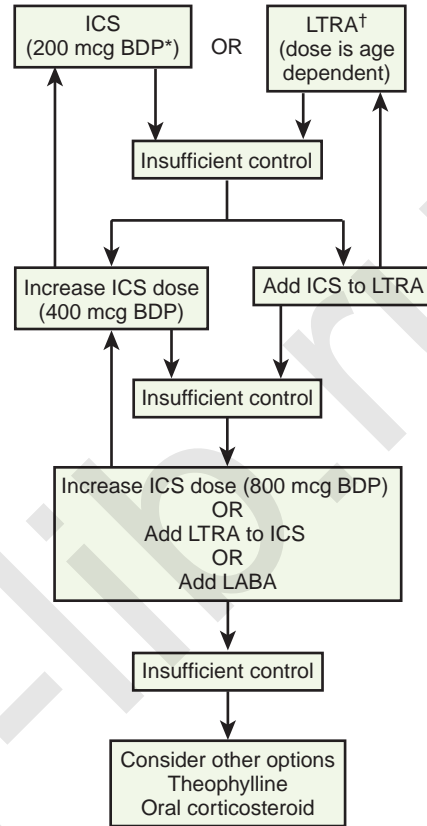

FIGURE 36-6. Algorithm for treatment of RAD. Once control is achieved, therapy may be stepped down to previous level. ICS, Inhaled corticosteroid; BDP, beclomethasone equivalent; LTRA, leukotriene receptor antagonist, for dose, see Table 36-10. (Modified from Bacharier LB, et al: *Diagnosis and treatment of asthma in childhood: a PRACTALL consensus report*, Allergy 63:5, 2008.)

(or nedocromil). Because of safety concerns, long-acting β_2 -agonists such as salmeterol are now reserved for patients with poor control despite use of an ICS and leukotriene-receptor antagonists (Martinez, 2005). Theophylline has reentered the treatment algorithm if patients have exacerbations despite ICS and β -adrenergic agonists. Oral corticosteroids in brief high-dose pulses are reserved for patients with moderate to severe asthma that is unresponsive to combinations of the other drugs (Stempel, 2003). Drugs commonly used in children are listed in Table 36-10.

Corticosteroids

ICSs have become popular for the treatment of asthma because of their potent antiinflammatory effect on the airways with limited systemic effects (as compared with oral steroids) and are a first-line regimen recommended in treatment guidelines. Regular use of an ICS allows effective control of symptoms and improvement in lung function, reduces airway inflammation, and results in a gradual reduction in airway hyperreactivity (Konig, 1988; Juniper et al., 1991). Although corticosteroids inhibit the in vitro proliferation of airway smooth muscle

Box 36-6 Precipitating Factors for Bronchospasm

- Lower respiratory infection (adenovirus, RSV)
- Irritants (cigarette smoke, inhaled anesthetics)

TABLE 36-10. Drugs Used for Asthma

Drug	Formulation	Dosage
Antiinflammatory Drugs		
<i>Inhaled Corticosteroids</i>		
Beclomethasone dipropionate (QVAR)	MDI, 40, 80 mcg/puff	2-4 puffs bid (5-11 yr)
Budesonide (Pulmicort)	DPI, 90, 180 mcg/inhalation	1-2 inhalations bid (6-17 yr)
Flunisolide (AeroBid)	MDI, 250 mcg/puff	2 puffs bid (6-15 yr)
Fluticasone propionate (Flovent)	MDI, 44, 110, or 220 mcg/puff	1-2 puffs bid (max, 440 mcg/d) (4-11yr)
Fluticasone propionate (Flovent Diskus)	DPI, 50 mcg/inhalation	1-2 inhalations bid (4-11 yr)
Triamcinolone acetonide (Azmacort)	MDI, 75 mcg/inhalation	2-4 inhalations bid (6-12 yr)
<i>Oral Corticosteroids</i>		
Prednisone/prednisolone	Oral tablets (1, 2.5, 5, 10, 20 mg)	Acute: 1 mg/kg q d/bid × 5-14 d
Prednisone/prednisolone (Prelone, Pediapred)	Oral liquid (1 mg/mL)	Chronic: 0.25-2 mg/kg qod Preoperative: 1 mg/kg/d × 3 d Max, 60 mg/d
<i>Leukotriene Receptor Antagonist</i>		
Montelukast (Singulair)	Oral granules, 4 mg; chewable tablets, 4.5 mg	12 mos-5 yrs: 4 mg qd; 6-14 yrs: 4.5 mg qd
<i>Cromolyn Sodium (Intal)</i>		
Cromolyn (generic)	Solution for nebulization (10 mg/mL)	1-2 inhalations tid-qid
<i>Inhaled β-2 Agonists (Bronchodilators)</i>		
Short-acting (SABA)		
Albuterol (Proventil, Ventolin)	MDI, 90 mcg/inhalation	2 puffs q 4-6 hr prn
Albuterol (generic)	Nebulized solution (0.63, 1.25, or 2.5 mg/3 mL; 2.5 mg/0.5 mL)	0.63 or 1.25 mg tid-qid prn
Levalbuterol (Xopenex)	Nebulized solution (0.31, 0.63, or 1.25 mg/3 mL)	0.31-0.63 mg tid prn (6-11 yrs)
Long-acting (LABA)*		
Salmeterol (Serevent)	DPI, 50 mcg/blister	50 mcg bid (\geq 4 yrs)
Theophylline (generic)	Oral solution, 80 mg/15 mL Tablet (immediate release), 100 mg Capsule (sustained release), 125, 200, 300 mg	<1 yr: max, 0.2 × (age in weeks) + 5 = dose in mg/kg/d >1 yr: 10 mg/kg/d; max, 16 mg/kg/d
Anticholinergics		
Ipratropium bromide (Atrovent)	MDI, 17 mcg/puff	3-14 yr: 1-2 puffs qid (for acute exacerbation); >14 yr: 2 puffs qid
Ipratropium bromide (generic)	Nebulized solution (500 mcg/2.5 mL)	125-250 mcg q 6-8 hr mixed with albuterol (5-12 yr) 250-500 mcg q 6-8 hr (>12 yr) [†]

*Recommended only for use in combination with inhaled corticosteroid for children >4-5 years of age. Data from Bacharier LB et al.: Diagnosis and treatment of asthma in childhood: a PRACTALL consensus report, *Allergy* 63:5, 2008; modified from *Treatment guidelines from the medical letter* 6:86, 2008.

DPI, Dry powder inhaler; MDI, metered-dose inhaler; prn, as needed

cells from subjects without asthma, they do not do so in airway smooth muscle cells from patients who have asthma (Roth et al., 2004). Recommended doses of ICS generally have minimal effects on the HPA axis; however, high doses, especially of fluticasone, have resulted in reduction of cortisol levels and symptomatic adrenal insufficiency in children (Barnes and Pedersen, 1993; Todd et al., 2002; Sim et al., 2003). Oral or parenteral corticosteroids are most effective for acute exacerbations of asthma unresponsive to maximal bronchodilator therapy (Chapman et al., 1991; Schuh et al., 2000).

Leukotriene-Receptor Antagonists

Leukotriene-receptor antagonists are a class of drugs developed for the prevention and treatment of bronchial asthma. They are an alternative first-line treatment or may be added if ICSs do not provide adequate control. The formation of leukotrienes through the 5-lipoxygenase pathway depends on lipoxygenation of arachidonic acid, a major constituent of cell membrane phospholipids, detached by phospholipase A₂ activity. Leukotrienes are potent bronchial smooth muscle

constrictors; on a molecular basis, leukotrienes C₄ and D₄ (LTC₄ and LTD₄) are approximately 1000 times more potent than histamine (Undem and Lichtenstein, 2001). Bronchial smooth muscle constriction by leukotrienes is considered a major cause of asthmatic symptoms. Leukotriene-receptor antagonists (e.g., zafirlukast, montelukast) are selective high-affinity LT₁-receptor antagonists (Jones et al., 1995). Their use is associated with increased exhaled nitric oxide (NO) (Straub et al., 2005). Montelukast has been reported to be effective as maintenance therapy in children with moderate to severe asthma, with or without concomitant steroid therapy, with minimal side effects (Knorr et al., 2001; Phipatanakul et al., 2003).

β₂-Adrenergic Agonists

β₂-adrenergic agonists initiate their action on the receptor sites of airway smooth muscle cells and increase adenylate cyclase activity, which produces cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP) and results in smooth muscle relaxation and bronchodilation.

For maintenance therapy in more severe RAD and for the prevention of exercise-induced bronchoconstriction, long-acting β₂-agonists (LABAs) are recommended (Bacharier et al., 2008). Studies suggest a small risk of increased asthma-related deaths in patients older than 12 years of age who take LABAs, especially if they are used regularly without an ICS; thus, the FDA requested that a “black box warning” be added to the labels of salmeterol and salmeterol/fluticasone in 2003 (Nelson et al., 2006). An FDA meeting was later convened to consider safety concerns regarding LABAs in adults and children. Although few children younger than 12 years of age have been studied, the risk of asthma exacerbations and hospitalizations was higher in children 4 to 11 years of age who received a combination drug with LABA and ICS when compared with patients who received ICS alone (Bisgaard and Szefer, 2006; Kramer, 2009). Until further studies are undertaken, it has been recommended that LABA not be given as monotherapy but only in combination with ICS (Drazen and O’Byrne, 2009). This concern does not apply to the use of short-acting β₂-agonists (SABAs), which are the drugs of choice for the treatment of intermittent episodes, acute exacerbations, and prevention of exercise-induced asthma in patients with RAD. The recommended doses of commonly used β₂-agonists are listed in [Table 36-10](#).

Methylxanthines

Methylxanthines (e.g., theophylline) produce bronchodilation by inhibiting adenosine-induced bronchoconstriction in asthmatic patients—not as was formerly thought, by competitively inhibiting phosphodiesterase, which metabolizes cAMP (Holgate, 1984). Although theophylline was the mainstay of pediatric asthma therapy in the 1970s and 1980s, it is no longer used for therapy in acute exacerbations of RAD (Rooklin, 1989). Theophylline still has a role in decreasing the severity of persistent bronchospasm, especially that which occurs at night. Theophylline has a narrow therapeutic index, with greatest efficacy at serum levels of 5 to 15 mcg/mL. Levels greater than 20 mcg/mL are associated with symptoms of toxicity, such as nausea, gastroesophageal reflux, irritability, learning difficulties in children, and headache (Creer and Gustafson, 1989; Ellis, 1985). Vomiting, tachyarrhythmias, and seizures can occur at

higher levels. The great variability of drug metabolism and the necessity for monitoring of blood levels are two reasons the use of theophylline has declined (Drugs for Asthma, 2002).

Anticholinergics

Ipratropium bromide is an atropine derivative and is available as a metered-dose inhaler and as a nebulizable solution. Ipratropium has a slower onset of action than β₂-agonists, but the duration of action is longer (up to 8 hours). Side effects are uncommon.

Cromolyn Sodium and Nedocromil Sodium

Cromolyn sodium does not have a bronchodilator effect; therefore it is exclusively a prophylactic agent and has no bearing on anesthetic practice. It attenuates bronchoconstriction caused by allergen, exercise, and bronchial challenge (Stempel, 2003). Nedocromil sodium has similar chemical and biological properties to cromolyn, which became available in the early 1990s (van Bever and Stevens, 1992). Cromolyn and nedocromil are thought to act on pulmonary mast cells and stabilize cell membranes. They reduce IgE antibody-induced release of inflammatory mediators, including histamine and leukotrienes, from activated mast cells (Douglas, 1985). Maintenance therapy with cromolyn or nedocromil is recommended in children with moderate to severe asthma.

Preanesthetic Consideration

The goal of the preoperative assessment of children with asthma is to ensure that each patient receives optimal treatment before reaching the operating room. The patient’s history, physical examination, and laboratory tests are all helpful to determine whether the patient’s condition is adequately managed. Children with RAD rarely require preoperative pulmonary function testing, but they are commonly monitored by pulmonology or allergy and immunology services with frequent assessment of pulmonary function testing (i.e., spirometry with flow-volume curves). Some families use the peak expiratory flow rate for home assessment. If this is so, the family should be queried to ensure that the peak expiratory flow rate is maximized.

Careful history taking is the single most important element of the preoperative evaluation of children with asthma. The profile of a typical acute episode, precipitating factors, and time of the most recent episode of asthma should be obtained. Previous and current drug therapy, dosages, effectiveness, and side effects, if any, should also be documented. Specific points of importance in the history include the following:

1. Determine whether the child has had episodes of bronchospasm and bronchodilator treatment in the previous 4 to 6 weeks. Ideally, elective surgery should be postponed for at least 4 to 6 weeks after an episode of symptomatic asthma, because airway hyperreactivity may be worsened after acute exacerbations, and pulmonary gas exchange may still be impaired because of bronchoconstriction, mucosal edema, and mucus plugs.
2. Determine whether the patient has a recent history of a URI or if the symptoms of URI still exist. URI in children with RAD is often associated with the exacerbation of bronchospasm and requires a more conservative approach

than in children who do not have asthma. Optimally, the child with a history of RAD should be free of URI symptoms for 4 to 6 weeks before an elective procedure, unless the URI symptoms recur so often that an asymptomatic period is difficult to attain. If the child has had a lower respiratory infection, such as influenza, within the previous 6 weeks, the postponement of scheduled surgery should be seriously considered, because airway hyperactivity would be exaggerated as long as 6 weeks, even in nonasthmatic patients.

3. Ascertain the child's steroid requirements over the previous year and the possible need for perioperative stress-dose steroid coverage (see preceding discussion). Children who often have bronchospasm that is poorly controlled with maximal therapy and require repeated courses of oral steroids may benefit from a short preoperative course of prednisone (1 mg/kg per day to a maximum of 60 mg once daily for 3 days, including the day of surgery), especially if endotracheal intubation is planned.

Physical examination should be focused on careful auscultation of the chest for clinical evidence of bronchoconstriction (i.e., expiratory wheezing), use of the accessory muscles of respiration, and a prolonged expiratory phase. During severe episodes of bronchospasm, air movement may become so limited that wheezing may be barely audible. Patients with a history of BPD and asthma are most likely to have lower-airway obstruction and small airway hyperactivity; wheezing and rhonchi may not be present (see Chapter 17, Neonatology for Anesthesiologists). The preanesthetic level of oxygen saturation should be obtained with a pulse oximeter while the child is breathing room air to determine the baseline oxygen saturation and assess for any preexisting hypoxemia. This information is exceptionally valuable for the postoperative assessment of lung function and gas exchange.

Anesthetic Management

The anesthesiologist must get to know the child with asthma and his or her parents and gain their confidence to minimize the child's anxiety before anesthesia induction. The child should be well sedated to avoid struggle and hyperventilation, which can provoke exercise-induced asthma. Midazolam, which may be administered transmucosally (i.e., orally, nasally, or rectally) in infants and young children and orally or intravenously (if IV access is present) in older children, works well for sedation. A β_2 -adrenergic agonist may be given prophylactically using a metered-dose inhaler or nebulizer before induction (Table 36-10). Otherwise, the drug can be given after the induction of anesthesia through the ETT using the metered-dose inhaler and an aerosol chamber inserted in between the ETT adapter and the anesthesia circuit.

The anesthetic approach is similar to that for children with URIs. After applying standard monitors (a minimum of a pulse oximeter and precordial stethoscope if the child is uncooperative), the inhalation induction should be smooth and progress swiftly with sevoflurane and nitrous oxide (see Chapter 11, Monitoring). For infants and young children, heated humidification should be used if available; the dry gas mixture from the anesthesia machine is a perfect environment for provocation of bronchospasm secondary to irritation and reduced tracheal

temperature from evaporative heat loss of the tracheal mucosa in a child with asthma (McFadden and Gilbert, 1994).

For IV induction, propofol may be a better agent of choice than thiopental because it suppresses airway reflexes as compared with barbiturates, although thiopental, despite risk of histamine release, is not necessarily contraindicated in patients with asthma (Brown et al., 1992; Gal, 1994). Propofol may also produce bronchodilation in patients with other types of airway disease (Conti et al., 1993). Regardless of the drug chosen, it is important to give sufficiently large IV doses to blunt the reflex response, and sevoflurane should be added before the peak effect of the IV agent is lost.

Whenever possible, endotracheal intubation should be avoided in patients with asthma, because the ETT stimulates large airway irritant receptors and can trigger bronchospasm (Hirshman, 1983). When no contraindications exist, an LMA is a good choice for patients with RAD, as its use avoids the laryngeal and tracheal stimulation of intubation (Groudine et al., 1995). It may also be prudent to avoid anesthetic agents that might release histamine (e.g., atracurium and morphine), although clinical evidence that such drugs actually cause intraoperative bronchospasm is limited.

An anesthetic technique using a volatile anesthetic may be preferable to a balanced technique (i.e., nitrous oxide, opioid, and muscle relaxant) for patients who have asthma because of the salutary bronchodilating properties of volatile agents. Regional anesthesia can be combined with inhalation anesthesia with sevoflurane or isoflurane. Desflurane may cause more airway irritation in patients with RAD and lead to bronchospasm and associated coughing, especially during emergence (von Ungern-Sternberg et al., 2008).

Intraoperative Wheezing

The differential diagnosis of intraoperative wheezing includes "light anesthesia," kinked ETT, mainstem bronchial intubation, increased airway secretions, foreign body in the airway, pulmonary edema, embolus, and aspiration. In the child with RAD, wheezing can result from exacerbation of airway hyperactivity and requires immediate attention. The treatment of intraoperative bronchospasm is detailed in Box 36-7. Treatment should begin after chest auscultation to confirm that there are bilateral breath sounds and therefore no mainstem intubation. The first step includes increasing the inhaled concentration of oxygen and deepening the level of anesthesia with volatile anesthetics, or administering IV propofol or

Box 36-7 Treatment of Intraoperative Bronchospasm

Confirm diagnosis (exclude mainstem bronchus intubation, mucus plug, pneumothorax, anaphylaxis, and congestive heart failure).

Deepen anesthesia with volatile agent.

Administer inhaled β -agonists and ipratropium.

Consider propofol or ketamine to further deepen anesthesia.

Consider IV lidocaine, atropine, or both.

Administer an IV corticosteroid.

Modify ventilation to avoid stacking breaths, gas trapping, and barotrauma.

ketamine (0.5 to 2 mg/kg), a known bronchodilator (Corssen et al., 1972; Hirshman et al., 1979). Lidocaine (1 mg/kg) may also be given intravenously to reduce airway reactivity at the earliest sign of bronchospasm. Administration of muscle relaxant and suctioning of the ETT may be performed if the patient is intubated. The second step consists of the administration of β_2 -agonists given by a metered-dose inhaler and adapter through the ETT, followed by the squeezing of the anesthesia bag manually to provide a vital-capacity maneuver to distribute the bronchodilator mist to the tracheobronchial tree. Because only 5% to 10% of the administered dose may reach the end of the ETT and contact the airway, 4 to 8 puffs of the β_2 -agonist should be administered through the ETT. This maneuver may be repeated two or three times. Parasympatholytic agents (atropine, 0.02 to 0.03 mg/kg) or antihistamines (diphenhydramine, 0.5 mg/kg) are indicated when wheezing is associated with increased vagal tone or histamine release, respectively. The development of hypotension, urticaria, or flushing should lead to the consideration of anaphylaxis. Corticosteroids (e.g., 2 mg/kg of IV hydrocortisone) should be given, and circulation should be supported with appropriate vasoactive agents.

Techniques of Extubation

At the conclusion of surgery and anesthesia, the patient with asthma can be extubated “deep” or “awake” to avoid laryngospasm. Upper airway obstruction caused by soft-tissue collapse in the pharynx is the major disadvantage of deep extubation. Deep extubation can be accomplished safely provided the maintenance of upper airway patency was satisfactory during the induction of anesthesia before intubation and that no excessive secretions or blood are in the airway. If maintaining airway patency was difficult during induction, the patient’s airway may become obstructed during emergence. If this is the case, airway patency may be facilitated by prophylactic placement of an oropharyngeal or nasopharyngeal airway, well lubricated with lidocaine or lubricant jelly, when the patient is still deeply anesthetized. Successful deep extubation is facilitated by the attainment of spontaneous breathing before attempted extubation.

For a successful “awake” extubation, prophylactic treatment with the inhalation of a β_2 -agonist must be given even if a dose was previously given during or after the induction of anesthesia. Tracheal suction of any secretions before emergence may decrease coughing caused by migration of mucus plugs. Lidocaine (1 mg/kg) given intravenously on emergence is helpful in minimizing tracheal stimulation as the patient awakens. The use of IV atropine (0.02 mg/kg), given for its vagolytic and bronchodilator effects, may be an additional safety precaution before extubation.

Bronchopulmonary Dysplasia

BPD is a chronic disease of lung parenchyma and small airways with chronic respiratory insufficiency that occurs in prematurely born infants (see Chapter 17, Neonatology for Anesthesiologists). As originally described by Northway’s group (1967), BPD develops after a period of acute and subacute ventilator-induced lung injury and oxygen toxicity, in prematurely born infants with severe respiratory distress syndrome (Hazinski, 1990). Although Northway’s original series

involved infants born at a mean gestational age of 34 weeks, all of whom had received excessive concentrations of oxygen during mechanical ventilation with a primitive ventilator by modern standards, over time, BPD has been seen in infants who had prolonged barotrauma (or volutrauma) in the absence of “excessive” oxygen. Early series were characterized by a high incidence of mortality with persistent respiratory symptoms and oxygen requirement beyond 4 weeks of age. Chest radiographs were abnormal and characterized by hyperinflation of the lungs with focal areas of increased density. Northway et al. called this condition BPD to “emphasize the involvement of all the tissues of the lungs in the pathologic process” (Northway et al., 1967; Northway, 2001).

The number of infants with BPD has not decreased over the past two decades despite improved neonatal intensive care, probably because of the survival of more infants who are premature. However, the clinical picture has changed with the advent of antenatal steroids, the use of surfactant therapy, and advances in ventilatory strategies for reducing volutrauma and ventilator-induced lung injury, including noninvasive techniques such as nasal continuous positive airway pressure (Geary et al., 2008, Greenough et al., 2008). Currently, most infants who develop BPD are born at 24 to 28 weeks’ gestation and are rarely born later than 32 weeks’ gestation, whereas the mean gestational age of Northway’s original series was 34 weeks (Hazinski, 1990). Because of changes in neonatal intensive care and affected patient population, many aspects of BPD have changed, including the definition, theories of pathogenesis, pathology, and clinical picture (Jobe and Ikegami, 2000; Jobe and Bancalari, 2001).

Infants with BPD today are likely to have a minimal respiratory distress syndrome that does not progress after surfactant administration. The reason for prolonged ventilation in these premature infants is more commonly apnea or poor respiratory effort, which may be related to immaturity of central respiratory control mechanisms. These infants rarely require the high airway pressures and high oxygen concentration that led to the “old BPD.” This newer clinical picture had been referred to as chronic lung disease or “new BPD,” but it is now simply called BPD. The current definition of BPD is oxygen dependence for at least 28 postnatal days. Evaluation for the presence of BPD and grading of severity is assessed at 36 weeks’ postconceptual age in infants born at fewer than 32 weeks’ gestation and at 56 days after birth in infants born at or after 32 weeks’ gestation (Jobe and Bancalari, 2001). BPD is graded as mild, moderate, or severe, based on oxygen requirement and the need for ventilatory support (Table 36-11). Prevalence ranges from 67% in the smallest weight group to 1% in the largest, with an overall prevalence of 20% of infants born at less than 1500 g (Lemons et al., 2001; Bancalari et al., 2003).

Pathogenesis

In the past, the development of BPD was associated with a condition that caused respiratory failure in the neonatal period (e.g., prematurity with respiratory distress syndrome, meconium aspiration syndrome, or congenital diaphragmatic hernia). Mechanical ventilation with high concentrations of oxygen (i.e., an acute insult to immature lungs) was employed, usually lasting longer than 1 week. Oxygen free radicals, which are not well handled by an immature antioxidant host-defense system in the neonatal lungs, can cause direct cellular injury (Ackerman, 1994). Although much lower concentrations of oxygen are now used

TABLE 36-11. Assessment of the Severity of Bronchopulmonary Dysplasia*

Grade	Fio ₂ and Ventilatory Support	
	GA at Birth <32 wks Assessed at 36 Weeks' PCA	GA at Birth ≥32 wks Assessed at 56 Days Postnatally
Mild	0.21	0.21
Moderate	0.22-0.30	0.22-0.30
Severe	>0.30 and/or continuous positive airway pressure or mechanical ventilation	>0.30 and/or continuous positive airway pressure or mechanical ventilation

Modified from Baraldi E, Filippone M: Chronic lung disease after premature birth, *N Engl J Med* 357:1946, 2007.

*Applies to patients who have been treated with >21% oxygen for at least 28 days.

GA, Gestational age; PCA, postconceptual age.

than in the past, even room air (21% oxygen) is relatively hyperoxic for a premature infant whose in utero Po₂ is less than 30 mm Hg (Hazinski, 1990). Excessive hydration and patent ductus arteriosus with increased pulmonary fluid have been recognized as additional important factors contributing to the development of BPD (Gerhardt and Bancalari, 1980; van Marter et al., 1992). The current theory of the mechanism of injury in BPD also emphasizes the role of infection and inflammation (Gonzalez et al., 1996; Sadeghi et al., 1998). Recurrent bacterial or viral infections in these infants may cause persistent alveolitis, which worsens alveolar and airway damage (Rojas et al., 1995; Hannaford et al., 1999). Multiple markers of inflammation (e.g., lipid mediators, proteases, oxygen free radicals, and cytokines) are elevated (Bose et al., 2008; Ryan et al., 2008). Nutritional deficiencies may also play a role (Sosenko et al., 2000; Geary et al., 2008).

Immature, inflamed lungs with decreased compliance are most susceptible to high-volume (i.e., volutrauma) and low-volume (i.e., shear stress trauma) trauma with marked distortion and distention of terminal bronchioles at high positive pressures (Hazinski, 1990). In earlier pathologic examination of lungs of infants dying with BPD, peribronchiolar fibrosis and smooth muscle thickening were seen. They were also found in animal models exposed to prolonged positive pressure ventilation and hyperdistention (Coalson, 1999). The pathology now seen in extremely premature infants reflects the immature state of their pulmonary parenchyma, with enlarged and simplified alveolar structure and reduced numbers of capillaries that are dysmorphic in appearance. Therefore, the new BPD is now regarded primarily as a disorder of lung development with superimposition of mechanical factors. Fibroproliferation may still occur but is more variable. Changes in larger blood vessels are less prominent with less indication of pulmonary hypertension than seen in old BPD. Airway smooth muscle hyperplasia may still occur, but it is also more variable (Coalson, 2006). After this damage has occurred to immature lungs, infants may require prolonged mechanical ventilation and high oxygen concentration for weeks or months, despite having not required high oxygen concentrations in the first few weeks of life. Although less common than with old BPD, progressive respiratory failure with associated pulmonary hypertension, with or without cor pulmonale, may follow.

Even after the perinatal period, RAD persists in infants with BPD. Mallory et al. (1991) studied lung function longitudinally in infants with moderate to severe BPD during the first 4 years of life with the forced deflation technique and found that airway hyperresponsiveness or hyperreactivity continued to be present in all children studied. They postulated that airway hyperreactivity is an important etiologic factor for the pathogenesis of lower airway obstruction in BPD. Attributing the cause of RAD to BPD is confounded by the recent evidence that antenatal steroid therapy to hasten lung maturation is a risk factor for the development of RAD between the ages of 3 and 6, as well as by the fact that the rates of RAD-like symptoms occur more often in prematurely born children than in those born at term (Doyle, 2006; Pole et al., 2009). Most long-term studies of lung function are reports of infants who had the old form of BPD. Little information is available regarding long-term outcomes of infants with new BPD.

Preanesthetic Considerations

Most infants with moderate to severe BPD remain dependent on oxygen, with or without CPAP, or dependent on a ventilator beyond 4 weeks of age. They have persistent lower airway obstruction and airway hyperreactivity (Mallory et al., 1991). Tachypnea and dyspnea may be intermittently or chronically present. Growth failure because of chronic hypoxia despite oxygen therapy may occur, as well as cor pulmonale associated with pulmonary hypertension (Hazinski, 1990). Wheezing may or may not be present on auscultation, because the site of airway hyperreactivity is primarily in the periphery of the lungs as a result of increased thickness of the airway wall (Tiddens et al., 2008). In addition to lower airway obstruction primarily involving small airways, infants who have been intubated for prolonged periods sometimes develop large airway disease such as subglottic stenosis (that may or may not be recognized), tracheomalacia, and bronchomalacia (Miller et al., 1987; McCubbin et al., 1989). A later study also found a greater degree of upper airway obstruction in children with history of BPD, as compared with age-matched children with asthma (Sadeghi et al., 1998).

Infants with mild forms of BPD improve with age and may become asymptomatic, but airway hyperreactivity may persist. Parents of such an infant may not be aware of the history of BPD even when their child received prolonged mechanical ventilation as a neonate. It is appropriate, therefore, to assume that a child has or had BPD and has RAD if he or she was born prematurely and was mechanically ventilated for more than 1 week during the neonatal period. Inguinal hernia is often present in infants with BPD, probably owing to prematurity and continually increased abdominal pressure that results from airway obstruction and increased inspiratory effort. Prematurely born infants may require postoperative admission for monitoring, because they have an increased risk of postoperative apnea as discussed in Chapters 3, Respiratory Physiology in Infants and Children; 17, Neonatology for Anesthesiologists; and 18, Anesthesia for General Surgery in the Neonate.

As with asthmatic patients, careful history taking is of utmost importance before anesthetizing an infant with BPD or a history of BPD. These patients may have failure to thrive (a sign of chronic hypoxia). With lower respiratory tract infection, worsening of symptoms or even respiratory failure may occur. The patient may be taking SABAs or other treatments for asthma. Other medications may include diuretics. A family history of

allergy and asthma is significant, because premature birth may be linked to smooth muscle hyperresponsiveness and asthma (Bertland et al., 1985). Relatively common surgical conditions in infants and children with BPD or a history of BPD include inguinal hernia, direct laryngoscopy and bronchoscopy for subglottic stenosis, and surgical procedures of the larynx for the complications of prolonged intubation or tracheostomy (e.g., excision of granuloma or laryngotracheoplasty).

Anesthetic Management

Anesthetic management of infants and children with BPD or a history of BPD is similar to that for those with asthma. Before anesthetizing a child in this population, it is imperative to obtain a baseline oxygen saturation measurement with a pulse oximeter (SpO₂), although a normal oxygen saturation level does not necessarily guarantee the absence of lung dysfunction. Many infants and young children with a history of BPD maintain remarkably good SpO₂ values, presumably because of hypoxic pulmonary vasoconstriction (HPV). The infant with BPD with near-normal SpO₂ in room air may develop marked desaturation after induction with sevoflurane, presumably because of a loss of HPV under general anesthesia, although HPV in healthy human volunteers may be insignificant (Benumof, 1994). In these patients, oxygen saturation may be maintained better with IV induction and maintenance techniques using opioids and propofol; however, no evidence supports this management protocol. Preoperative prophylactic treatment with a β₂-adrenergic agonist by a metered-dose inhaler or handheld nebulizer may be beneficial for patients with potential airway hyperreactivity to prevent perioperative bronchoconstriction. In intubating a child with a history of mechanical ventilation, it is prudent to start with an ETT one size (0.5 mm inner diameter) smaller than the appropriate size for the age in anticipation of subglottic narrowing, which may be the result of prolonged intubation. If rapid sequence intubation is required because of fasting violation or intestinal obstruction, desaturation may be rapid when apnea occurs, and gentle ventilation by mask with maintenance of cricoid pressure may be necessary to maintain saturation if intubation is not rapidly accomplished.

Cystic Fibrosis

Cystic fibrosis (CF), an autosomal-recessive disorder, is the most common life-limiting inherited disorder among whites (Rosenstein and Cutting, 1998). In the United States, the gene frequency (heterozygotes) in whites is approximately 1 in 28; it is uncommon among Hispanics (1 in 46) and African Americans (1 in 65) and lowest among Asians and Native Americans (1 in 90) (Hamosh et al., 1998). The disease incidence among whites is approximately 1 in 2500 live births. Owing to early diagnosis and aggressive treatment over the past 40 years, in 2007 the median survival of a CF patient had increased to 37 years (Cystic Fibrosis Foundation, 2007).

In 1985, Tsui et al. localized the gene responsible for the manifestation of CF to 250 kilobases on the long arm of chromosome 7. The deletion of three base pairs, removing a phenylalanine residue at position 508 (d508) from a 1480-amino acid protein called *CF transmembrane conductance regulator* (CFTR), a cAMP-dependent chloride ion channel, accounts for approximately 70% of CF chromosome abnormalities (Moskowitz et

al., 2008). Of the other 1000 documented mutations, 20 account for most of the remaining 30% of cases, with the prevalence of mutations varying among ethnic groups (Tsui and Zielenski, 2007). Although the type of CFTR mutation does correlate with pancreatic function, poor correlation exists between the type of mutation and the severity of lung disease. Evidence suggests that other genetic polymorphisms influence the severity of lung disease (Drumm et al., 2005).

Pathogenesis

CF is characterized by exocrine gland dysfunction that results in chronic pulmonary disease, pancreatic dysfunction, and abnormalities in electrolyte reabsorption in the sweat duct, with increases in sweat sodium and chloride concentrations and electrolyte imbalance. The fact that CF patients have sweat chloride levels in excess of 60 mEq/L (normal is less than 40 mEq/L), as measured by pilocarpine iontophoresis, is the basis of the sweat chloride test, which is still the gold standard for making the diagnosis of CF. Increasingly, the diagnosis of CF is being made earlier because of newborn screening techniques that are designed to detect elevated serum levels of immunoreactive trypsinogen and the most common CFTR mutations (Comeau et al., 2007). Such screening accounted for 21.6% of the diagnoses of CF in the United States in 2006 (Cystic Fibrosis Foundation, 2007). Even if these screenings are found to be positive, two sweat chloride test results of greater than 60 mEq/L are necessary to make the diagnosis of CF. Significant clinical manifestations of CF, other than pulmonary disease, include those listed in Table 36-12.

Pulmonary disease is the most common cause of morbidity and death. Enhanced absorption of sodium across the airway

TABLE 36-12. Organ System Involvement in Cystic Fibrosis

Organ System	Incidence (%)

epithelium and failure to secrete chloride and fluid toward the airway lumen is thought to lead to dehydration and thickening of airway mucus and abnormal mucociliary clearance with subsequent bronchial inflammation and infection. Patients are initially colonized with *Haemophilus influenzae* and then by *Staphylococcus aureus*, and eventually by the mucoid variant of *Pseudomonas aeruginosa*. Colonization with *Aspergillus* and atypical mycobacteria may occur. The chronic infection in the periphery of the tracheobronchial tree results in bronchiolitis, which may lead to airway hyperresponsiveness, bronchiectasis, lobar or segmental atelectasis, and pneumothorax. Advanced disease is associated with destruction of airway architecture, fibrosis of lung parenchyma, and development of abscesses. Hemoptysis and eventually, cor pulmonale and respiratory failure ensue (Eckles and Anderson, 2003).

Small airway obstruction, hyperinflation, and ventilation-perfusion imbalance are the most common and important pulmonary changes in children with moderate-to-severe CF. The early signs of lung dysfunction include a reduction in maximum expiratory flow rates at low lung volumes (e.g., FEF_{25-75} , FEF_{50} , and FEF_{75}) and an increase in the ratio of residual volume to total lung capacity (RV/TLC) (see Chapter 3, Respiratory Physiology in Infants and Children). Airway hyperreactivity is often present, probably in response to airway inflammation. Some patients have a good response to bronchodilators, but others have inconsistent or even paradoxical responses, sometimes worsening airway function because of the relaxation of airway smooth muscles and resultant increases in airway collapsibility (Brand, 2000).

Treatment

Patients with CF take multiple medications. In 2007, a committee organized by the Cystic Fibrosis Foundation published guidelines for long-term medication used for optimal pulmonary symptom control in CF patients older than 6 years (Flume et al., 2007). Patients with a prominent bronchospastic component are on long acting β_2 -agonist therapy (Hordvik et al., 2002). They often take inhaled or oral antibiotics for prophylaxis or treatment of pulmonary infection. Patients infected with *P. aeruginosa* often take aerosolized tobramycin, which when administered on a bimonthly basis has been shown to preserve pulmonary function and reduce hospitalization (Ramsey et al., 1999). Patients with infectious exacerbations are treated with IV antibiotics in a hospital or at home. Chest physiotherapy several times per day is a mainstay of CF treatment. Inhaled mucolytics (N-acetylcysteine) have long been used to decrease the viscosity of pulmonary secretions, but little is found in the literature documenting their efficacy (Duijvestijn and Brand, 1999). Inhaled hypertonic saline, which is thought to improve fluidity of pulmonary secretions, has been shown to decrease the frequency of pulmonary exacerbations (Flume et al., 2007). Dornase alfa (i.e., human recombinant DNase), which dissolves deoxyribonucleic acid (DNA) released from neutrophils, has improved pulmonary function and reduced the frequency of infection (Jones et al., 2003; Flume et al., 2007). High-dose ibuprofen therapy has been found to slow the decline of forced expiratory volume during the first second of measurement (FEV_1) in children and adolescents if started when the FEV_1 is greater than 60% of that predicted (Lands and Stanojevic, 2007). This effect is related to reduction in inflammation (Nichols et al., 2008). Doses between 20 and 30 mg/kg every 6 hours are administered to achieve plasma concentrations of 50 to 100 mcg/mL

(Arranz et al., 2003). Ibuprofen treatment has been associated with a significant increase in gastrointestinal (GI) bleeding compared with patients who are not taking ibuprofen, although the absolute number of patients affected is small (Konstan et al., 2007). Patients with pancreatic impairment require pancreatic enzyme replacement.

Preanesthetic Considerations

Common surgical indications in infants and children with CF are listed in Table 36-13. Although some patients with CF require surgery in the neonatal period for meconium ileus, no special anesthetic considerations are necessary. Management of children with CF is a challenge to the anesthesiologist. These patients are often frail and malnourished. Decreased plasma albumin levels may affect anesthetic potency. Intravascular volume may be diminished because of chronic diarrhea, poor oral intake, and diuretic therapy. Electrolyte imbalance may result from excessive chloride and sodium losses. Pulmonary function ranges from near normal without airway obstruction to severe obstruction, air trapping, hypoxemia, and hypercapnia. Copious thick secretions and resultant ventilation-perfusion imbalance may prolong mask induction with volatile anesthetics. Secretions may irritate the larynx and precipitate laryngospasm. Nasal polyps may block the nasal airway completely during mask induction. Pathophysiologic considerations in patients with CF that may affect anesthetic management are listed in Table 36-14.

The preoperative evaluation should include the assessment of pulmonary function by history, physical examination, and pulmonary-function testing. Pulmonary-function testing should include assessments of maximum expiratory flow-volume curves, lung volume measurements, and response to bronchodilators. An increase in TLC and the RV/TLC ratio with decreased vital capacity indicates the presence of hyperinflation and air trapping. Lower airway obstruction with small airway involvement is demonstrated when FEF_{25-75} , FEF_{50} , and especially FEF_{75} are markedly decreased from predicted values. A recent preoperative chest radiograph is needed in patients with moderate to severe pulmonary disease. Preoperative oxygen saturation should be obtained by means of pulse oximetry in room air for postoperative comparison. Recent tracheal

TABLE 36-13. Surgical Indications for Patients with Cystic Fibrosis

Conditions	Typical Age Range
Meconium ileus or equivalent	1 d-3 yr
Nasal polyp/sinusitis	10-18 yr
Other procedures	10-18 yr
Bronchoscopy	
Feeding gastrostomy; central venous access (port or PICC)	
Lobectomy or thoracoplasty/thoracoscopy	
Organ transplantation (double lungs; heart-lungs)	

PICC, Peripherally inserted central catheter.

TABLE 36-14. Pathophysiology of Cystic Fibrosis: Effect on Anesthetic Management

Pathophysiology	Possible Outcome
Pulmonary Dysfunction	
Airway obstruction V/Q imbalance	Prolonged mask induction
Copious secretions Airway hyperreactivity	Laryngospasm, bronchospasm
Nasal polyp	Upper airway obstruction
Gastrointestinal and Hepatobiliary Disorders	
Decreased serum albumin levels	Increased drug potency
Coagulopathies	Increased bleeding
Diabetes or glucose intolerance	Hyperglycemia, acidosis
Abnormal sweat gland function	Electrolyte imbalance
Cor pulmonale	Hemodynamic instability; dysrhythmia

culture results should be reviewed as a guide to choice of perioperative antibiotic therapy. In patients with significant lower airway obstruction and air trapping, preoperative arterial blood gas measurement is recommended to assess the degree of hypoxemia more accurately and to evaluate the presence of hypercapnia and acid-base status. In those with long-standing hypoxemia, pulmonary hypertension and cor pulmonale should be suspected. These patients should have preoperative electrocardiography and echocardiography to evaluate myocardial function and reserve. Blood sugar, liver-function tests, and coagulation studies may be indicated. Eight percent of CF patients between the ages of 11 and 17 develop CF-related diabetes mellitus as a result of fibrosis and fatty infiltration of the pancreas (Cystic Fibrosis Foundation, 2007). Some, but not all, may require insulin, because some insulin continues to be produced. Malabsorption and liver disease may be associated with abnormal coagulation. Additional vitamin K supplementation may be necessary to correct coagulopathy. The patient's pulmonary physician should be consulted to ensure that the patient's condition is optimized as much as is possible before surgery. Ibuprofen should be stopped 2 days before surgery to allow its inhibitory effects on platelet aggregation to dissipate.

The child with CF and his or her family are exceedingly knowledgeable regarding the pathogenesis and treatment of the disease. A lack of knowledge of CF in general, and of the patient's past history and present conditions in particular, at the time of the preoperative visit could quickly undermine the confidence of the family in the anesthesiologist. More importantly, the patient with CF is often petrified by the thought of death under anesthesia, in part because of a long-held belief in the pulmonary medicine community that general anesthesia leads to prolonged deterioration of pulmonary function (Price, 1986). It is therefore prudent for the anesthesiologist to gain the patient's and the parents' confidence and administer preoperative sedation such as oral midazolam (Della Rocca, 2002). Opioid premedication should be avoided in severe cases because of possible respiratory depression and hypoxemia.

Anesthetic Management

Because of copious secretions in affected patients, it is preferable to schedule surgery later in the day to allow enough time for ambulation and chest physiotherapy in the morning to facilitate expectoration of secretions retained overnight. The baseline oxygen saturation in room air is measured with a pulse oximeter before administering oxygen and anesthetics.

In patients with significant pulmonary involvement, IV access should be established before the induction of anesthesia because of prolonged mask induction and possible nasal obstruction from nasal polyps. An anticholinergic may be given during induction. Concern about excessive drying of secretions is unfounded, because atropine decreases secretions without changes in viscosity and has not been a significant problem in clinical practice (Lamberty and Rubin, 1985). IV propofol may be preferred to thiopental because it is less irritating to the upper airways and actually causes bronchodilation. Ketamine, despite its bronchodilating properties, is relatively contraindicated because it tends to increase secretions and may cause laryngospasm. Fifty percent of children with CF have gastroesophageal reflux disease and may require rapid-sequence intubation, although chronic treatment with H₂-blockers and or a proton-pump inhibitor along with an adequate fasting interval mitigates the risk of aspiration. Inhalation induction is usually satisfactory in young children with mild lung disease. Anesthetic gases should be heated and humidified to prevent irritation of the upper airways and laryngospasm and to avoid drying and inspissation of secretions. When trapped gas volume is suspected or proven by pulmonary function test, nitrous oxide should be avoided to prevent expansion of the emphysematous area and the potential danger of bleb rupture.

Endotracheal intubation with muscle relaxation is mandatory in patients with severe respiratory involvement, although the anesthesiologist should be exceedingly careful not to overdistend already air-trapped lungs. When a nondepolarizing muscle relaxant is chosen, the effect of aminoglycoside antibiotics to prolong the duration of action of such drugs must be kept in mind, and monitoring of train-of-four should be used to guide relaxant administration. It is also mandatory to carefully monitor end-tidal carbon dioxide to prevent hyperventilation and to maintain preoperative arterial partial pressure of carbon dioxide (Pco₂) levels, which may be elevated. Sudden hypocapnia in a chronically hypercapnic patient can disrupt the patient's ventilatory control mechanisms, increasing the chance that the patient might require postoperative ventilation. After intubation, tracheobronchial suction should be performed and repeated at intervals throughout surgery and before extubation to improve pulmonary gas exchange. Although the use of an LMA might be an option for short cases, disadvantages include the inability to suction secretions, obstruction of the LMA by thick secretions, risk of laryngospasm, and risk of aspiration in patients with gastroesophageal reflux disease. For bronchoscopy for the purpose of removal of secretions for culture and bronchial lavage, the LMA has been safely used in patients with CF (Nussbaum and Zagnoev, 2001). Intraoperatively, glucose should be monitored in patients with glucose intolerance. Care should be taken to conserve heat in these patients with reduced body fat.

Regional anesthesia should be considered whenever applicable. Although regional anesthetic techniques without general anesthesia might be useful in some situations, these techniques

should be carefully considered in children with severe pulmonary disease. Depression of abdominal and intercostal muscle function by thoracic levels of spinal or epidural anesthesia may not be tolerated. Pediatricians and pulmonologists often request regional anesthesia instead of general anesthesia because of fear that severely affected patients with CF will not tolerate general anesthesia or may become dependent on a ventilator after endotracheal intubation. However, most of these sick patients with CF, dyspneic or orthopneic with hypercapnia and oxygen dependence, may not tolerate even a short surgical intervention, such as insertion of a central venous catheter or MediPort, with local anesthesia and sedation. Instead, general endotracheal anesthesia with an inhaled agent, supplemented by caudal, lumbar, or thoracic epidural anesthesia for abdominal or thoracic procedures, is much better tolerated, safer, and provides good operative conditions, rapid emergence, and a pain-free postoperative state (Dalens et al., 1986). If epidural anesthesia is to be used, coagulopathy should be ruled out, and the appropriate concentration of local anesthetic drugs should be chosen to minimize motor block. Continuous caudal or epidural anesthesia with local anesthetic with or without carefully chosen doses of an opioid provides prolonged postoperative pain relief and facilitates coughing and deep breathing after upper abdominal or thoracic procedures. If regional anesthesia is not appropriate, judicious use of inhalation agents and short-acting opioids and wound infiltration with local anesthetic by the surgeon should facilitate early extubation, which is desirable in most cases. After surgeries without a high risk of postoperative bleeding, the use of NSAIDs may be effective in reducing the amount of opioid needed for analgesia.

Cystic Fibrosis and Hemoptysis

Hemoptysis may occur in older children with more severe lung disease. These children may come to the hospital for angiography and bronchial artery embolization. Preanesthetic considerations as described above should be evaluated, and the patient's pulmonary status should be optimized to the greatest extent. Pulmonary hemorrhage has been reported after induction of general anesthesia, intubation, and institution of positive-pressure ventilation (McDougall and Sherrington, 1999). It is possible that airway and parenchymal distention associated with positive pressure ventilation results in the breach of relatively thin-walled vessels. These authors have recommended that sedation and local anesthesia may be safer in this situation (McDougall and Sherrington, 1999; Barben et al., 2002)

Cystic Fibrosis and Lung Transplantation

For patients with end-stage pulmonary disease, lung transplantation may be the final surgical option. Fifty percent of patients with CF and FEV₁ of less than 30%, partial pressure of oxygen (Pao₂) less than 55 mm Hg, or partial pressure of carbon dioxide (Paco₂) greater than 50 mm Hg will survive for 2 years and may be candidates for lung transplantation (i.e., double-lung or heart-lung procedure) (Belkin et al., 2006). Approximately 175 patients with CF per year undergo bilateral lung transplantation in the United States, of whom the minority are children (Cystic Fibrosis Foundation, 2007). The 3-year survival rate is 60%, which is similar to that seen in patients who do not have CF (Sweet et al., 1997). Some (27%) lung-transplant patients develop bronchiolitis obliterans, which is

responsible for 40% of deaths that occur more than 1 year after transplantation (Boucek et al., 2004). Among the survivors of lung transplantation, no recurrence of CF in the transplanted lungs has been reported, as measured by the transepithelial potential differences (Alton et al., 1991). The management of end-stage CF patients for lung transplantation is described in Chapter 3, Respiratory Physiology, and Chapter 28, Anesthesia for Organ Transplantation.

CARDIOVASCULAR DISORDERS

Cardiovascular disorders are commonly encountered in the pediatric population. The baseline incidence of congenital heart disease in the population is approximately 0.8 in 100 births, on which is superimposed an incidence of acquired heart disease. However, more and more congenital cardiac defects have been appreciated to have either a genetic or an environmental basis, either alone or in combination, such that incidence and risks in offspring may be higher in selected populations (Jenkins et al., 2007). Both congenital and acquired diseases have the ability to affect myocardial function, valve function, and conduction tissue, all of which can also be affected by anesthetics. In addition, anesthetic effects on vascular tone can have a positive or negative impact on myocardial function and shunting of blood through intracardiac defects.

Patients with cardiac disease should be identified preoperatively. Although children with congenital heart disease who undergo noncardiac surgery should generally do well with appropriate anesthetic and perioperative care, preliminary information suggests that in the aggregate, congenital cardiac disease of even a moderate degree can increase mortality and adverse events during and after noncardiac surgery (Baum et al., 2000). Even hemodynamically insignificant lesions may necessitate perioperative endocarditis prophylaxis (Table 36-15). However, not all surgical procedures or all children with cardiac disease require endocarditis prophylaxis. Recommendations for endocarditis prophylaxis were significantly changed in 2007, with a general decrement in the use of prophylaxis, because previous recommendations were recognized to be lacking in validity or efficacy or were overly complicated (Wilson et al., 2007). Current recommendations are outlined in Boxes 36-8 and 36-9.

Anesthetic Management

Although the specifics of the anesthetic management of individual cardiac problems are discussed in Chapters 20, Anesthesia for Congenital Heart Surgery, and 21, Anesthesia for Children with Congenital Heart Disease Undergoing Non-Cardiac Surgery, the following comments are generally applicable.

Preoperative Period

Prolonged preoperative fasting should be avoided in children who have cyanotic heart disease with significant erythrocytosis to avoid dehydration and further increase of elevated hematocrit and blood viscosity. Small infants with significant heart failure and failure to thrive can have inadequate glycogen reserves and are at risk for hypoglycemia if they fast for many hours. Otherwise conventional age-appropriate preoperative sedation is

TABLE 36-15. Endocarditis Prophylaxis Regimens for Dental Procedures

Reason	Agent	Regimen
Standard general prophylaxis	Amoxicillin	50 mg/kg orally (adults: 2 g)
Unable to take orally	Ampicillin	50 mg/kg IM or IV* (adults: 2 g)
	OR	
Allergic to penicillin	Cefazolin or ceftriaxone	50 mg/kg IM or IV* (adults: 1 g)
	Clindamycin	20 mg/kg orally (adults: 600 mg)
	OR	
	Cephalexin	50 mg/kg orally (adults: 2 g)
Allergic to penicillin and unable to take orally	OR	
	Azithromycin or clarithromycin	15 mg/kg orally (adults: 500 mg)
	Clindamycin	20 mg/kg IV* (adults: 600 mg)
Allergic to penicillin and unable to take orally	OR	
	Cefazolin or ceftriaxone	50 mg/kg IM or IV* (adults: 1 g)

Modified from Wilson W et al: Prevention of infective endocarditis: guidelines from the American Heart Association, *Circulation* 116:1736, 2007.

*It is appreciated that many children do not have IV access prior to surgery. IV antibiotics should be given as soon as possible and before surgical incision. Children's dose should not exceed adult dose. IM, Intramuscularly; IV, intravenously.

in no way contraindicated in children with cyanotic or acyanotic heart disease unless the child is in profound heart failure.

Intraoperative Period

Although much discussion is appropriately devoted to the specifics of cardiac pathophysiology, most children with congenital heart disease who develop problems during anesthesia do so for primarily noncardiac reasons, particularly airway compromise (Strafford and Henderson, 1991). Infants who are cyanotic, in particular, begin with decreased oxygen saturation and can rapidly desaturate with transient interruption in ventilation, whether as a result of apnea or airway obstruction. Children with severe congestive failure or cyanosis have a decreased margin of safety and tolerate failures of respiratory or hemodynamic management poorly.

Much time is spent discussing the effects of left-to-right and right-to-left shunts on the onset time of IV and volatile anesthetics. Although differences exist, with currently available anesthetic gases of relatively low solubility, these differences are almost always so small as to be clinically irrelevant. In the absence of a complication such as loss of the airway or the development of a hypercyanotic "tet" spell in children with tetralogy of Fallot or variants, oxygen saturation in children with cyanotic disease almost invariably increases with induction of anesthesia (Laishley et al., 1986; Greeley et al., 1986). Several reasons are possible, one of the most likely being a decrease in oxygen

Box 36-8 Changes in Most Recent Endocarditis Prophylaxis Recommendations

- The number of cardiac conditions that require prophylaxis has been reduced. Moderate- and high-risk groups are not differentiated.
- Dental prophylaxis is reserved solely for conditions in [Box 36-9](#) and solely for manipulation of gingival tissues or the periapical region of teeth, or for perforation of oral mucosa.
- Prophylaxis is reasonable for patients with conditions in [Box 36-9](#) for invasive procedures of the respiratory tract that involve incision or biopsy, such as tonsillectomy and adenoidectomy. For patients who have an established infection of the respiratory tract, treatment with an agent active against *Viridans streptococci* is recommended, unless the infection is known or suspected to be caused by staphylococcus, in which case the regimen should include an appropriate agent such as an antistaphylococcal penicillin, cephalosporin, or vancomycin.
- Prophylaxis for procedures on infected skin or musculoskeletal tissue is indicated only for patients with conditions in [Box 36-9](#). As tissue is already infected, it is reasonable to use an antibiotic such as an antistaphylococcal penicillin or a cephalosporin that is active against those organisms (staphylococcus and β -hemolytic streptococci) that cause these infections and may lead to endocarditis. Vancomycin or clindamycin can be substituted in case of allergy or antibiotic resistance.
- Antibiotic prophylaxis is not recommended for GI or genitourinary procedures, including vaginal delivery and hysterectomy. For patients in a high-risk group with established infections of the GI or genitourinary tracts who require surgery or cystoscopy, an appropriate antibiotic effective against enterococci, such as penicillin, ampicillin, piperacillin, or vancomycin, can be used, without empirical evidence of clinical efficacy in preventing endocarditis ([Box 36-9](#)).
- Prophylaxis is not required for endotracheal intubation.
- Prophylaxis is no longer required for patients with mitral valve prolapse.
- Timing is simplified to 30 to 60 minutes before incision for all regimens.

Data from Wilson W, et al: Prevention of infective endocarditis: guidelines from the American Heart Association, *Circulation* 116:1736, 2007.

Box 36-9 Cardiac Conditions that Necessitate Antibiotic Endocarditis Prophylaxis

Prosthetic valves (bioprosthetic and homograft)
 Previous bacterial endocarditis
 Complex cyanotic heart disease
 Systemic pulmonary shunts (e.g., Blalock-Taussig shunt)
 Unrepaired cyanotic heart disease
 Completely repaired congenital heart defects with prosthetic material or device, whether by surgery or by catheter intervention, during the first 6 months after procedure
 Cardiac transplant recipients who develop cardiac valvulopathy

Data from Wilson W, et al: Prevention of infective endocarditis: guidelines from the American Heart Association, *Circulation* 116:1736, 2007.

consumption that causes an increase in mixed venous oxygen saturation and subsequently higher arterial oxygen saturation when some of this blood is shunted right to left.

Minimization of right-to-left shunting at the atrial level is addressed primarily by increasing intravascular volume. Minimization of shunting at the ventricular and great vessel levels is primarily modulated by changes in pulmonary vascular resistance (PVR) and systemic vascular resistance. Increasing systemic resistance or decreasing PVR increases left-to-right shunting (or decreases right-to-left shunting) and vice versa. Although α -adrenergic receptors are found in the pulmonary circulation (stimulation of which can increase PVR), they are denser in the systemic circulation, and α -agonists increase systemic vascular resistance significantly more than they increase PVR, with a decrease in right-to-left shunting.

Nitrous oxide is a mild myocardial depressant. In adult patients, it can increase PVR, particularly in patients in whom PVR is already elevated. However, in children, no significant increase in PVR has been observed with 50% nitrous oxide, regardless of the preexisting PVR (Hickey et al., 1986).

Patients who are cyanotic, and in particular patients with elevated central venous pressure, are at risk for increased perioperative blood loss and require adequate IV access. Not only do all patients with cyanotic disease need IV catheters to be kept clear of air bubbles to avoid systemic air emboli, but small amounts of transient right-to-left shunting can occur during the cardiac cycle, even with lesions thought of as left-to-right shunting lesions. Therefore, IV catheters must be cleared of air for all patients with shunt lesions, regardless of predominant direction of shunt flow. Stopcocks are common sites where air can be introduced inadvertently.

End-tidal P_{CO_2} correlates with arterial P_{CO_2} in acyanotic patients. However, in children and adults with cyanotic congenital heart disease, end-tidal P_{CO_2} tends to underestimate arterial P_{CO_2} (Burrows, 1989).

Postoperative Period

The specific length of observation in a postanesthesia care unit is dependent on the patient and the surgical procedure and cannot be generalized. Patients with good hemodynamic function may undergo relatively minor noncardiac surgery on an ambulatory basis and are not automatically excluded because of their cardiac disease.

When not under anesthesia, patients with cyanotic disease have relatively little increase in systemic oxygen saturation

in response to supplemental oxygen. Similarly, oxygen saturation is not markedly decreased by removing supplemental oxygen (other causes for postoperative hypoxemia being absent). Knowledge of the patient's normal preoperative range of oxygen saturation helps avoid unnecessary prolongation of the PACU stay for fear of removing supplemental oxygen.

Hypovolemia from continued surgical blood or fluid loss postoperatively can worsen right-to-left shunting in patients with cyanosis and should be rapidly corrected. The onset of hypovolemia can be insidious if it is as a result of gradual oozing from surgical drains. Patients with cyanotic disease should have repeated measurement of Hb after surgery, especially after significant blood loss. They may require a higher than normal hematocrit level to ensure adequate oxygen delivery. In general, a level similar to the preoperative hematocrit should be maintained.

Patients with labile pulmonary arterial hypertension particularly benefit from good postoperative analgesia, because pain increases pulmonary vascular tone. Even patients with cyanosis have a normal ventilatory response to hypercarbia and respond in a normal fashion to appropriate doses of parenteral, intrathecal, or epidural opiates; therefore, age- and weight-appropriate doses of analgesic drugs should be given. Patients who have had a Glenn or Fontan procedure are dependent on low PVR for maintenance of adequate pulmonary blood flow. If these patients should require postoperative ventilation, PVR should be minimized by limiting positive inspiratory pressure and using low levels of positive end-expiratory pressure to optimize functional residual capacity, which in turn, minimizes PVR.

The Child with a Murmur and Possible Heart Disease

Cardiac murmurs are exceedingly common in healthy children, with an overall lifetime incidence of at least 50%. Most of these are the somewhat inappropriately named *functional* murmurs (also called *innocent*). The incidence of functional murmurs is highest at 3 to 4 years of age. Functional murmurs represent the sound of blood flowing through a structurally normal heart (Fig. 36-7). No anesthetic concern is associated with these murmurs, and the family should be reassured. Several functional murmurs are commonly recognized, almost all of which are short and soft but become louder when the patient lies supine.

■ **FIGURE 36-7.** Innocent murmurs.

Not shown is the mammary souffle over the breast of a pregnant or lactating woman. The pulmonary ejection murmur is similar to the murmur of peripheral pulmonic stenosis in neonates. Vibratory systolic murmur is also called *Still murmur*. (From Park MK: Pediatric cardiology for practitioners, ed 5, Philadelphia, 2008, Mosby.)

Most functional murmurs become louder with increased cardiac output, as would occur with anemia, fever, exercise, or anxiety.

The most common functional murmur is the Still murmur, which has a typical musical or vibratory quality and is a mid-systolic murmur heard between the midleft sternal border and the apex. Soft pulmonary flow murmurs at the upper left sternal border are commonly heard in thin-chested older children and adolescents. The murmur is softer than true pulmonic stenosis and is unaccompanied by a systolic ejection click. Peripheral pulmonic stenosis generates an ejection murmur from the left upper sternal border to the axillae and back and is common in neonates. It is generated by turbulent flow when blood passes from the main to the branch pulmonary arteries. In the neonate, the branch pulmonary arteries, unaccustomed to accommodating large amounts of pulmonary blood flow in utero, form an acute angle with the main pulmonary artery. By approximately 6 months of age the vessels remodel and the murmur disappears. Less common innocent murmurs are the *venous hum* and the *mammary souffle*, both of which are continuous murmurs and are thus exceptions to the rule that diastolic murmurs are always pathologic. The venous hum represents blood draining down the jugular into the subclavian veins. It is heard over the left or right upper chest with the patient upright and disappears when the patient lies down, with gentle compression of the jugular vein, or with a Valsalva maneuver. The mammary souffle can be heard over the breasts of pregnant or lactating women. Unlike functional murmurs, pathologic murmurs are generated by a normal amount of blood across an abnormal valve or opening or by an abnormal amount of blood passing through normal valves.

Occasionally, a murmur is appreciated for the first time when children arrive for a preanesthetic evaluation. The exact method of evaluation remains somewhat controversial (Yu et al., 2002). Isolated chest radiographs and electrocardiograms are generally

a poor investment (Yu et al., 2002). In addition, electrocardiograms that are interpreted by computer or an adult cardiologist may need to be reinterpreted using age-appropriate normal values. Location of the murmur can also aid in the diagnosis (see Chapter 9, Preoperative Preparation, Fig. 9-3).

In general, children who are acyanotic and growing well, with a soft systolic murmur and good exercise tolerance, tolerate anesthesia well. Signs of heart disease in infants differ somewhat from those in adults and older children. Perioral cyanosis can be a normal finding in neonates, especially with crying, and must be differentiated from central cyanosis (confirmed by pulse oximetry). Heart failure is often manifested in young infants by tachypnea, diaphoresis with eating (in excess of the normal sweating of the head that many infants have), and hepatomegaly. Increased pulmonary blood flow can impinge upon small bronchioles, causing airway obstruction and expiratory wheezing (“cardiac asthma”). Peripheral edema as a result of congestive failure is distinctly uncommon in children. Blood pressure measurements in both arms and a leg help detect or exclude coarctation of the aorta.

When caring for children with known heart disease or a history of cardiac surgery, the child’s pediatrician or cardiologist should be contacted, and a copy of the most recent evaluation should be obtained.

Noncardiac Manifestations of Congenital Heart Disease

Longstanding cyanotic and acyanotic congenital disease can have effects on the function of a variety of other organ systems. Some of these effects may not become clinically apparent until years after surgical correction of the underlying cardiac defect (Table 36-16).

TABLE 36-16. Potential Noncardiac Manifestations of Congenital Heart Disease

System	Causes/Implications for Anesthetic Management
Pulmonary/Thoracic	
Decreased lung compliance	Occurs in lesions with increased pulmonary blood flow (i.e., left-to-right shunting) or pulmonary venous obstruction; can require higher airway pressure for ventilation; can impinge on small airways, resulting in air trapping, wheezing
Scoliosis	More common with cyanotic lesions; can manifest in adolescence, years after corrective cardiac surgery
Hemoptysis	Can occur in end-stage Eisenmenger syndrome (pulmonary hypertension caused by prolonged excessive pulmonary blood flow)
Phrenic nerve injury	From prior surgery; more common after surgery at the apices of the thorax (e.g., patent ductus arteriosus ligation, coarctation, pulmonary artery banding, or Blalock-Taussig shunt)
Recurrent laryngeal nerve injury	From prior surgery or from an enlarged hypertensive pulmonary artery; see phrenic nerve injury (above)
Blunted ventilatory response to hypoxemia	In cyanotic patients; normalizes after surgical repair; normal ventilatory response to hypercarbia
Hematologic	
Symptomatic hyperviscosity	Due to chronic hypoxemia; occurs with hematocrit above approximately 65% (or lower if iron deficient); may cause neurologic symptoms
Bleeding diathesis	Abnormalities of a variety of factors have been described in patients who have cyanosis with no consistent pattern; elevated central venous pressure can cause increased operative bleeding, as can increased tissue vascularity with cyanotic disease (collateral blood vessel formation); increased risk of bleeding with prior thoracic surgery during subsequent thoracic procedures
Gallstones	Calcium bilirubinate stones from increased heme turnover in cyanotic disease; may not become symptomatic until years after corrective cardiac surgery

TABLE 36-16. Potential Noncardiac Manifestations of Congenital Heart Disease—cont'd

System	Causes/Implications for Anesthetic Management
Neurologic	
Paradoxical emboli to central nervous system	Can manifest even with a predominantly left-to-right shunt lesion
Brain abscess in patients with right-to-left shunts	Can manifest with seizure focus years later
Cerebral thrombosis	In children with erythrocytosis but not in adults
Compression of nerve by vascular structure	Recurrent laryngeal nerve by enlarged, hypertensive pulmonary artery
Nerve injury during prior surgery	Recurrent laryngeal, phrenic, or sympathetic chain; see phrenic nerve injury (above) for high-risk surgeries
Vascular	
Femoral vein complications	Thrombosis or ligation from prior cardiac catheterization
Anatomic discontinuity of inferior vena cava and right atrium	Congenital, associated with polysplenia syndrome
Anatomic discontinuity of right internal jugular and innominate vein with right atrium	As a result of Glenn shunt
Reduced lower extremity blood pressure	Coarctation of the aorta; left arm involvement is variable
Discontinuity of subclavian artery	With classic Blalock-Taussig anastomosis; stenosis of the subclavian artery after the modified Blalock-Taussig anastomosis; currently, classic Blalock-Taussig shunt is rarely performed
Artificially elevated right arm blood pressure	Supravalvar aortic stenosis (the Coanda effect)

Kawasaki Disease

Originally named *mucocutaneous lymph node syndrome* after its major manifestations, Kawasaki disease is the most common cause of acquired heart disease in children in the United States. The etiology for this disease, with characteristics of an infectious disease without an identifiable agent and a vasculitis that is not easily treated with steroids, has yet to be determined. In the United States, the peak incidence occurs between 13 and 24 months of age. Diagnosis and therapy have been reviewed in detail, and a general overview has been presented by Burns (2007) (Newburger et al., 2004). No diagnostic test has been developed. The acute illness is associated with fever; intense conjunctival injection; red, cracked lips and oral mucosa; erythema of the palms and soles; and less commonly, cervical lymphadenitis of the neck followed weeks later by desquamation of the skin of the fingers and toes. Arthritis and arthralgia can also develop. Other uncommon systemic manifestations include transient high-frequency hearing loss, gastrointestinal complaints, hepatomegaly, and hydrops of the gallbladder. Erythema and induration at the site of a previous bacillus Calmette-Guérin (BCG) vaccination can also occur. The most concerning feature of the disease is that it causes an infantile periarteritis nodosa-like vasculitis of medium and large arteries in 10% to 15% of children. Of particular concern is involvement of coronary arteries, with the risk of subsequent thrombosis or, less commonly, rupture (Fig. 36-8). The risk of coronary artery aneurysms is higher in infants. In addition, the acute phase of the illness can be associated with myocarditis—usually mild but sometimes associated with heart failure. Myocarditis is usually transient, lasting several weeks. Laboratory findings during the acute phase reveal an intense acute-phase response that includes neutrophilia, elevated sedimentation rate and C-reactive protein, and thrombocytosis to over 800,000/mcL³.

FIGURE 36-8. Angiogram of the left main coronary artery in a young child with Kawasaki disease showing multiple fusiform aneurysms of both the right and left coronary arteries. (Courtesy Jonathan Rome, MD).

Coronary artery aneurysms become apparent within the first 2 weeks of disease in 3% to 5% of children who have been treated with IV gamma globulin (IVIG) and in 20% to 25% of children who have not. Early aneurysms can resolve spontaneously or progress.

Treatment in the acute phase includes IVIG and aspirin. Aspirin is begun at a high dosage (80 to 100 mg/kg per day) and continued either until the child is afebrile or until day 14 of illness, after which the high antiinflammatory dose is decreased to antiplatelet levels (3 to 5 mg/kg per day). The lower dose is continued until the child shows no evidence of aneurysm formation (6 to 8 weeks after onset) or is continued indefinitely if coronary aneurysms develop. Although the mechanism is undetermined, IVIG (2 g/kg) is an effective acute therapy that is successful in approximately 80% of cases. If IVIG therapy fails, children are at high risk for the development of coronary artery complications, which may be treatable with steroids, although a recent study suggests this may not be effective (Newburger et al., 2007).

If coronary artery aneurysms do develop, approximately one half to two thirds regress within 2 years, and approximately one fifth develop coronary stenoses. Smaller aneurysms (less than 8 mm in diameter) and fusiform aneurysms are more likely to regress than larger or saccular aneurysms. Larger aneurysms can develop thromboses or stenoses with subsequent ischemia, or they can rupture. Rupture is rare and usually occurs within the first month or two of disease. Ischemia can develop years after the acute illness. Even if aneurysms regress, intimal proliferation can result in endothelial dysfunction (Furuyama et al., 2003). Warfarin has been used at some centers to treat children with giant aneurysms. Angioplasty has been attempted at several centers with mixed results, and surgical bypass grafting has been performed on occasion for high-grade obstruction of the left main coronary artery or at least two of the major coronary arteries. Because of the young age of the patients, grafting is completed with arterial rather than venous grafts (Kitamura et al., 1994).

Takayasu Arteritis

Takayasu arteritis, a vasculitis of the aorta and its major branches that is sometimes known by its catchy synonym “pulseless disease,” is an uncommon disease in children. However, 75% of patients will have begun to develop symptoms during adolescence. An important cause of hypertension in teenagers in Asia, where it is more common, it occurs 8 times more often in females. Narrowing of major arteries results in limb claudication or end-organ disease. Blood pressure in limbs can be artifactually low or unobtainable. Early vessel inflammation is followed by fibrosis. Headaches are a common symptom. The subclavian artery is involved in 90% of cases, and two thirds of all cases involve the aorta, both supradiaphragmatic and infradiaphragmatic. The carotid artery, almost always the left, is involved in half of cases. Stenoses are more common than occlusion, and occlusion is more common than aneurysm formation. Mural inflammation and thickening occur, and coronary and pulmonary arteries are uncommonly affected. Aortic root dilation can result in aortic valve insufficiency. Initial treatment is with corticosteroids. Long-term therapy is often required, and cytotoxic drugs are sometimes added. Once fibrosis has occurred, treatment is by stenting or surgery (Rigby et al., 2002; Kalangos et al., 2006). Unfortunately, there is often recurrence with tapering of steroid therapy or with time after surgical treatment (Maksimowicz-McKinnon et al., 2007).

HEMATOLOGY AND ONCOLOGY ISSUES: HEREDITARY AND CONGENITAL DISORDERS

Hemoglobinopathies

Hemoglobin Structure, Development, and Function

A Hb molecule is composed of two pairs of subunits comprised of protoheme and globin. The globin imparts the spatial structure responsible for characteristics of Hb, including oxygen affinity. Globin chains differ in the number and sequence of amino acids and are designated by α , β , γ , δ , ϵ , ζ , and θ . Human adult red blood cells (RBCs) contain three types of Hb: 95% HbA ($\alpha_2\beta_2$), 2% to 3% HbA₂ ($\alpha_2\delta_2$), and less than 2% HbF ($\alpha_2\gamma_2$). The physical properties and spatial relationships of the four chains determine oxygen affinity and Hb solubility.

At birth, erythrocytes contain 70% to 90% HbF, and HbF predominates until 2 to 4 months of age in normal patients. β -chain production begins and γ -chain production decreases before birth, resulting in a normal adult Hb profile by the age of 4 months. Therefore, disorders of β -chain production do not manifest clinically, nor can they be reliably detected by Hb precipitation tests, before 4 months of age. However, neonatal Hb electrophoresis screening is included as part of testing for inborn errors of metabolism and detects most newborn patients with sickle cell disease (SCD) in the nursery. Persistence of HbF may occur naturally; it also results from hydroxyurea administration. An elevated HbF concentration is protective against complications of SCD.

Hemoglobinopathies result from either production of abnormal Hb or decreased production of a chain. The most relevant example of the former mechanism is amino acid substitution. Decreased chain production results in thalassemia. Hb profiles for clinically relevant hemoglobinopathies are detailed in [Table 36-17](#) (Lane, 1996).

Genetics and Pathophysiology of Sickle Cell Disease

SCD refers to a clinical phenotype marked by erythrocyte deformation, hemolysis, anemia, microvascular occlusion, and recurrent ischemic injury in all organ systems. In the United States, 8% of the African American population carries one of the recessive genes that result in the sickle cell trait (HbAS, SCT), and one in 625 African Americans is homozygous for mutant alleles that result in sickle cell anemia (HbSS, SCA). SCD is a leading cause of morbidity and mortality among African Americans and is associated with important considerations for perioperative management.

The expression of the SCD phenotype is not limited to patients with SCA. Its expression is caused by the inclusion of a mutant β -globin chain in the Hb tetramer, resulting in clinical courses of variable severity. SCD phenotypes of clinical relevance include the following genotypes: sickle cell anemia (HbSS, SCA), HbSCD (HbSC), sickle- β^0 thalassemia (S- β^0), sickle- β^+ thalassemia (S- β^+), and HbS-O_{Arab} (HbS-O_{Arab}).

By definition, patients with the sickle cell trait (HbAS) have at least 50% HbA. Under physiologic conditions, clinical problems are rare. Hb polymerization begins below oxygen saturations of 85% in patients with HbSS, but this does not occur in patients with HbAS until saturations are less than 40%. Thus, it is accepted that patients with HbAS do not require preoperative

TABLE 36-17. Clinical Severity and Diagnostic Testing for the Common Sickle Cell Syndromes

transfusion and are managed with standard attention to hydration, oxygenation, and temperature control.

The fundamental defect in SCD genotypes is amino acid substitution of valine for glutamine at position 6 of the β chain. The resulting HbS is prone to polymerization under conditions of oxygen desaturation caused by formation of bonds between the β-6 valine and the β chains of adjacent tetramers, resulting in the formation of erythrocyte-deforming Hb polymers, erythrocyte cell membrane dysfunction, intracellular oxidant injury, cellular dehydration, and irreversible erythrocyte membrane deformity (Eaton and Hofrichter, 1987; Hebbel et al., 1988; Repka and Hebbel, 1991; Aslan et al., 2000). Deformed erythrocytes obstruct the microvasculature, resulting in tissue ischemia and organ injury. Polymerization is not initially irreversible, however, and prompt return of damaged erythrocytes to the oxygenated state can result in restoration of Hb and cell membrane properties.

Survival of sickle cells in vivo is 5 to 15 days, compared with 120 days for RBCs that contain HbA. The oxygen-dissociation curve in SCA is shifted to the right (i.e., the Hb molecules' affinity for oxygen is less), and theoretically the cells are predisposed to sickling. The cause of this rightward shift is not known, but it is probably related to increased 2,3-diphosphoglycerate levels and to increased mean corpuscular Hb concentration. Of interest is the heterogeneous nature of the P₅₀ (PaO₂ at 50% Hb saturation) values among the erythrocyte population of individuals with sickle cell disease (Fig. 36-9) (Seakins et al., 1973).

Although it is apparent that erythrocyte and Hb factors are critical in the pathogenesis of the complications of SCD, recent investigations have identified other important contributors that include the coagulation cascade, platelets, leukocytes, endothelial cells, systemic inflammation, oxidant-mediated injury, and abnormalities of NO metabolism (Hammerman et al., 1999; Belcher et al., 2000; Morris et al., 2000a; Aslan et al., 2001; Pawloski et al., 2001; Cosby et al., 2003; Assis et al., 2005; Morris et al., 2005). The endothelium interacts with sickle erythrocytes, platelets, leukocytes, and the coagulation cascade through the expression of vascular cell adhesion molecule-1 (VCAM-1) and elaboration of potent vasoconstrictor compounds responsible for exacerbation

FIGURE 36-9. Oxygen-Hb dissociation curves from top and bottom layers of HbS RBCs. Notice the heterogeneous nature of the P₅₀ values. (From Seakins M, et al: Erythrocyte HbS concentration: an important factor in the low oxygen affinity of blood in sickle cell anemia, *J Clin Invest* 52:422, 1973.)

of tissue ischemia and pulmonary artery hypertension (PAH) (Mehta and Mehta, 1980; Brittain et al., 1993; Kurantsin-Mills et al., 1994; Peters et al., 1994; Gee and Platt, 1995; Hagger et al., 1995; Hammerman et al., 1997, 1999; Hebbel, 1997; Graid-Gonzalez et al., 1998; Liesner et al., 1998; Belcher et al., 2000; Assis et al., 2005). Systemic inflammation and oxidant-mediated injury also appear to propagate endothelial injury and tissue ischemia (Hebbel et al., 1982; Schacter et al., 1988; Dias-Da-Motta et al., 1996; Xia et al., 1996; Solovey et al., 1997; Demiryurek et al., 1998; Belcher et al., 2000; Aslan et al., 2001; Assis et al., 2005). SCD is a systemic vasculopathy adversely affecting every organ system in the body.

Abnormalities in the arginine-NO pathway are well described in SCD. Arginine, the precursor for the production of NO, is deficient in SCD and is depleted further during acute chest syndrome (ACS) and vasoocclusive crisis (VOC) (Enwonwu et al., 1990; McDonald et al., 1997; Morris et al., 2000a, 2000b, 2005). The pathophysiology of vasoocclusion and its biochemical contributors are detailed in **Figure 36-10** (Gladwin and Vichinsky, 2008). NO is bound by Hb and is exported to the peripheral vasculature in the forms of nitrite and S-nitrosohemoglobin (Pawloski et al., 2001; Cosby et al., 2003). Deficient NO bioactivity occurs secondary to excessive NO and arginine consumption, arginase-mediated destruction of arginine, and abnormal conversion of arginine and NO to injurious oxidative metabolites (Boucher et al., 1999; Hammerman et al., 1999; Mori and Gotoh, 2000; Morris et al., 2000a). Deficient NO bioactivity contributes to the pathogenesis of SCD through diminished inhibitory effects of NO on VCAM-1 expression, leukocyte adhesion, coagulation cascade, and platelet activation, and through diminished NO-mediated vasodilation, which promotes vasoconstriction, ischemia, and resultant erythrocyte sickling. The interactions of deoxygenated sickle Hb, deformed erythrocyte cell membranes, and activated endothelial cells can be summarized by the “four S’s”; unstable Hb that precipitates and becomes insoluble, leading to sickling deformation of erythrocyte membranes, which stick to activated endothelial cells.

Acute Complications of Sickle Cell Disease Relevant to Pediatric Anesthesia

Pediatric anesthesiologists encounter patients with SCD when the patients are experiencing acute complications of their disease. Acute splenic sequestration usually occurs in children between the ages of 5 months and 2 years and may appear as late as teenage years in patients with sickle-thalassemia (S- β^+). This condition results from the pooling of large quantities of blood in the spleen and leads to shock with profound anemia. Aplastic crisis results when the normal brisk reticulocytosis associated with SCD is suppressed, usually as a result of an intercurrent viral infection with parvovirus B19. Hemolytic crisis occurs when a patient with SCD is exposed to a precipitant that causes an abrupt increase in hemolytic stress (infection or medication). Many patients with hemolytic crisis are also deficient in the enzyme glucose-6-phosphate dehydrogenase (G6PD). These disorders are treated with intravascular volume expansion and transfusion of packed RBCs. Treatment of infection and discontinuation of offending medications are also required for hemolytic crisis. Sepsis and septic shock are serious complications that occur in patients with SCD, who generally experience autoinfarction of the spleen in early childhood, rendering them susceptible to infection with encapsulated organisms. The importance of aseptic techniques and wound infection prophylaxis cannot be overstated.

■ **FIGURE 36-10.** Hypothetical mechanisms of clinical subphenotypes of SCD. It is hypothesized that many of the complications of SCD can be divided into two overlapping subtypes, each driven by distinct mechanisms. Cutaneous leg ulceration, priapism, pulmonary hypertension, sudden death, and stroke are associated with low steady-state Hb levels and an increased rate of intravascular hemolysis, shown on the left side of the figure. These vasculopathic complications probably result from endothelial dysfunction, mediated by inactivation of NO by plasma-free Hb and vascular reactive oxygen species, and by arginine catabolism by plasma arginase. The process of hemolysis-associated endothelial dysfunction may also cause hemostatic activation and intimal and smooth muscle proliferation. Such clinical complications (e.g., VOC, ACS, avascular necrosis of bones, and retinal vasculopathy) are associated with high steady-state leukocyte counts and high Hb levels and are likely to result from obstruction of capillaries and postcapillary venules by erythrocytes that contain polymerized HbS and by leukocytes (a monocyte is shown), as shown on the right side of the figure. *ET-1*, Endothelin 1; *NOS*, nitric oxide synthase; O_2^- , superoxide, *VCAM-1*, vascular cell adhesion molecule 1; *XO*, xanthine oxidase. (From Gladwin MT, Vichinsky E: Pulmonary complications of sickle cell disease, *N Engl J Med* 359:2254, 2008.)

VOC manifests as episodes of painful ischemia and tissue infarction that result from small-vessel occlusion by sickle cells. The most common types of VOC include dactylitis (hand-foot crisis) in infancy, painful crisis in children and adolescents, and priapism in male patients. Stroke and ACS are the most serious forms of VOC that warrant further discussion.

ACS is a common and potentially lethal complication of SCD with complex pathophysiology that can occur in the perioperative period (Fig. 36-11). ACS is the second most common cause of hospital admission and is a leading cause of premature death (mortality rates of 2% to 12%) (Castro et al., 1994; Vichinsky et al., 1997). The etiology of ACS is multifactorial and includes regional hypoxemia secondary to atelectasis or pneumonia, pulmonary vasoocclusion, abnormal NO metabolism, fat emboli, and systemic liberation of inflammatory mediators (Garza, 1990; Vichinsky et al., 1994; Castro, 1996; Styles et al., 1996). ACS occurs in the setting of pulmonary infection or painful crisis, and the symptoms of pneumonia (i.e., fever, pleuritic chest pain, cough, dyspnea, hypoxemia, and progressive infiltrates on chest radiograph) may be difficult to distinguish

from ACS. Respiratory failure may develop quickly, and patients with ACS are treated with hydration, oxygen, antibiotics, simple transfusion, and in severe cases, exchange transfusion. Case reports have described treatment with inhaled NO and extracorporeal membrane oxygenation (Atz and Wessel, 1997; Pelidis et al., 1997; Sullivan et al., 1999). The best treatment for ACS is prevention.

Stroke is the other serious complication of SCD that may occur in the perioperative period. Stroke in children with SCD is most commonly ischemic, but one third of strokes in adult patients with SCD are hemorrhagic (Pavlikis et al., 1989). Many more patients with SCD suffer silent ischemic infarcts that are evident only on neuroimaging, and their presence predicts future ischemic neurologic injury. Indeed, 20% of asymptomatic adolescents have evidence of silent cerebral infarction on neuroimaging studies. Because of the prevalence of silent infarcts in the SCD population, hematologists monitor middle cerebral artery flow velocity with transcranial Doppler (TCD) ultrasonography. Patients who suffer stroke, as well as those with abnormally elevated TCD flow rates, are treated with chronic HbS erythrocyte

■ **FIGURE 36-11.** The vicious cycle of the ACS. ACS is a lung-injury syndrome initiated by three major triggers, all related to vasoocclusion by sickle cells: infection, embolization of bone marrow fat, and intravascular sequestration of red cells. All of these cause lung injury and infarction. Lung injury results in ventilation-perfusion mismatch and hypoxemia, which leads to increased deoxygenation of HbS, followed by Hb polymerization and erythrocyte vasoocclusion, which in turn promotes bone marrow infarction and pulmonary vasoocclusion. NO, Nitric oxide; VCAM-1, vascular cell adhesion molecule 1. (From Gladwin MT, Vichinsky E: *Pulmonary complications of sickle cell disease*, N Engl J Med 359:2254, 2008.)

transfusion to keep HbA at less than 30%. Patients are treated with chronic transfusion for 10 years or longer, because cessation of therapy is associated with increased risk of stroke and recurrence of abnormal TCD flow rates (Adams and Brambilla, 2005). Alloimmunization to erythrocyte antigens is associated with chronic transfusion. Iron overload may also result and may require parenteral deferoxamine or oral deferasirox chelation therapy. Extended phenotypical matching of patient and donor red-cell antigens may result in decreased alloimmunization.

Angiographic and pathologic studies of patients with SCD who have experienced stroke have demonstrated proximal intracranial arterial stenosis of the internal carotid artery, which can be associated with segmental thickening of the arterial wall, and intimal hyperplasia, which tends to occur at sites of arterial bifurcation. A subset of patients with SCD may also demonstrate predominantly small-vessel disease of the CNS vasculature. The potential for presence of flow-limiting lesions in the CNS should be considered when modulating mean arterial blood pressure in the anesthetic management of patients with SCD.

Chronic Complications of Sickle Cell Disease Relevant to Pediatric Anesthesia

Chronic complications of SCD reflect the accumulation of a lifetime of ischemic insults and subsequent decrements in function in all organ systems. Complications include decreased growth and maturation, increased nutritional requirements, retinopathy, stroke, cognitive dysfunction, cardiac dysfunction, elevated PVR, chronic lung injury, diminished renal tubular function, icterus, bone and joint destruction, leg ulceration, and splenic infarction with consequent susceptibility to infectious risk. Of particular importance to the perioperative physician is an appreciation for chronic changes that occur with time in the cardiovascular, respiratory, and renal systems.

The effects of SCD on the cardiovascular system may not be clinically evident to the anesthesiologist. Patients with chronic anemia maintain systemic oxygen delivery through increases in stroke volume and, to a lesser degree, heart rate (in older children and adolescents). Stroke volume increases secondary to increased end-diastolic volume with minimal change in ejection fraction. This condition manifests clinically as cardiomegaly with ventricular dilation.

More ominous than the common changes evident in the left heart is the development of PAH and right ventricular dysfunction. Children with SCD may demonstrate elevated pulmonary vascular resistance during adolescence and early adulthood, and the development of PAH is a robust predictor of premature death (Castro et al., 2003). Most concerning is that in several series of echocardiographic evaluations of patients with SCD, the incidence of PAH was found to be between 20% and 32%, and many of the patients were asymptomatic (Sutton et al., 1994; Gladwin et al., 2004). The mechanisms for the development of PAH in patients who have SCD have been postulated to include diffuse arteriolar thrombosis, scavenging of NO by free Hb in the circulation, arginase-mediated destruction of arginine (limiting NO bioavailability), systemic oxidant-mediated vascular injury, and increased expression of cellular adhesion molecules. SCD patients with or without acute lung injury may have significant PAH and right ventricular dysfunction.

Older patients with SCD may also have significant chronic deterioration of pulmonary function. Sickle cell chronic lung

disease is marked by recurrent episodes of chest pain associated with progressive pulmonary fibrosis and dyspnea (Powars et al., 1988). The etiology of this disease is not known but is associated with chronic hemolysis and increased plasma arginase activity. Anesthesiologists should be aware that restrictive lung disease, obstructive lung disease, airway smooth muscle hyperreactivity, and significant derangements of ventilation-perfusion matching have all been described in SCD.

Repeated ischemic insults to the kidneys may result in significant deterioration in glomerular and tubular function in patients who have SCD. Although this condition is rare in children, older patients may suffer impairment severe enough to require dialysis or transplantation. Patients with SCD demonstrate isosthenuria—an inability to concentrate urine—making the patient prone to dehydration. The potential for presence of renal dysfunction should be considered in the management of perioperative fluids, acid-base balance, electrolyte levels, and medications.

Anesthetic Management of Patients with Sickle Cell Disease

Patients with SCD are surviving later into adulthood as a consequence of availability of more effective immunization, antimicrobial prophylaxis and treatment of sepsis, surveillance measures to detect PAH and impending stroke, and disease-altering therapies such as hydroxyurea, chronic transfusion, and stem cell transplantation. Optimal perioperative management of this population requires an understanding of the pathophysiology of the serious complications of SCD and emphasizes basic strategies to minimize their occurrence. Perioperative care of these patients can be considered in terms of preoperative care (including the role for prophylactic preoperative RBC transfusion), intraoperative care, and postoperative care.

Preoperative Preparation of Patients with Sickle Cell Disease

The goal of preoperative preparation of the patient with SCD is to optimize medical conditions that impact the patient's surgery. Identification of patients with SCD is accomplished through newborn Hb electrophoresis screening. Most patients with a SCD phenotype will have been referred to a pediatric hematology practice for longitudinal follow-up care. Rarely, a child may elude detection, with potentially catastrophic results caused by lack of daily antibiotic prophylaxis. Patients older than 6 months can be screened for sickle hemoglobinopathies with "sickle prep" tests in which Hb polymerization is provoked *in vitro*. In the presence of significant HbF concentrations, these sickle prep examinations lack sensitivity, and Hb electrophoresis is required. Children younger than 6 months and older children with positive sickle prep results require Hb electrophoresis to delineate their hemoglobinopathy. By their tenth birthday, 90% of patients with SCD have clinical manifestations of their disease. Cardiovascular, respiratory, and renal systems, as well as the CNS should be screened for dysfunction that may impact perioperative management. Patients should be treated for infection when appropriate, because infection and systemic inflammation contribute to development of VOC and ACS.

In that dehydration may predispose to VOC and ACS, patients with SCD should be well hydrated before surgery. Administration of IV hydration at 1.5 times the maintenance

rate overnight before surgery has been recommended in the past; however, this is not a practice supported by randomized trials. A recent small retrospective study demonstrated the safety and effectiveness of outpatient preoperative management (transfusion and liberal oral hydration) and goal-directed postoperative management, which obviated the need for preoperative admission and extended postoperative observation in this cohort of patients with SCD who were undergoing adenotonsillectomy (Duke et al., 2006). In short, patients with SCD should not be permitted to become dehydrated or volume overloaded during any phase of perioperative management.

Role of Routine Preoperative Blood Transfusion for Patients with Sickle Cell Disease

The most debated topic relevant to the perioperative management of patients with SCD concerns the role of prophylactic preoperative blood transfusion. It has long been appreciated that surgical morbidity and mortality are increased in this population. Early reviews reported mortality rates as high as 10% and complication rates of 50% (Holzmann et al., 1969). Data reflective of more recent advances in anesthetic monitoring and pharmacology demonstrate a 1.1% perioperative mortality rate among adult and pediatric patients with SCD—a level still clearly greater than that of the general population (Koshy et al., 1995). No perioperative deaths were reported in children younger than 14 years of age, nor were perioperative deaths noted in 54 children who underwent 66 elective surgical procedures without preoperative transfusion (Griffin and Buchanan, 1993; Koshy et al., 1995). Although perioperative mortality among patients with SCD is recognized to be more common in older children and adults, serious complications and mortality are well described in all age groups and warrant meticulous attention to perioperative management.

Beginning in the late 1980s, anesthesiologists, hematologists, and surgeons became interested in preoperative transfusion as a means of decreasing the perceived risk associated with surgery and anesthesia for patients with SCD. *Simple transfusion* strategies refer to the transfusion of small aliquots of blood with the goal of increasing the Hb level to 10 g/dL without regard to the final HbS percentage. *Aggressive transfusion* strategies refer to either repetitive, simple transfusions over time or acute exchange transfusion with the goals of Hb concentration of 10 g/dL and HbS less than 30%. The rationale for preoperative transfusion in both cases is to increase the oxygen-carrying capacity of the blood and in the case of aggressive transfusion to decrease the percentage of HbS in the circulation to prevent red cell sickling.

Potential detrimental effects of preoperative prophylactic transfusion include increased risk for acquisition of blood-borne infection, hemolytic transfusion reactions, febrile reactions to leukocyte antigens, transfusion-associated acute lung injury, iron overload, and immunosuppression. Alloimmunization to foreign RBC antigens may develop, which results in difficulty in cross-matching RBCs for transfusion.

The past two decades have witnessed the publication of numerous trials of variable quality and size that have attempted to define the utility of routine preoperative transfusion in the population with SCD. A succinct answer to whether preoperative transfusion is beneficial remains elusive because of confounding variables that include the following:

- Different surgical procedures appear to be associated with different degrees of risk for morbidity and mortality;
- Perioperative morbidity and mortality risk from the same surgical procedures may not be equivalent in infants, children, adolescents, and young adults;
- Changes in surgical and anesthetic techniques, as well as advances in disease-altering medical therapies for SCD, may result in changes in perioperative morbidity and mortality;
- Differing thresholds among studies for exclusion and inclusion of perioperative complications to be considered as clinically relevant endpoints to warrant transfusion in an effort to minimize its occurrence; and
- Lack of randomized prospective data that compare outcomes in patients with SCD who are managed with simple transfusion or exchange transfusion with those who are managed without preoperative transfusion.

Despite the difficulties discussed above, approximately 14 studies published during the past 20 years addressed, in some fashion, the utility of preoperative transfusion (Bischoff et al., 1988; Griffin and Buchanan, 1993; Koshy et al., 1995; Vichinsky et al., 1995, 1999; Haberkern et al., 1997; Neumayr et al., 1998; Waldron et al., 1999; Hirst and Williamson, 2001; Wali et al., 2003; Buck et al., 2005; Fu et al., 2005; Leff et al., 2007; Al-Samak et al., 2008). Considering these studies together, the practitioner can glean the following conclusions:

- Patients with SCD are at much higher risk for perioperative morbidity and mortality, and meticulous attention to preoperative, intraoperative, and postoperative care is warranted.
- Different surgical procedures are associated with different degrees of perioperative risk, and it may not be reasonable to require the same preoperative therapy and preparation for all surgical procedures.
- Among surgical procedures, adenotonsillectomy, laparotomy, and thoracotomy are common procedures associated with the greatest perioperative risk.
- Preoperative transfusion may be associated with improved perioperative outcomes (but not as low as in the population without SCD).
- When transfusion is used for preoperative management, simple transfusion is as effective as exchange transfusion in decreasing SCD-related morbidity for most patients.
- Simple transfusion is more effective than exchange transfusion in reducing transfusion related morbidity (Table 36-18) (Vichinsky et al., 1995).

Data from large, randomized, prospective studies that stratify patients according to age, hemoglobinopathy, surgical procedure, and prior morbidity have not been published. Therefore, the approach to preoperative transfusion should be appropriately individualized after considering the patient's comorbidities, history of SCD-related complications, proposed surgical procedure, and the opinions of the surgeon, anesthesiologist, and hematologist involved in the patient's care. Typically, patients with SCD who are undergoing procedures associated with moderate and increased risk (i.e., laparotomy, thoracotomy, and adenotonsillectomy) are managed with simple transfusion to correct anemia. High-risk patients, such as those with stroke and recurrent ACS, and patients who

TABLE 36-18. Aggressive vs. Simple Transfusion Protocols for Sickle Cell Patients

Characteristic	Aggressive Arm	Simple Arm
Hemoglobin S (HbS)	31%	59%
Hemoglobin (Hb)	11.1 g/dL	10.6 g/dL
Units transfused	5	2.5
Hospital days (for transfusion)	4	2.5
Complications	31%	35%
Transfusion-related	14%	7%
Acute chest syndrome	10%	10%
Death	1%	0

Data from Vichinsky EP, et al: A comparison of conservative and aggressive transfusion regimens in the perioperative management of sickle cell disease: the preoperative transfusion in sickle cell disease study group, *N Engl J Med* 333:206, 1995.

are undergoing very high-risk procedures (i.e., cardiovascular and cerebrovascular surgery) may require an aggressive exchange-transfusion approach that targets a particular HbS percentage (less than 30%).

Many patients with a history of stroke are treated with a chronic-transfusion protocol designed to maintain the Hb concentration at 10 to 11 g/dL and the HbS percentage at less than 30% to 40%. For such patients, further preoperative transfusion therapy is probably not necessary provided the patients have been compliant with the chronic-transfusion regimen. Verification of appropriate Hb concentration and HbS percentage through consultation with the referring hematology staff is appropriate in these circumstances.

In summary, in most patients undergoing most procedures, some form of simple transfusion to correct anemia is usually provided. Close consultation with the hematology service should be sought to help to determine which low-risk patients and low-risk procedures may be managed without transfusion. To maximize the benefit of transfusion therapy while preventing acute increase in viscosity and risk of stroke, the targeted Hb concentration after transfusion should be 10 to 11 g/dL.

Operative Anesthetic Management of Patients with Sickle Cell Disease

Monitoring and maintenance of arterial oxygenation are recommended in the anesthetic management of all patients. Although it is intuitive that maintenance of oxygenation is particularly critical in patients who have SCD, the medical literature contains many descriptions of patients with SCD who were exposed to hypoxemia (i.e., cyanotic congenital heart disease, occlusive tourniquet use, experimental inhalation of hypoxic gas mixtures, and chronic lung disease) and did not suffer immediate SCD-related complications. Similarly, postoperative SCD-related complications continue to occur despite administration of supplemental oxygen and avoidance of intraoperative hypoxemia. Nevertheless, close monitoring of arterial oxygenation and administration of supplemental oxygen are recommended to maintain arterial oxygen saturations in the normal range.

The consequences of Hb desaturation may be mitigated if Hb is promptly reoxygenated after short transit time through the circulation. It is imperative to avoid physiologic perturbations that result in both Hb desaturation and vascular stasis. Preservation of cardiac output, oxygen-carrying capacity, and oxygen saturation, and avoidance of dehydration, hypotension, and vasoconstriction are recommended to minimize conditions conducive to Hb desaturation and prolonged vascular transit time.

Maintenance of normal body temperature is also probably advisable during the anesthetic management of patients with SCD. Whereas hypothermia inhibits oxygen unloading at the tissue level and in this sense might be protective against Hb polymerization, it also results in vasoconstriction in vascular beds and prolongs vascular transit time, thus promoting Hb polymerization. Hyperthermia promotes oxygen unloading at the tissue level and may be associated with vasoconstriction or vasodilation. Close monitoring and maintenance of normal body thermal homeostasis are the basic tenets of critical care and anesthetic management.

At the tissue level, systemic acidosis promotes—and alkalosis inhibits—oxygen unloading. Clinical evidence linking acidosis to precipitation of SCD events is lacking, and sodium bicarbonate administration has not been shown to prevent SCD complications. Further, it is usually difficult to separate the clinical effects of acidosis from its underlying cause. It is recommended to keep systemic acid-base balance close to the normal range.

No particular anesthetic management technique has proven to be more or less effective than others. Arguments can be made for and against regional techniques for patients with SCD. In The Cooperative Study of Sickle Cell Disease, non-SCD-related complications of fever and infection were noted more often in the patients who received regional anesthesia than in those who received general anesthesia (Koshy et al., 1995). However, the group that received regional anesthesia contained more obstetric patients, a subpopulation known to have higher complication rates than other surgical groups. The theoretical rationale for the development of more complications in the regional group includes the presence of compensatory vasoconstriction in areas above the block, lack of controlled ventilation, and the potential for vascular stasis during regional anesthesia (Scott-Conner and Brunson, 1994). Other authors feel that regional techniques do not increase SCD complication risk and, in fact, have used them to treat complications of SCD, including painful crisis and priapism (Yaster et al., 1994). The anesthetic technique chosen is probably not as important as proper preoperative preparation and meticulous intraoperative attention to control of precipitating physiologic factors.

The safety of tourniquet use in orthopedic surgery for patients with SCD has been debated. Although prospective studies that examine the safety of tourniquet use in this population are lacking, retrospective studies supporting its safety have been published (Adu-Gyamfi et al., 1993). If a tourniquet is to be used, it is recommended that the extremity be meticulously exsanguinated before inflating the tourniquet.

Otolaryngology procedures are among the most common surgical procedures performed on children. In a 1999 study that compared patients who underwent adenotonsillectomy and myringotomy after simple and aggressive transfusion, 118 patients were enrolled and randomized to one of the two preoperative transfusion regimens, and an additional 47 patients were enrolled and not randomized; 20 of the 47 nonrandomized

patients were not transfused (Waldron et al., 1999). No differences between transfusion strategies were reported with respect to complications. History of pulmonary disease predicted perioperative SCD-related complications in adenotonsillectomy patients. The authors speculated that because myringotomy is associated with short duration of surgery, minimal blood loss, and surgery remote from the airway, preoperative transfusion might not improve the safety of myringotomy. However, this hypothesis was not specifically studied, and the importance of attention to all other aspects of perioperative care (hydration, oxygenation, and temperature control) was emphasized. Patients with SCD who have sleep-disordered breathing require meticulous perioperative observation, because they have particularly severe nocturnal oxygen desaturation and hypercarbia when compared with age- and gender-matched patients in a control group (who do not have SCD) with sleep-disordered breathing (Kaleyias et al., 2008).

Cholecystectomy is another common procedure performed in patients with SCD (Haber Kern et al., 1997). Increased use of laparoscopic techniques for gall bladder removal results in less postoperative pain, splinting, and atelectasis. Wales and colleagues (2001) examined the effect of laparoscopic vs. open cholecystectomy in this patient population. Increased risk for ACS in all types of abdominal surgery was noted, irrespective of technique (20% overall, 22% in laparoscopic cases, 15% in open cases), but most of these patients were not transfused. The authors concluded that the postoperative benefits of laparoscopic surgery do not result in decreased SCD complications, but they questioned whether more liberal preoperative transfusion would have resulted in improved outcomes.

Postoperative Management of the Patient with Sickle Cell Disease

Most serious SCD-related complications occur in the postoperative period, and therefore the advisability of outpatient surgery for patients with SCD is questionable. VOC is the most common postoperative SCD-related complication. For this reason, it is prudent to comply with the paradigm used by the Preoperative Transfusion in Sickle Cell Disease Study Group, which included postoperative hospitalization, oxygen supplementation, hydration, and pulse-oximeter monitoring. The importance of adequate postoperative analgesia (e.g., oral or IV opioids, NSAIDs, and regional anesthesia techniques) cannot be overstated, because inadequate pain management results in pulmonary splinting, hypoventilation, and ACS. On the other hand, excessive administration of pain medication may result in hypoventilation, atelectasis, and ACS. Postoperative length of stay in the hospital is dictated to a large degree by the type of surgery performed, but patients can be considered for discharge when they are able to sustain oral hydration, are free from fever, can demonstrate good oxygen saturations and pulmonary toilet, and when pain is well controlled on oral analgesics.

Other groups have advocated an individualized approach to the perioperative management of surgical patients with SCD. For children undergoing adenotonsillectomy, Duke and colleagues (2006) recommended preoperative outpatient transfusion, liberal oral clear liquid hydration at home, postoperative monitoring with pulse oximeter, and oxygen administration only to those patients with saturations of less than 94%. With this paradigm, which mandated controlled responses to hypoxemia and fever in the postoperative period, complications were noted

that included 20% with hypoxemia, 10% with fever, and 8% with ACS. Most of their patients were discharged from the hospital after fewer than 24 hours without adverse sequelae.

Thalassemia

Thalassemia refers to any of several genetic defects in the production of globin chains of Hb. Patients may have deficient production of the α -globin chain (α thalassemia) or the β -globin chain (β thalassemia). The clinical thalassemic syndromes can be understood in terms of the corresponding genotypes.

The α -thalassemia syndromes, which contain four allele loci, have more genotypical possibilities than the β thalassemias. The severity of the syndrome is dependent on how many of the four α -globin genes are absent. The absence of functional α -globin genes ($-\alpha-$) is not compatible with life and leads to death in utero (hydrops fetalis). One functional α -globin gene ($-\alpha-$) leads to a severe microcytic, hemolytic anemia called *HbH disease*. Two nonfunctional genes ($\alpha\alpha-$) gives rise to a mild anemia (α thalassemia minor syndrome). A single nonfunctional α -globin gene is clinically silent.

For the β thalassemias (with two β -globin gene loci), mutations on both of the β -globin gene loci result in homozygous disease; however, each locus has more than 60 possible mutations that result in heterogeneous clinical syndromes for homozygous patients, depending on which mutant alleles are present at the two loci. For some patients with very dysfunctional mutant genes present at the two loci, severe anemia results with a lifelong transfusion requirement—referred to as *β -thalassemia major*. Other patients with more functional mutant alleles at these loci also have severe anemia but do not require lifelong transfusions—this condition is referred to as *β -thalassemia intermedia*. Patients who are heterozygous (one normal β -globin gene and one mutant β -globin) have more moderate anemia and produce enough β -globin chains to obviate the need for ongoing transfusions—referred to as *β -thalassemia trait*, or *β -thalassemia minor*.

In patients with thalassemia, the issues encountered by the anesthesiologist are anemia, the problems associated with chronic anemia, and numerous transfusions. These patients do not recover from surgical blood loss with RBC production, as is expected in other patients. It should be remembered that thalassemia patients can be heterozygous for two different disorders of β -globin production. The most clinically relevant examples are patients who have both a sickle gene and a mutant β -thalassemia gene at the β -globin chain loci. The modifiers β^+ and β^0 are included as descriptive terminology for these patients. β^0 indicates that the patient cannot produce any normal β -globin chains; therefore, patients with S- β^0 thalassemia have no HbA. Their clinical course is similar to those of patients with HbSS disease. β^+ does not refer to a specific genotype but indicates that the patients can produce variable quantities of normal β -globin chains (depending upon the mutant gene present). Patients with S- β^+ thalassemia produce variable amounts of HbA and generally have a more benign clinical course than patients with HbSS. Both groups of heterozygotes warrant the same meticulous perioperative management that is provided to patients with sickle cell anemia.

Oncology Issues

Relationship to the Pediatric Anesthesiologist

As anesthesiologists play greater roles in the management of pediatric patients with cancer, their interactions with these patients and their families have become increasingly important. From the time children are diagnosed with malignancy until the end of a successful treatment, the anesthesiologist has assumed an increasingly important role in their care. Historically, repetitive painful procedures such as lumbar puncture, bone marrow aspiration, and others were performed with physical restraint under local anesthesia and without sedation. This protocol was minimally effective in relieving pain and anxiety, and families were confronted not only with the anxiety and uncertainty of the diagnosis and prognosis of their children, but also with the dread of repetitive painful procedures.

In many pediatric hospitals, an anesthesiologist is present when diagnostic procedures are performed, tumors are removed, central venous access devices are implanted and removed, and radiation treatments are administered. Increasingly, anesthesiologists are also being asked to assist with pain management during end-of-life care, in response to painful complications of chemotherapy, and during recovery from hematopoietic stem cell transplantation (HSCT).

Childhood cancer remains one of the leading causes of disease-related mortality among pediatric patients, but progressive advances in its management have led to increased numbers of long-term survivors. Indeed, 79% of children diagnosed with cancer before the age of 15 survive for at least 5 years (Jemal et al., 2006). Acute lymphoblastic leukemia and CNS tumors are the two most common malignancies in children, and advances in their management have exposed the anesthesiologist to increased numbers of surviving children with delayed organ toxicity related to treatment. The following section is a review of the anesthetic implications of chemotherapy, radiation therapy, and HSCT.

Myelosuppression

Acute and delayed toxicities result from the administration of chemotherapy. Acute toxicities common to most chemotherapy agents include myelosuppression, alopecia, nausea, vomiting, mucositis, and liver dysfunction. Myelosuppression results in profound pancytopenia and is of concern in perioperative management. Neutropenia renders patients susceptible to bacterial and viral infections. Recommended precautions to prevent introduction of bacterial infections include protective and reverse isolation, avoidance of rectal temperature measurement and medication administration, strict hand washing, and aseptic technique during procedures, including before and during medication administration through central venous catheters.

Thrombocytopenia is common in oncology patients, and the need for perioperative platelet transfusion is dependent on the type of procedure to be performed, the potential for bleeding, and the function of the existing platelets. Neuraxial anesthesia may be contraindicated in these situations. These decisions should be made in consultation with the patient, the family, and the hematologist directing the patient's care. The decision as to when to transfuse packed RBCs should also be discussed with the hematologist. In the absence of significant cardiac or pulmonary disease or the need for increased

oxygen-carrying capacity, hematocrit values in the low to mid 20s are common and well tolerated. RBCs may require radiation to prevent graft-versus-host disease (GVHD) in the immunocompromised oncology patient, as well as leukocyte depletion to prevent transmission of cytomegalovirus.

Individual chemotherapeutic drugs and radiation produce unique toxicities that are of concern in the anesthetic management of oncology patients (Table 36-19) (Bleyer, 2007). Particularly important among them are medications that, alone or in combination with anesthetic drugs, result in cardiac and pulmonary toxicity, and these are discussed in detail.

Cardiac Toxicity

Anthracycline Antibiotics

Several chemotherapeutic agents cause cardiac toxicity that may be acute or chronic. The agents most commonly associated with cardiac toxicity are the anthracycline antibiotics doxorubicin, daunorubicin, epirubicin, and idarubicin (Giantris et al., 1998; Singal and Iliskovic, 1998; Balis et al., 2002). Acute cardiac changes associated with anthracycline administration include decreased QRS amplitude, nonspecific ST-T wave changes, supraventricular and ventricular rhythm disturbances, and reduction in ventricular ejection fraction, reaching a nadir at 24 hours after administration. A severe form of this constellation of effects, called *myocarditis-pericarditis syndrome*, results in congestive heart failure with cardiogenic shock.

Chronic toxicity may also occur weeks, months (early form), and years (late form) after anthracycline administration. The early form is associated with cytoplasmic vacuolization, myofibrillary lysis, and degeneration of nuclei and mitochondria. Oxidative damage that results from anthracycline metabolism is believed to be responsible for these changes. Myocardial dysfunction with congestive heart failure that is poorly responsive to cardiotoxic medications occurs with a cumulative dose-dependent risk. Acute myocardial injury occurs in fewer than 1% of pediatric patients; the incidence of congestive heart failure increases with doxorubicin doses higher than 450 mg/m² but has been observed with doses as low as 220 mg/m² (Giantris et al., 1998). The toxic threshold for idarubicin is not known, but doses up to 150 mg/m² appear to be tolerated (Allen, 1992; Swafford and Gibbs, 1998). Mediastinal irradiation increases the risk of anthracycline-induced myocardial dysfunction.

Late-form cardiotoxicity, which occurs 7 to 14 years after therapy, is more common in children and may be related to the inability of the heart to grow with the child. Late toxicity is associated with cumulative doses of doxorubicin more than 300 mg/m² but has been described to occur in children after lower doses. Children treated with these medications receive follow-up care with baseline and serial echocardiograms for many years after treatment. Risk for death from cardiac-related events is eight times higher among survivors of pediatric malignancies than it is in the general population (Green et al., 2001; Mertens et al., 2001). Risk factors for anthracycline-mediated cardiac toxicity are listed in Table 36-20 (Swafford and Gibbs, 1998).

Methods to prevent or minimize anthracycline-induced cardiac disease have been and continue to be investigated. These include limiting cumulative dose and altering administration methods of anthracycline, coupling anthracyclines with liposomal carriers and polyethylene glycol, using anthracycline analogues, and adding cardioprotective medications

TABLE 36-19. Common Chemotherapeutic Agents Used in Children

Drug	Mechanism of Action or Classification	Indication(s)	Adverse Reactions	Monitoring Drug Level	Comments
Methotrexate	Folic acid antagonist; inhibits dihydrofolate reductase	ALL, non-Hodgkin lymphoma, osteosarcoma, Hodgkin lymphoma, medulloblastoma	Myelosuppression, mucositis, stomatitis, dermatitis, hepatitis; With long-term administration, osteopenia and bone fractures; With high-dose administration, renal and CNS toxicity; With intrathecal administration, arachnoiditis, leukoencephalopathy, leukomyelopathy	Plasma levels must be monitored with high-dose therapy and when low doses are administered to patients with renal dysfunction and leucovorin rescue applied accordingly	Systemic administration may be PO, IM, or IV; also may be administered intrathecally
6-Mercaptopurine (Purinethol)	Purine analogue; inhibits purine synthesis	ALL	Myelosuppression, hepatic necrosis, mucositis; allopurinol increases toxicity	Therapeutic drug monitoring not available or indicated	Allopurinol inhibits metabolism
Cytarabine (Ara-C)	Pyrimidine analogue; inhibits DNA polymerase	ALL, AML, non-Hodgkin lymphoma, Hodgkin lymphoma	Nausea, vomiting, myelosuppression, conjunctivitis, mucositis, CNS dysfunction; With intrathecal administration, arachnoiditis, leukoencephalopathy, leukomyelopathy	Therapeutic drug monitoring not available or indicated	Systemic administration may be PO, IM, or IV; may also be administered intrathecally
Cyclophosphamide (Cytosan)	Alkylates guanine; inhibits DNA synthesis	ALL, non-Hodgkin lymphoma, Hodgkin lymphoma, soft tissue sarcoma, Ewing sarcoma	Nausea, vomiting, myelosuppression, hemorrhagic cystitis, pulmonary fibrosis, inappropriate ADH secretion, bladder cancer, anaphylaxis	Therapeutic drug monitoring not available or indicated	Requires hepatic activation and is thus less effective in presence of liver dysfunction
Ifosfamide (Ifex)	Alkylates guanine; inhibits DNA synthesis	Non-Hodgkin lymphoma, Wilms tumor, sarcoma, germ cell and testicular tumors	Nausea, vomiting, myelosuppression, hemorrhagic cystitis, pulmonary fibrosis, inappropriate ADH secretion, bladder cancer, CNS dysfunction, cardiac toxicity, anaphylaxis	Therapeutic drug monitoring not available or indicated	
Doxorubicin (Adriamycin) and daunorubicin (Cerubidine)	Binds to DNA, intercalation	ALL, AML, osteosarcoma, Ewing sarcoma, Hodgkin lymphoma, non-Hodgkin lymphoma, neuroblastoma	Nausea, vomiting, tissue necrosis on extravasation, myelosuppression, radiodermatitis, arrhythmia	Therapeutic drug monitoring not available or indicated	
Dactinomycin	Binds to DNA, inhibits transcription	Wilms tumor, rhabdomyosarcoma, Ewing sarcoma	Nausea, vomiting, tissue necrosis on extravasation, myelosuppression, radiosensitizer, mucosal ulceration	Therapeutic drug monitoring not available or indicated	
Bleomycin (Blenoxane)	Binds to DNA cleaves DNA strands	Hodgkin disease, non-Hodgkin lymphoma, germ cell tumors	Nausea, vomiting, pneumonitis, stomatitis, Raynaud phenomenon, pulmonary fibrosis, dermatitis	Therapeutic drug monitoring not available or indicated	

Continued

TABLE 36-19. Common Chemotherapeutic Agents Used In Children—cont'd

Drug	Mechanism of Action or Classification	Indication(s)	Adverse Reactions	Monitoring Drug Level	Comments
Vincristine (Oncovin)	Inhibits microtubule formation	ALL, non-Hodgkin lymphoma, Hodgkin disease, Wilms tumor, Ewing sarcoma, neuroblastoma rhabdomyosarcoma	Local cellulitis; peripheral neuropathy, constipation, ileus, jaw pain, inappropriate ADH secretion, seizures, ptosis, minimal myelosuppression	Therapeutic drug monitoring not available or indicated	IV administration only; must not be allowed to extravasate
Vinblastine (Velban)	Inhibits microtubule formation	Hodgkin disease; Langerhans cell histiocytosis	Local cellulitis, leukopenia	Therapeutic drug monitoring not available or indicated	IV administration only; must not be allowed to extravasate
L-Asparaginase	Depletion of L-asparagine	ALL; AML, when used in combination with asparaginase	Allergic reaction pancreatitis, hyperglycemia, platelet dysfunction and coagulopathy, encephalopathy	Therapeutic drug monitoring not available or indicated	PEG-asparaginase now preferred to L-asparaginase
Pegaspargase (Pegaspar)	Polyethylene glycol conjugate of L-asparagine	ALL	Indicated for prolonged asparagine depletion and for patients with allergy to L-asparaginase	Therapeutic drug monitoring not available or indicated	
Prednisone and dexamethasone (Decadron)	Lymphatic cell lysis	ALL; Hodgkin disease, non-Hodgkin lymphoma	Cushing's is syndrome, cataracts, diabetes, hypertension, myopathy, osteoporosis, infection, peptic ulceration, psychosis	Therapeutic drug monitoring not available or indicated	
Carmustine (nitrosourea)	Carbamylation of DNA; inhibits DNA synthesis	CNS tumors, non-Hodgkin lymphoma, Hodgkin disease	Nausea, vomiting, delayed myelosuppression (4-6 wk); pulmonary fibrosis, carcinogenic stomatitis	Therapeutic drug monitoring not available or indicated	Phenobarbital increases metabolism, decreases activity
Carboplatin and cisplatin (Platinol)	Inhibits DNA synthesis	Gonadal tumors; osteosarcoma, neuroblastoma, CNS, tumors, germ cell tumors	Nausea, vomiting, renal dysfunction, myelosuppression, ototoxicity, tetany, neurotoxicity, hemolytic-uremic syndrome, anaphylaxis	Therapeutic drug monitoring not available or indicated	Aminoglycosides may increase nephrotoxicity
Etoposide (VePesid)	Topoisomerase inhibitor	ALL, non-Hodgkin lymphoma, germ cell tumor	Nausea, vomiting, myelosuppression, secondary eukemia	Therapeutic drug monitoring not available or indicated	
Etretinate (Tegison) (vitamin A analogue) and tretinoin	Enhances normal differentiation	Acute promyelocytic leukemia, neuroblastoma	Dry mouth, hair loss, pseudotumor cerebri, premature epiphyseal closure	Therapeutic drug monitoring not available or indicated

TABLE 36-20. Risk Factors for Anthracycline Cardiac Toxicity

Risk Factor	Description
Cumulative dose	Risk <1% for doses <300 mg/m ² 5%-10% for doses 350-450 mg/m ² 30% for doses >550 mg/m ²
Schedule of administration	Risk greatest with bolus administration Less risk with continuous infusion Less risk with dexrazoxane
Mediastinal irradiation	Strong association with increasing risk
Cardiac disease	Preexisting coronary artery disease, valvular heart disease, hypertension
Age	Young children Adults aged >70 years

From Swafford J, Gibbs HR: Cardiac complications of cancer treatment, *Anesth Clin N Am* 16:598, 1998.

such as dexrazoxane (that chelate iron molecules and prevent anthracycline-induced oxidative injury) into the chemotherapy regimen (Legha et al., 1982; Shapira et al., 1990; Dorr et al., 1991; Herman et al., 1997; Cottin et al., 1998; Creutzig et al., 2001; Lipshultz et al., 2002a; O'Byrne et al., 2002; Safra, 2003; Levitt and Dorup, 2004; O'Brien et al., 2004; Barry et al., 2007).

Patients who suffer from anthracycline-induced cardiotoxicity are treated with afterload-reducing medications to minimize ventricular wall stress. The most common medications used for this purpose are the angiotensin-converting enzyme (ACE) inhibitors. ACE inhibitors administered to survivors of pediatric cancers have been beneficial in improving left-ventricle dimensions, fractional shortening, left-ventricle mass, and decreasing afterload (Lipshultz et al., 2002b). However, this benefit appears to be transient, because many patients regress to baseline and deteriorate further after 6 to 10 years of treatment (Lipshultz et al., 2002b, 2004). Other medications used for cardiac dysfunction and congestive heart failure include β -blockers such as carvedilol. The beneficial effects of β -blockers in the setting of idiopathic dilated cardiomyopathy and ischemic heart disease with congestive heart failure in adult patients include reduction in mortality, increase in left-ventricular ejection fraction, and prevention of adrenergically mediated intrinsic myocardial dysfunction and remodeling (Bristow, 1997; Lechat et al., 1998).

Cyclophosphamide

Cyclophosphamide, especially in high doses (exceeding 100 to 200 mg/kg), can cause severe congestive heart failure and hemorrhagic myocarditis. Pericardial tamponade has also been described with cyclophosphamide and has resulted in cardiac tamponade. Toxicity occurs with lower doses in children who have also received anthracyclines.

Radiation

Radiation, when used for the treatment of thoracic tumors, has also resulted in cardiac toxicity, with early toxicity associated with pericarditis, pericardial effusions, and tamponade.

Radiation dose is expressed in terms of joules deposited per kilogram of body weight (J/kg), which is denoted as Gray (Gy) units. One Gy is equal to 100 rads in the old system; thus, 1 rad is equivalent to 1 cGy. Most long-term effects occur with cumulative doses that exceed 40 Gy and may not become manifest for up to 10 years after treatment (Applefield et al., 1982).

The anesthetic management of patients with known or suspected cardiomyopathy necessarily includes cardiology consultation and echocardiographic assessment of myocardial and valvular function. Oncology patients may have clinically silent deterioration in cardiovascular function for many years after completion of therapy. Selection of induction agents, maintenance agents, and invasive hemodynamic monitors is made on the basis of cardiovascular status. Intraoperative fatalities have occurred in children with chemotherapy-induced cardiomyopathy.

Pulmonary Toxicity

Many chemotherapeutic agents have some element of pulmonary toxicity. The etiology of pulmonary dysfunction in the immunosuppressed, and especially in stem cell-transplant recipients, may include infectious etiologies, nonspecific lung injury related to dysregulated inflammation and immune function, and toxic injury from medications and radiation. Because of the multifactorial causes for lung injury in oncology patients, it is often difficult to pinpoint the offending agent responsible for the injury.

Alkylating agents

Drugs such as carmustine, lomustine, busulfan, melphalan, chlorambucil, and cyclophosphamide are all associated with cytotoxic lung injury. Busulfan may cause lung injury when given as a single agent, whereas the other medications usually do so only in high doses or when part of multidrug therapy. Busulfan lung injury occurs 6 weeks to 10 years after therapy, with an average time interval from treatment to symptoms of 3 years. Dyspnea, fatigue, nonproductive cough, weight loss, unexplained fever, and bi-basilar pulmonary infiltrates are hallmarks of this complication, and it carries a poor prognosis.

Bleomycin (a cytotoxic antibiotic) and mitomycin (an alkylating agent) have pulmonary toxicities. Bleomycin lung injury is the prototype for interstitial pneumonitis and pulmonary fibrosis. It has been clearly recognized that a toxic synergistic relationship exists between high inspired-oxygen concentration and bleomycin. Although the exact mechanism is unclear, oxygen concentrations above 30% can rapidly precipitate acute lung injury and acute respiratory distress syndrome in patients who have previously received bleomycin (Maher and Daley, 1993; Mathes, 1995). Mortality from this injury ranges between 13% and 83% in various studies. High-dose corticosteroids have had a beneficial effect in the treatment of this injury (Maher and Daley, 1993). Antimetabolites such as cytosine arabinoside, fludarabine, methotrexate, and 6-mercaptopurine also cause varying degrees of lung injury in dose-related fashion but generally carry better long-term prognoses than does bleomycin-mediated pulmonary toxicity.

Radiation

Thoracic radiation causes clinically significant lung injury in 5% to 15% of patients. Several phases of lung injury are described.

The latent or early phase occurs within 1 to 2 months of exposure; the exudative phase occurs 4 to 6 months afterward, and symptoms of pneumonitis develop. The late phase is heralded by the development of pulmonary fibrosis from 6 to 12 months after exposure. Factors that influence the development of pulmonary toxicity include the total dose of irradiation, volume of lung treated, fraction size (radiation given per treatment), and patient age at the time of treatment (younger patients are more prone to toxicity). Pulmonary toxicity has decreased significantly over the past decade because of refined techniques of radiotherapy (Hassink et al., 1993). Toxicity usually does not occur until more than 30 Gy are delivered to more than 50% of the lung when radiation is used alone in adults. The mechanism of injury appears to be different in children younger than 3 years of age, in whom interference with lung and chest wall growth may occur (Miller et al., 1986). In these children, restrictive lung disease has developed with radiation doses as low as 11 to 14 Gy.

Anesthetic management of patients who have—or who are at risk for the development of—radiation or chemotherapy-induced pulmonary toxicity requires careful preoperative assessment and intraoperative management. Preoperative assessment may include chest x-ray or CT, spirometric assessment, oxygen saturation or arterial blood gas measurement, and pulmonology consultation. Children at risk for pulmonary toxicity should be treated with the lowest inspired oxygen concentration that provides acceptable oxygen saturation values, and the lowest airway pressures (peak inspiratory pressure and positive end-expiratory pressure) that provide adequate ventilation and preservation of functional residual capacity should be selected.

Hematopoietic Stem Cell Transplantation

HSCT has become an accepted therapy for many pediatric disorders, including hematologic malignancies, aplastic anemia, immunodeficiency disorders, congenital hematologic defects, inborn errors of metabolism, and some solid tumors. Pediatric patients who have received HSCT present several unique considerations for anesthetic management, including pretransplant conditioning, acute and chronic GVHD, adverse organ system effects of GVHD, non-GVHD-related morbidity, and unique pharmacologic considerations.

Pretransplant Conditioning

All patients who have undergone HSCT first undergo pretransplant conditioning to ablate or impair the native bone marrow. Chemotherapeutic agents commonly employed for this conditioning include cyclophosphamide, busulfan, and fludarabine with or without total body irradiation. In addition to the adverse effects of the chemotherapy agents already discussed, adverse effects of cyclophosphamide include hemorrhagic cystitis and pulmonary fibrosis, and busulfan causes hepatic venoocclusive disease and seizures (Stein et al., 1990; Culshaw et al., 2003). Patients with hemorrhagic cystitis may require blood transfusion or may need anesthesia for cystoscopy and possible suprapubic tube placement. Total body irradiation is associated with restrictive cardiomyopathy, interstitial pneumonitis, and hypothyroidism. Appropriate preoperative evaluation, induction and maintenance drug selection, placement of invasive hemodynamic monitors, and

provision for postoperative analgesia and monitoring are dictated by cardiovascular status and pulmonary reserve.

Graft-versus-Host Disease

Acute GVHD is a clinical syndrome that usually develops in 40% to 60% of patients receiving HSCT by 60 to 100 days after allogeneic HSCT. It is characterized by the development of erythematous skin rash; hepatic involvement with cholestatic jaundice; GI disease marked by the presence of abdominal pain, excessive vomiting, ileus, bleeding, and diarrhea; fever, thrombocytopenia, and anemia; and occasional pulmonary involvement with vascular leak. Chronic GVHD occurs in 20% to 40% of patients who have undergone HSCT and may occur as an extension of acute GVHD, or it may occur in the absence of preceding GVHD (Table 36-21) (Venkatesan and Jacob, 2007). The diagnosis is occasionally made after day 100 of HSCT and is rarely made after more than 500 days after HSCT (Arai and Vogelsang, 2000). Chronic GVHD is a distinctive syndrome that resembles autoimmune collagen vascular disease, with manifestations evident in every organ in the body.

Organ System Considerations in Patients with HSCT

The respiratory system is a major source of morbidity among patients receiving HSCT. Diffuse lung injury is a major

TABLE 36-21. Clinicopathologic Features of Chronic Graft-Versus-Host Disease

System	Features
Systemic	Recurrent infections with immunodeficiency, weight loss, sicca syndrome, debility
Skin	Lichen planus, scleroderma, hyperpigmentation or hypopigmentation, dry scale, ulcerated, freckling, flexion contractures
Hair	Alopecia
Mouth	Sicca syndrome, depapillation of tongue with variegations scalloping of lateral margins, lichen planus and ulcer, angular tightness, salivary gland inflammation, fibrosis
Joints	Decreased range of motion, diffuse myositis/tendonitis
Eyes	Decreased tearing, injected sclerae, conjunctivae
Liver	Cholestasis, cirrhosis
Gastrointestinal	Failure to thrive, esophageal strictures, malabsorption, chronic diarrhea
Lung	Bronchiolitis obliterans can manifest as dyspnea, cough, wheezing with normal CT scan and marked obstructive ventilatory defects, pneumothorax, chronic sinopulmonary symptoms and/or infections
Heart	Bradycardia, chest pain
Hematopoietic	Refractory thrombocytopenia, eosinophilia
Immune system	Profound immunodeficiency, functional asplenia, risk of pneumococcal sepsis

From Venkatesan T, Jacob R: Anesthesia and graft-versus-host disease after hematopoietic stem cell transplantation, *Pediatr Anesth* 17:7, 2007.

complication of HSCT that accounts for 50% of transplant-related mortality and may be classified as either infectious or noninfectious. Acute noninfectious lung injury is called *idiopathic pneumonia syndrome* and refers to widespread alveolar injury that occurs in the absence of left-ventricular dysfunction or respiratory tract infection. Current treatment strategies for idiopathic pneumonia syndrome include oxygen administration, mechanical ventilation with small tidal volumes and low peak-inspiratory pressures, broad-spectrum antibiotic administration, and increased immune suppression.

Chronic GVHD may involve the respiratory system, resulting in recurrent sinopulmonary infections and restrictive or obstructive lung disease. A severe form of obstructive lung disease associated with chronic GVHD is bronchiolitis obliterans, which is characterized by progressive dyspnea, cough, wheezing, reduced FEV₁, reduced expiratory flow rates, and increased residual lung volume. Small-airway plugging with inflammatory cells, emphysematous distal airways, hyperinflation, interstitial pneumatoxis, and pneumothorax may be noted. Patients with bronchiolitis obliterans have a very poor prognosis, and no therapies have been demonstrated to favorably influence the outcome of this disease.

Therapy for pulmonary disease with expiratory obstruction associated with chronic GVHD includes administration of supplemental oxygen, bronchodilators, enhanced immune suppression, antimicrobial prophylaxis, and IV immune globulin (Arai and Vogelsang, 2000; Yanik and Cooke, 2006). Patients with pulmonary involvement may need anesthesia for bronchoscopy with bronchoalveolar lavage or biopsy to discern the etiology of pulmonary disease (e.g., infectious vs. bronchiolitis obliterans). Pulmonary function may temporarily worsen after bronchoscopy, especially if bronchoalveolar lavage is performed. The parent/guardian should be informed of this possibility during the consent process. Preoperative evaluation of patients with advanced respiratory disease may include chest radiographs, spirometry, arterial blood gas measurement, and pulse oximetry. Intraoperative management emphasizes monitoring of airway pressure, humidification and warming of airway gases, and continuation of perioperative antibiotics. Patients with severe lung disease may require postoperative mechanical ventilation or placement of an arterial catheter for blood gas analysis.

The skin and its appendages are targets in chronic GVHD, resulting in dermal sclerosis with loss of hair and sweat glands. Patients with sclerotic disease have fragile skin prone to tissue trauma and have impaired ability to sweat, resulting in predisposition to the development of hyperthermia. The oral manifestations of acute and chronic GVHD can result in severe mucositis, restricted mouth opening, and difficult orotracheal intubation (Schubert et al., 1984; Arai and Vogelsang, 2000). Ocular manifestations of chronic GVHD include decreased lacrimation, which predisposes patients to corneal ulceration (Grover et al., 1998). The musculoskeletal system may be adversely affected by HSCT, resulting in polymyositis, polyserositis, and myopathy (Reyes et al., 1983; Beredjikian et al., 1998). Joint involvement in the form of flexion contractures and ulcerations may be present. Decreased range of motion between cervical vertebrae and diminished mouth opening should be sought in sclerodermoid chronic GVHD, as these may complicate airway management. Polyserositis may be associated with ascites as well as pericardial and pleural effusions. Careful attention to assessment of potential for oral airway difficulties, positioning,

padding, monitoring of temperature, application of warming devices, eye lubrication, and eye protection is required.

The immune system can be assumed to be significantly impaired in recipients of HSCT (Atkinson et al., 1982; Lapp et al., 1985). Continuation of antibacterial, antiviral, and antifungal therapies during the perioperative period is imperative, and many clinicians insert bacterial and viral filters into the breathing circuit. Strict aseptic technique is required during invasive procedures. The rectal route of medication administration and temperature monitoring is discouraged.

The GI tract is a major source of morbidity in recipients of HSCT. Acute GVHD manifests with diarrhea, abdominal pain, GI bleeding, ileus, and loss of electrolytes, fluid, and blood. GI tract signs seen in chronic GVHD include esophageal, gastric, and duodenal ulcerations, esophageal web, diarrhea, vomiting, chronic malabsorption, and gastroesophageal reflux (Arai and Vogelsang, 2000). Because of mucosal abnormalities, it is prudent to avoid the use of esophageal stethoscopes and rectal temperature probes. Rapid-sequence induction and intubation should be considered if GI dysfunction appears to put the patient at risk for aspiration pneumonia. Mucositis and swelling of oral structures may impede visualization of airway structures.

Hepatic dysfunction is common in GVHD. Acute GVHD results in cholestatic jaundice, and chronic GVHD is associated with elevation of alkaline phosphatase, bilirubin, and transaminases. Many patients with GVHD are also dependent on parenteral nutrition, which may exacerbate hepatic injury. Selection of anesthetic agents with minimal hepatic metabolism and toxicity and minimal effects on hepatic blood flow may be indicated. Close attention to glucose homeostasis is necessary to prevent hypoglycemia under anesthesia. Monitoring and correction of coagulation parameters are essential for operative procedures associated with significant bleeding and when regional anesthesia is contemplated.

Hematologic dysfunction after HSCT may manifest as refractory thrombocytopenia, isolated neutropenia or anemia, or pancytopenia. Adequate blood and blood products should be available for cases in which blood loss is expected to be high and when hemostasis is critically important at the surgical site (CNS and ocular cases).

Non–Graft-versus-Host Disease HSCT Complications

Complications of HSCT not related to GVHD include renal dysfunction, hepatic venoocclusive disease, and impaired thyroid and adrenal function. Renal dysfunction occurs commonly as a result of nephrotoxic medications and immunosuppressive therapy. Preoperative assessment of renal function, careful attention to intravascular volume status, preservation of cardiac output, and avoidance of nephrotoxic medications (when possible) are the cornerstones of preservation of renal function. Hepatic venoocclusive disease is a nonspecific hepatic injury that occurs after the administration of some drugs used for pretransplant conditioning (e.g., busulfan or actinomycin D). The mechanism is unclear, but pathology involves vasculitis of the sinusoids of the hepatic venules. Hepatic venoocclusive disease initially presents as jaundice, right upper-quadrant pain, and ascites, but it may progress to include coagulopathy and encephalopathy. Thyroid and adrenal function are critical for cardiovascular stability and drug clearance. Endocrinology consultation and appropriate hormone replacement are recommended.

Pharmacologic Considerations

Immune-modulating medications used in HSCT include cyclosporine A, azathioprine, tacrolimus, mycophenolate mofetil, and corticosteroids. Relevant side effects of azathioprine include pancytopenia, and those of steroids include hypertension, diabetes, and neurotoxicity. Hypertension, seizures, diabetes, and renal insufficiency are toxicities associated with cyclosporine and tacrolimus (Kostopanagiotou et al., 2003). Adverse effects of immunosuppressive medications particularly relevant to children include growth retardation, hirsutism, obesity, and osteoporosis (Ellis et al., 2000).

In the presence of adequate renal and hepatic function, no contraindications exist to the use of anesthetic agents. Sevoflurane can be used for the induction of anesthesia, and sevoflurane, desflurane, and isoflurane, can be used for the maintenance of anesthesia. IV agents and local anesthetics can also be used. Cyclosporine increases the effects of nondepolarizing muscle relaxants, resulting in decreased dosage requirement. Neuromuscular blockade should be monitored closely to prevent inadvertent overdose. The use of cisatracurium is preferred with renal or hepatic impairment.

Nitrous oxide inhibits bone marrow function after prolonged exposure (longer than 6 hours) at high concentrations (Weimann, 2003). Methotrexate inhibits folate metabolism as well as marrow function. Nitrous oxide may amplify the side effects of methotrexate therapy and therefore should probably be avoided for long procedures in patients who are treated with methotrexate and in patients with marginal marrow function. NSAIDs may potentiate nephrotoxicity of cyclosporine and tacrolimus.

Potent anesthetic opioids (e.g., fentanyl, sufentanil, and alfentanil) and some of the benzodiazepines (e.g., midazolam and diazepam) are metabolized by the cytochrome P₄₅₀ enzymes (Leather, 2004). Serum concentrations of these drugs are elevated if drugs that inhibit the cytochrome P₄₅₀ system (e.g., azole antifungals, calcium-channel blockers, and macrolide antibiotics) are coadministered. Calcium-channel blockers, azole antifungals, and macrolide antibiotics increase levels of tacrolimus and cyclosporine through enzyme inhibition.

Children with extensive systemic involvement after HSCT as well as patients undergoing extensive surgical procedures may require postoperative admission to an intensive care unit as a result of limited physiologic reserve. Neuraxial blocks, local anesthesia infiltration, and parenteral opioids are appropriate methods for the provision of postoperative analgesia under close monitoring.

COAGULATION: DEVELOPMENTAL ASPECTS, DISORDERS OF COAGULATION, AND PERIOPERATIVE MANAGEMENT OF HEMOSTASIS

Coagulation abnormalities provide many challenges for the pediatric anesthesiologist. Children with known coagulation disorders require disease-specific perioperative management and must often be treated for complications of their bleeding diathesis. More challenging is the intraoperative investigation and management of children who develop a coagulopathy in the OR, either from preexisting, albeit undiagnosed, diseases or from acquired disorders. The following sections focus on

endogenous control of hemostasis, developmental changes in coagulation, and commonly inherited coagulopathies and their management.

Overview of Hemostasis

The hemostatic system is designed to maintain blood in a fluid state until vessel injury occurs, at which point an explosive cascade of events terminates blood loss by sealing off the vascular defect. Hemorrhage occurs if the response is inadequate; thrombosis occurs if the response is dysregulated. The vascular endothelial cell is at the fulcrum of this delicate balance. The normal endothelial cell maintains blood in its fluid state by inhibiting platelet aggregation and blood coagulation through the production of prostacyclin, NO, and the ectonucleotidase CD39, as well as by promoting fibrinolysis through the anti-thrombin III-mediated conversion of plasminogen to plasmin (Ignarro et al., 1987; Marcus et al., 2005).

Physically, the endothelial cell is a barrier between the platelets and procoagulant proteins derived from reactive components present in the deeper layers of the vessel wall. These components include collagen, fibronectin, von Willebrand factor (vWF), and tissue factor (TF), all of which stimulate platelet adhesion and aggregation and trigger the coagulation cascade (Fig. 36-12).

Primary Phase of Hemostasis

The platelet is central to the primary phase of hemostasis (Fig. 36-13). The normal circulating platelet count ranges from 150,000 to 400,000/mL. An additional 33% of all platelets are

■ **FIGURE 36-12.** Response to vascular injury. Collagen and tissue factor (TF) associated with the vessel wall provide a hemostatic barrier to maintain the high-pressure circulatory system. Collagen (white arrows), located in the subendothelial matrix beneath the endothelium, is not exposed to flowing blood under normal conditions. TF (black arrows), located in the medial (smooth muscle) and adventitial layers of the vessel wall, comes in contact with flowing blood when the vessel is disrupted or punctured. Both collagen and thrombin initiate thrombus formation. Collagen is a first line of defense, and TF is a second line of defense. (From Furie B, Furie BC: *Mechanisms of thrombus formation*, N Engl J Med 359:938, 2008.)

FIGURE 36-13. The clotting cascade. Coagulation is initiated by the exposure of blood to TF bound to cell membranes. TF interacts with factor VIIa to convert factor IX to factor IXa and factor X to factor Xa (only the activated forms are shown). Factor IXa converts factor X to factor Xa. Factor Xa generates factor IIa (thrombin) from factor II (prothrombin). Each of these reactions takes place on an activated cell surface. Once factor IIa is generated, it cleaves plasma fibrinogen to generate fibrin. The TF-pathway inhibitor forms a quaternary structure with TF, factor VIIa, and factor Xa (shown in blue). The thrombomodulin-protein C-protein S pathway (shown in yellow) inactivates factors Va and VIIIa. Antithrombin III inactivates factors Xla, IXa, Xa, and IIa (shown in orange) in a reaction that is accelerated by the presence of heparin sulfate. In the fibrinolytic pathway, tissue-type plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA) convert plasminogen to plasmin. Once generated, plasmin proteolytically degrades fibrin (shown in purple). (From Rosenberg RD, Aird WC: *Vascular-bed-specific hemostasis and hypercoagulable states*, N Engl J Med 340:1555, 1999.)

sequestered within the spleen. After vascular injury, the affected vessel constricts proximally, diverting blood flow away from the site of endothelial disruption. Extravasated blood is exposed to subendothelial structures, and the platelets are stimulated by their contact with collagen. The platelets become adherent to the subendothelial infrastructure, anchored by the binding of vWF to the platelet surface glycoprotein Ib, as well as by the interaction of platelet glycoprotein VI with collagen (Ruggeri, 2000). Once platelet adhesion occurs, platelet activation results in the glycoprotein VI-mediated release of platelet agonists such as epinephrine and serotonin from the dense granules (Furie

and Furie, 2008). The synthesis of thromboxane- A_2 (TXA $_2$) from arachidonic acid by COX and thromboxane is then released from the platelet lipid membrane, and there is a 50% increase in the number of platelets and a conformational change in the platelet surface glycoprotein receptor IIb-IIIa (GPIIb-IIIa), which binds to fibrinogen, vWF, and fibronectin (Shattil et al., 1998). GPIIb-IIIa is now referred to as $\alpha_{IIb}\beta_3$ (Bennett, 2005).

TF can also trigger platelet activation independent of endothelial disruption, vWF contact, or glycoprotein VI (Dubois et al., 2006). The TF VIIa (factor VIIa) complex activates factor IX, which ultimately generates thrombin. Thrombin then cleaves the platelet surface receptor Par1, activating the platelet (Dubois et al., 2007).

A developing thrombus recruits unstimulated platelets. Platelet activation increases integrin $\alpha_{IIb}\beta_3$'s affinity for fibrinogen and vWF, clustering this receptor on the platelet surface (Bennett, 2005). Platelet aggregation, through the linkage of $\alpha_{IIb}\beta_3$ to the $\alpha_{IIb}\beta_3$ on other platelets bridged by fibrinogen or vWF, increases the size of the initial platelet plug, creating a mass of aggregated platelets at the injury site. At low shear rates, fibrinogen is the principle ligand, whereas at higher shear rates vWF plays a predominant role (Goto et al., 1998). Synthesized TXA $_2$ induces aggregation of other platelets and promotes vascular smooth muscle constriction, producing local vasoconstriction, which limits blood loss and increases the effectiveness of the platelet plug by decreasing the effective surface area that the platelet plug needs to cover. TXA $_2$ amplifies the platelet's responses to weak agonists such as ADP and epinephrine (Funk, 2001). Not all of the recruited platelets undergo activation. Many remain loosely associated but inactive and ultimately fall away from the initial platelet plug (Dubois et al., 2007).

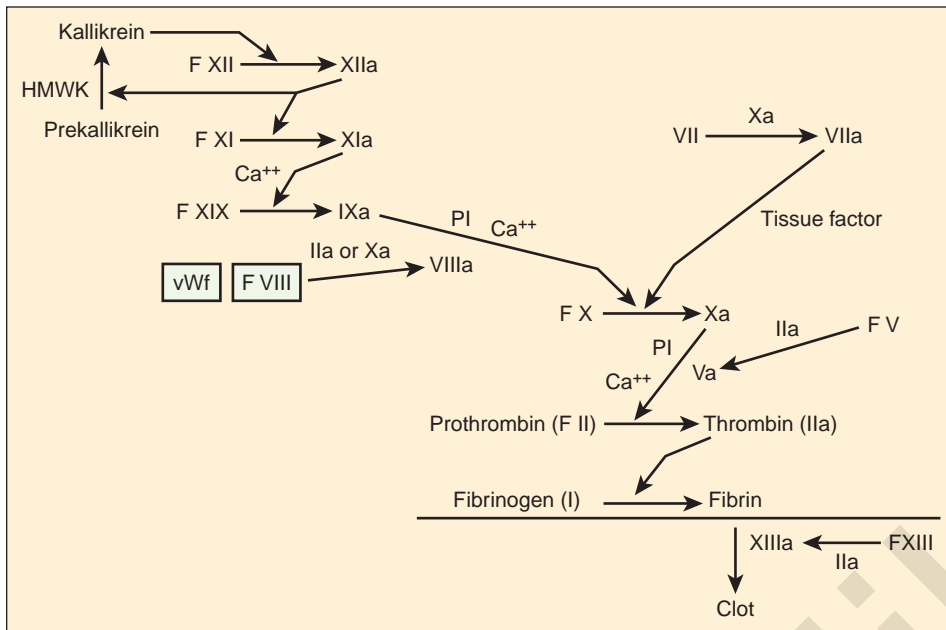

TXA $_2$ binds to a G protein-coupled receptor on the platelet surface, leading to an increase in intracellular calcium and activation of protein kinase C. The initial platelet plug is friable. It is stabilized by the increase in platelet cytosolic calcium, which initiates actin filament turnover that in turn modulates the cytoskeletal changes. These changes enable integrin $\alpha_{IIb}\beta_3$ clustering and the binding of both fibrinogen and vWF. The conformational change of $\alpha_{IIb}\beta_3$, induced through ligand binding, exposes new ligand binding sites and further merging of platelet surface receptors, resulting in clot retraction (Wartier et al., 2002).

Secondary Phase of Hemostasis

The exposure of subendothelial structures to circulating blood simultaneously activates the coagulation cascade (the secondary phase of hemostasis) to produce a cross-linked fibrin clot. Of the coagulation proteins, prothrombin (II), protein C, protein S, and factors VII, IX, and X are synthesized as prozymogens and activated to serine proteases through a vitamin K-dependent hepatic enzyme (Furie and Furie, 1990). This modification is required for calcium binding, serving as a bridge for binding the factors to the phospholipid surface.

New Model of Cell-Based Coagulation

In earlier schemes, the coagulation cascade had been divided into intrinsic (e.g., factors XII, XI, IX, and VIII) and extrinsic (e.g., TF and factor VII) pathways (Fig. 36-14). This model is primarily useful for the interpretation of the in vitro laboratory

■ **FIGURE 36-14.** Mechanism of hemostasis. *HMWK*, High-molecular-weight kininogen; *vWf*, von Willebrand factor.

tests, the activated partial thromboplastin time (aPTT) and the prothrombin time (PT). The common pathway of the clotting cascade is the production of factor Xa, which in concert with factor Va, cleaves prothrombin to thrombin, resulting in fibrin production. It became apparent that deficiencies in the intrinsic pathway did not produce bleeding conditions and that the model was not clinically relevant.

In vivo, the critical component in coagulation initiation is TF, a membrane protein receptor for factor VII. TF is expressed constitutively on cells that are not in direct contact with blood, such as vascular smooth muscle, fibroblasts, and macrophages, forming a hemostatic envelope around the vascular endothelium (Mann et al., 1998). The endothelium acts as a barrier that separates the cellular sources of TF from factor VIIa in flowing blood, preventing inadvertent coagulation initiation. Once endothelial injury occurs, activated endothelial cells and platelets activate TF through the release of protein disulfide isomerases (Cho et al., 2008; Reinhardt et al., 2008). Activated TF forms a complex with factor VII, producing factor VIIa. The TF/factor VIIa complex then activates factors X and IX (Orfeo et al., 2005). Factor IXa binds to factor VIII, forming the “tenase complex” (factor IXa/VIII). This complex inefficiently activates factor X. The TF/factor VIIa complex also converts factor X to factor Xa directly. Factor Xa combines with its cofactor (factor Va) on the TF-bearing cell and generates small amounts of thrombin. Although this limited amount of thrombin is sufficient to activate platelets in the local area and to activate factors V, VIII, and IX, it is insufficient to cleave fibrinogen. Factor VIII is cleaved off vWF and is then activated to factor VIIIa, which complexes with factor IXa to form the “activated tenase complex” (factor VIIIa/IXa).

The activated tenase complex binds to the negatively charged phospholipids that coat the surface of activated platelets and produce factor Xa. This platelet-localized factor Xa binds to factor Va, also bound to the platelet surface, and catalyzes the conversion of prothrombin to thrombin at the rapid rate necessary for adequate hemostasis. Thrombin formation is accelerated, fibrinogen is cleaved, and the coagulation complex is

further activated, augmenting thrombin production. The fibrin monomers undergo spontaneous polymerization to form the fibrin clot, which is then stabilized by crosslinking, mediated by factor XIIIa. A firm platelet-fibrin clot results, which over the course of time, mediated by platelets, decreases in size. The graphic representation of this new model of cell-based coagulation, which replaces the former intrinsic pathway, is shown in [Figure 36-15](#) (Gailani and Broze, 1991).

Although factor XII is not involved in physiologic hemostasis, accruing evidence suggests that it plays a key role in abnormal thrombosis (Renne and Gailani, 2007). Extracellular ribonucleic acid (RNA) released from damaged cells induces arterial thrombosis through factor XII activation (Kannemeier et al., 2007). Inorganic polyphosphates released from activated platelets trigger factor XII activation and provide an additional pathway for fibrin formation by stimulated platelets (John et al., 2006).

Modulators of Coagulation

Coagulation is modulated by a number of plasma proteins, the most important of which are antithrombin III, thrombomodulin, TF pathway inhibitor, protein C, protein S, and factor V. Antithrombin III is a potent inhibitor of thrombin and factors IXa, Xa, and XIIIa. Heparin potentiates the inhibition of thrombin by antithrombin III. Thrombomodulin, expressed on the endothelial cell surface, binds and neutralizes thrombin. TF pathway inhibitor limits factor Xa production by the activated tenase complex (factor IXa/VIIIa). Activated protein C (APC), activated by the presence of thrombin and accelerated by thrombin-thrombomodulin, proteolytically inactivates factor VIII/ VIIIa and factor V/Va, thereby down-regulating the production of factor Xa and thrombin. Protein S has two anticoagulant roles; it acts as a cofactor for APC in the inactivation of factors Va and VIIIa and as a cofactor for TF pathway inhibitor in the inactivation of factors Xa and VIIa (Castoldi and Hackeng, 2008). Factor V uniquely has procoagulant and anticoagulant

FIGURE 36-15. activities. Genetic alterations in factor V (i.e., factor V Leiden) or deficiencies of protein C may result in excessive procoagulant activity, which may lead to venous thromboembolism (Tormene et al., 2002). When factor V is cleaved by thrombin, a number of intermediates are formed in addition to factor Va, the essential cofactor to factor Xa. These intermediates are cofactors for APC and act as anticoagulants. APC can cleave factor V directly, producing an anticoagulant and precluding factor V's transformation to factor Va (Thorelli, 1999).

Fibrinolysis

Fibrinolysis occurs simultaneously with the initiation of clot formation, limits thrombosis to the local area of injury, and begins the processes of clot revision, vascular damage repair,

and ultimately, vessel recanalization. During the initial phase of hemostasis, endothelial cells and platelets release plasminogen activator inhibitors (PAIs), which facilitate fibrin formation. In response to thrombin, endothelial cells begin to release tissue plasminogen activator (TPA) that along with prourokinase, converts plasminogen to plasmin. The plasminogen, which is bound to fibrin in the hemostatic plug, is much more reactive to TPA than circulating plasminogen. After plasmin is produced locally at the site of the hemostatic plug, fibrinolysis or fibrin degradation can occur. Fibrinolysis at the hemostatic plug is opposed by ongoing coagulation and by antifibrinolysis, mediated by α_2 -plasmin inhibitor, which is also bound to fibrin.

The spectrum of endothelial cell and platelet interactions in the setting of clotting factors, adhesive proteins, fibrinolytic proteins, and the myriad inhibitors promotes an equilibrium

that promotes fluidity of circulating blood, and localization of hemostasis and injury repair. Derangements in any portion of this precariously balanced mechanism can lead to a hemorrhagic or thrombotic complication. A defect in clot formation in the setting of physiologic fibrinolysis leads to bleeding, as does normal clot formation in the setting of premature fibrinolysis. Thrombosis can occur in the setting of endothelial cells expression of TF, reduction in antithrombin function, and when platelet aggregation and activation are excessive.

Antiplatelet and Anticoagulant Drugs

The increased understanding of physiologic hemostasis has led to the development of new antithrombotic agents to modulate the consequences of thrombosis in critical illness and many systemic diseases. Antiplatelet drugs target key steps in platelet secretion, adhesion, and activation. COX-1 inhibitors such as acetylsalicylic acid (ASA) inactivate platelet COX-1, a pivotal enzyme in TXA₂ and prostacyclin synthesis, important for platelet secretion and aggregation. Some COX-1 drugs inhibit the enzyme transiently, whereas others (e.g., ASA) permanently inhibit TXA₂ production for the lifespan of the platelet. ADP antagonists such as ticlopidine irreversibly block platelet receptor P2Y₁₂, inhibiting platelet aggregation by the platelet agonists, thrombin, epinephrine, ADP, and collagen (Savi and Herbert, 2005). $\alpha_{IIb}\beta_3$ -receptor antagonists block platelet integrin $\alpha_{IIb}\beta_3$ from binding to fibrinogen and vWF on activated platelets, thus reducing platelet aggregation by 80% (Warltier et al., 2002; Patrono et al., 2004).

Anticoagulant drugs are designed to perturb the precariously balanced factor-based physiologic coagulation system and its modulators. Vitamin K antagonists, exemplified by warfarin, inhibit the vitamin K-dependent γ -carboxylation of factors II, VII, IX, and X, and proteins C and S (Levy et al., 2008). The antithrombin (AT) III agonist unfractionated heparin binds to AT, resulting in a 1000-fold increase in both thrombin and factor Xa inactivation. Factor Xa inhibitors such as low-molecular-weight heparin (LMWH) and fondaparinux also bind to AT, augmenting factor Xa inhibition; however, these drugs are too small to simultaneously bind both AT and thrombin, which is necessary for thrombin inactivation. Increasingly, LMWH is replacing unfractionated heparin in the treatment of pediatric thrombotic disease (Dix et al., 2000; Merkel et al., 2006). Direct thrombin inhibitors lepirudin, bivalirudin, and argatroban, bind to thrombin's active site, preventing the conversion of fibrinogen to fibrin, both in the circulation as well as on the evolving thrombus. Argatroban has been successfully used as an anticoagulant for cardiopulmonary bypass in an infant with heparin-induced thrombocytopenia (Malherbe et al., 2004).

Laboratory Evaluation of Coagulation

The panel of tests routinely used to evaluate coagulation includes the platelet count, PT, aPTT, and bleeding time. The normal platelet count is between 150,000 and 500,000/mcL, but increased bleeding as a result of thrombocytopenia rarely occurs at counts above 50,000/mcL. Bleeding may also occur when platelets are relatively normal in number but dysfunctional with regard to their role in coagulation.

The normal PT, which ranges from 11.5 to 14 seconds, reflects normal amounts of factors II, V, VII, and X, which are the vitamin K-dependent factors. Defects in vitamin K-dependent clotting factors may be caused by a deficiency of the vitamin, poor responsiveness to the vitamin because of liver disease, or exposure to warfarin agents that impair vitamin K's transition to the reduced form. The International Normalized Ratio (INR) can be used to estimate the degree of factor deficiency. An INR in the range of 2 to 3 correlates with factor concentrations of 10%; between 3 and 4 correlates with concentrations of 5%; and an INR higher than 4 correlates with concentrations of 1% (Boullis et al., 1999).

The normal aPTT is between 25 and 40 seconds and requires normal levels of vWF and factors XII, XI, IX, and VIII.

The bleeding time test assesses the integrity of the vascular and platelet aspects of coagulation and is prolonged in patients with reduced numbers of platelets (fewer than 100,000/mcL), in patients with defective platelet function (e.g., after aspirin, NSAID, or valproic acid administration), and in patients with vWD. The test is performed using a standardized template device to guide the incision with a tourniquet placed on the arm at 40 mm Hg for children, 30 mm Hg for newborns at term, and 20 mm Hg for premature infants. The bleeding-time evaluation has suffered from a reputation of being difficult to perform and poorly reproducible, especially in newborns and infants. Results may be affected by skin thickness and the device used to puncture the skin (e.g., surgical blade or manufactured bleeding time device), location of incision, and body temperature. Recently, a bleeding-time device (Surgicut; ITC, Edison, New Jersey) has been developed that comes in three sizes for adults, children (5 months to 15 years), and newborns (up to 5 months). The blades are different lengths (and depths for newborns) and afford a standardized incision rather than a puncture. This standardization should decrease the variability in bleeding times that result from varying incision techniques and skin thicknesses related to age, but this hypothesis has not yet been studied in a controlled fashion. The blood is blotted with filter paper every 30 seconds. Normal bleeding time is between 4 and 8 minutes in adults and may be as low as 2 minutes in newborns. The bleeding time is prolonged in very-low-birth-weight infants with hematocrit of less than 28%; bleeding time may be reduced in these infants after transfusion to hematocrit of more than 28% (Sola et al., 2001). It is unknown whether the longer bleeding times at lower hematocrits are associated with an increased risk of clinical bleeding.

Developmental Hemostasis

The hemostatic system of the newborn and young child is significantly different than that of the adult. Although considered immature, the hemostatic system is functional; the young child is successfully protected from hemorrhagic and thrombotic complications. These differences are most exaggerated in the hemostatic mechanism of the newborn. As the coagulation and fibrinolytic factors do not cross the placenta, the proposed causes for the differences in the newborn's hemostatic system include decreased factor synthesis, enhanced clearance, general activation of the coagulation system with resulting factor consumption, and the synthesis of less active fetal forms of some proteins.

■ **FIGURE 36-16.** Developmental hemostasis: changes in plasma concentration of coagulation proteins over the course of development. (Redrawn from Andrew M: *Developmental hemostasis: relevance to thromboembolic complications in pediatric patients*, *Thromb Haemost* 74[Suppl]:415, 1995.)

One of the most notable features of the coagulation system of the infant is that plasma clotting factors are inconsistently different from adult levels (Fig. 36-16). The most well-known ontogenetic differences in the hemostatic system involve the vitamin K–dependent factors. These proteins are present in low levels at birth, and coagulation is severely impaired in the absence of vitamin K supplementation; this is called hemorrhagic disease of the newborn (discussed more fully in the next section). The levels of the four vitamin K–dependent coagulation factors (factors II, VII, IX, and X) and the contact factors (factors XI and XII, prekallikrein, and kininogen) are all less than 50% of adult values and slowly rise to within 20% of adult levels by 6 months of age (Andrew et al., 1990a). Factor VII levels increase rapidly after birth in premature and full-term infants. Factors II and VII remain less than adult values for most of childhood (Andrew et al., 1992). Factor IX activity can be as low as 15% of adult levels and reach adult levels at 9 months of age. On the other hand, the levels of fibrinogen and factors V, VIII, and XIII are normal at birth; fibrinogen and factor VIII levels are at the high end of the normal range (Andrew, 1997). vWF levels are increased during the first weeks of life and return to adult levels

TABLE 36-22. Concentration of Coagulation Factors in the Term and Preterm Newborn Relative to Adult Values

Factor	Level at Term (% of Adult Value)	Level at Preterm (% of Adult Value)
Thrombin	50	40
Factor VII	66	66
Factor IX	50	35
Factor X	40	40
Fibrinogen	100	100
Factor V	75	88
Factor VIII	100	110
Factor X	40	40
Factor XI	40	40
Factor XII	50	30
Factor XIII	75	80
Heparin cofactor II	25	33
Antithrombin	50	40
α_2 -Macroglobulin	150-200	150-200
Protein C	25	10
Protein S	40	25
Plasminogen	50	55
α_2 -Antiplasmin	100	130
Tissue plasminogen activator	200	200
Plasminogen activator inhibitor	180	180

between 2 and 6 months of life (Thomas et al., 1995). The net effect of these differences in the newborn’s hemostatic system is delayed thrombin generation, similar to that seen in adults on receiving anticoagulant medications such as warfarin or subcutaneous heparin (Andrew et al., 1990b).

The concentration of coagulation factors in term and preterm infants relative to adult values is summarized in Table 36-22.

Laboratory Evaluation of Coagulation in the Newborn

Newborns with suspected coagulopathies are evaluated with PT, aPTT, platelet count, and levels of fibrinogen and fibrin degradation products. In newborns, as a result of the developmental differences in the coagulation protein levels, both PT and aPTT are prolonged compared with adult values. Because of the low plasma concentrations of many of the clotting factors in the newborn, the aPTT is markedly elevated. The developmental progression of the PT and aPTT in term and preterm infants is summarized in Table 36-23. Infants with vitamin-K deficiency have a prolonged PT when compared with age-appropriate norms. Fibrinogen concentrations less than 100 mg/dL and platelet counts of less than 100,000/mcL are indicative of a pathologic process (Manco-Johnson, 2008).

TABLE 36-23. Developmental Changes in the Prothrombin Time and Activated Partial Thromboplastin Time

Age of Infant	Day 1	Day 5	Day 30	Day 90	Adult
Term					
PT	13 ± 1.4	12.4 ± 2.5	11.8 ± 1.3	11.9 ± 1.2	12.4 ± 0.8
aPTT	42.9 ± 5.8	42.6 ± 8.6	40.4 ± 7.4	37.1 ± 6.5	33.5 ± 3.4
Preterm (30-36 weeks)					
PT	13 ± 1.5	12.5 ± 1.3	11.8 ± 0.9	12.3 ± 1.2	12.4 ± 0.8
aPTT	53.6 ± 13	50.5 ± 12	44.7 ± 9	50.5 ± 12	33.5 ± 3.4

Developmental Changes Beyond the Neonatal Period

Many of the proteins that regulate coagulation and thrombin generation are also decreased in early infancy. Antithrombin III and heparin cofactor II are markedly decreased to levels that might predispose to spontaneous thromboembolic events. The α_2 macroglobulin levels at birth are greater than those of adults and remain so until the third decade of life. By 6 months of life, AT III levels exceed levels seen in adults. Protein C and protein S concentrations at birth are also substantially less than those seen in adults and remain low throughout childhood (Andrew et al., 1992). Fibrinolysis is suppressed throughout childhood. During childhood, plasminogen levels increase to adult levels, but the TPA/PAI-1 ratio is significantly lower than that in adults, which explains the decrease in fibrinolysis in children (Siegbahn and Ruusuvaara, 1988).

Developmental Aspects of Platelet Number and Function

Although normal in number, neonatal platelets are hyporeactive. Neonatal platelet aggregation is diminished in response to certain physiologic agonists such as ADP, thromboxane, and epinephrine (Levy-Shraga et al., 2006). Intracellular calcium transport is decreased as well, resulting in diminished granule release and slowed conformational change (Kuhne and Imbach, 1998). Increased vWF levels in the newborn period contribute to decreased bleeding times (Andrew, 1997). Platelet function in the neonate is aided by a relatively high hematocrit, causing an increased concentration of platelets directed to the wall by the dynamics of laminar flow. Platelet function improves over the first 2 weeks of life (Israels, 2009).

The most serious manifestation of thrombocytopenia in the newborn period is intraparenchymal brain hemorrhage. Of neonates with spontaneous intraparenchymal hemorrhage, one third have an associated coagulopathy such as vitamin-K deficiency, hemophilia, or thrombocytopenia. Neonates with a platelet count of less than 50,000/mcL are at significant risk for intraparenchymal hemorrhage (Sandberg et al., 2001; Jhavar et al., 2003).

Inherited Coagulopathies

Hemostasis usually requires activity levels of coagulation factors at least 30% of normal. The aPTT may be normal with a factor level as low as 15% to 18% of normal. Past medical

history and family history are invaluable tools in the evaluation of a bleeding patient. Substantial hemorrhage after oral cavity manipulation (whether by dentist or toothbrush) is often a sign of an underlying bleeding disorder, reflecting an imbalance between abnormal clot formation and normal salivary fibrinolysis. Patients with mild bleeding disorders who have never had trauma or surgery may experience symptoms rather late in life and may have normal screening tests. Prenatal diagnosis of most congenital factor deficiencies can now be made from fetal DNA.

Hemophilia

Of the inherited deficiencies of coagulation factors, the most common are the X-linked recessive hemophilias; hemophilia A is factor VIII deficiency, and hemophilia B (Christmas disease) is factor IX deficiency. Thirty percent of cases arise from spontaneous mutation. Approximately 50% of mutations of factor VIII result from inversions of the DNA sequence within intron 22. The incidence of hemophilia A is 1 in 5000 male live births, and that of hemophilia B is 1 in 30,000. Hemophilia B can result from spontaneous mutations, which cause decreased rates of activation of factor IX, altered binding of factor IX to phospholipid membranes, or reduced circulation times. Patients with hemophilia B, Leyden, a single nucleotide substitution in the transcriptional promoter, have severe hemophilia until puberty, at which point, factor IX spontaneously increases to 50%, suggesting that transcription of the factor IX gene is in part hormonally mediated. Factor IX is a smaller molecule than factor VIII and has a greater volume of distribution.

The clinical severity of hemophilia is usually dictated by the degree of clotting factor deficiency. Patients with severe hemophilia, less than 1% of normal plasma levels, have an annual average of 20 to 30 bleeds; these are bleeding events that may be spontaneous or marked by excessive bleeding after minor trauma, characteristically into joints or muscle. These patients are usually diagnosed within the first 2 years of life. Bleeding is less common in the newborn period than in later months, but when it occurs, it is most common after circumcision. In a study of newborns with hemophilia, 30% bled from circumcision sites, 27% had intracranial hemorrhage, 16% had persistent bleeding from puncture sites, and 1% had subgaleal hematomas or cephalohematomas (Kulkarni and Lusher, 2001). Infants with severe hemophilia A or B have a 2% to 8% risk of spontaneous intracranial hemorrhage (Rodriguez et al., 2005).

Hemophilia A and hemophilia B are characterized by a prolonged aPTT with a normal PT. Because the neonate's aPTT is physiologically prolonged, a factor VIII level must be directly measured to establish the diagnosis. Factor IX levels are physiologically low at birth and do not reach adult levels until 6 months of age, making confirmation of the diagnosis of hemophilia B uncertain until later infancy, except in severe cases. The treatment of hemophilia has changed dramatically over the past three decades from the availability of plasma-derived replacement factors in the 1970s to the engineering of recombinant factors in the 1990s to the recently begun trials of gene replacement therapy (Mannucci and Tuddenham, 2001).

Patients with mild and moderate disease, corresponding to 6% to 30% and 1% to 5% of normal factor levels, respectively, usually bleed excessively only after trauma or surgery and are managed with on-demand factor replacement. These patients are often diagnosed later in life.

Preoperative Preparation of the Child with Hemophilia

Preparation of the child with hemophilia for surgery depends on the severity of the patient's disease and the proposed procedure. Patients with mild hemophilia A who have demonstrated an adequate response to DDAVP in the past can undergo minor procedures after IV DDAVP administration (0.3 mcg/kg) 30 minutes before surgery (Mannucci, 1997; Rodriguez and Hoots, 2008).

Factor Replacement

Hemophilia A. The type, timing, and dose of factor to be administered should be decided in advance in consultation with the patient's hematologist. In general, children with hemophilia A who require major procedures should have their factor VIII level maintained close to 100% of normal from 30 minutes before surgery through the first 2 to 7 days of the postoperative period. Factor VIII levels can then be reduced to 30% to 50% of normal for the next 3 to 7 days. Children who undergo minor procedures can be adequately covered with factor VIII levels of 50% after the second postoperative day (Martlew, 2000). In determining factor replacement, it should be remembered that the plasma volume is 45 to 50 mL/kg. Because 1 mL of plasma contains 1 unit of factor VIII, 50 units/kg of factor VIII will increase the patient's level to 100% (rise of 2% per unit of factor VIII/kg). In the absence of inhibitors, the half-life of factor VIII in vivo is 8 to 12 hours; subsequent doses are timed to maintain the desired level of activity. The first dose has a somewhat shorter half-life than subsequent doses. Therefore, the second dose should be given after a somewhat shorter interval (6 hours). Factor VIII may be administered as cryoprecipitate (0.2 bags/kg should raise factor VIII level to 50%), but the factor VIII level in cryoprecipitate is variable, and plasma levels should be followed if bleeding is not well controlled. The use of heat- or detergent-treated factor concentrates (e.g., Monoclate-P and Hemofil-M) has been replaced with recombinant factor VIII (rFVIII) preparations (e.g., Humate-P). Although the treated factor concentrates had a lower risk of transmission of viruses (e.g., human immunodeficiency virus [HIV] and hepatitis A, B, or C) compared with cryoprecipitate, rFVIII carries no risk of viral transmission; however, it is unknown whether the albumin in the recombinant preparation may have a risk of prion

transmission. Albumin-free rFVIII concentrate has become available, which may eliminate concerns about infection (Josephson and Abshire, 2004).

Hemophilia B. As in the case of hemophilia A, rFIX has started to replace plasma-derived factor IX concentrate for prophylaxis and treatment of bleeding in children with hemophilia B (Shapiro et al., 2005). In adults, 1 IU/kg of rFIX increased circulating factor IX activity by 0.8 IU/dL. Children have been found to have a smaller increase—0.68 IU/dL per 1 IU/kg infused in children 1 month to 12 years, 0.46 IU/dL in neonates, and 0.93 IU/dL in adolescents, but sample sizes were small. A mean dose of 90 IU/kg (range 29 to 260 IU/kg) was given to 23 patients before surgery (Shapiro et al., 2005). Because of the low yield of circulating factor IX in neonates after rFIX administration, as noted, higher doses are required in this population with regular measurement of serum factor IX levels. A recent report described the administration of rFIX by continuous infusion at a rate of 30 to 35 IU/kg per hour for successful treatment of intracranial and extracranial hemorrhages in the neonate (Guilcher et al., 2005). Because the half-life of factor IX is 12 to 24 hours, it requires less frequent dosing than does factor VIII to maintain adequate levels. As with factor VIII, the second dose should be given at a somewhat shorter interval than subsequent doses (6 to 8 hours). If rFIX is unavailable, the factor IX level is raised 1% for each unit of factor IX concentrate/kg.

Hemophilia C. Hemophilia C is factor XI deficiency (Rosenthal syndrome), an autosomally recessive disease that is most commonly reported in Ashkenazic Jews. The incidence in the Ashkenazic population is 3 in 1000, compared with a rate of 1 in 1,000,000 in the general population (Gomez and Bolton-Maggs, 2008). Incidence of hemophilia C is increased among people with Noonan syndrome (Bertola et al., 2003). Factor IX deficiency presents with a prolongation of the aPTT, with a normal PT. There is an incomplete correlation between the severity of factor deficiency and hemorrhagic symptoms, in that some patients with very low factor levels have no history of bleeding. Bleeding typically occurs after trauma or surgery and is commonly seen in sites that have a high fibrinolytic rate, such as the genitourinary tract, and after circumcision (Andrew, 1997). Because factor XI levels are physiologically low in the neonatal period, the diagnosis is confirmed through levels obtained in later infancy. The perioperative management of these patients is dictated by their bleeding risk. Patients with factor XI levels of more than 15% without a previous history of bleeding, or patients with levels of 5% to 14% who have had previous surgery without significant bleeding in the absence of fresh frozen plasma (FFP) administration can be considered to be at low risk. Patients with factor levels of less than 15%, a history of spontaneous bleeding, bleeding during previous surgeries, or those with a family history of such bleeding complications can be considered to be at high risk. Depending on the surgical procedure, patients who are considered to be at low risk for bleeding can be managed with FFP immediately available. High-risk patients should receive FFP 2 hours before surgery.

Factor Inhibitors in Patients with Hemophilia A and B

Factor replacement results in the development of neutralizing antibodies called *inhibitors*, which complicates the treatment of affected hemophiliacs. The incidence of inhibitors in hemophilia

A is 30%; in hemophilia B, it is 5% (Astermark, 2006). These antibodies are classified as low- or high-titer inhibitors. Patients with low-titer inhibitors may be treated with high doses of factor replacement. Patients with high titers of these inhibitors often develop severe bleeding complications that are recalcitrant to standard factor replacement algorithms and require bypassing agents such as rFVIIa or activated prothrombin complex concentrates (Matthew, 2006; Young, 2006; Rodriguez and Hoots, 2008). For patients with inhibitory antibodies, immunomodulation therapy should be instituted concomitantly with hemostatic therapy. No consensus has been reached on the optimal regimen. IV immune globulin, corticosteroids, and alkylating agents all have been shown to reduce inhibitor levels.

Adjuvant Treatment Options for Hemophilia Patients

Antifibrinolytics. These agents (ϵ -aminocaproic acid [EACA] and tranexamic acid) are very useful adjuvants for patients with mild to severe hemophilia who are experiencing mucosal bleeding, primarily of oral, nasal, and menstrual origins. They are discussed in greater detail below.

Recombinant Factor VIIa (rFVIIa). rFVIIa was initially licensed for use in hemophilia patients with inhibitors (Roberts, 2001). rFVIIa binds to TF and to the surface of activated platelets, both of which result in factor X activation and thrombin production. The standard dose is 90 to 120 mcg/kg every 2 to 3 hours until hemostasis is achieved. More than 90% of patients with hemophilia who have a low risk for thrombosis have an effective response to rFVIIa (O'Connell et al., 2002). Anecdotally, a child with hemophilia A and inhibitors was successfully managed intraoperatively with rFVIIa in combination with EACA (Simic and Milojevic, 2007).

von Willebrand Disease

Characteristics

vWD, the most common congenital bleeding disorder, is a deficiency or dysfunction of the adhesive glycoprotein, which is produced in endothelial cells and megakaryocytes and is stored in Weibel-Palade bodies in endothelial cells and platelets. vWF is fundamental in the binding of platelets to damaged endothelial surfaces, promotes the secretion of factor VIII, and binds, carries, and protects factor VIII in plasma. vWD affects 1 in 100 individuals and is inherited in an autosomal fashion (usually dominant), with males and females affected equally. It is characterized by impaired platelet adhesion to exposed subendothelium in high shear vessels (Federici, 2006). Because of the reduced or defective vWF, factor VIII is reduced to a mild and variable degree because of decreased secretion and enhanced clearance. Because vWD is a disorder of the protein responsible for the adherence of platelets to damaged endothelial surfaces, the clinical manifestations in affected individuals resemble those seen in patients with platelet disorders (i.e., mucocutaneous bleeding [e.g., nose or gingiva], menorrhagia, and increased bleeding with trauma or surgery).

vWD has three variants. Patients with the type 1 variant, the most common (80%), have a heterozygous quantitative deficiency of vWF (20% to 40% of normal) associated with diminished factor VIII levels. Patients with type 1 vWD often have menorrhagia or mild to moderate bleeding from mucocutaneous sites. Medications that affect platelet function (e.g., NSAIDs)

can cause hemorrhage in a previously asymptomatic patient with type 1 vWD. Type 2 vWD (17% of patients with vWD) is characterized by the production of qualitatively abnormal vWF. Some of these patients have an associated thrombocytopenia, whereas others have a factor VIII deficiency that is out of proportion to the level of vWF. Type 3 vWD (3%) is marked by profound deficiencies of vWF and factor VIII. Homozygous patients may experience severe bleeding and spontaneous hemarthrosis. Because vWF levels are higher at birth and the proportion of the most functional high-molecular-weight multimeric units is increased, the incidence of bleeding in newborns is very low. When newborns with vWD bleed, it is the result of concomitantly low factor VIII levels. Acquired vWD has been associated with Wilms tumor, systemic lupus erythematosus (SLE), congenital heart defects, and HbE thalassemia.

The laboratory diagnosis of vWD is based on a prolonged bleeding time and on decreased levels of vWF antigen and factor VIII in the face of normal PT, fibrinogen, and platelet count. The aPTT may be normal or mildly prolonged. Ristocetin cofactor assay, which measures vWF-induced platelet agglutination, is used to identify type 2 vWD. It is recommended that screening be performed on three separate occasions before ruling out vWD, because functional and antigenic vWF levels may overlap those of normal patients and vWF levels can fluctuate in unpredictable ways. The vWF levels rise during pregnancy. There is a significant linkage between ABO locus and the vWF antigen, such that patients with A and B blood types have markedly higher levels (100% to 115%) of factor than those with type O (75%) (Souto et al., 2000).

Preoperative Preparation

Most patients with type 1 disease respond to the IV administration of 0.3 mcg/kg of DDAVP 30 minutes before surgery. DDAVP induces the release of vWF from endothelial storage granules (Weibel-Palade bodies) into the circulation and results in a 2- to 3-fold increase in plasma von Willebrand antigen levels within 30 to 60 minutes, with the effect lasting more than 6 hours (Mannucci, 1997; Robertson et al., 2008). DDAVP may be administered two to three times a day, although tachyphylaxis may develop (Federici, 2008). Because 10% of patients with type 1 vWD fail to respond to DDAVP, the response (increased factor VIII levels and normalization of bleeding time) should be documented before surgery to make sure it is adequate to prevent excessive perioperative bleeding (Nolan et al., 2000). If it is effective, it may be used as the sole agent for the treatment of minor bleeding (e.g., epistaxis) or perioperatively for minor surgery, such as dental extraction.

Patients with type 2 or type 3 diseases usually require replacement factor VIII and vWF to control bleeding. DDAVP is contraindicated in type 2b disease, because it may exacerbate thrombocytopenia. Those who do respond to DDAVP may also need factor replacement before major surgical procedures or for major trauma. Plasma-derived human factor VIII concentrate, which has a high concentration of vWF (e.g., Humate-P), is effective and is approved for replacement therapy in vWD (Federici et al., 2002).

If the patient's response to DDAVP is adequate and bleeding is not a problem, liberal DDAVP administration may be substituted for factor concentrate in the postoperative period. Close monitoring of bleeding and communication with the hematologist should guide postoperative management of these patients.

Factor XIII Deficiency

The role of factor XIII in hemostasis is to stabilize newly formed clots by crosslinking fibrin monomers. Plasma levels as low as 1% to 2% are usually adequate for hemostasis. Patients with factor XIII deficiency have bleeding despite a normal PT, aPTT, and platelet count. Factor XIII deficiency is a rare bleeding disorder that is inherited in an autosomal-recessive manner and has an estimated incidence of 1 in 2 million. Typical symptoms are delayed hemorrhages after mild trauma. The most common manifestation is prolonged bleeding from the newborn's umbilical stump, which is virtually pathognomonic for this deficiency, or after circumcision. The major morbidity in children with factor XIII deficiency is a marked propensity for intracranial hemorrhages (Gordon et al., 2008). Seriously affected patients are treated with cryoprecipitate or purified factor concentrate. All traumatic brain or closed-head injuries are treated prophylactically.

Factor VII Deficiency

Factor VII has the shortest half-life of all of the clotting factors, estimated to be 6 hours. Factor VII deficiency is a rare autosomal-recessive disorder. The severity of the hemorrhagic diathesis does not correlate with factor VII levels. Many individuals have mutations of factor VII but are asymptomatic, and they come to medical attention as a result of an isolated PT prolongation. Much more common than an inherited factor VII deficiency is an acquired factor VII deficiency. Because of the exquisitely short half-life of factor VII, liver failure, vitamin-K deprivation, or oral anticoagulant toxicity first manifests as factor VII deficiency with an isolated increased PT value.

Platelet Abnormalities

Congenital Coagulopathies as a Result of Platelet Abnormalities

Inherited coagulopathies also include diseases associated with quantitative and qualitative platelet dysfunction. Wiskott-Aldrich syndrome is an X-linked syndrome characterized by thrombocytopenia, immunodeficiency, and eczema. Newborns typically have thrombocytopenia caused by underproduction. These platelets are abnormally small. The disease results from the mutation of the Wiskott-Aldrich syndrome protein (WASP), a cytoskeletal regulatory protein found in megakaryocytes and lymphocytes (Caron, 2002). Symptomatic bleeding is treated with platelet transfusions. Congenital bone-marrow-failure syndromes that result in congenital thrombocytopenia include Diamond-Blackfan syndrome anemia, Schwachman-Diamond syndrome, and Fanconi anemia. These infants have severe mucocutaneous bleeding or intracranial hemorrhage as a result of profound thrombocytopenia, and they depend on platelet transfusions. Thrombocytopenia with absent radii is another cause of neonatal thrombocytopenia that is associated with skeletal anomalies. The thrombocytopenia is most pronounced in the first year of life, when mucocutaneous bleeding commonly occurs, and platelet transfusions are required.

Thrombocytopenia of Critical Illness

Thrombocytopenia is a common problem in the neonatal and pediatric intensive care units, with a prevalence of 25%. A manifestation of endothelial activation in critically ill children, thrombocytopenia is an independent predictor of mortality and prolonged length of hospital stay (Krishnan et al., 2008).

Thrombocytopenia of Immune Origin

Immune-mediated thrombocytopenias occur in the setting of isoimmunization, with transplacental transfer of maternal alloantibodies directed against paternally inherited antigens present on fetal platelets or with transfer of maternal autoimmune diseases such as idiopathic thrombocytopenic purpura (ITP) and SLE. Isoimmune thrombocytopenia occurs in 1 of 1000 deliveries. The distinguishing characteristic is the maternal platelet count, which is normal in isoimmune disease and decreased in autoimmune disease. Infants are usually asymptomatic unless the platelet count is less than 10,000. Mucocutaneous, spinal cord, and intracranial hemorrhages are seen prenatally and postnatally in isoimmune disease (Abel et al., 2003). The bleeding in autoimmune thrombocytopenia is usually not as severe, but the risk of intracranial hemorrhage increases when the platelet count is less than 40,000 in the newborn. Both diseases are treated with platelet transfusions, IVIG, and corticosteroids. The established treatment of alloimmune thrombocytopenia is the administration of washed, irradiated maternal platelets (10 mL/kg), but donor platelets screened for the absence of human platelet antigen 1a (HPA-1a) have been shown to be effective (Rothenberger, 2002; Rayment et al., 2003).

Thrombocytopathies

Inherited qualitative platelet defects are uncommon conditions that also present with bleeding in the newborn period. Glanzmann thrombasthenia is an autosomal-recessive deficiency of $\alpha_{1b}\beta_3$ that impairs fibrinogen binding to platelets. Patients experience mucocutaneous bleeding in the neonatal period and have a lifelong risk of bleeding. Platelet count and morphology are normal; however, bleeding time, clot retraction, and platelet aggregation tests are all abnormal, and flow cytometry is required to confirm the $\alpha_{1b}\beta_3$ deficiency. Bleeding is managed with platelet transfusions. Bernard-Soulier syndrome is an autosomal-recessive deficiency of the platelet vWF receptor. These patients have mild to moderate bleeding and have unusually large platelets. The diagnosis is confirmed by failure of agglutination in the presence of ristocetin.

Bleeding Diathesis Associated with Blood Vessel Abnormalities

Hereditary blood vessel disorders associated with bleeding diathesis include uncommon connective tissue diseases such as Ehlers-Danlos and Marfan syndromes. Osteogenesis imperfecta, a heterogeneous group of disorders of collagen synthesis, may have increased perioperative bleeding as a result of increased capillary fragility and abnormalities in collagen-induced platelet aggregation (Edge et al., 1997).

Acquired Coagulopathies

Vitamin K Deficiency

Hemorrhagic disease of the newborn is a bleeding disorder that is caused by a deficiency of vitamin K. Clinical bleeding occurs in 1 in 1000 to 1 in 10,000 babies who do not receive vitamin K supplementation. Vitamin K is poorly transferred across the placenta and is present only in low concentration in breast milk. Hemorrhagic disease of the newborn can be temporally divided into three types: early, classic, and late onset. Bleeding within the first 24 hours of life is defined as *early disease* and is generally seen in infants born to mothers who receive oral anticoagulants or antiepileptic drugs. These infants often have serious bleeding, including intracranial hemorrhage. Bleeding within the first week of life is *classic disease* and usually involves cutaneous, GI, or circumcision bleeding in infants who did not receive vitamin K supplementation at birth and who are usually breastfed. Bleeding in the first 3 months of life is referred to as *late-onset disease*, and it is seen in exclusively infants who were breastfed and in those with disorders of fat absorption such as CF, biliary atresia, and celiac disease. The diagnosis is confirmed with a prolonged PT, increased levels of proteins produced in the absence of vitamin K, and a low vitamin K level. Administration of vitamin K subcutaneously or intravenously increases coagulation factors within 2 hours, with complete correction within 24 hours. Serious bleeding may be treated with FFP (10 to 20 mL/kg) or with purified factor IX product.

Hepatic Dysfunction-Related Coagulopathy

Liver disease that results in synthetic dysfunction has a major impact on hemostasis because many of the coagulation factors are synthesized in the liver. Levels of these proteins are the first to decline with worsening liver disease, especially the very short-lived factor VII. Measurement of factor V, a hepatically synthesized, non-vitamin K-dependent protein, which is present in similar amounts in the newborn and the adult, is useful in differentiating vitamin K deficiency from hepatic dysfunction. Fibrin-degradation products are increased as a result of their decreased clearance in the setting of hepatic dysfunction. The development of ascites results in further loss of coagulation proteins.

Perioperative management of these patients includes determination of their exact deficiencies and correcting them with targeted management. Prolongation of the PT, resulting from depletion of vitamin K-dependent factors, can be treated with vitamin K or FFP. Vitamin K should normalize the PT in as little as 6 to 8 hours. Hypofibrinogenemia should be treated with cryoprecipitate. rFVIIa has been used successfully to correct the coagulopathy associated with liver failure (Atkison et al., 2005). Factor VIIa has been used in small numbers of patients to decrease transfusion requirements during liver transplantation, despite the fact that bleeding in that setting is multifactorial in nature (Busani et al., 2008).

Anticoagulant-Related Coagulopathy

Pediatric thrombotic complications are being recognized, diagnosed, and treated in great numbers; neonates are at higher risk for thromboembolic complications than are older children

(Kenet and Nowak-Gottl, 2006). Patients who receive therapeutic anticoagulation are at risk for devastating hemorrhagic complications. They have a 0.25% to 1% annual risk of intracranial hemorrhage, either intracerebral or subdural, both associated with high morbidity and mortality rates (Leissinger et al., 2008). If surgery is contemplated or when procedural heparinization must be reversed, protamine can be administered IV over 10 minutes. The dosage of protamine is based on the time since the last dose of heparin and can be calculated using the formula shown in Table 36-24 (Monagle, et al., 2008).

LMWH anticoagulation is also reversed with protamine, in a dose of 1 mg of protamine per 1 mg (100 units) of LMWH (Monagle et al., 2001). Protamine is given slowly, because rapid administration may cause profound hypotension. It only partially (60%) reverses the anti-Xa effects of LMWH administered within the previous 3 to 4 hours (Monagle et al., 2001). Although fondaparinux and the direct thrombin inhibitors have no specific reversal agents, some experience with using rFVIIa has been reported (Bijsterveld et al., 2002).

Children receiving oral anticoagulation may be difficult to maintain in a therapeutic range because of variations in diet, concurrent medications, and underlying disease processes. Breastfed infants are very sensitive to oral anticoagulants because of low concentrations of vitamin K in breast milk. Many of the common medications that are prescribed for children, including prednisone, amoxicillin, trimethoprim-sulfamethoxazole, and ranitidine, increase the INR of children taking oral anticoagulants. In preparation for elective surgery, vitamin K antagonists can be discontinued 4 days before the procedure, with the goal to restore the patient's INR to the range of 0.8 to 1.2 (Ansell et al., 2008). In this setting, vitamin K supplementation normalizes the INR within 18 to 24 hours after IV administration (Douketis et al., 2008). In situations of acute bleeding or when more rapid reversal is necessary, both IV vitamin K and either FFP or prothrombin complex concentrate should be used. In adults, the INR is corrected at a rate of 0.18 INR/hour after FFP and IV vitamin K administration (Boullis et al., 1999). Prothrombin complex concentrate rapidly normalizes the INR more effectively than does FFP, at a much smaller volume, with a low risk of thrombotic events (Leissinger et al., 2008; Levy et al., 2008). rFVIIa has been used as an alternative agent; it quickly corrects elevated INR in the setting of intracranial hemorrhage, which has been reported to allow for rapid neurosurgical intervention or, in some cases, to actually successfully halt the progression of hemorrhage, obviating the need for a craniotomy (Bartal et al., 2007).

TABLE 36-24. Protamine Reversal of Heparin Therapy

Time Since Last Heparin Dose (minutes)	Protamine Dose* (mg/100 units Heparin)
<30	1
30-60	0.5-0.75
60-120	0.375-0.5
>120	0.25-0.375

Data from Monagle P, et al.: Antithrombotic therapy in neonates and children. In American College of Chest Physicians evidence-based clinical practice guidelines, ed 8, *Chest* 133:887S, 2008.

*Maximum protamine dose = 50 mg; Infusion rate should not exceed 5 mg/min.

Acquired Thrombocytopenia

Aspirin and NSAIDs are the most commonly used medications that affect the coagulation system. These medications inhibit platelet COX, blocking thromboxane synthesis and leading to a partial impairment of platelet function. Two COX isoenzymes have been characterized: COX-1, which is always present on platelets and the gastric mucosa, and COX-2, which is up-regulated during inflammation. Nonspecific COX inhibitors have been shown to increase perioperative bleeding complications after adenoidectomy. Aspirin ingestion prolongs the bleeding time by 2 to 3 minutes. Perioperative administration of NSAIDs (e.g., ketorolac) increased the number of children with bleeding after tonsillectomy (Marret et al., 2003; Dsida and Cote, 2004).

Many anesthetic agents have been implicated in platelet dysfunction, as measured by platelet aggregometry; among them are inhaled anesthetics such as sevoflurane and the IV anesthetics propofol and ketamine (Nakagawa et al., 2002). However, no data demonstrate that these agents increase perioperative bleeding or transfusion requirements in the clinical setting.

Another class of drugs that may interfere with platelet function is the anticonvulsants such as sodium valproate. Valproate has caused mild thrombocytopenia, neutropenia, and even red cell aplasia, and patients taking valproate should be evaluated before surgery with a complete blood count with platelet count. Bone marrow suppression usually occurs with levels higher than 100 mcg/mL and usually responds to a decrease in dose (Acharya and Bussel, 2000). Bleeding time may be prolonged in patients taking valproic acid but usually not to a clinically significant extent. In a small series of patients taking valproic acid, 20% were shown to have acquired vWD, with low ristocetin cofactor activity, although only 2 of 6 affected children were symptomatic (epistaxis) (Serदारoglu et al., 2002; Koenig et al., 2008). One case report documented profound factor XIII deficiency that resulted in severe intracranial bleeding after craniotomy for epilepsy surgery (Pohlmann-Eden et al., 2003). This deficiency was resolved after discontinuation of valproic acid therapy. In a small study of children with cerebral palsy who underwent femoral osteotomy, those children who took valproic acid had greater blood loss and need for transfusion than did those with cerebral palsy who were either taking no anticonvulsants or anticonvulsants other than valproic acid (Carney and Minter, 2005). Therefore, the anesthesiologist should have a heightened awareness of the possibility of excessive surgical bleeding, especially during and after craniotomy, in patients taking valproic acid. Some hematologists recommend a bleeding time for children who are taking valproic acid and who are scheduled for craniotomy, with further investigation including vWF and ristocetin cofactor, as well as possible preoperative administration of DDAVP if indicated (Acharya and Bussel, 2000; Koenig et al., 2008).

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is the unregulated activation of the hemostatic system characterized by the generation of activated clotting factors, fibrin, and accelerated fibrinolysis. Conditions associated with DIC are listed in [Box 36-10](#). Patients can have bleeding or thrombosis or may have only laboratory evidence of DIC. DIC is the result of significant

exposure of circulating blood to TF, commonly from endothelial disruption or from hypoxia, acidosis, and sepsis.

No single laboratory test can establish or exclude the diagnosis of DIC. The most common laboratory abnormalities include thrombocytopenia or a rapidly falling platelet count and elevated D-dimer levels. Less commonly, microangiopathic hemolytic anemia, hypofibrinogenemia, and PT and aPTT prolongation are seen. D-dimers may be present in premature infants without DIC. Antithrombin III levels can be markedly depressed as well. The treatment of DIC is principally focused on eradicating the precipitating process; treatment of the consequences without treating the underlying cause is certain to fail. No evidence exists that prophylactic administration of platelets or plasma improves the outcome of a patient who is not bleeding. FFP, cryoprecipitate, and platelet transfusions are used only to treat active bleeding in the older child. However, in the neonatal period, because of the risk of intracerebral hemorrhage, many aim to correct platelet counts of less than 50,000, fibrinogen levels of less than 100 mg/dL, and INR of higher than 1.5. Sequential thromboelastograms (TEGs) are useful in monitoring the correction of DIC in the perioperative period (see "Thromboelastograph").

Nutritional Coagulopathies

In addition to vitamin K deficiency, vitamin C deficiency (i.e., scurvy) can result in a bleeding diathesis. Because vitamin C plays a fundamental role in collagen formation, patients with vitamin C deficiency have impaired collagen synthesis and capillary fragility, which leads to gingival bleeding and petechiae. Children with scurvy are at risk for significant oropharyngeal bleeding during airway manipulation (Disma et al., 2008).

Acquired Hemophilia

Antibodies to coagulation factors develop in patients with hemophilia who are treated with factor replacement and in patients who do not have hemophilia who have no prior exposure to hemostatic therapy. These acquired inhibitors to coagulation factors occur most commonly against factor VIII. Although many patients with acquired hemophilia are elderly, children can be affected in a devastating manner. Patients who develop inhibitors commonly have coexisting diseases such as lupus or rheumatoid arthritis, or they have been recently treated for rheumatic fever or nephrotic syndrome (Sakai et al., 2005). Transplacental transfer of acquired inhibitors has been reported, resulting in hemorrhagic complications in the newborn period. Patients with acquired inhibitors most commonly have bleeding into fascial planes and mucous membranes, rather than into joints. The diagnosis is elusive because of inconsistent test results. No correlation exists between inhibitor titers and the severity or pattern of bleeding (Huth-Kuhne et al., 2009).

In patients with inhibitors, even large amounts of cryoprecipitate or FFP may not promote satisfactory hemostasis. FFP administration leads to an anamnestic response, increasing inhibitor levels. Factor VIII autoantibodies in acquired hemophilia are usually incompletely inhibitory, so that factor VIII levels are usually detectable and may be as high as 10% to 20% of normal values. First-line therapy for inhibitor-associated hemorrhage is either rFVIIa or one of the commercially available activated prothrombin complexes. If one of these agents is not immediately available, DDAVP can be employed (Huth-Kuhne et al., 2009).

Recombinant Factor VIIa (rFVIIa)

The success of rFVIIa, a synthetic clotting factor, originally developed for use in patients with hemophilia and inhibitors to

factors VIII or IX, dramatizes the new paradigm of cell-based hemostasis presented earlier and offers an additional therapeutic option for other bleeding situations in the perioperative period (Roberts et al., 2004). Because of deficiencies in either factors VIII or IX, patients with hemophilia are unable to generate the platelet-localized factor Xa that is necessary for explosive thrombin production. rFVIIa forms a complex with TF exposed at areas of vascular injury, acting as a local catalyst for coagulation. The resultant rFVIIa-TF-Xa complex can overcome a deficiency of factor VIII or IX, the foundation for rFVIIa's primary indication. rFVIIa also binds to activated platelets and enhances thrombin generation. rFVIIa's mechanism of action is illustrated in [Figure 36-17](#) (Mannucci and Levi, 2007).

Intraoperative Coagulopathies

Patients with no preoperative disorders of coagulation who have surgery may develop coagulopathy because of a combination of blood loss, fluid replacement, and other intraoperative circumstances. Conditions associated with the development of intraoperative coagulopathy are listed in [Box 36-11](#).

Colloid-Induced von Willebrand Syndrome

The administration of some synthetic colloids as volume expanders may be associated with the development of acquired vWD (Chappell et al., 2008; Bailey et al., 2010). Large amounts of dextran decrease vWF and factor VIII levels and enhance fibrinolysis. The increase in bleeding times after dextran infusion can be completely normalized by the administration of DDAVP.

FIGURE 36-17. rFVIIa's mechanism of action. When the vessel wall is disrupted, subendothelial TF becomes exposed to circulating blood and may bind factor VIIa (**A**). This binding activates factor X, and activated factor X (factor Xa) generates small amounts of thrombin. The thrombin (factor IIa) in turn activates platelets and factors V and VIII. Activated platelets bind circulating factor VIIa (**B**), resulting in further factor Xa generation, as well as activation of factor IX. Activated factor IX (factor IXa) (with its cofactor VIIIa) yields additional factor Xa. The complex of factor Xa and its cofactor Va then converts prothrombin (factor II) into thrombin (factor IIa) in amounts that are sufficient to induce the conversion of fibrinogen to fibrin. (From Mannucci PM, Levi M: *Prevention and treatment of major blood loss*, N Engl J Med 356:2301, 2007.)

Of the available colloids, children commonly receive human serum albumin and only rarely receive hydroxyethyl starch. Human serum albumin has minimal effects on coagulation (Schramko et al., 2009). However, albumin does prolong the bleeding time based on impairment of platelet aggregation. In adult studies, when albumin is compared with dextran and high-molecular-weight hydroxyethyl starch, albumin is associated with less postoperative blood loss. Preliminary studies comparing middle-molecular-weight hydroxyethyl starch and albumin suggest that a minimal difference exists between them in postoperative blood loss. In patients with even mild forms of vWD, the administration of artificial colloid in patients can be associated with significant hemorrhagic complications; albumin or crystalloid should be used preferentially (De Jonge and Levi, 2001).

Hypothermia

Substantial data suggest that hypothermia is an independent and dramatic contributor to coagulopathy. Mild hypothermia of 35° C significantly prolongs the PT, aPTT, and bleeding time. At a core temperature of 34° C, coagulation and platelet function are severely altered, despite normal fibrinolytic function

(Wolberg et al., 2004). The coagulopathy of hypothermia is exacerbated by acidosis (Dirkman et al., 2008). Transfusion of platelets and clotting factors does not correct the hypothermic coagulopathy completely in the absence of rewarming.

Both components of the hemostatic mechanism appear to be deleteriously affected by hypothermia. Platelet function is seriously impaired by mild hypothermia as a result of a reduction in TXA₂ release. The clotting cascade involves a series of enzymatic reactions, all of which are slowed by hypothermia (Hoffman and Monroe, 2007). The laboratory detection of hypothermic coagulopathy is often missed because most laboratories perform clotting tests at 37° C (Rossaint and Spahn, 2006). The results of the PT and aPTT performed at the patient's actual core temperature are prolonged. TEG data suggest that hypothermia impairs clot formation rather than enhancing fibrinolysis (Dirkman et al., 2008). Thromboelastography can be adjusted to a patient's core body temperature to adequately evaluate the role played by hypothermia in hypothermic coagulopathy (Ramaker et al., 2009).

Hemodilution

Acute normovolemic hemodilution to minimize red cell transfusion requirements often results in alterations of hemostasis, especially when colloid is used as the diluent. Quantitative modeling of acute normovolemic hemodilution demonstrates that patients often develop inadequate fibrinogen levels (less than 100 mg/dL) before they reach the hematocrit threshold for red cell transfusion or the threshold for platelet transfusions (Singbartl et al., 2003). Fibrinogen administration has been shown to reverse the hemostatic consequences of colloid hemodilution (Mittermayr et al., 2007).

Massive Transfusion

Massive blood loss is defined as the loss of more than 1 blood volume in a 24-hour period, the normal blood volume being 7% of ideal body weight in an adult and 8% to 9% in an infant. In the operating room, early recognition of major blood loss can be appreciated using the definitions of massive blood loss as occurring at the rate of 2 to 3 mL/kg per minute or 50% of blood volume in over 3 hours.

The progression from dilutional coagulopathy to dilutional thrombocytopenia is seen in massive transfusion and in extreme hemodilution. During the era of whole-blood administration, thrombocytopenia was the initial coagulopathic event. Currently, blood loss is most often replaced with plasma-poor RBC products that are devoid of most coagulation factors. Under these conditions, the initial coagulopathic event is the dilution of coagulation factors (marked by prolongation of the PT); hypofibrinogenemia is the first factor deficiency that occurs, at a time when the platelet count remains more than 150,000/mcL (Perkins et al., 2008). The PT becomes prolonged when less than 1 blood volume is lost, but a clinical coagulopathy does not occur until the PT and PTT exceed 1.5 to 1.8 times the control values (Hirshberg et al., 2003). In the clinical setting, fibrinogen concentrations fall below the hemostatically critical level of 100 mg/dL when blood loss is in excess of 150% of the patient's blood volume, and the remaining coagulation factors fall below 25% after 200% blood loss. A platelet count of less than 50,000 should be anticipated when more than 2 blood volumes have been lost (Stainsby et al., 2000).

FFP is the first choice in treating a coagulopathy that results from massive transfusion (Gonzalez et al., 2007). Although the optimal FFP/RBC ratio is unknown, aggressive adherence to a ratio of 1:1 to 1:2 helps prevent the onset of a dilutional coagulopathy and minimize the need for cryoprecipitate (Hirshberg et al., 2003; Ho et al., 2005). These authors have also suggested an ideal platelet-to-RBC ratio of 0.8:1 for the massively transfused patient (Hirshberg et al., 2003). Survival in both civilian and combat victims requiring massive transfusions was dependent on the FFP/RBC ratio that they received; mortality was lowest when this ratio was approximately 1:1.5 (Borgman et al., 2007; Sperry et al., 2008). In this setting, if rapid laboratory corroboration is possible, a complete coagulation profile should be obtained to determine the patient's specific replacement needs. In the absence of timely data, or with continuing hemorrhage, empirical therapy with FFP is justified. FFP at a dose of 20 mL/kg increases fibrinogen by approximately 60 mg/dL and increases clotting factors by 20%.

Traumatic Coagulopathy Independent of Blood Loss or Replacement

Laboratory manifestations of trauma-related coagulopathy include abnormal PT and aPTT, decreased protein C levels, and an increase in plasma thrombomodulin. These patients have increased transfusion requirements. Abnormal aPTT and low protein C are independent predictors of mortality (Macleod et al., 2003; Brohi et al., 2007a).

Traumatic coagulopathy manifests as a hypocoagulable state associated with hypothermia, acidosis, clotting factor dilution, and tissue destruction, all of which are directly proportional to the severity of the traumatic injury (Hess et al., 2008). Nearly 25% of trauma patients arrive at the emergency department with an established clinically significant coagulopathy, and these patients are four times more likely to die than are trauma victims without a coagulopathy (Brohi et al., 2007b). The variables responsible for this coagulopathy include tissue trauma, shock, dilution, hypothermia, acidemia, and inflammation (Armand and Hess, 2003). Mild to moderate hypothermia affects coagulation and platelet function and is associated with clinical bleeding (Martini et al., 2005). Animal investigation confirms that acidemia slows the kinetics of coagulation reactions and enhances fibrinolysis (Martini et al., 2007).

Shock and the hemodilution that result from fluid resuscitation are the early instigators of the traumatic coagulopathy process. The aggressive fluid management required by these trauma patients produces a concomitant dilutional coagulopathy as well. Vigorous fluid resuscitation can result in a confluence of circumstances that in and of itself contributes to the traumatic coagulopathy. By increasing intravascular volume, blood pressure, and vasodilation, hemorrhage is further potentiated. These hemodynamic and rheologic perturbations increase the likelihood that hemostatic plug formation will not occur.

Specific injuries modulate the course of the coagulopathy. Extensive tissue destruction releases tissue thromboplastins, which activate the clotting process and result in a consumptive coagulopathy. tPA and PAI-1 are released from the extensively damaged tissue bed. In the first few hours after traumatic injury, tPA increases out of proportion to PAI-1 and produces a systemic activation of fibrinolysis (Brohi et al., 2008). This coagulopathy resembles that of DIC, but the diffuse microthrombi that are classically seen in DIC are not seen in traumatic coagulopathy.

Traumatic brain injury produces a consumptive coagulopathy as the result of the release of TF and other tissue thromboplastins into the circulation and fibrinolysis activation, which is associated with a dramatic increase in mortality (Stein and Smith, 2004; Talving et al., 2009). Long-bone fractures are also associated with coagulopathy, perhaps through the mechanism of subclincial fat embolism.

Intraoperative Evaluation of the Bleeding Patient

Activated clotting time (ACT) is a modification of a whole-blood clotting test that uses kaolin or Celite to accelerate coagulation by activating the contact pathway (Box 36-12). A fixed volume of blood is placed into a tube with activator at 37° C for 60 seconds, after which the contents are stirred until a clot is formed. The normal ACT range is 80 to 120 seconds. This test can be performed easily at the bedside using commercially available equipment. ACT levels correlate well with antifactor Xa heparin levels in the precardiopulmonary bypass period and are commonly used to monitor the adequacy of heparin anticoagulation

levels during extracorporeal circulation. The relationship of ACT with heparin dosing is linear in the setting of normal antithrombin III concentrations and factor XII activity, normothermia, a platelet count of more than 50,000, intact platelet function, and a fibrinogen level of more than 100 mg/mL. However, in the absence of extracorporeal circulation, ACT has a much poorer correlation with plasma heparin concentrations than does the aPTT. ACT is insensitive to many coagulation abnormalities; clotting deficiencies and platelet abnormalities can be present with a normal ACT (Girardi et al., 2000). Nevertheless, in the setting of major trauma, intraoperative ACT measurements were able to discriminate between patients who became coagulopathic and those who did not. However, because the ACT test is performed at 37° C, the contribution of hypothermia to the development of this coagulopathy is underappreciated (Aucar et al., 2003). ACT levels do not correlate well with LMWH anti-Xa levels.

Thromboelastograph

The TEG is a point-of-care evaluation of a patient's hemostatic balance, from initial clot formation to clot retraction or dissolution. Coagulation of blood has been compared with the building of a house: TEG profiling does not end when the foundation stone is laid, as do the other clinically employed clotting studies. The TEG also reflects the speed of the building process, whether the building will be sturdy, and whether it is likely to be damaged soon after it is built. The TEG examines the viscoelastic properties of blood as it clots. Placed into a rotating cup with an immersed pin, liquid blood begins to clot by forming fibers between the cup and the pin, transmitting motion to the pin. The TEG measures the elastic shear modulus of the clot, providing information about the rate of clot formation, clot strength, platelet function, and fibrinolytic activity, reflected in the characteristics of the tracing produced (Venkatesh et al., 2001). The maximal elastic shear modulus depends on platelet count and function and the amount of fibrin deposited on the pin.

A typical TEG tracing and the parameters of the TEG are illustrated in [Figure 36-18](#) and described in the following list:

R (reaction time): Latency to initial clot formation; from onset of tracing until a 2-mm amplitude on tracing. This

■ **FIGURE 36-18.** Parameters of the thromboelastograph.

is similar to whole-blood clotting time; it depends on an intact intrinsic pathway and an adequate generation of thrombin. Prolonged R is associated with clotting deficiencies, heparin administration, and thrombocytopenia. The coagulation test that correlates with R is aPTT.

K (coagulation rate): Rate of fibrin buildup and crosslinking, occurring from 2 to 20 mm. Prolonged K is associated with clotting deficiencies, platelet dysfunction, thrombocytopenia, and hypofibrinogenemia.

α (angle) (rate of increase in elastic shear modulus): The rate of fibrin buildup and crosslinking; slope of divergence of tracing from R.

MA (maximal elastic shear modulus): Measured at maximal divergence of the graph, after the clot is entirely formed, this is the maximal clot strength. A typical clot has an MA of 50 mm, which is equivalent to 5000 dynes/cm². MA is the best description of the competency of the clot. It depends on platelet count and function and on the fibrinogen level (Chandler, 1995):

Decreased MA is associated with thrombocytopenia, platelet dysfunction hypofibrinogenemia, and deficiencies of factors VIII and XIII. Increased MA is associated with a prothrombotic state.

The tracings seen on the TEG for common disorders of hemostasis are shown in [Figure 36-19](#). The TEG is a global measure of hemostasis, useful when multiple hemostatic defects are present. The weakness of TEG is its inability to identify specific clotting abnormalities. The TEG is a sensitive indicator of hypocoagulable and hypercoagulable perturbations. The typical hypercoagulable TEG profile has the appearance of a cognac glass (Traverso et al., 1995).

The R of patients receiving coumadin increases with increased INR, but it may remain within a normal range. Patients with decreased clotting factors have decreased R and K values and prolonged PT, or they have decreased angle and prolonged aPTT. Hypofibrinogenemia is associated with decreased R and K times, decreased angle, and decreased MA. Hyperfibrinolysis is characterized by reduced amplitude at 30 and 60 minutes (decreased A₃₀, A₆₀).

In addition to its point-of-care availability, the conditions under which a TEG is performed can be optimized to best define the clinical scenario. TEG offers a number of other advantages

■ **FIGURE 36-19.** Thromboelastographic tracings of common hemostatic abnormalities. 1, Normal; 2, hemophilia; 3, thrombocytopenia; 4, fibrinolysis; 5, hypercoagulation.

in the assessment of hemostasis that conventional coagulation tests do not. It is performed at the patient's temperature to reflect its effects on hemostasis; conventional parameters are measured at 37° C. The anticoagulation effects of LMWH can be rapidly assessed with TEG tests, whereas factor Xa measurements are not readily available (Coppell et al., 2006). Hypercoagulability can be diagnosed by TEG but usually cannot be determined through conventional means (Ganter and Hofer, 2008). The patient's state of coagulability can be quantified with the coagulation index (CI) (Chan et al., 2007):

$$CI = (-0.6516)R - (0.3772)K + (0.1224)MA + (0.0759)\alpha - 7.7922$$

CI > 3, hypercoagulable stage

CI < 3, hypocoagulable stage

TEG has been employed in the pediatric population. The parameters of children younger than 1 year of age undergoing noncardiac surgery were different from those of an adult control group. The rates of clot initiation and clot buildup, as well as clot strength were all greater in the infant groups. Despite their observations of developmental differences in clotting factor concentrations, the authors concluded that the hemostatic mechanism of the infant is balanced (Chan et al., 2007). TEG has been used in a variety of clinical pediatric perioperative settings, including cardiac surgery, extracorporeal membrane oxygenation, liver transplantation, and neurosurgery (Miller et al., 2000; Goobie et al., 2001; Davis et al., 2006;).

Because TEG has been a registered trademark since 1996 and because of the availability of other similar devices (rotation thromboelastometry [ROTEM] and Sonoclot), it has been suggested that the term *viscoelastic point-of-care coagulation analysis* should replace TEG as the generic term for this methodology. As of this writing, these newer devices have not been extensively used in children.

TREATMENT OF THE BLEEDING PATIENT

Safety of Transfusion and Factor Replacement

Complications of life-threatening bloodborne virus transmission have been markedly reduced by the institution of multiple screening steps in the procurement of donor-derived plasma products. However, the risks of transfusion-associated transmission of thermostable viruses such as hepatitis A and parvovirus B19 remain. Reports of transfusion-associated transmission of West Nile virus highlight the continued risks of using the blood supply as the principal source for hemostatic agents. Nucleic acid amplification testing for West Nile virus has now been shown to be effective in detecting virus in asymptomatic donors (Busch et al., 2005). The list of potential bloodborne pathogens is long and continues to grow, although not all bloodborne viruses have been demonstrated to be pathogenic to humans. Unfortunately, these concerns are not completely alleviated by the use of recombinant factor concentrates. With the outbreak of variant Creutzfeldt-Jakob disease in the United Kingdom, concern has been raised that the human albumin used in the manufacture and formulation of some recombinant factors may contain and transmit prion proteins. In countries where bovine spongiform encephalopathy has occurred, strategies to minimize the risk of transmission of Creutzfeldt-Jakob disease have

been developed, including screening potential blood, plasma, and platelet donors and leukoreducing whole-blood and red cell products (Ludlam and Turner, 2006).

Safety of Hemostatic Agents

Recently, the medications that have been most extensively evaluated as alternative or adjunctive hemostatic agents include the antifibrinolytic lysine analogues, EACA and tranexamic acid (a bovine-derived protease inhibitor), DDAVP, and rFVIIa. Designed to assess therapeutic efficacy, most trials were not optimally designed to assess potential adverse effects; therefore, definitive safety data are lacking for all agents. Although these drugs are often associated with dramatic success—"the liquid intracranial hemorrhage became a clot pancake before my eyes"—they are not panaceas. Adverse events should be anticipated when tightly regulated systems such as the hemostatic and fibrinolytic systems are pharmacologically perturbed. Of particular concern are the thrombotic adverse events associated with these hemostatic agents (Mannucci and Levi, 2007).

Most safety data regarding the complications of these hemostatic agents are based on results of studies in adult patients. Is it reasonable for pediatric providers to extrapolate safety concerns from the adult experience? Until sufficiently large pediatric studies are conducted to evaluate the safety of these agents, they must certainly pay close attention to the concerns raised by the adult studies. Given that these drugs have life-saving potential, the dilemma, as Twite and Hammer (2008) point out, is that in the absence of data, providers must balance "do what is best" with "do no harm." Informed consent, when deemed necessary, and heightened vigilance for the occurrence of adverse events must accompany the use of such agents in children.

Anticoagulant-Induced Coagulopathy

Patients who are experiencing severe bleeding should receive FFP in a dose of 20 mL/kg until vitamin K administration increases endogenous synthesis. Infusion of factor IX complex concentrate, which contains high concentrations of the activated vitamin K–dependent factors (II, VII, IX, and X) can correct the effects of anticoagulants rapidly without the excessive volume exposure of FFP. Factor IX complex (40 IU/kg) in addition to FFP infusion (as compared with FFP alone) successfully corrected the INR in patients with intracranial hemorrhage in one third of the time with 9% of total fluid volume administered (Boulis et al., 1999). rFVIIa can also correct oral anticoagulant-induced coagulopathy.

Agents Used to Control Bleeding

DDAVP

DDAVP is an analogue of vasopressin that recruits factor VIII from storage sites within endothelial cells via activation of the endothelial vasopressin V2 receptor and cAMP-mediated signaling; it may raise baseline factor VIII levels by 2- to 20-fold in normal patients and in patients with mild hemophilia (Mannucci, 1997; Kaufmann and Vischer, 2003). This increase in factor level is often sufficient to prevent or limit minor bleeding.

DDAVP also increases the release of ultra large vWF multimers from the endothelium. DDAVP is the treatment of choice for children with type 1 vWD, mild hemophilia, or platelet dysfunction, including uremia and drug-induced bleeding diatheses. DDAVP is also effective in treating hemorrhage in patients with acquired inhibitors to factors VIII or IX. Anecdotally, DDAVP has controlled perioperative bleeding in patients with Ehlers-Danlos syndrome, Marfan syndrome, and osteogenesis imperfecta, in which bleeding is thought to be the result of dysfunctional platelet aggregation caused by abnormal collagen (Keegan et al., 2002; Franchini, 2007).

DDAVP has been employed in a variety of pediatric procedures associated with risk of large blood loss in an attempt to decrease perioperative blood loss and transfusion requirements. Despite early studies to suggest that DDAVP reduced blood loss in cardiac surgery patients, most studies suggest that DDAVP is not efficacious in uncomplicated cardiac surgery. Children undergoing complex congenital heart repair did not have any reduction in bleeding or transfusion requirements with the prophylactic use of DDAVP (Oliver et al., 2000). Similarly, DDAVP does not appear to reduce blood loss in spinal fusion in patients with idiopathic scoliosis or in those with cerebral palsy-associated neuromuscular scoliosis (Theroux et al., 1997; Alanay et al., 1999).

A dose of 0.3 mcg/kg administered IV over 20 to 30 minutes or intranasally (150 mcg for children weighing less than 50 kg, and 300 mcg for those weighing more than 50 kg) increases factor VIII levels by 62%, and this dose may be repeated every 8 to 12 hours to control bleeding. Peak effects occur within 30 to

60 minutes after IV infusion and 60 to 90 minutes after intranasal administration. Tachyphylaxis may occur after three or four doses. Because severe hyponatremia-associated seizures have been reported with the use of DDAVP, close observation of fluid status and electrolyte balance is mandated. Although thrombotic complications have been reported, in two meta-analyses of DDAVP use in the adult perioperative period, no significant difference in the incidence of these complications between DDAVP and placebo was reported (Mannucci, 1997; Crescenzi et al., 2008).

Antifibrinolytics

Two classes of antifibrinolytics have been employed to optimize hemostasis in the setting of a bleeding diathesis and to reduce blood loss and transfusion requirements during major procedures: the synthetic lysine analogues EACA and tranexamic acid, and the serine protease inhibitor aprotinin. Their mechanism of action is illustrated in [Figure 36-20](#). Antifibrinolytic drugs are commonly employed when bleeding occurs in sites that are rich in plasminogen activator and other fibrinolytic enzymes, such as the endometrium, the GI tract, and the urinary tract (Mannucci, 1998). These drugs are contraindicated in the setting of hematuria, DIC, or thromboembolic disease. EACA has been successfully used in managing bleeding crises in patients with hemophilia and inhibitors (Ghosh et al., 2004). EACA binds to the lysine site on plasminogen and plasmin, preventing plasmin from binding to fibrin; fibrinolysis is inhibited and clot stabilization continues. EACA has been shown to be

■ **FIGURE 36-20.** Antifibrinolytic mechanism of action. Activation of plasminogen by endogenous plasminogen activators results in plasmin, which causes degradation of fibrin. Binding of plasminogen to fibrin makes this process more efficient and occurs through lysine residues in fibrin that bind to lysine-binding sites on plasminogen (**A**). In the presence of lysine analogues, these lysine-binding sites are occupied, resulting in an inhibition of fibrin binding to plasminogen and impairment of endogenous fibrinolysis (**B**). (From Mannucci PM, Levi M: *Prevention and treatment of major blood loss*, N Engl J Med 356:2301, 2007.)

effective in decreasing blood loss in children undergoing cardiac surgery (Eaton, 2008). Children undergoing posterior lumbar fusion who received 100 mg/kg of EACA followed by an infusion of 10 mg/kg per hour had less blood loss and required less RBC transfusions than did a randomized control group (Florentino-Pineda et al., 2001).

Aprotinin is a naturally occurring serine protease inhibitor that affects hemostasis through several mechanisms; it is an antifibrinolytic and inhibits kallikrein, plasmin, trypsin, and APC. Aprotinin inhibits the initiation of fibrinolysis and the contact phase of coagulation, but it has no effects on platelet function. It is inactive when given orally. Aprotinin was first shown to be effective in reducing blood loss in coronary-artery-bypass graft operations and subsequently was shown to be effective in reducing perioperative bleeding and transfusion requirements in pediatric cardiac surgery, liver transplantation, hip replacements, and posterior spine fusion (Lemmer et al., 1996; Urban et al., 2001; Samama et al., 2002; Eaton, 2008).

Mouth bleeding is common in hemophilia patients, resulting in part from the potent fibrinolytic activity of saliva. For oral or GI bleeding in patients with hemophilia, EACA is often very effective and may dramatically reduce the need for additional coagulation factor infusions when given at a dose of 100 mg/kg orally every 6 hours for 5 to 10 days after a hemorrhagic episode. Antifibrinolytic mouthwashes allow for the performance of dental extractions on patients receiving long-term oral anticoagulant treatment without lowering the degree of anticoagulation (Patatanian and Fugate, 2006).

Safety of Antifibrinolytic Agents

Clinical trials demonstrate that all three drugs (EACA, aprotinin, and tranexamic acid) are effective at reducing transfusion requirements as compared with placebo (Henry et al., 2007). Recent studies of aprotinin's use in adult patients have documented an increased incidence of renal failure and cardiovascular complications; a study called *Blood Conservation Using Antifibrinolytics in a Randomized Trial (BART)* reported an increase in perioperative mortality (Mangano et al., 2006; Fergusson et al., 2008). Safety data on pediatric aprotinin use are limited. The largest pediatric review of aprotinin usage (865 children) was designed to evaluate the incidence and impact of aprotinin hypersensitivity reactions; this study was not designed to identify thrombotic events or renal impairment, and none was reported (Jaquiss et al., 2002). In a retrospective review of aprotinin's use in pediatric cardiac surgery, using historical controls, no differences in the complication rates were reported; however, thrombotic events were not one of the primary end points (Backer et al., 2007). Recent retrospective studies found no increase in renal dysfunction in neonates who received aprotinin during cardiopulmonary bypass (Guzzetta et al., 2009a; Manrique et al., 2009). At the current time, the issue of whether aprotinin is safe and effective in children is moot, as the manufacturer has removed the drug from the market because of concerns raised by the BART trial.

Recombinant Activated Factor VIIa (rFVIIa)

rFVIIa is a synthetic clotting factor that was originally developed for use in patients with hemophilia who developed inhibitors to factors VIII or IX. The rationale behind the development and clinical success of rFVIIa underscores the new paradigm

of cell-based hemostasis presented earlier. Those with hemophilia are unable to generate the platelet-localized factor Xa necessary for explosive thrombin production because of deficiencies in factors VIII or IX. Administered factor VIIa is effective in improving hemostasis in patients who have hemophilia by complexing with TF exposed at areas of vascular injury and by binding to activated platelets and restoring platelet surface-thrombin generation. This augmented thrombin production further increases platelet activation and thrombin-activatable fibrinolysis inhibitor (TAFI), which decreases fibrinolysis. In this way, the resultant factor VIIa-TF-Xa complex thus overcomes a deficiency of factor VIII or IX. For patients with hemophilia who have high inhibitor titers, randomized, controlled trials in adults and children have shown that rFVIIa minimizes spontaneous bleeding and decreases intraoperative blood loss (O'Connell et al., 2002).

After rFVIIa's dramatic use in an exsanguinating 19-year-old soldier with a vascular injury, an increasing number of anecdotal and small case series have described rFVIIa's successful use in mitigating uncontrollable bleeding in patients without hemophilia in a variety of clinical situations—hepatic dysfunction, thrombocytopenia, platelet dysfunction, dilutional coagulopathies, DIC, and after cardiopulmonary bypass (Kenet et al., 1999; Poon et al., 1999; Martinowitz et al., 2001; Blajchman, 2003; Goodnough, 2003; Tobias et al., 2003a, 2003b; Guzzetta et al., 2009b). Because factor VII is the first of the clotting factors to become deficient in liver failure, rFVIIa has been used in the setting of hepatic dysfunction and vitamin K antagonism. The enhanced platelet activation that results from increased thrombin production has led to the use of rFVIIa in treating quantitative and qualitative platelet dysfunction (Patel et al., 2001). rFVIIa resulted in a reduction in bleeding time in 50% of patients with thrombocytopenia. The clot formed with rFVIIa use has a denser mesh of fibrin fibers that is more resistant to plasmin degradation (Hedner, 1998). rFVIIa has been used in the patient receiving massive transfusions whose coagulopathy has been unresponsive to conventional plasma-component therapy.

The recommended dose of rFVIIa is 90 mcg/kg administered over 2 to 5 minutes. Because of its short half-life, additional doses must be given every 2 to 4 hours until hemostasis is achieved. The dose for patients with factor VII-deficiency is 25 mcg/kg.

rFVIIa has many advantages. It is completely synthetic, decreasing the risks of infectious complications; it can be quickly reconstituted from powder, eliminating the time needed for thawing and procurement of products from the blood bank; and it is dissolved in a small volume, minimizing excessive volume load, electrolyte perturbations, and the latency between institution of treatment and correction of the hemostatic defect. rFVIIa has limitations as well. Its efficacy depends on the presence of the other clotting factors. In the setting of a massive transfusion, factor VIIa is not the only clotting factor that is deficient. Most anecdotal reports concerning the use of rFVIIa in massive transfusion-associated bleeding are in the context of earlier administration of FFP. rFVIIa has a short half-life, necessitating frequent dosing. In the context of liver failure or dilutional coagulopathy, dosing is required every 12 hours. In the presence of inhibitors to factors VIII or IX, doses must be given every 2 to 4 hours until hemostasis is maintained.

The risk of rFVIIa's thrombotic complications in hemophiliacs appears to be low. In contrast, most of the rFVIIa's thrombotic complications are in the context of its "off-label usage" and

are associated with serious morbidity and mortality (O'Connell et al., 2006; Abshire, 2008; Abshire and Kenet, 2008).

Although potentially promising, at the present time the role of rFVIIa in the treatment of perioperative bleeding should be restricted to that of rescue therapy for the intractably bleeding patient unresponsive to conventional transfusion treatment. Specifically, rFVIIa should be used cautiously in patients at risk for catastrophic thrombotic complications (e.g., as children with small-vessel anastomoses or palliative cardiac shunts) until further experience is garnered. After randomized, controlled trials have been completed to better define the thrombotic and pulmonary risks, rFVIIa could become a first-line agent for many of the coagulopathies that plague patients in the perioperative period (Alten et al., 2009).

Hemostatic Formulary

The blood-based components available for treatment of the bleeding patient, their constituents, and indications for their use are summarized in Table 36-25.

The American Society of Anesthesiologists Task Force on Blood Component Therapy (2006) recommended that the triggers for treatment of the patient who is at risk for bleeding be multiple and not depend on a single factor. Often, the critically ill child may require an emergent invasive procedure before a complete hemostatic profile has been determined. In these circumstances, bleeding from puncture sites or general oozing in the surgical field may necessitate empirical treatment with FFP. Generally accepted treatment triggers for component therapy are listed in Box 36-13.

Platelets

Each unit of platelets contains 5.5 to 7.5×10^{10} platelets diluted in 50 mL of plasma. An apheresis platelet unit contains more than 3×10^{11} platelets in 250 to 300 mL of plasma. Normally, one third of all transfused platelets undergo splenic sequestration.

Box 36-13 Recommendations for Blood-Component Therapy

PLATELETS
 Less than 50 k for acute bleeding
 Less than 100 k for intracranial, subarachnoid, or extracorporeal circulation procedures

FFP
 aPTT more than 1.5 times normal
 PT more than 1.5 times normal

FIBRINOGEN
 Less than 100 mg/dL

In nonsurgical patients with platelet counts of more than 20,000/mcL, spontaneous bleeding is uncommon. ASA guidelines suggest that patients receive transfusions for platelet counts less than 50,000/mcL and that platelet transfusions be considered for platelet counts between 50,000 and 100,000/mcL, taking into consideration the risks and consequences of postoperative bleeding from the surgical site. A platelet count of 50,000/mcL is considered sufficient for spinal anesthesia, 80,000/mcL for epidural anesthesia, and 100,000/mcL is recommended for neurosurgical or posterior ophthalmologic procedures (Rochon and Shore-Lesserson, 2006). Because of the risk of intracranial hemorrhage, sick premature infants are transfused when their platelet counts fall below 50,000/mcL (Roseff et al., 2006). If concurrent platelet dysfunction exists, the threshold for platelet transfusion should be lowered. The ideal platelet dose is between 0.07 and 0.15×10^{11} platelets/kg, which is approximately 10 mL/kg. A dose of 5 to 10 mL/kg or 1 unit/10 kg increases the platelet count by 50,000/mcL.

Platelets are much more likely than RBCs to cause bacterial sepsis, because they are stored at room temperature for up to 5 days and potentially have a higher bacterial load. The reported incidence of bacterial contamination of platelet products is 1 case per 2000 units (Blajchman et al., 2005). Storing the

TABLE 36-25. Hemostatic Formulary

Component	Contents	Indications	Dose	Outcome
Whole blood	Hematocrit: 30%-40% Most clotting factors ↓ FV, FVIII No platelets	Neonatal surgery Massive transfusion		
Fresh frozen plasma, 225 mL	All clotting factors 2 mg/mL fibrinogen	Hemodilution Liver failure DIC Warfarin toxicity FXI deficiency	10-15 mL/kg (max, 2 units) 5-8 mL/kg	↑15% in factors ↑40 mg/dL fibrinogen
Platelets, 50 mL	$>5.5 \times 10^{10}$ 50 mL plasma	Thrombocytopenia Platelet dysfunction	1 unit/10 kg (max, 10 units)	↑50,000
Cryoprecipitate, 25 mL*	Fibrinogen >150 mg Factor VIII >80 units von Willebrand factor >80 units FXIII >80 units	↓ fibrinogen Hemophilia A vWD	1-2 units/10 kg (max, 10 units)	↑ 60-100 mg/dL fibrinogen

*Cryo units = [(desired fibrinogen - initial fibrinogen) × plasma volume (dL)]/150 mg fibrinogen/unit.
 DIC, Disseminated intravascular coagulation; vWD, von Willebrand disease.

platelets in galactose-containing solution has been found to preserve platelet function despite chilling, and this approach may reduce the risk of bacterial contamination (Jhang and Spitalnik, 2005; Hornsey et al., 2008).

Platelet transfusions can also be associated with the development of pulmonary microvascular injury, called *transfusion-related acute lung injury (TRALI)*. TRALI is clinically similar to acute respiratory distress syndrome (discussed in a later section). Within 6 hours of receiving a plasma-containing product, fever, tachypnea, dyspnea, progressive hypoxemia, radiographic evidence of pulmonary edema, and hypotension occur. The prevalence of TRALI in patients who have received platelet transfusions is estimated to be 3 per 1000 units of concentrate (Silliman, 1999).

Fresh Frozen Plasma

FFP contains 250 mL of plasma and 500 mg of fibrinogen in a citrate anticoagulant. One unit of FFP has a concentration of coagulation factors similar to that of 4 to 5 units of platelet concentrates, 1 apheresis unit of platelets, and 1 unit of fresh whole blood. FFP, 1 mL/kg, raises most factor levels by approximately 1%. After a dose of 10 to 15 mL/kg of FFP, plasma clotting factors rise approximately 15%, and the fibrinogen rises by 40 mg/dL. However, FFP contains only 0.6% of factor VIII.

FFP use is indicated for treatment of microvascular bleeding in patients who have had massive transfusions, for documented coagulopathy (PT more than 1.5 times normal) in patients who have had massive transfusions, for urgent reversal of anticoagulant therapy, and for active bleeding in patients with history or course suggestive of an inherited or acquired coagulopathy for which specific factor concentrates are not available.

Cryoprecipitate

Cryoprecipitate is the most practical source for fibrinogen replacement. Each unit contains approximately 200 mg of fibrinogen, as well as more than 80 units of factor VIII, vWF, fibronectin, and factor XIII. Achieving fibrinogen plasma levels of 80 to 100 mg/dL and maintaining this level above 50 to 60 mg/dL usually controls hemorrhagic symptoms. To raise the fibrinogen level 100 mg/dL, 0.17 unit of cryoprecipitate per 1 kg of body weight should be infused. Fibrinogen has a long half-life; therefore, replacement therapy can be given at intervals of 3 to 4 days.

Cryoprecipitate is indicated for several uses:

- For prophylactic use in patients with congenital fibrinogen deficiencies, vWD unresponsive to DDAVP, and factor VIII deficiency when factor VIII concentrate is not available;
- In bleeding patients with vWD or factor VIII deficiency when factor VIII concentrate is not available;
- For consumptive coagulopathies when the fibrinogen level is less than 80 to 100 mg/dL; and
- For microvascular bleeding in the patient who has had massive transfusion when hypofibrinogenemia cannot be immediately documented.

Factors V, X, XI, and XIII

The only current source of factor V is FFP. Normal hemostasis is achieved with levels higher than 25 units/dL. These levels can be achieved with a loading dose of 20 mL/kg of FFP followed by infusions of 6 mL/kg every 12 hours. Factor

V is very labile in FFP, and recently donated FFP should be used. FFP (1 mL/kg) increases the plasma level of factor X by 1 unit/dL. FFP (1 mL/kg) increases circulating factor XI by 1.5 unit/dL. Hemostatic levels of factor XIII are 2 to 3 units/dL. FFP (5 to 10 mL/kg) is adequate to achieve therapeutic levels. Cryoprecipitate may also be used. One bag of cryoprecipitate contains 75 units of factor XIII.

Complications of Blood Product Administration

Citrate Intoxication

Citrate, when infused rapidly as the storage solution of blood products, can cause a temporary reduction in ionized calcium levels. FFP has considerably more citrate than do RBCs in citrate-phosphate-dextrose-adenine (CPDA-1). The signs of citrate intoxication include hypotension, narrow pulse pressure, flattening of the instantaneous slope of the arterial catheter tracing, elevated end-diastolic pressures, prolongation of the QT interval, widening of the QRS complexes, and flattening of the T waves. Hypocalcemia is directly related to the rate of citrate administration and is unlikely to occur unless transfusions exceed 1 mL/kg per minute. Impaired perfusion or liver dysfunction lowers this threshold for potential hypocalcemia. Slow calcium administration during rapid or large-volume blood product administration can avert this induced hypocalcemia.

Transfusion-Related Acute Lung Injury (TRALI)

TRALI usually manifests as bilateral pulmonary infiltrates within 4 hours of transfusion. The clinical picture consists of acute respiratory distress syndrome, with hypoxia, hypotension, and bilateral pulmonary edema, leading to radiographic opacification and fever within 2 to 6 hours of transfusion (Roseff et al., 2006). Although in most patients, TRALI symptoms usually resolve within 48 to 72 hours, a 5% to 10% mortality rate is associated. TRALI has two proposed mechanisms. In the first mechanism, leukocytes from transfused blood products interact with antibodies in the pulmonary microvasculature, leading to endothelial injury and alveolar exudation. Antileukocyte antibodies are found in this group of patients (Roseff et al., 2006). The other proposed mechanism involves clinical settings such as trauma, sepsis, or massive transfusion, in which cytokine production partially activates endogenous neutrophils. These neutrophils become adherent to the pulmonary microvascular endothelium. On exposure to the lipids contained in transfused blood products, neutrophil activation becomes complete and endothelial damage results in the clinical picture of TRALI (Silliman, 1999). The care of the patient with TRALI is supportive; the role of diuretics and steroids is unproven.

Transfusion-Associated Graft-Versus-Host Disease

Transfusion-associated GVHD (TA-GVHD) results when immunocompetent donor lymphocytes are transfused into an immunodeficient host patient who is unable to destroy them. These transfused lymphocytes react with host antigens, producing fever, skin rash, pancytopenia, diarrhea, and abnormal liver function test results. TA-GVHD can occur 4 to 30 days after transfusion (Alter and Klein, 2008). The pancytopenia is profound, and

mortality approaches 100% (Slichter, 2007). Median survival is only 21 days after transfusion. Patients who are at high risk for developing TA-GVHD include neonates; patients with congenital immunodeficiency, leukemia, or lymphoma; and those who have received intensive chemotherapy and bone marrow or solid-organ transplants. Infants and children with severe combined immunodeficiency syndrome (SCIDS) are of most concern, in part because SCIDS is often unrecognized at birth or in early infancy. Although many children with SCIDS are diagnosed by 6 months of age, children have been diagnosed with SCIDS up until 2 years of age. Children with the DiGeorge syndrome (22q11 deletion) and those with conotruncal defects or tetralogy of Fallot in whom immunodeficiency has not been excluded should be considered at risk for TA-GVHD as well. Patients with HIV do not appear to be at increased risk for TA-GVHD. The absence of TA-GVHD in HIV patients may underscore the key role of the recipient's CD4 cells (depleted early in the course of HIV infection) in the pathogenesis of TA-GVHD (Alter and Klein, 2008).

TA-GVHD can occur in patients who do not have an immunodeficiency. Patients who receive products from a donor who is homozygous for a shared haplotype are also at risk for TA-GVHD. The chance of receiving haplotype-homozygous blood from an unrelated donor varies among countries, ranging from 1 in 874 in Japan to 1 in 7147 whites in the United States, and 1 in 16,835 in France. Trauma patients with no known risk factors for TA-GVHD had evidence of microchimerism for as long as 1.5 years after transfusion (Lee et al., 1999). The spectrum of patients who are at potential risk for TA-GVHD is likely to increase with the use of immunosuppressive regimens in the treatment of autoimmune and inflammatory bowel diseases.

The prevention of TA-GVHD lies in attenuation of donor lymphocyte reactivity. The only method approved by the FDA is irradiation (Alter and Klein, 2008). Irradiation damages the DNA in donated T cells, which precludes their proliferation and prevents the development of TA-GVHD (Shlomchik et al., 1999). Most blood centers rely on a nominal dose of 25 Gy. Patients at risk for TA-GVHD should receive only irradiated RBCs, platelets, and granulocytes. A summary of situations in which irradiated blood products should be administered is presented in [Box 36-14](#).

Box 36-14 Indications for Irradiated Blood Products

Intrauterine transfusions
 Patients younger than 2 years old
 Transplantation
 Bone marrow transplantation
 Organ transplantation
 Oncologic conditions
 Lymphoma
 Neuroblastoma
 Glioblastoma
 Rhabdomyosarcoma
 Immunodeficiency
 Congenital immunodeficiency
 ● Wiskott-Aldrich syndrome
 ● Conotruncal abnormalities
 Acquired immunodeficiency
 ● HIV infection
 ● Patients receiving immunosuppressive drugs
 Recipients of blood products from first-degree relatives

To avoid the risk of TA-GVHD in patients with late-presenting SCIDS, many blood banks routinely irradiate all cellular blood products given to young children. At present, no consensus exists as to the cut-off age for this practice (Roseff et al., 2006). The Children's Hospital of Philadelphia irradiates products for children who are younger than 3 months of age, whereas Johns Hopkins Hospital irradiates all products for recipients younger than 6 years of age. Blood components donated from first- or second-degree relatives should be irradiated because of the possibility of HLA haplotype homozygosity. FFP and cryoprecipitate need not be irradiated, because most authorities feel that the freezing and thawing process destroys any donor T cells (Luban, 2002).

Hyperkalemia

Acute hemodynamic decompensation after red cell transfusions should be considered hyperkalemia, until proved otherwise. Large volumes (more than 25 mL/kg) of stored red cells given rapidly to infants have been associated with hyperkalemic cardiac arrest (Smith et al., 2008). The combination of perturbations of calcium and potassium concentrations in the context of central venous blood administration may be sufficient to produce hyperkalemic dysrhythmia (Eder, 2002).

MISCELLANEOUS PROBLEMS

Acquired Immunodeficiency Syndrome

Epidemiology

The epidemic of HIV and acquired immunodeficiency syndrome (AIDS) has had an enormous deleterious impact on worldwide health, and children have not been spared. In 2007, the World Health Organization (WHO) estimated that 33 million people worldwide were infected with HIV. Of this number, 2 million were younger than 15 years of age (WHO, 2007). Most of those infected with HIV live outside of the United States. The Centers for Disease Control and Prevention (CDC) estimated that 1 to 1.2 million people in the United States were infected with HIV in 2003; during 2006, the most recent year with complete statistics, approximately 50,000 new HIV infections were reported (Glynn, 2005; CDC, 2007a; Hall et al., 2008). The incidence of HIV infection varies by both ethnicity and geography. In the United States, AIDS is seen more often in Hispanic and African American children than in Caucasians. In 2008, the HIV/AIDS surveillance system of the CDC reported that 49% of children with AIDS were African American, 18% were Hispanic, and 30% were Caucasian. Most cases in the United States have been reported in the Northeast (23%) and South (25%), primarily in the large metropolitan areas (CDC, 2007a).

Transmission of HIV can occur through parenteral exposure to blood, sexual contact, or through vertical transmission from mother to child. In the United States, nearly all HIV infections in children younger than 13 years are the result of vertical transmission. Approximately 6000 to 7000 children are born to HIV-positive mothers annually in the United States. Women of childbearing age comprise one of the fastest growing groups with HIV infection in the United States, accounting for more than 27% of adult HIV cases reported (CDC, 2007b). Although transmission of HIV from mother to child can occur before, during, or after delivery, the highest percentage of HIV-infected children acquire the virus during delivery, most likely through exposure

to infected blood and secretions during delivery. Chance of transmission is increased with preterm birth, low birth weight, low maternal CD4 counts, and IV drug use during pregnancy. With cesarean section and prenatal, intrapartum, and neonatal antiretroviral treatment, vertical transmission in the United States has been decreased dramatically (AAP Committee on Pediatric AIDS, 2000; CDC, 2007b). In the United States, postpartum transmission via breastfeeding is the least common mode of perinatal transmission; however, it is quite common in developing countries. The number of perinatally acquired HIV cases in the United States peaked in 1992 at nearly 1000 and decreased to fewer than 100 in 2006 (Mofenson et al., 2006). This decline is thought to be related to more widespread use of the Public Health Service guidelines for universal counseling and voluntary HIV testing of pregnant women and more effective use of retroviral therapy in these patients (AAP Committee on Pediatric AIDS, 2000).

Although adolescents account for a small percentage of AIDS cases, the number of adolescents with AIDS is growing rapidly. In 2007, nearly 2000 young people in the United States were diagnosed with HIV infection or AIDS (CDC, 2007a). Transmission of HIV through contaminated blood or blood products accounts for approximately 3% of cases of HIV infection in the United States. Screening of blood products for HIV began in the United States in 1985, and since then the risk of transmission has decreased dramatically. Sexual transmission of HIV, although relatively rare in pediatrics, is a growing problem (Romero et al., 2007). The age at which HIV infection is diagnosed in children varies with the mode of transmission. Children who were infected by transfusion of contaminated blood or blood products, primarily between the years of 1978 and 1985, are now adults (Grubman et al., 1995). Children who

acquired the disease during birth can be diagnosed as infants, with detection of the virus as early as 1 week of age. The viral load increases with time, and the virus is detectable in the peripheral blood of almost all infected infants by the age of 4 months. HIV has three patterns of progression. Newborns who were infected during gestation develop symptoms within the first few months of life and have detectable virus early in life. Without treatment, they often die before their first birthday. Most newborns with HIV have acquired the infection during birth, and these infants have a much slower progression of disease. The viral load increases in the first few months of life and then declines over the subsequent 2 years. A small percentage of infants with perinatal infection survive for an extended time with minimal progression of the disease.

Children infected with HIV have generally the same immunologic manifestations as adults. Because infants and children have a lymphocytosis at baseline, true lymphopenia is relatively rare. However, relentless depletion of CD4 lymphocytes occurs, resulting in the development of opportunistic infections. Infants and children with HIV/AIDS have many opportunistic infections. The most common serious infections are pneumonia, bacteremia, and sepsis, and nearly every organ system may be affected. The CDC has classified HIV in young children based on the presence of signs and symptoms, the state of immunodeficiency, and the immunologic category of the disease (Caldwell et al., 1994). The current recommendations for initiation of antiretroviral therapy in infants, children, and adolescents were summarized in 2008 by the Working Group on Antiretroviral Therapy and Medical Management of HIV Infected Children, and these guidelines can be found on the CDC website and in [Box 36-15](#) (Guidelines for Use of Antiretroviral Agents, 2009).

Box 36-15 Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection

Preferred Regimen

Children 3 years and older: two NRTIs plus efavirenz*
Children younger than 3 years old or who cannot swallow capsules: two NRTIs plus nevirapine

Alternative

Two NRTIs plus nevirapine¹ (children 3 years and older)

PROTEASE INHIBITOR-BASED REGIMENS

Preferred Regimen

Two NRTIs plus lopinavir/ritonavir

Alternative

Two NRTIs plus atazanavir plus low-dose ritonavir (children older than 6 years)

Two NRTIs plus fosamprenavir plus low-dose ritonavir (children older than 6 years)

Two NRTIs plus nelfinavir (children older than 2 years)

USE IN SPECIAL CIRCUMSTANCES

Two NRTIs plus atazanavir unboosted (for treatment-naïve adolescents older than 13 years and weighing more than 39 kg)

Two NRTIs plus fosamprenavir unboosted (children older than 2 years)

Two NRTIs plus saquinavir plus low-dose ritonavir only in post-pubertal adolescents who weigh enough to receive adult doses

Zidovudine plus lamivudine plus abacavir

TWO NRTI BACKBONE OPTIONS

Preferred

Abacavir plus (lamivudine or emtricitabine)

Didanosine plus emtricitabine

Tenofovir plus (lamivudine or emtricitabine) (for Tanner stage 4 or postpubertal adolescents only)

Zidovudine plus (lamivudine or emtricitabine)

Alternative

Abacavir plus zidovudine

Zidovudine plus didanosine

Use In Special Circumstances

Stavudine plus (lamivudine or emtricitabine)

From Working Group on Antiretroviral Therapy and Medical Management of HIV-Infected Children, 2009: *Guidelines for the use of antiretroviral agents in pediatric HIV infection*. Available at <http://aidsinfo.nih.gov/ContentFiles/PediatricGuidelines.pdf>; accessed May 8, 2009.

*Efavirenz (a nonnucleoside reverse transcriptase inhibitor [NNRTI]) is currently available only in capsule form and should only be used in children aged 3 years and older who weigh 10 kg or more; nevirapine would be the preferred NNRTI for children aged younger than 3 years or who require a liquid formulation. Unless adequate contraception can be assured, efavirenz-based therapy is not recommended for adolescent females who are sexually active and may become pregnant.
PI, Protease inhibitor; NRTI: nucleoside/nucleotide reverse transcriptase inhibitors.

Clinical Presentation

In the perioperative environment, caring for children with HIV/AIDS is focused on two major considerations: effects of this systemic infection and its treatment on a child's readiness for anesthesia and surgery, and protection of health care workers from acquiring infection as a result of exposure to the blood or secretions of these children.

As many as 80% of children with HIV develop lung disease (McSherry, 1996). Pulmonary function is compromised by bacterial and viral infections, but in addition many children with AIDS also develop lipoid interstitial pneumonia (LIP) (Rubinstein et al., 1986). The incidence of LIP in children infected by HIV is 20% to 30%. Clinical characteristics of this condition include tachypnea, wheezing and cough, hypoxemia, and even clubbing. This condition presents with bilateral infiltrates. Severely affected children may have bronchiectasis and lung cysts. The most common opportunistic infection responsible for pneumonia in children with HIV infection is *Pneumocystis carinii* pneumonia. Most people are infected with this common organism in childhood, but disease is caused only in immunocompromised individuals. The peak incidence of this infection occurs in children who are younger than 1 year of age. *P. carinii* is often characterized by the acute onset of fever, hypoxemia, and respiratory distress, but a disease with a more desultory onset is also seen (Simonds et al., 1998). Infection with respiratory viruses in children with HIV is common and often more severe in these patients. In children with AIDS, infections with RSV, parainfluenza, and influenza viruses are more likely to be symptomatic, and infections with adenovirus or measles may lead to serious morbidity (Englund et al., 1998).

Children with LIP or infectious pneumonia may come to the operating room for bronchoscopy and bronchoalveolar lavage for diagnosis (Birriel et al., 1991). They are often hypoxemic and in respiratory distress before the procedure. These cases are often quite challenging, because the diagnosis must be established to prescribe the correct therapy; the procedure cannot be delayed until the child's condition improves. Children who are infected in the perinatal period with HIV often have involvement of the CNS, although opportunistic infections of the CNS are uncommon. In children infected during birth, encephalopathy is seen in 10% of those infected with HIV and in 23% of those diagnosed with AIDS (Navarro and Hanson, 1996). In toddlers, the presentation is that of a progressive encephalopathy with loss of developmental milestones or arrest of development. CNS pathology includes low brain weight, acquired microcephaly, inflammatory infiltrates, and calcific vasculopathy of the basal ganglia vessels. As the encephalopathy progresses, loss of fine and gross motor skills and language skills may occur and behavioral problems may develop. In older children, the clinical picture often becomes one of a static encephalopathy (Bowers et al., 1998). Seizures and focal neurologic signs are unusual and their presence should prompt a search for other causes, such as infection, stroke, or a tumor. It is important to document signs and symptoms of encephalopathy or other CNS involvement in the preoperative evaluation.

Approximately 10% to 20% of children with HIV infections have clinically significant cardiovascular involvement. Careful echocardiographic and electrocardiographic evaluations of children with HIV infections may uncover subtle abnormalities in a much higher percentage of patients (Lipshultz et al., 1989). Common abnormalities include resting sinus tachycardia, sinus

dysrhythmias, and ventricular hypertrophy. Echocardiography studies of children with HIV infection have demonstrated both left ventricular diastolic and systolic dysfunction. One center reported that 10% of children with HIV required temporary treatment for congestive heart failure, generally during an intercurrent illness (Luginbuhl et al., 1993; Keesler et al., 2001). Hepatosplenomegaly and a gallop are indications of congestive heart failure in these patients, and medical therapy has been generally effective in reversing the symptoms. In children with advanced AIDS, hemodynamic instability may occur (Evenhouse et al., 1987; Stewart et al., 1989).

Children with AIDS often have lowered counts of all the formed elements of the blood. Poor bone marrow function in these patients may be caused by the disease itself, by poor nutrition, or as a side effect of the medications used to treat the disease. As with many chronic conditions, the anemia seen in AIDS patients is often normochromic and normocytic, with low reticulocyte counts. In the preoperative evaluation of these children, other causes for anemia, such as occult bleeding, should be ruled out (Russell and Nedeljkovic, 2001). Treatment of anemia in HIV-infected children should address the cause and should include administration of erythropoietin (rh-EPO). Perioperative transfusion of RBCs should be undertaken only to provide a minimum level of oxygen delivery and after careful consideration of the possible deleterious effects in patients with HIV/AIDS (Hillyer et al., 1999). Only cytomegalovirus-negative, leukocyte-depleted RBCs should be used. Patients with HIV have a high prevalence of thrombocytopenia. The cause is sometimes difficult to determine, but both impaired production and increased destruction have been found in patients with AIDS. In addition, a lupus-type anticoagulant was found in 20% of AIDS patients undergoing routine coagulation testing (Cohen et al., 1986).

GI and nutritional problems can be common and difficult to treat in children with AIDS. Infections of the GI tract cause major morbidity and can be quite severe (Doyle and Pickering, 1990). Oral infections with *Candida* or ulcerative gingivitis are seen in children infected with HIV. Bacterial, viral, or fungal infections may cause diarrhea. With recurrent or chronic diarrhea, children develop malnutrition and failure to thrive. Growth failure in these children can result from malabsorption, poor nutrient intake, and possibly altered energy use. Hepatosplenomegaly is seen in up to 80% to 90% of children infected with HIV and is associated elevated serum aminotransferases. Coinfection with hepatitis B or C virus is more prevalent in children with HIV than in the general population. Pancreatitis can occur, usually as a complication of the drug therapy used to treat HIV or one of the opportunistic infections. Other clinical signs of HIV infection include various skin rashes such as eczema or seborrhea and manifestations of renal dysfunction such as proteinuria, hematuria, hypoalbuminemia, and edema.

Anesthesia and Procedures

Children with HIV/AIDS often undergo diagnostic bronchoscopies with bronchoalveolar lavage or biopsy, diagnostic upper and lower endoscopies, placement of gastrostomy tubes for nutritional support, and placement of central venous catheters (Birriel et al., 1991). In addition to procedures specific to their underlying systemic viral infection, these children can require anesthesia for any other routine or emergent surgical or diagnostic procedure such as myringotomy or herniorrhaphy. In the

evaluation of these children before anesthesia, the effects of the infection on organ systems as outlined above should be evaluated. The anesthesiologist should be aware of medications taken, their effects, and their side effects. In addition to medications specific for the treatment of AIDS, these children are often being treated with antibiotics and corticosteroids. Pulmonary insufficiency is often seen in patients with AIDS and despite meticulous management during the procedure, clinical deterioration commonly occurs after the procedure. During the pre-anesthetic visit, the anesthesiologist should, when indicated, discuss the possibility of postoperative intubation and ventilation. In an advanced case in which a do not resuscitate (DNR) order or other advance directive is in place, the anesthesiologist should discuss these thoroughly with the child and family (Truog et al., 1999). It may be that the person caring for the child is not a biological parent, necessitating additional administrative steps in the informed consent process.

Although the specific agents and techniques chosen for a case depend on the particular child and situation, the physician should consider several points when making those choices. CNS involvement is relatively common; therefore, CNS depressants such as barbiturates, benzodiazepines, and opioids should be carefully titrated. If liver or renal dysfunction is present, drug metabolism and elimination are impaired. Attention to sterile technique, often not a priority among anesthesiologists, is paramount in these children who are severely immunocompromised.

Pain Management

Children with HIV/AIDS may have many causes for pain and suffering independent of postoperative pain (Box 36-16) (Nedeljkovic, 2001). The anesthesiologist or pediatric pain specialist should be prepared to participate in the management of both the acute and chronic pain that afflicts these children. In one report, 59% of children with HIV described pain as having an important impact on their lives (Hirschfeld et al., 1996; Yaster and Schechter, 1996). The clinical presentations of pain and suffering in children with AIDS are varied, and the pharmacologic and nonpharmacologic treatments that may be employed are broad (Box 36-16) (Gaughan et al., 2002). Assessment is often difficult because of the nature of the discomfort and the difficulty in communicating with children who are afflicted with encephalopathy.

HIV/AIDS and Health Care Providers

Individuals who care for HIV-infected children must take prudent steps to prevent transmission (CDC, 2002). Although HIV has been isolated from saliva, the titer is generally low. Studies of hundreds of household contacts have confirmed that the risk of transmission from casual contact is nearly zero. It is therefore unlikely that operating-room personnel would contract HIV from passive contact with an child who is HIV positive. Exposures that place these health care personnel at risk for contracting HIV include needlesticks, cuts with sharp objects, and contact of mucous membranes or nonintact skin with blood, tissue, or other body fluids. The greatest risk of contracting HIV for health care workers is via needlestick with a contaminated needle. Hollow-bore needles (those used to administer medications) give a much larger inoculum of blood and infectious agent than do solid needles. Estimates of the average risk for various types of exposure are 0.3% to 0.4% after percutaneous exposure (needlestick or laceration), 0.09% after mucous membrane exposure, and less than 0.09% after exposure to nonintact skin.

After parenteral exposure to HIV, specific steps should be taken; within existing state and local laws, evaluation of the HIV status of the source of the exposure, postexposure prophylaxis, postexposure treatment, and follow-up care should occur. A health care worker who has a parenteral exposure to blood or body fluids from a child known or suspected to be infected with HIV should have the wound thoroughly washed and then irrigated with saline. Exposed mucous membranes should be thoroughly irrigated with saline. The exposure should be immediately reported to the institutional employee health service or to the "stick" team if one exists. In addition, the patient should be tested for hepatitis, which may coexist with HIV. If the source is known to be HIV positive, details of the infection (such as CD4+ count, viral-load tests, and the source's current treatment) should be gathered quickly, so that the medications for postexposure prophylaxis can be chosen. Postexposure prophylaxis should be undertaken as close to immediately after parenteral exposure to the blood or body fluid from a child suspected of having or known to have HIV (Panlilio et al., 2005). In situations in which the HIV status is not known, prophylaxis should be given on a case-by-case basis. In most cases, administration of two antiretroviral drugs is indicated. The addition of a third medication should be considered in cases with increased risk for transmission. Before prophylaxis is begun, the employee should be tested to document HIV status, with subsequent testing at 6 and 12 weeks.

A retrospective study undertaken by the CDC to determine the rate of seroconversion of health care workers in England, France, and the United States reported three conclusions: exposure to a large quantity of blood was associated with a higher rate of seroconversion; seroconversion was more likely when the exposure was from a patient in the terminal stages of AIDS; and a 79% decrease in seroconversion occurred when zidovudine was begun after exposure. Anesthesiologists should be familiar with the needlestick policies of their institutions and be prepared to follow them and advise others of the policies in the event of an exposure. Universal precautions, as recommended by the CDC, should be followed by all health care workers who have direct patient contact or exposure to a patient's body fluids (CDC, 2009).

Latex Allergy

The first published report in an American medical journal about an allergy to rubber gloves appeared in 1933 (Downing, 1933). Sporadic reports followed until the late 1980s and early 1990s, when reporting of allergic reactions to latex rose sharply. This increase is thought to have been the result of increased exposure of health care workers and patients after the publication of the Universal Precautions Guidelines by the CDC in 1987 (CDC, 1987). After 1987 the use of surgical gloves in the United States increased by a factor of 25, from 800 million to 20 billion annually. Allergic reactions to latex were first reported by pediatric anesthesiologists in 1991, before circulation of the Medical Alert (in 1991) by the FDA that warned health care workers of this emerging problem (Holzman, 1993). Latex allergy is a significant problem in health care. As of 1997, through its mandatory reporting mechanism, the FDA had received more than 2300 reports of allergic reactions involving medical products that contain latex, with 225 cases of anaphylaxis, 53 cardiac arrests, and 17 deaths. Individuals at high risk for latex allergy have certain common characteristics, which are listed in [Box 36-17](#) (Hochleitner et al., 2001; Randolph, 2001; Hourihane et al., 2002).

Many children who have had latex reactions in the operating room have had spina bifida or urinary tract anomalies (Cremer et al., 2007). These two groups, not surprisingly, undergo multiple surgical procedures, making it difficult to ascertain whether the high prevalence of latex allergy is simply the result of repeated exposure or to an immunologic response associated with specific conditions. Reactions to latex have been divided into three types: irritant contact dermatitis, type IV hypersensitivity (skin reactions similar to poison ivy), and type I, or IgE-mediated, hypersensitivity. Type I hypersensitivity is by far the more severe reaction. All 17 of the above-mentioned deaths reported to the FDA were the result of type I hypersensitivity. This type of response to latex has been reported in many clinical settings, including intraabdominal surgery, genitourinary surgery, and dental procedures. Some have reported reactions associated with airborne exposure as a result of being in the vicinity of someone donning latex-containing gloves. Manifestations of type I hypersensitivity are listed in [Box 36-18](#).

Box 36-17 Individuals at High Risk for Latex Allergy

Patients who have undergone multiple surgical procedures
 Patients with spina bifida (meningomyelocele)
 Health care personnel
 Individuals with a history of atopy
 Individuals with a history of allergy to tropical fruits

Box 36-18 Manifestations of Type I (IgE-Mediated) Hypersensitivity

Hives, urticaria, red eyes, angioedema of the eyelids
 Nasal congestion
 GI cramping, nausea, diarrhea
 Headache, anxiety
 Shortness of breath, bronchospasm, tachycardia, hypotension, anaphylaxis

Generally, intraoperative type I hypersensitivity does not occur immediately at the beginning of a surgical procedure, but rather after exposure of the peritoneum or other mucous membranes to latex. The presentation includes bronchospasm, hypoxemia, hypotension, and tachycardia. Skin manifestations, such as urticaria or flushing, may also occur. In a series of patients reported by Holzman, the mean SpO₂ fell from 100% to 92% (Holzman, 1993). Bronchospasm and hypotension are difficult to treat, even with IV epinephrine, and the manifestations may persist until the exposure is stopped.

Treatment of Intraoperative Anaphylaxis

As increasingly more latex-free medical equipment is manufactured, it is important to remain vigilant for the possibility of inadvertent latex exposure with an at-risk patient. Delay in diagnosis of an episode of latex anaphylaxis only makes treatment more difficult and likely continues exposure to the offending allergen. The mainstays of treatment are stopping the latex exposure and resuscitation. All latex must be removed from the surgical field, as well as those materials for which the latex content is unknown, and the procedure must be ended as rapidly as possible. If blood or antibiotics are being administered, this administration should be stopped. Consideration should be given to evaluating the patient for a transfusion reaction if the symptoms and signs of anaphylaxis began during blood administration. Resuscitation efforts are directed toward stabilization of vital signs and reversal of the pathophysiology of anaphylaxis. Because these reactions often occur during intraabdominal surgery, patients are often already intubated when the reaction occurs. If the patient is not intubated, strong consideration should be given to intubation. If possible, based on the progress of the surgery and the patient's vital signs, administration of anesthetic agents should be stopped. IV fluid and epinephrine doses (starting at 0.001 mg/kg) should be given to maintain blood pressure in the normal range for the patient, a Foley catheter should be placed, invasive hemodynamic monitoring should be instituted, and if bronchospasm is present, inhaled bronchodilators should be given through the ETT. If repeated doses of epinephrine are needed, as often occurs, an infusion of 0.05 to 0.1 mcg/kg per minute should be started. The patient may require treatment as outlined above for several hours, and admission to the intensive care should be arranged. A *Latex Alert* sign should be placed outside of the patient's operating room and in the intensive care unit, and the condition should be noted prominently in and on the medical record. Once the vital signs are stable, secondary treatments can be instituted, including administration of diphenhydramine, ranitidine, and hydrocortisone. Further therapy depends on the patient's condition as the resuscitation progresses.

Diagnosis of Latex Anaphylaxis

After the patient is stabilized, tests to document the diagnosis of latex allergy can be performed. Although many tests are available to confirm diagnosis, a universally accepted serum test for the diagnosis of a type I hypersensitivity reaction is not available. An elevated level of serum tryptase occurs within the first 4 hours in patients who have experienced anaphylaxis with mast-cell degranulation, regardless of the cause. The radioallergosorbent (RAST) or enzymeallergosorbent (EAST) tests are available for specific proteins. Blood should be sent for testing,

with the realization that a specific individual may or may not react to that particular protein. To determine type I hypersensitivity to latex, current practice is to use a skin prick test that employs antigen extracted from latex similar to that in medical products. Testing materials and methods have been standardized for some time (Hamilton et al., 2002). The patient should be referred to a specialist in allergy and immunology for complete evaluation. Skin testing should be delayed for 4 to 6 weeks after the episode of anaphylaxis to allow time for cellular inflammatory mediators released during the reaction to be reconstituted (Dakin and Yentis, 1998). Testing before allowing time for these proteins to be reconstituted increases the risk for false-negative results. This testing must be performed carefully and in the proper setting; severe reactions have been seen in sensitive individuals even with the minimal exposure that occurs with this test (Kelly et al., 1993). Once the diagnosis is confirmed, patients should be encouraged to wear a medical alert bracelet.

Recommendations

Avoidance of latex exposure is by far the best safeguard against the risks associated with latex sensitivity (Holzman, 1997). Although operating rooms nationwide are working toward becoming completely free of latex, 100% compliance has not yet been achieved. Avoidance, therefore, depends on recognizing those at risk for latex sensitivity (Box 36-17). Most pediatric anesthesiologists in the United States avoid latex exposure from birth in patients with meningocele because of the high prevalence of sensitivity. In some hospitals, children with bladder exstrophy are treated similarly. The preanesthetic assessment should include questions about atopy and allergies to foods, especially tropical fruits. Children thought to be at risk based on history simply should not be exposed to latex. If a child who is thought to be at risk for latex sensitivity by virtue of a medical or surgical condition denies (or the parents deny) facial redness after touching balloons or after dental care and has not undergone latex-sensitivity testing, it still seems prudent to avoid latex-containing products, especially as more and more products are manufactured to be free of latex. All equipment used by anesthesiologists can be obtained in forms that are free of latex, including IV sets and tubing, breathing circuits and breathing bags, and sterile and nonsterile gloves. Most multidose vials are made with latex-free stoppers. *Latex Alert* warning signs should be placed outside the operating room door to avoid inadvertent latex exposure in these patients. Clinicians must keep themselves informed about the progress in this area. It is important to note that not all medical equipment and products are free of latex; therefore, each new product should be checked for possible latex content. It is true that products that were formerly unsafe become safe with a change in manufacturing. However, given the high morbidity of an anaphylactic reaction, it is essential that caregivers be certain of the safety of medical products used in children at risk for latex sensitivity.

The FDA approved the marketing of a patient-examination glove that is produced from a new form of natural rubber latex made from the guayule bush, a desert plant found in the American Southwest. Available data on this glove show that individuals who are allergic to latex made from the sap of the rubber tree (*hevea brasiliensis*) do not, on first exposure, react to the guayule latex (FDA, 2008).

Prophylaxis and Desensitization

Although it is difficult to create a completely latex-free environment, the current consensus seems to be that prophylaxis of patients with known or suspected latex sensitivity need not be undertaken. Those who endorse prophylaxis propose administration of diphenhydramine, ranitidine, and corticosteroids from the preoperative through the postoperative period. The literature contains case reports of patients who developed anaphylaxis after exposure to latex despite preoperative administration of the recommended prophylactic medication (Kwittken et al., 1992; Setlock et al., 1993). Desensitization has been successful in a limited number of reported cases (Patriarca et al., 2002a, 2002b). Many of the participants in these efforts were actually health care workers with documented IgE-mediated latex allergy, but none of them had previously suffered anaphylaxis after exposure to latex. The clinical manifestations of latex allergy included asthma, angioedema, and urticaria. Although most patients were adults, one report included subjects as young as 8 years of age. Techniques used were cutaneous exposure over a 12-month period and 4-day desensitization via sublingual exposure. At this point, however, desensitization does not appear to be an option for children with type I hypersensitivity to latex. As more details of the immunologic basis for latex reactions become known, new and safer desensitization programs may be developed (Rolland and O'Hehir, 2008).

Occupational Latex Allergy

In 1998, a report of latex sensitivity among the staff of the Department of Anesthesiology at the Johns Hopkins University School of Medicine documented a 24% incidence of irritant or contact dermatitis and nearly 13% incidence of latex-specific IgE positivity, although pediatric anesthesiologists may have a somewhat lower incidence (Brown et al., 1998; Greenberg et al., 1999). A large meta-analysis of studies in health care workers showed a 0% to 30% prevalence of type I latex allergy in that group. The authors did not have data that elucidated the reasons for the large variation in prevalence (Garabrant and Schweitzer, 2002). Other reports suggest that avoidance of latex reverses the sensitivity, at least in health care workers (Zeldin et al., 1996). The creation of a latex-free operating room environment will benefit both the patients and those who care for them.

Epidermolysis Bullosa

Epidermolysis bullosa (EB) encompasses a heterogeneous group of congenital, hereditary, blistering disorders and is subdivided into three major subtypes: EB simplex, junctional EB, and dystrophic EB. These types differ in histology, clinical severity, and mode of inheritance, but all are characterized by the easy development of blisters after minor trauma or friction. The literature contains several reviews of the perioperative and anesthetic care of children with one of the variants of EB (Tetzlaff and Fleisher, 2005; Lin and Golianu, 2006; Lindemeyer et al., 2009). Junctional EB is often clinically apparent early in life and heals with scarring. A discriminating feature of this variant is the relative sparing of the hands and feet. However, involvement of the mucous membranes may be severe, and ulceration of the respiratory epithelium has been documented. The recessive variant of dystrophic EB may be the most severe

form of the condition, in which mucous membrane lesions are common. Treatment of children with this condition is supportive. Infections are common and should be promptly treated. Adequate nutrition is paramount but often difficult to provide in cases with esophageal blisters with subsequent stricture formation. Children with the more severe forms may come to the operating room for a variety of procedures such as scar revisions, corrections of digital fusions, placement of gastrostomy tubes, or even colonic interpositions.

Anesthetic Management

The preanesthetic evaluation of a child with EB should involve the patient's dermatologist and pediatrician, who can advise the anesthesiologist of the child's general course with regard to blistering, skin infections, nutritional status, and the possible usefulness of additional steroid administration. In addition to assessing the child's general condition and health, the physical examination should focus on the airway (that may be compromised by scarring around the mouth), IV access sites, and the location and condition of existing and recent blisters.

Friction and, secondarily, pressure must be avoided in caring for children with this condition in the perioperative period. Monitoring must adhere to the ASA standards, but the application of the monitors should be modified. Pulse oximetry may be accomplished with an adult clip-on probe (that may be impossible if the patient has complete pseudosyndactyly of the fingers and toes), or the adhesive strip oximeter probe may be placed over a clear plastic bag covering the hand or foot that is then wrapped with Webril or Coban (3M; Saint Paul, Minnesota) (Fig. 36-21). The precordial stethoscopes should simply be placed (without adhesive) onto the chest; temperature should be monitored with an axillary probe; soft padding should be placed between the skin and noninvasive blood pressure cuffs; electrocardiograph leads should be nonadhesive (e.g., needle electrodes); and IV and arterial catheters should be sutured and lightly covered with a gauze bandage (e.g., Webril or Coban). A nonadhesive, silicone-based dressing (Mepilex; Mölnlycke Health Care AB, Göteborg, Sweden) that is used for protecting blistered areas in these patients has recently become available. It has been found to be useful for securing venous and arterial catheters, holding precordial stethoscopes in place, and facilitating contact

of electrocardiograph gel pads in which the adhesive has been removed (Figs. 36-22, 36-23, and 36-24). It can also be used to cover the contact surfaces of the anesthesia mask to substitute for the previous practice of coating the mask surface with steroid ointment, which creates a slippery environment for subsequent handling of the patient. The eyes should be lubricated but not taped closed with adhesive tape. (Mepilex may be used.)

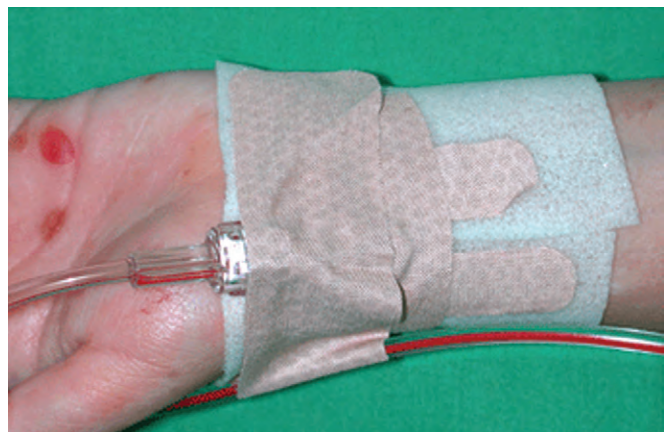

A variety of techniques for anesthetic induction and maintenance have been reported for procedures performed on these challenging patients (Holzman et al., 1987; Farber et al., 1995; Herod et al., 2002; Lindemeyer et al., 2009). An oral premedication may be useful in children with EB who are taken to the operating room, because a struggling child who is restrained may develop blisters where held by the operating team. Alternatively, intramuscular ketamine has been used to both induce and maintain anesthesia in these patients (Ames et al., 1999). The

■ **FIGURE 36-22.** The IV cannula and tubing are held in place with a strip of Mepilex transfer.

■ **FIGURE 36-21.** A thin plastic bag is placed over the digit; the adhesive pulse oximeter probe is then placed over the plastic bag. The extremity is then wrapped with Webril to keep the pulse oximeter bag assembly in place.

■ **FIGURE 36-23.** An arterial cannula and tubing are held in place with Mepilex transfer strips on the skin and adhesive tape applied to the Mepilex transfer.

■ **FIGURE 36-24.** Adhesive is trimmed from the contact area of infant electrocardiograph pads. Contacts consisting only of gel and wire are secured to patient with strips of Mepilex transfer.

induction technique chosen depends on the preoperative assessment and the planned procedure. The induction of general anesthesia can be via an inhalational technique, but contact with the child's face must be gentle. Oropharyngeal airways should be avoided. Laryngoscopy with a straight blade without contact with the epiglottis is preferred, and intubation with a smaller-than-predicted, softened (in warm, sterile saline), lubricated ETT after administration of muscle relaxant will minimize trauma to the oral, supraglottic, and tracheal mucosa. Most physicians recommend securing the tube with umbilical tape tied around the back of the head. If there are no contraindications, a deep extubation decreases tracheal trauma caused by coughing. Cases of postoperative bullae in the pharynx, some of which caused airway obstruction, have been reported, but predisposing factors are difficult to identify (James and Wark, 1982). Most series report no airway complications despite the formation of new oral bullae.

Limited mouth opening in many patients with EB necessitates fiberoptic nasotracheal intubation. This route is a good choice for all patients with EB—even those with adequate mouth opening—because oral intubation causes more trauma and bulla formation to the tongue and oral mucosa because of pressure of the laryngoscope on the supraglottic area (Baum and O'Flaherty, 2006). The nasal mucosa is composed of pseudostratified cylindrical ciliated epithelium with goblet cells (i.e., respiratory epithelium), stratified cuboidal epithelium, and stratified squamous nonkeratinized epithelium. The first two types of epithelium are less vulnerable to bulla formation than the latter two, which comprise the epithelium of the oral mucosa. In addition, the nasotracheal tube may be secured more easily without tape than an oral tube (Fig. 36-25). Care should be taken to use a tube small enough to avoid pressure on the skin surface at the entrance to the naris. As is customary for

■ **FIGURE 36-25.** A nasal ETT is secured to a head wrap. No adhesive is applied to the face.

nasal intubation, the nare should be prepared with lubrication and vasoconstriction (e.g., oxymetazoline 0.05% or phenylephrine 0.25%), and the tube should be softened as described.

Oral rehabilitation procedures, commonly required by EB patients because of the inability to brush their teeth, are more easily accomplished with a nasotracheal tube (Griffin and Mayou, 1993). Some clinicians have recommended nasal intubation (with fiberoptic guidance) to eliminate the trauma and friction of direct laryngoscopy. It is also thought that the passage of the tube is not as traumatic and the nasopharyngeal mucosa is not as vulnerable to bulla formation as is the oral, gingival, and supraglottic mucosa, especially with the pressure of a laryngoscope blade. In addition, a nasal tube can be secured to a head-wrap dressing, eliminating the need for any ties that may abrade the face. The decision to admit these children after the procedure must be made on an individual basis. However, they warrant careful observation in a well-monitored environment after surgery and anesthesia. Even though general anesthesia is used often in these patients, reports of successful regional techniques have been published (Kaplan and Strauch, 1987; Cakmakkaya et al., 2008; Nasr et al., 2008).

Down Syndrome

The incidence of Trisomy 21 is 1 in 600 to 800 live births. More than half of Trisomy conceptions spontaneously abort early in pregnancy. The syndrome has many clinical manifestations, some of which are of particular note to the anesthesiologist.

Approximately 40% of children with Trisomy 21 have anomalies of the cardiovascular system. The three most common anomalies seen in these children are complete atrioventricular canal (CAVC) (comprising approximately 40% of the total), ventricular septal defect (25%), and atrial septal defect (10% to 15%). Children with Down syndrome who undergo repair of CAVC have significantly higher perioperative mortality than those without Trisomy 21. However, the outcome after surgery

is not different for other cardiac anomalies. These defects have in common the propensity for increased pulmonary blood flow, which the anesthetic management should plan to minimize. Repair or palliation of a cardiac defect does not eliminate the need for particular attention to the cardiovascular system in the evaluation of these patients preoperatively.

Children with Down syndrome have varying degrees of mental retardation, and it is important to be aware of the degree of intellectual impairment when meeting and talking with them. Hypotonia is one of the most common clinical features seen in these children, and it may affect the patency of their upper airways. The relatively large tongue, short neck, and crowded midface and laryngomalacia contribute to upper airway obstruction (Kanamori et al., 2000; Mitchell et al., 2003). Partial airway obstruction, while awake and during sleep, is often seen in children with Trisomy 21. This situation is exacerbated by the administration of sedatives and during inhalation induction (Luscari and Tobias, 2006; Ng et al., 2006). Children with Trisomy 21 have an increased incidence of subglottic stenosis, and often the proper size of ETT for a given child is smaller than would have been predicted. The incidence of tracheal stenosis is also significant because of complete tracheal rings. An orthopedic anomaly of great concern in these children is ligamentous laxity of the atlantoaxial joint, which may predispose affected individuals to C₁-C₂ subluxation and possible spinal cord damage. The incidence of this anomaly is 12% to 32%, depending on the ages of the children studied and the exact definition of laxity used (Hata and Todd, 2005; Pizzutillo and Herman, 2005). The incidence of hearing loss and of hypothyroidism is increased in these children (Tuysuz and Beker, 2001). Other associated findings in patients with Down syndrome are included in [Box 36-19](#).

Perioperative Management

The preoperative evaluation of a child with Down syndrome should give particular attention to the organ systems commonly affected by this condition (Mitchell et al., 1995). The history of prior surgeries should be reviewed. These children may have undergone cardiac procedures, removal of the tonsils and adenoids, myringotomy tube placement, and other common pediatric procedures. Records from other doctors may contain helpful information about associated conditions such as obstructive sleep apnea syndrome, atlantoaxial laxity, or subluxation. Management of these children regarding possible C₁-C₂ subluxation is a difficult matter. The American Academy of Pediatrics (AAP) has published statements by the AAP Committee on Genetics and AAP Committee on Sports Medicine and Fitness that include a discussion of this clinical problem. The Committee on Genetics policy statement on health care supervision of children with Down syndrome recommends that radiographs looking for evidence of atlantoaxial instability or subluxation be obtained at between 3 and 5 years of age (AAP Committee on Genetics, 2001). The Committee on Sports Medicine and Fitness reviewed the topic of atlantoaxial instability in Down syndrome in a 1995 publication and tentatively concluded that lateral plain films are of potential but unproved value in detecting patients at risk for developing spinal cord injury during participation in sports (AAP Committee on Sports Medicine and Fitness, 1995). The Special Olympics does not plan to remove its requirement that all athletes with Down syndrome receive lateral spine radiographs (Special Olympics,

1983). Some conclusions can be drawn from the published case reports summarized in the AAP Committee on Sports Medicine Subject Review and the recommendations cited above.

The preoperative history and physical examination should include a careful search for evidence of cervical instability. Of course, the parent should be questioned about past cervical x-rays, if they were taken. The family and patient should be questioned about the occurrence of any type of neck pain, limitation of neck mobility, tortocollis, head tilt, abnormalities of gait, or other signs of upper motor neuron dysfunction. The examination should also look for spasticity, hyperreflexia, extensor-plantar reflex, or clonus. If the history and physical examination reveal problems or the cervical radiographs show an atlantodens interval of greater than 5 mm, the child's elective surgery should be delayed and neurosurgical consultation sought (Hata and Todd, 2005). If the child had previous negative radiographs and the history and physical do not suggest a problem, it is not clear whether the films should be repeated (Pueschel, 1998).

Although the incidence of worsening of the atlantodens interval over time is low, some patients do show progression. Even in asymptomatic patients, the possibility exists that a postoperative neurologic disability may occur (Williams et al., 1987; Litman and Perkins, 1994). Whatever the result of the evaluations, if surgery and anesthesia are undertaken, the general consensus is that the heads and necks of these patients should be kept in the neutral position throughout the perioperative period. A reassuring study of children with Down syndrome with normal cervical radiographs who underwent tonsillectomy and adenoidectomy in the usual position showed no changes in the latency or amplitude of the somatosensory potentials (Abramson et al., 1995). Atlantoaxial instability occurs in conditions other than Down syndrome and at a higher rate (Box 36-20).

GENETIC MUSCLE DISORDERS

The last decade has seen a tremendous increase in genetic and genomics research, which has allowed researchers to reach a clearer picture of the molecular causes of genetic-based muscle diseases. In most cases, identification of the proteins altered in the disease states has added to the understanding of the development of muscle and the neuromuscular junction, and the anesthetic management suggested for these diseases and syndromes is beginning to be modified as a result of this knowledge. This section contains a review of what is presently known concerning the molecular nature of diseases of the neuromuscular system and their clinical presentations. A general overview of the generation of muscle contraction in a normal cell (Fig. 36-26) is followed by a discussion of recent molecular and genetic studies that involve the major muscle diseases, because knowledge of their results may be of use to the clinician in the near future.

General Overview

The genetic muscle diseases can be divided into 4 broad categories—muscular dystrophies, myotonic syndromes, mitochondrial myopathies, and myasthenic syndromes. To these,

■ **FIGURE 36-26.** Schematic diagram of the muscle cell and motor neuron. An action potential (AP), generated in the membrane of the muscle by sodium influx through voltage-gated sodium channels, travels down the motor neuron, causing the release of acetylcholine at the synapse. It travels along the membrane and down the transverse tubules. There it causes the influx of calcium at the base of the tubules (through the dihydropyridine receptor). The small calcium currents trigger release of larger amounts of calcium (through the ryanodine receptor) from the sarcoplasmic reticulum into the matrix of the muscle cell, activating the actin-myosin filaments to contract. The filaments attach (not shown) to the surface of the cell and the extracellular matrix to cause effective mechanical contraction (see Fig. 36-27, D).

malignant hyperthermia (MH) must be added as a separate category, though some overlap between MH and the other diseases does exist (see Chapter 37, Malignant Hyperthermia). Of course, a few muscle diseases do not easily fit into these groupings. Each of these categories is discussed separately and related to the MH syndrome where possible. The general locations in the muscle cell of the molecular changes that lead to these classes of disease are shown in Figure 36-27. The syndromes are caused by changes listed below:

- The myasthenic syndromes affect transmission of the action potential (AP) from the motor neuron to the muscle cell; this involves a disruption of the signal carried by the neurotransmitter, acetylcholine, at the synapse (see Fig. 36-27, A).
- Myotonic syndromes affect transmission of the AP along the muscle membrane and are caused by abnormalities in sodium, chloride, potassium, or calcium channels (see Fig. 36-27, B). These changes cause a prolonged depolarization of the muscle membrane, which leads to prolonged contraction of the muscle.
- Mitochondrial myopathies are (as their name implies) caused by abnormalities in mitochondrial function. Because mitochondria are important for supplying ATP in most tissues (most importantly nerve and muscle), the symptoms often involve the nervous system and muscle (see Fig. 36-27, C). The lack of ATP in muscle leads primarily to weakness and wasting of muscle. Mitochondria are also important in triggering cell death, or apoptosis; therefore, mitochondrial diseases may also lead to muscle wasting via this mechanism.

Box 36-20 Conditions Associated with Atlantoaxial Dislocation

Congenital abnormalities
Trisomy 21
Klippel-Feil syndrome
Larsen syndrome
Mucopolysaccharidoses
Spondyloepiphyseal dysplasia
Metatropic dwarfism
Kniest syndrome
Chondrodysplasia punctata
22q syndrome
Infection
Pharyngeal
Tumors
Trauma
Postoperative complications (especially after airway surgery)
Arthritis
Rheumatoid
Ankylosing spondylitis

■ **FIGURE 36-27.** Detail of Figure 36-26 that shows the main areas of defects that lead to muscle disease. **A**, Disruption of the signal across the synapse leads to myasthenic syndromes. **B**, Defects in the calcium, potassium, and sodium channels in the muscle cell membrane give rise to myotonias. The membranes remain depolarized too long, causing the inability to relax. **C**, Mitochondrial dysfunction leads to decreased intracellular levels of ATP and to cell death. The decreased ATP concentration is responsible for the inability of the muscles to contract strongly and for insufficient reuptake of calcium into the sarcoplasmic reticulum. The latter effect may lead to inability to relax under certain circumstances. **D**, Defects in the attachment of the actin-myosin filaments to the cell surface and extracellular matrix produce muscular dystrophies. These attachments are important for mechanical force and for organizing and stabilizing the membrane.

- Muscular dystrophies result from the dissociation of contractile force from the muscle to the surrounding connective tissue. The actin-myosin filaments contract, but they are no longer connected well to the cell membrane or the surrounding tissue. As a result, the equivalent of electromechanical dissociation occurs; i.e., the electrical signal is not translated into effective mechanical force (see Fig. 36-27, *D*). In addition, the membrane defects cause instability in the cell membrane integrity that may result in deleterious responses to anesthetic agents.

The dotted circles in each panel of Figure 36-27 indicate the locations of the molecular changes. It is important to note that this figure is an oversimplification, but it gives the general pattern of the molecular causes of the syndromes.

Skeletal muscle contraction is accomplished by the generation of a neuronal AP that terminates at the neuromuscular synapse (see Fig. 36-26). The neuronal AP stimulates sodium channels in the neuronal axon that propagate the signal along the axon. As the AP reaches the end of the axon, voltage-gated calcium channels are activated that allow the influx of calcium

into the neuron. This influx of calcium, in turn, stimulates the release of a neurotransmitter, acetylcholine, from the nerve terminal into the synapse. The acetylcholine binds to receptors on the cell surface of the postsynaptic cell—the muscle, in this case. Binding of the acetylcholine to its receptors allows influx of sodium into the muscle and generates a new AP, which propagates a transmembrane signal that spreads along the membrane of the cell.

The AP is carried from the cell surface into the interior of the cell by a series of invaginations of the cell membrane known as *T tubules*. These structures allow for transmembrane electrical depolarizations to be carried deeply within the cell, where they would otherwise not be generated. At the ends of the T tubules, the sodium currents are again replaced by calcium currents, resulting from the activation of a voltage-gated calcium channel known as the *dihydropyridine receptor* (Fig. 36-28). These calcium currents, in their turn, stimulate larger calcium release from the sarcoplasmic reticulum through a calcium-sensitive calcium channel called the *ryanodine receptor*. These larger fluxes of calcium stimulate movement of the

■ **FIGURE 36-28.** Further detail of the region of the T tubules. Sodium, potassium, and calcium channels on the cell surface are responsible for propagation of the AP along the cell membrane and into the T tubules. When the AP reaches the terminus of the T tubule, the sodium currents are replaced by calcium currents through the voltage-gated dihydropyridine receptor. These calcium currents trigger release of calcium through the ryanodine receptor from the large calcium stores in the sarcoplasmic reticulum.

actin-myosin filaments, an ATP-requiring step (and therefore dependent on functioning mitochondria). The filaments are attached to the surface of the muscle and the surrounding matrix through a variety of proteins, most notably, *dystrophin*. Movement of the filaments is transduced into shortening of the cell (muscle contraction) by the connection to the cell surface and surrounding matrix. Relaxation is accomplished by reuptake of the intracellular calcium primarily back into the sarcoplasmic reticulum. This reuptake is energy requiring and dependent on mitochondrial function, ATP generation, and ATP-dependent calcium pumps. Loss of this energy source is the cause of rigor mortis.

The normal flow of electrical signal transduced to mechanical force can be disrupted at many places. Anesthesiologists often inhibit the transmission of the signal across the neuromuscular junction with the use of neuromuscular blockers (NMBs) such as vecuronium. Such an effect is conceptually similar to a myasthenic syndrome. Local anesthetics applied to the motor neuron inhibit the propagation of an AP along the neuron, resulting in decreased release of neurotransmitters. In this manner, they also mimic the effect of myasthenia. The use of local anesthetics directly on muscle blocks voltage-gated sodium channels in the muscle membrane, with the resulting inhibition of AP propagation, acting in the opposite manner to the changes seen in myotonic syndromes. Volatile anesthetics are also inhibitors of the voltage-gated membrane channels (e.g., sodium, potassium, and calcium) and thus also act in a manner opposite to that seen in myotonia. However, these drugs also inhibit mitochondria and are capable of causing a relaxation effect in a manner similar to a mitochondrial myopathy. These examples are given only to further acquaint the anesthetist with the underlying causes of the myopathies; drugs certainly do not cause these diseases. However, these similar effects help explain the interaction of the drugs with the disease states.

Myasthenic Syndromes

Myasthenic syndromes are the result of the failure of transmission of the signal from the terminal of a motor neuron to the muscle innervated by the neuron. Most myasthenic syndromes are the result of immune responses against components of the neuromuscular junction (primarily the postsynaptic acetylcholine receptors) and are not classic genetic diseases. The symptoms result from decreased neurotransmission across the neuromuscular junction, and task-specific fatigue is the hallmark of these diseases (see Fig. 36-27, A). The well-known disease *myasthenia gravis* (MG) is an example of such a disorder, although it is primarily a disease of adulthood. MG can occur in the neonatal period because of placental transfer of maternal antibodies. In addition, juvenile-onset MG is seen in association with thymoma (Kiran et al., 2000).

Congenital myasthenic syndromes (CMSs) are genetic in origin, and analyses have identified more than ten different genes that are important in development of the neuromuscular synapse (Palace and Beeson, 2008). Rarely, inherited disorders of neuromuscular transmission (CMSs), can result from acetylcholine receptor mutations or other mutations that involve the release of acetylcholine. Included in this group are familial infantile myasthenia, familial limb-girdle myasthenia, endplate acetylcholinesterase deficiency, and syndromes with altered or deficient acetylcholine receptors (Menold et al., 1998; Maselli et al., 2001). In addition, CMS may result from defects in development of the synapse. One such form of congenital myasthenia is caused by a defect in the gene *DOK7*, which is important in the formation or maintenance of synaptic structure (Müller et al., 2007). These genetic diseases mimic MG in their presentation and implications for anesthesia, and they manifest during infancy or childhood (Dalal et al., 1972).

Anesthetic Considerations for Myasthenic Syndromes

The primary concern during the perioperative period for patients with myasthenic syndromes is to avoid respiratory compromise from weakened respiratory muscles or upper airway muscles (Brown et al., 1990; Abel and Eisenkraft, 2002). For this reason, nondepolarizing muscle relaxants are used sparingly, if at all, in these patients. As a result of the blockade and destruction of acetylcholine receptors, patients with MG or myasthenic syndromes are often resistant to succinylcholine (Baraka, 2001). It is important to remember that patients can appear strong on awakening only to become fatigued later in the recovery period. Itoh and others (2002) showed that seronegativity for the antiacetylcholine receptor antibody did not predict a normal response to muscle relaxants. In particular, patients with MG who were successfully treated with thymectomy may also retain a high sensitivity to muscle relaxants. The conclusion of these reports is that the anesthetist must presume a high sensitivity to muscle relaxants in all patients with myasthenic syndromes, even if they are functioning well after medical or surgical treatment.

Techniques that employ a variety of short-acting anesthetics without the addition of muscle relaxants have been very successful (Della Rocca et al., 2003; Bouaggad et al., 2005). Others have reported encouraging results after use of regional anesthesia in these patients (Caliskan et al., 2008). However, one report cautions that even with a stable anesthetic, tourniquet release may trigger an exacerbation of symptoms (Brodsky and Smith, 2007).

Myotonias

Myotonia is a temporary involuntary contraction of muscle fibers caused by transient hyperexcitability of the surface membrane (Miller, 1989; Bernard and Shevell, 2008). The persistent contracture of the skeletal muscle generally occurs after muscle stimulation but may be triggered by other stimuli such as cold, pain, or stress. A classic finding in patients with myotonia is the inability to easily relax after a firm handshake. Myotonias can be subdivided into 2 general groups — dystrophic and nondystrophic. The dystrophic group (represented by myotonic dystrophy [DM]) shows a progressive wasting of muscle mass and strength; the nondystrophic group does not show such progressive changes.

In general, the myotonias may be thought of as a family of channelopathies that mostly affect muscle (Jurkat-Rott et al., 2002; Rosenbaum and Miller, 2002; Bernard and Shevell, 2008). The abnormalities in the channels lead to prolonged depolarization in the membrane once an AP is generated (Fig. 36-28). This in turn leads to prolonged or increased release of calcium into the cell, resulting in prolonged contraction. Two forms of myotonia (myotonia congenita and Becker disease) result from defects in the same skeletal muscle chloride channel (termed *CLC1*) (Jurkat-Rott et al., 2002; Pusch, 2002; Renner and Ptacek, 2002). Myotonia congenita (Thomsen disease) is an autosomal-dominant disease that manifests in childhood and is associated with a normal life expectancy and minimal symptoms (Grunnet et al., 2003). Becker disease, not to be confused with Becker muscular dystrophy (BMD), is an autosomal recessive form of this channelopathy that also appears in childhood (Pusch, 2002). In addition, some mutations in this chloride channel cause a variant of dominant myotonia with a milder phenotype, myotonia levior (Ryan et al., 2002; Farbu et al., 2003). These myotonic diseases are nonprogressive and do not have a dystrophic component (i.e., the muscle does not deteriorate over time). Other less severe myotonias result from abnormalities in sodium or potassium channels on the muscle cell membrane. These include paramyotonia congenita (sodium channel), hyperkalemic periodic paralysis (sodium channel), and hypokalemic periodic paralysis (calcium, sodium, or potassium channel) (Jurkat-Rott et al., 2002).

As noted above, myotonic contractions may be precipitated by stress, cold, and pain. Thus, these triggering factors must be aggressively avoided in this population during the perioperative period. Regional anesthesia and NMBs do not reverse the contractions, because they act upstream from the molecular causes of the syndrome (compare Fig. 36-27, A and B). However, succinylcholine has been noted to precipitate contractions, as have anticholinesterases when used for NMB reversal. These contractions have been most notable in the occurrence of masseter spasm after the use of succinylcholine but can also involve other muscles and lead to extreme difficulty with positive pressure ventilation and intubation (Farbu et al., 2003). For these reasons, the use of succinylcholine is discouraged in patients with myotonia. If an episode of myotonia occurs during anesthesia, volatile anesthetics, quinine, or procainamide can be used for relaxation. If a myotonic episode occurs in patients with periodic paralysis, use of the carbonic anhydrase inhibitor dichlorophenamide has been shown to be useful (Cleland and Griggs, 2008). In that the myotonias occur as the result of abnormal ion channels, great care must be taken to keep electrolytes normal at all times. Whereas myotonic syndromes may have symptoms

in common with MH, they are not associated with true MH (see Chapter 37, Malignant Hyperthermia).

Steinert muscular dystrophy (DM) is the most common form of myotonia (Anderson and Brown, 1989). This disease is a form of muscular dystrophy and includes congenital DM. It is discussed here rather than with other muscular dystrophies, because its presentation is different—it more closely resembles the myotonias.

DM was shown to actually include two different molecular diseases (Ranum and Day, 2002). DM type 1 (DM1) results from alterations in the human dystrophin myotonia-protein kinase gene (DMPK), leading to an increase in unstable CTG repeats in the 3' untranslated region of the DMPK gene (Amack and Mahadevan, 2004; Botta et al., 2008; Orenco et al., 2008). DMPK codes for a serine-threonine protein kinase. The changes in DMPK lead to abnormal splicing of the message for the calcium channel protein CLCN1, with resulting defects in function of the channel (Lueck et al., 2007). The myotonia may then result from defects in calcium channels, resulting in altered transmembrane potentials in muscle (Kaliman and Llagostera, 2008). However, others have suggested that the myotonia is probably the result of abnormal phosphorylation of sodium channels, resulting in delayed inactivation after channel opening (Lee et al., 2003). The precise mechanisms by which this mutation causes the changes in muscle function are not yet clear, but they appear to involve several pathways (Dansithong et al., 2008). As noted above, the changes in the protein kinase gene are in the promoter or starting region of the gene and are the result of duplications in short repetitive sequences (CTG triplets). The number of repetitive sequences is often increased in the offspring compared with an affected parent. As a result, each successive generation tends to exhibit a more severe form of the disease.

DM type 2, or DM2, has a clinically diverse presentation, including myotonia, proximal muscle wasting, and endocrine, cardiac, and cerebral abnormalities. It results from expansion of a similar sequence in an intron of a gene; however, the gene is separate from the one that causes DM1 and codes for a probable transcription factor, ZFN9 (Liquori et al., 2001; Finsterer, 2002; Liquori et al., 2003). The precise physiologic changes that lead to myotonic or dystrophic changes are not known. In both disease states, the abnormalities result from abnormal RNA species that disrupt normal development of the cells (Mankodi and Thornton, 2002).

Anesthetic Considerations for Myotonias

Attainment of muscle relaxation can be difficult in these patients. As with the other forms of myotonia discussed previously, cold, stress, pain, and succinylcholine can precipitate myotonia. Additionally, because this is a dystrophy with muscle wasting, succinylcholine can elicit a hyperkalemic response and should be avoided. Unlike the other myotonias, DM leads to deterioration of the muscle fibers and is associated with weakness and hypotonia in the infant and child. Paradoxically, however, these patients can still experience a myotonic episode as well. They can have profound respiratory depression, severe cardiac conduction abnormalities, cardiomyopathy, developmental delay, dysphagia, and decreased gastric motility. Muscle relaxants must be used with great care, if at all, in these patients. Smaller doses are probably indicated, and an NMB monitor is advised. As with nondystrophic myotonias, reversal agents may induce myotonic episodes.

Because respiratory muscle weakness is notable in these patients, the respiratory status is potentially fragile when any narcotic or general anesthetic is used. Thus, their care presents challenges involving several physiologic systems. White and Bass (2003) presented a thoughtful review of the anesthetic care of patients with DM. DM is also commonly thought to be associated with MH. However, as with the myotonias discussed above, although this syndrome shares features with MH, it is not associated with true MH (see Chapter 37, Malignant Hyperthermia).

Mitochondrial Myopathies

Mitochondrial dysfunction is being recognized as the cause of an increasingly large list of disease syndromes. The more commonly seen mitochondrial syndromes are Leigh disease, Kearns-Sayre syndrome, and Leber hereditary optic neuropathy. However, mitochondrial dysfunction is also associated with unnamed myopathies and encephalopathies and with symptoms of failure to thrive. Mitochondrial abnormalities have been shown to be involved with some forms of autism and Parkinson's disease (Shoffner et al., 1991; Schaefer et al., 2004). It is clear that the presentation of mitochondrial disease may be quite varied.

Mitochondria are the principal source of energy metabolism within cells, especially those of nerve and muscle (see Fig. 36-27, C). Within mitochondria reside the enzymes responsible for the Krebs cycle, fatty acid β oxidation, and most importantly, oxidative phosphorylation (Fig. 36-29). Mitochondria contain the enzymes that metabolize glucose, fatty acids, and amino acids to generate NADH and succinate, which in turn, are used as electron donors for the electron transport chain (ETC). By passing electrons down the ETC (complexes I to IV), a proton gradient is generated across the

mitochondrial inner membrane and electrons are donated to oxygen to generate water. The proton gradient is then used to drive an ATP synthase (complex V). The coupling of electron transfer to phosphorylation is known as *oxidative phosphorylation* and is overwhelmingly the major source of ATP and other high-energy phosphate bonds that supply energy to the cell.

Mitochondrial complexes are composed of groups of proteins, ranging from just a few (complex II) to over 40 (complex I). In addition, the dehydrogenases, membrane transporters, and structural proteins raise the number of functional proteins in the mitochondria into the hundreds. Genes in the cell's chromosomes encode for most of the proteins of the ETC, whereas mitochondrial DNA encodes a minority of the ETC proteins. The other enzymes in the mitochondria are entirely encoded by the nuclear genome. The genetics of mitochondrial disease are complicated by the fact that mitochondria are inherited from the mother. However, different populations of the maternal mitochondria may be passed to different offspring, so the inheritance pattern can be quite varied. Finally, mitochondrial dysfunction has effects other than energy depletion. Increased free radical damage to other cellular components and alterations in protein phosphorylation may be seen with mitochondrial disease. Each of these effects can give rise to mixed but wide-ranging functional changes in affected individuals.

It is a common mistake to group all mitochondrial diseases together as similar entities; however, mutations in any of the mitochondrial proteins may result in dramatically different functional changes. In addition, mitochondria in different tissues can be quite varied in their activity. The differences between tissues in sensitivity to abnormalities of mitochondrial function (and the varied inheritance pattern discussed previously) give rise to different symptoms even within members of a family who carry the identical mutation. Because of this variability, it is dangerous to imply that because an anesthetic

FIGURE 36-29. ETC of mitochondria. Substrates for the ETC are transported into the mitochondria (light blue arrow) and NADH, or succinate, is generated via the Krebs cycle. NADH donates electrons to the ETC at complex I; they then follow the path indicated by the dark blue arrows. Succinate donates electrons to complex II; they follow the path indicated by the red arrows. Once the electrons reach complex III, their paths are functionally the same (gray arrow). Protons are pumped into the intermembrane space (green arrows) to generate a transmembrane gradient. The protons then leak back into the matrix through complex V to generate the energy to drive the ATPase (red oval). DHQ and TMPD/ascorbate are indicated and are artificial electron donors that can be used experimentally to drive complexes III and IV, respectively. DHQ, Dihydroquinidine; TMPD, tetramethyl-p phenylenediamine.

technique was successful in a few patients with mitochondrial disease, the technique is safe for all patients with mitochondrial dysfunction.

Muscle and nerve cells are uniquely dependent on the energy delivered by the mitochondria. Mutations in mitochondrial proteins are responsible for striking clinical features in those two tissues, including myopathy, cardiomyopathy, encephalopathy, seizures, and cerebellar ataxia. Of course, cardiac muscle and the CNS are also the two main targets of general anesthetics. Thus, particular care must be taken when exposing such a patient to these agents. As motor neurons may be affected, a hyperkalemic response to succinylcholine may be seen. Lastly, MH is thought to be associated with some forms of mitochondrial myopathies, but the nature of this relationship is unclear (Keyes et al., 1996; Fricker et al., 2002).

Anesthetic Considerations for Mitochondrial Myopathies

The perioperative period is a time during which a patient may be exposed to periods of stress. Under conditions of stress, ATP levels may be inadequate to meet demand. Shivering caused by hypothermia probably represents the greatest threat to these patients. However, hyperthermia and stress from untreated pain also represent serious risks. The failure of ATP production to meet metabolic demands inevitably leads to lactic acidosis, often of profound significance. To avoid such problems, great care must be taken to keep patients normothermic during surgical cases and to provide adequate treatment for postoperative pain. Postoperative pain represents a particularly troublesome problem, because narcotics can further compromise respiratory status.

Mitochondrial patients may become acidotic, caused by high levels of lactate as a result of hypovolemia. Prolonged preoperative fasting should be avoided in these patients. If fasting is necessary, IV fluids should be started with glucose added to avoid anaerobic metabolism. As cyanide inhibits the respiratory chain, sodium nitroprusside should probably be avoided. For similar reasons, tourniquets should be avoided if possible. It is not clear what hematocrit value is adequate in these patients, but it is probably wise to maintain hematocrit at closer to normal levels than at the reduced levels allowed in other patients. Lastly, whereas mild levels of hypotension are commonly used in many patients to avoid blood loss, such an approach is less desirable in patients with mitochondrial disease. These patients are probably less able to compensate for decreased oxygen delivery.

Essentially, every general anesthetic studied has been shown to depress mitochondrial function. The most notable of these are the volatile anesthetics and propofol. It is often said that these agents only depress mitochondria at doses higher than their clinical concentrations. However, Miro and colleagues (1999) showed that even at doses commonly used in the operating room, anesthetics cause a significant depression of mitochondria in normal patients. Studies in model organisms have shown that when complex I is abnormal, sensitivity to volatile anesthetics is markedly increased (Kayser et al., 1999). Case reports have also indicated that some children exhibit an increased sensitivity to sevoflurane (Morgan et al., 2002). In addition, a strong clinical impression exists that children with mitochondrial myopathies have an increased risk during surgery (Morgan et al., 2002; Bolton et al., 2003; Farag et al., 2005). Because metabolism is altered in patients with mitochondrial

disease, the abilities of the cell to generate ATP and to effectively use oxygen are diminished, and exposure to anesthetics may represent an increased risk compared with other patients (Bolton et al., 2003). In contrast, others have found in retrospective studies that patients with mitochondrial defects did not appear to have an increased rate of perioperative complications (Driessen et al., 2007). Clearly, a prospective study is warranted to resolve these concerns. The use of regional anesthetics should be considered if appropriate for the case. However, it has also been noted that mitochondria are the probable target for the cardiac complications of bupivacaine; thus, patients with mitochondrial myopathies may be at increased risk with this drug as well (Weinberg et al., 2000).

From an anesthesiologist's point of view, the primary complications of mitochondrial myopathies include respiratory failure, impairment of myocardial function, conduction defects, and dysphagia. Each of the volatile anesthetics depresses respiration, though to varying degrees. Isoflurane and desflurane depress the ventilatory response to CO₂ more than does sevoflurane. In addition, isoflurane and desflurane cause more direct muscle relaxation. Thus, from this standpoint, sevoflurane would seem to be advantageous. However, isoflurane and desflurane are noted for their ability to maintain cardiac output to a greater degree than does sevoflurane (Weiskopf, 1995; Lowe et al., 1996). In short, each of the volatile anesthetics presently in use is capable of interacting negatively with a mitochondrial myopathy. Fortunately, patients may be supported during the perioperative period to avoid the theoretic or real side effects of these drugs. The volatile anesthetics do not require metabolism for excretion; rather, they are removed by ventilation, thus representing an advantage over IV anesthetics, which are dependent on energy-requiring metabolism. Lastly, the respiratory status of these patients (as with all patients with myopathies) must not be stressed, even when not exposed to anesthetics. Great care must be exercised while weaning them from ventilatory support to ensure adequate spontaneous ventilation.

During the past decade, the IV anesthetic propofol has become increasingly popular as a maintenance anesthetic. However, it has many of the same side effects as volatile anesthetics and is a profound inhibitor of several aspects of mitochondrial function. One notable exception is that it is not known to cause much muscle relaxation. However, it is quite capable of decreasing ventilatory drive as well as cardiac output and contractility. Although it is viewed as a short-acting drug, its ultimate elimination is metabolism dependent. Theoretic concern exists that patients with mitochondrial myopathy may have an increased risk of developing propofol-infusion syndrome during prolonged exposure. However, propofol has been used successfully both as an induction agent and as an infusion and seems to have little effect in this setting (Driessen, 2008). All of the general anesthetic agents are known to directly inhibit mitochondrial function and may add to preoperative problems. However, each of the anesthetics already discussed has been used successfully when caring for patients with mitochondrial disease. It may be that, as the various types of mitochondrial disease are better defined, anesthetic preferences in certain cases may become clear. However, such a recommendation cannot be made at the present time. What is clear is that these patients must be monitored more closely than other patients when a general anesthetic is used and that great care must be exercised to document that the effects of the anesthetics are largely gone before assuming that the patient can ventilate adequately.

Patients with mitochondrial myopathies respond well to the nondepolarizing relaxants, although they probably have an increased sensitivity. These drugs should be titrated to the desired effect and monitored closely by nerve stimulation. As noted for general anesthetics, great care must be exercised to ensure that these patients are fully reversed before removing them from ventilatory support. As motor neurons may be affected, a hyperkalemic response to succinylcholine may be seen. This drug should only be used when absolutely necessary in these patients. Succinylcholine and volatile anesthetics are also known as triggers for MH. MH is thought to be associated with some forms of mitochondrial myopathies, but the nature of this relationship is unclear. It may be that a group of mitochondrial myopathies mimics MH by having inadequate ATP for reuptake of calcium from the cytoplasm of muscle cells into the sarcoplasmic reticulum. Such a failure could cause prolonged muscle contraction and lead to increased metabolism. Clearly, this represents a complicated problem in these patients. Whether they increase their temperature or become acidemic depends on the nature and severity of their disease.

In general, regional anesthesia is well tolerated by patients with mitochondrial myopathies. This tolerance is in spite of data that indicate that local anesthetics, especially bupivacaine, are capable of potently depressing mitochondrial function. Although most neural blockade uses doses of anesthetic that are well below the doses necessary for mitochondrial effects, it is important to be aware that these drugs are also capable of such effects, especially on the heart. Despite this risk, however, because of the low doses commonly used, regional anesthesia represents a valuable mode of treatment. Ideally, such blocks avoid exposure of the CNS and cardiac muscle to potentially toxic side effects. Not all cases can be completed solely with regional anesthesia, especially in children. However, consideration should be given to this approach when possible, owing to the benefits of effective postoperative analgesia without sedation or respiratory compromise. It is important to remember that mitochondria are inhibited by local anesthetics. If a muscle biopsy is being performed for the diagnosis of mitochondrial disease, the muscle itself must not be exposed to the local anesthetic. Such exposure would likely lead to a false defect in mitochondrial function. A similar concern can be raised for the use of propofol in muscle biopsy cases, although it would be expected that the concentration of propofol in the muscle should be quite low.

At the present time, there is no perfect anesthetic for these patients. When possible, consideration should be given to the use of local anesthetics in small amounts for a regional anesthetic. When a general anesthetic is necessary, probably each of the general anesthetics in use has its place. At present it is not possible to entirely eliminate one group as less safe than others. What is clear is that these patients must be monitored more closely than other patients. The use CNS monitors to gauge their depth of anesthesia more closely may allow anesthesiologists to expose these patients only to the minimum amount of drug necessary to carry out the surgical procedure.

Muscular Dystrophy

At least five forms of muscular dystrophy are clinically relevant for anesthesiologists: Becker, Duchenne, facioscapulohumeral, Emery-Dreifuss, and limb-girdle muscular dystrophies (Farrell, 1994). These entities vary greatly in severity of presentation;

however, many of their implications for anesthesiologists are similar (Kerr et al., 2001; Schmidt et al., 2003). Duchenne's muscular dystrophy (DMD) is an X-linked disorder that results from deletion mutations in the dystrophin gene and leads to a complete lack of dystrophin in the skeletal muscles (see Fig. 36-27, D). The defect is present in approximately 1 in 3500 live births, with the onset of disease often before school age and progressing to wheelchair dependence by the second decade of life. Dystrophin is a large protein that helps to anchor the contractile components (the actin myosin filaments) to the cell membrane and indirectly to the surrounding extracellular matrix (Fig. 36-30). Loss of this protein leads to profound muscle weakness and then respiratory failure, cardiomyopathy, cardiac conduction defects, and occasionally, mild mental retardation (Finsterer and Stollberger, 2003; Muntoni et al., 2003). Other, less global changes in this same gene cause Becker Muscular Dystrophy (BMD) and the related disease, X-linked dilated cardiomyopathy. Cardiomyopathy is occasionally seen in female carriers of the mutation. The clinical presentation of patients with various forms of muscular dystrophy are known to most anesthesiologists and are not reviewed in detail here other than as affects their anesthetic implications.

Anesthetic Considerations for Muscular Dystrophy

The approach to patients with DMD or BMD has changed in recent years. The main anesthetic implications of DMD and BMD are related to the severity of these profound myopathies. As would be expected in patients with muscle weakness, significant respiratory insufficiency can occur postoperatively with either disease. Cardiac muscle and conduction are also involved, and drugs that further depress cardiac function or that increase the likelihood of dysrhythmias should be avoided. All patients with DMD or BMD should receive a full cardiology evaluation with echocardiography within 3 months of surgery and pulmonary function testing before any surgery. Lastly, dysphagia is common, and gastric motility may be decreased, requiring expeditious control of the airway. The specific history of each patient

■ **FIGURE 36-30.** Dystrophy-related proteins; attachments of the actin filaments to the cell membrane and extracellular matrix. Disruption of these attachments alters protein distribution in the membrane and membrane stability. Some of the specific proteins (e.g., laminin, sarcoglycan, and dystrophin) that cause dystrophies are shown. *ACh*, Acetylcholine.

with DMD or BMD must be evaluated closely to determine the best technique to secure the airway.

In addition to playing a key role in anchoring contractile components to the cell membrane and the surrounding extracellular matrix, dystrophin is also important in organizing the postsynaptic acetylcholine receptors (Muntoni et al., 2003). In its absence, abnormalities occur both in the types of receptors and in their number and location, which may lead to abnormal responses to depolarizing muscle relaxants. Patients with BMD or DMD can have rhabdomyolysis and hyperkalemia in response to succinylcholine; thus, succinylcholine is contraindicated for them. It should also be noted that congenital forms of muscular dystrophy exist that probably involve other proteins necessary for attaching the contractile machinery to the extracellular matrix (see Fig. 36-30). Although this is a heterogeneous group of mutations, it is probably best to treat these patients as if they had DMD.

In the past few years, appreciation has increased concerning the risk of rhabdomyolysis and hyperkalemia in patients with DMD (and BMD) from exposure to volatile anesthetics alone. Hayes and colleagues (2008) present an important review of patients who had apparent hyperkalemic arrest after exposure to volatile anesthetics. These patients were felt to not have MH but to be still at risk for an untoward response to a volatile anesthetic. Although these events may be confused with MH, the association of DMD and BMD with true MH appears to be only coincidental. As a result, the authors strongly suggest using a “trigger-free” anesthetic in patients with known muscular dystrophy. This opinion is reinforced in a Consensus Statement from the American College of Chest Physicians (Birnkranz et al., 2007). However, at present no such recommendation has come from the ASA. The Association of Unusual Enzymopathies, Channelopathies, and Muscular Disorders with MH has been reviewed in a series of articles (Benca and Hogan, 2009; Davis and Brandom, 2009; Gurnaney et al., 2009; Hogan and Vladutiu, 2009; Klingler et al., 2009; Litman and Rosenberg, 2009; Parness et al., 2009).

Other Dystrophies

The remaining dystrophies—facioscapulohumeral (FSH), Emery-Dreifuss, and limb-girdle muscular dystrophy (LG)—are much milder in their presentations (Emery, 2002). FSH is one of the most common dystrophies; it is the most benign and usually is associated with little respiratory involvement (Fitzsimons, 1999). However, the neck, face, and scapular stabilizing muscles are often weak, and the ability to raise the head may be of little use in determining respiratory muscle strength (Dresner and Ali, 1989). Defects in the gene *FRG1* are associated with FSH and with disrupted muscle growth in vertebrates; however, the function of *FRG1* is unknown at present (Hanel et al., 2009).

Emery-Dreifuss muscular dystrophy usually has its onset in the teenage years and results from mutations in lamin (part of the nuclear matrix) or in emerin, an inner nuclear membrane protein that interacts with lamin and transcription regulators (Bione et al., 1994; Méjat et al., 2009). These patients have cardiac conduction defects, dilated cardiomyopathy, contractures (positioning problems), and often, fusion of C₃ to C₅, resulting in a less mobile neck (associated with difficult intubation) (Aldwinckle and Carr, 2002; Shende and Agarwal, 2002).

LG results from mutations in several proteins (at least 11 known), such as α -sarcoglycan, which associate with dystrophin. Some of these mutations are in proteins that overlap with those causing congenital muscular dystrophy. As in Emery-Dreifuss muscular dystrophy, LG is associated with some respiratory muscle weakness and cardiac conduction abnormalities, and at least some cases result from a defect in a protein that interacts with muscle cell membrane and is implicated in membrane repair (Capanni et al., 2003). The literature contains little regarding experience with the interaction of anesthetics with LG dystrophy (Pash et al., 1996).

In all three forms of muscular dystrophy, succinylcholine should be avoided, because hyperkalemia can result. MH is not reported in these three milder forms of muscular dystrophy. Thus, although not universal, the recurring themes with muscular dystrophy are to avoid succinylcholine, to watch for respiratory depression, and to avoid cardiac depressants and arrhythmogenic drugs. Volatile agents must be used with extreme caution because they are associated with rhabdomyolysis.

It is important to note that anesthetic complications have been reported in most of these types of muscular dystrophy (Farrell, 1994). These events most commonly involve a hyperkalemic episode, and sudden cardiac arrest may occur. Such events can occur in patients who are still in a subclinical stage of their disease and in whom the crisis may be the first manifestation. For this reason, many clinicians reserve their use of succinylcholine in children to only those cases in which there exists a specific indication for its use.

Metabolic Diseases

Several other genetic diseases of muscle exist that are of interest to anesthesiologists, including primary diseases of metabolism that lead to chronically weak muscles or muscles that are prone to damage when exposed to high metabolic stress. McArdle disease, an inherited disorder of muscle phosphorylase activity that down-regulates a Na⁺K⁺ membrane pump, is a prototypical disorder of this type (Clausen, 2003). Muscle from patients with McArdle disease can function normally until stressed by exercise or ischemia, at which time severely painful, electrically silent contracture develops, which can be followed by rhabdomyolysis, myoglobinuria, renal failure, and death. This sequence shares many elements with anesthesia-induced MH. Several MH-susceptible patients exhibited altered energy balance in response to caffeine, raising the possibility that disorders of intracellular energy production may contribute to the MH phenotype (Textor et al., 2003).

Patients with other less common diseases, such as Schwartz-Jampel syndrome, King-Denborough syndrome, and Brody disease, are also prone to anesthetic complications. In each case, MH-like responses have been reported, but their exact relationship to MH is not clear. King-Denborough syndrome is a progressive myopathy in which patients have short stature, severe scoliosis, pectus deformities, ptosis, low-set ears, and cryptorchidism (Heiman-Patterson et al., 1986). Anesthesia-related deaths, fulminant episodes of MH, and positive in vitro contracture test results have been commonly associated with this disorder (Isaacs and Badenhorst, 1992). Because this disease is so rare, information about its genetic etiology is still lacking.

Patients with Brody disease (also known as Lambert-Brody disease) elicit a decreased ability to relax on repeated activation

of their muscle, which results from an identified defect of the sarcoplasmic reticulum Ca^{2+} -ATPase (Odermatt et al., 2000). An in vitro contracture test performed on muscle from such a patient was abnormal, which may indicate that such patients may be at risk for MH-like syndrome (Froemming and Ohlendieck, 2001). Severe myotonia or neuromyotonia is a common feature of Schwartz-Jampel syndrome, in which hyperexcitability can be exacerbated by anesthetic agents and muscle relaxants are considered to be triggering agents for MH (Seay and Ziter, 1978; Ray and Rubin, 1994). It is unclear whether true MH is associated with this syndrome. In addition, difficult intubation because of neck and laryngeal anatomic abnormalities has been reported (Stephen and Beighton, 2002).

Clearly, these studies present as many questions as they do answers. Precise recommendations for the anesthetic care of these patients are not available. However, in general, the anesthesiologist probably should avoid the use of succinylcholine and volatile anesthetics while otherwise delivering normal meticulous anesthetic care. At present, the use of nontriggering anesthetics seems safe for this population, although any muscle relaxant must be used with the utmost caution. These patients should have prolonged observation for prolonged or recurrent weakness in the postoperative period.

The Undiagnosed Myopathy

In reviewing the above suggestions, an unpleasant scenario becomes apparent. What is the best anesthetic approach in the child with an undiagnosed myopathy? Depending on the molecular basis for the myopathy, the patient may turn out to have a diagnosis of mitochondrial defect or muscular dystrophy and may possibly be at risk for MH. The first possibility carries the recommendation to avoid propofol, and the second and third scenarios carry the recommendation to avoid volatile anesthetics (absolutely, if MH, and if possible, if muscular dystrophy). An insightful discussion of this conundrum was presented by Ross (2007) and Davis and Brandom (2009).

It is clear that volatile agents should be avoided if MH is a serious possibility. In those cases in which MH is not a concern, the choice of anesthetics depends on the likelihood of a mitochondrial defect vs. muscular dystrophy. Two reports of anesthetic management of children with muscle weakness who underwent muscle biopsy found that the likelihood of untoward effects using either class of drugs was low, in the range of 1% or lower (Driessen et al., 2007; Flick et al., 2007). To improve this number, it is incumbent on the anesthesiologist consult, the referring neurologist, and the geneticist/metabolism specialist to be aware of all aspects of the patient's history to determine which disease group is more likely. Until further information is available to guide the anesthesiologist, it remains crucial to closely monitor these patients during any anesthetic exposure and to maintain the close observation for several hours postoperatively.

SUMMARY

The anesthetic care of the pediatric patient with a systemic disorder provides myriad challenges for the anesthesiologist. A thorough understanding of the patient's disease and the effect that the anesthetic will have on the disease process are the two most important issues the anesthesiologist must address. For some of these patients, appropriate consultation with the surgeon, pediatrician, and pediatric subspecialist is essential to the proper management of these potentially difficult and challenging anesthetics.

Deaths during anesthesia associated with high fever and tachycardia were described repeatedly in the first half of the 20th century (Moschowitz, 1916; Burford, 1940). These deaths were sometimes ascribed to heat stroke and dehydration, because at that time intravenous hydration and air conditioning were not available. In 1915 and 1919, two deaths in one family occurred during chloroform anesthesia; in these cases, severe muscle spasm was observed before cardiac arrest. In 1987 a young child from this same family died during anesthesia for dental surgery. Subsequent *in vitro* contracture testing demonstrated susceptibility to malignant hyperthermia (MH) in several relatives in the family (Harrison and Isaacs, 1992). Even though MH is often suspected in cases such as these, in the 21st century it can still take years to complete MH diagnostic testing for a family.

Denborough was the first to investigate MH as a clinical entity (Denborough and Lovell, 1960; Denborough et al., 1962). Dr. James Villiers anesthetized a young Australian man for repair of a broken leg; the man was afraid to undergo general anesthesia because many of his relatives had died during ether anesthesia. Although during halothane anesthesia the patient became febrile, tachycardic, cyanotic, and hypotensive, he was aggressively cooled in the recovery room and he survived. Villiers asked his medical colleagues to investigate this patient and family. They found a pattern of anesthetic deaths consistent

with an autosomal dominant trait. In 2009, despite many investigations, the genetic change associated with abnormal muscle calcium homeostasis in this family was still not identified (Ball, 2007).

An episode of MH is recognized by documentation of an increasing metabolic rate after exposure to a triggering agent such as a potent inhalation anesthetic. Rhabdomyolysis may also be observed. Susceptibility to MH is rarely associated with clinically evident hypermetabolism in the absence of drugs used during anesthesia (Gronert et al., 1980; Tobin et al., 2001). Halothane and succinylcholine, two drugs formerly used often in pediatric anesthesia, are two of the most potent triggers of MH. A review of 25 years of halothane anesthetics in one pediatric hospital found the incidence of acute MH episodes to range from 1:20,000 to 1:40,000 anesthesia procedures (Warner et al., 1984). Because choices of anesthetic and neuromuscular blocker influence the development of this potentially lethal syndrome, MH is a disease of particular concern to the pediatric anesthesiologist who chooses to administer inhalation anesthetics or succinylcholine. Indeed, in 2008 administration of succinylcholine during potent inhalation anesthesia precipitated cardiac arrest and death from MH (North American Malignant Hyperthermia Registry, 2008). The purpose of this chapter is to review the clinical manifestations, management, and underlying pathophysiology of MH.

MUSCLE PHYSIOLOGY

Normal Muscle Physiology

The propagation of an action potential down a motor nerve fiber produces depolarization of that fiber and release of acetylcholine (ACh) at the neuromuscular junction. When two molecules of ACh interact with the ACh receptor, the channel opens, allowing sodium to enter the cell and potassium to flow out. This initiates a wave of depolarization along the muscle cell membrane or sarcolemma. The propagated depolarization wave spreads internally via transverse tubules that abut onto the sarcoplasmic reticulum (SR) (Fig. 37-1). The SR is an internal cellular structure and a major storage site for calcium ions. The wall of the transverse tubule contains the dihydropyridine receptor, a voltage-dependent calcium channel that interacts with the calcium-sensitive ryanodine receptor (RyR), the footplate between the transverse tubule and the SR. Within a voltage window, calcium is released from the SR (Melzer and Dietze, 2001) into the sarcoplasm through RyR type 1 (RyR1). Increased calcium in the sarcoplasm also induces further calcium release from the SR.

Furthermore, when calcium has been depleted from the SR, a process known as store-operated calcium entry (SOCE) allows calcium entry into the sarcoplasm from the extracellular milieu (Fig. 37-2) (Zhao et al., 2006). Excitation-coupled calcium entry (ECCE) refers to the process by which extracellular calcium enters the sarcoplasm through the plasma membrane after depolarization (Cherednichenko et al., 2004; Lyfenko and Dirksen, 2008). The RyR has influence on both SOCE and ECCE.

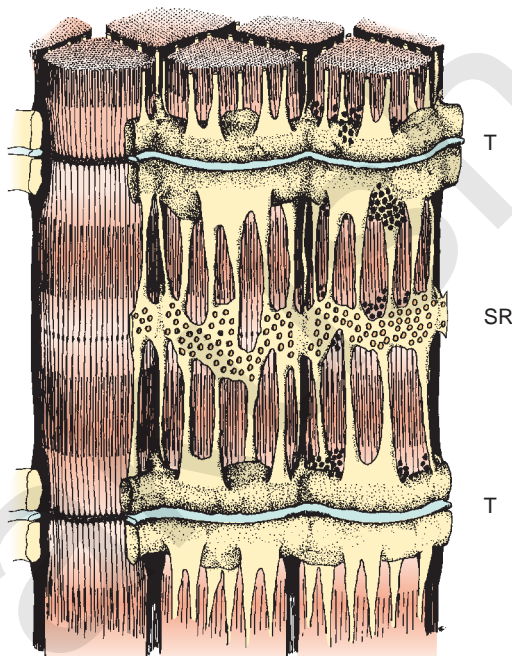

FIGURE 37-1. This three-dimensional reconstruction of the sarcoplasmic reticulum (SR) illustrates the continuity of the transverse tubules (T) surrounding the myofibrils and the fenestrations of the collar of the sarcoplasmic reticulum overlying the center of the A band of the myofibril. (From Engel AG, Banker BQ, editors: *Myology basic and clinical*, New York, 1986, McGraw-Hill; modified from Peachey LD: *The sarcoplasmic reticulum and transverse tubules of the frog's sartorius*, J Cell Biol 25:209, 1965.)

FIGURE 37-2. This diagram illustrates movement of calcium through the muscle cell after depolarization of the sarcolemma. Note several processes that contribute to elevation of calcium in the sarcoplasm during excitation-contraction coupling. (Modified from Parness J et al.: *The myotonias and susceptibility to malignant hyperthermia*, Anesth Analg 109:1054, 2009.)

Type 1 RyRs are found in all skeletal muscle, smooth muscle, neurons, and B lymphocytes. Type 2 RyRs are found in cardiac muscle, brain, and some hematopoietic cells. Type 3 RyRs are found in skeletal and smooth muscle and to a lesser extent in the brain. The function of RyR1 is modified by other proteins and by the redox state of the cell (Fig. 37-3) (Aracena-Parks et al., 2006; Goonasekera et al., 2007; Durham et al., 2008; Cornea et al., 2009; Protasi et al., 2009).

FIGURE 37-3. This cryoelectron microscopic model illustrates the shape of the ryanodine receptor (RYR1) and indicates areas where two other proteins interact with RYR1. On the left is a side view of RYR1. The red dashed circle is the FK506 protein-binding site. The dashed blue oval is the approximate binding site of Ca^{2+} calmodulin (CaM) binding, between RYR1 cytoplasmic domains 3 and 8. On the top right is an atomic model of Ca^{2+} CaM in complex with RYR1 amino acids 3614–3640. The lower row is a space filling representation of CaM-RYR1 interaction from the side and from the cytoplasmic face of RYR1. (From Cornea RL et al: FRET-based mapping of calmodulin bound to the RyR1 Ca^{2+} release channel, *Proc Natl Acad Sci USA* 106:6128, 2009.)

Calcium released from the SR combines with troponin, allowing cross-bridges to form between actin and myosin filaments and muscle to contract. When the wave of depolarization ceases, calcium ions dissociate from troponin and are removed from the sarcoplasm by adenosine triphosphate (ATP), requiring calcium pumps in the SR and other organelles. Thus, coupling of the excitation of the muscle membrane and contraction of the muscle cell entails changes in intracellular calcium concentration. Calcium increase in the sarcoplasm also initiates the breakdown of ATP and metabolic processes that support the energy needed for muscle contraction (e.g., glycolysis).

Pathophysiology of Malignant Hyperthermia

In classic MH, mutation of the *RYR1* gene produces enhanced activation of RYR1 by intraluminal calcium and reduced threshold for spontaneous calcium release during store calcium overload (store-overload-induced calcium release) (Jiang et al., 2008). In pigs, a specific single-point mutation in the RYR1 exists in all major breeds that are susceptible to malignant hyperthermia (Fuji et al., 1991). This point mutation is seen in a minority of human families who are susceptible to MH; however *RYR1* on chromosome 19q13.1 has been linked to MH susceptibility in the majority of families studied. Of the four other loci proposed as linked to MH susceptibility, only the *CACNA1S* on chromosome 1q13.1, coding for the α_1 subunit of the dihydropyridine receptor, has been linked to MH in more than two human families (Carpenter et al., 2009). The heterogeneous nature of human MH may be the result of a number of

different mutations in *RYR1* or to abnormalities in other proteins such as the dihydropyridine receptor (Gallant and Lentz, 1992). In humans who have MH susceptibility, *RYR1* compound heterozygotes have been observed in several countries. This supports the claim that the incidence of a MH-causative genotype could be as great as 1 in 3000 people (Monnier et al., 2002; Ibarra et al., 2006).

The metabolic dysfunction of MH is caused by increased intracellular ionized calcium (Mickelson and Louis, 1996). A direct result of increased intracellular calcium is an increased need for intracellular ATP to drive pumps that transfer calcium into the SR, across the sarcolemma into the extracellular fluid, or into mitochondria. Increased demands for ATP lead to the clinically detectable manifestations of MH (e.g., an increase in metabolism). The elevation of intracellular calcium observed in MH muscle is decreased by dantrolene (Lopez et al., 1985; Mickelson and Louis, 1996; Cherednichenko et al., 2008).

Motor nerve activity and neuromuscular transmission are normal in patients who have MH susceptibility (Gronert, 1980). However, susceptible porcine muscle has a lower mechanical threshold than does normal muscle, and compared with normal muscle, less depolarization is required to initiate contraction (Moulds and Denborough, 1974; Okumura et al., 1979; Gronert, 1980). Calcium release from the SR occurs at more negative potentials in the presence of *RYR1* MH mutations, and calcium-induced calcium release from the SR is abnormal in subjects susceptible to MH. The abnormal RYR1 is resistant to the inhibitory effects of both calcium and magnesium (Mickelson and Louis, 1996).

During an episode of MH in pigs, lactate release from muscle increases before mixed venous oxygen tension decreases (Gronert and Theye, 1976a). This sequence is consistent with intracellular ATP depletion. Magnetic resonance imaging (MRI) techniques showed an increased ratio of inorganic phosphate to phosphocreatine in vivo in human muscle susceptible to MH. This ratio is an indicator of the energy state of the muscle (Chance et al., 1985a, 1985b). An increased ratio suggests either impaired synthesis of ATP or increased breakdown of ATP.

Mechanism of Action of Dantrolene

Since dantrolene was introduced in the 1970s, its use has remarkably improved the treatment and survival of patients with MH. It has been claimed that dantrolene inhibits the release of calcium from the SR by limiting the activation of the calcium-dependent RYR1, but more recently it was shown that dantrolene blocks ECCE across the plasma membrane (Fruen et al., 1997; Cherednichenko et al., 2008). Dantrolene does not act at the neuromuscular junction and has no effect on the passive or active electrical properties of the surface and tubular membranes of skeletal muscle fibers. Patients who have been given dantrolene have normal neuromuscular transmission and depressed force of muscle contraction. The protective effects of dantrolene against MH require significant depression of the force of contraction (Flewellen et al., 1983). Dantrolene can produce clinically significant weakness and decreased metabolism in normal muscle as well as in MH-susceptible muscle (Flewellen et al., 1983). It can reduce elevated creatine kinase (CK) in diseased muscle, independent of the presence of *RYR1* mutations (Bertorini et al., 1991; Kamper and Rodemann, 1992).

■ **FIGURE 37-4.** Plasma decay of dantrolene in children. (From Lerman J et al: *Pharmacokinetics of intravenous dantrolene in children*, *Anesthesiology* 70:625, 1989.)

The dose-response relationship of dantrolene in children has not been reported. Available data suggest that the half-life of dantrolene in children is somewhat shorter than that in adults: 7.3 to 9.8 hours and 12.1 hours, respectively (Fig. 37-4) (Lietman et al., 1974; Flewellen et al., 1983; Lerman et al., 1989). In adults, a cumulative dose of 2.2 to 2.5 mg/kg of dantrolene administered intravenously over 125 minutes produced a steady plasma concentration of dantrolene for longer than 5 hours (Flewellen et al., 1983). Orally administered dantrolene, a total of 5 mg/kg in 3 or 4 divided doses administered every 6 hours to adults with MH susceptibility, has also been shown to produce protective plasma concentrations of dantrolene for at least 6 hours after induction of anesthesia (Allen et al., 1988). In children, intravenous administration of 2.4 mg/kg of dantrolene infused over 10 minutes produced stable blood levels of about 3.5 mcg/mL for 4 hours, after which a slow decline in plasma concentration occurred (Lerman et al., 1989). Hence, it may be reasonable to repeat 1 mg/kg of dantrolene every 5 to 7 hours for prophylaxis. Alternatively, pharmacokinetic modeling with parameters derived in adults recommends a continuous infusion of dantrolene (Podranski et al., 2005). It is likely that when plasma concentrations of dantrolene are sufficient to inhibit an episode of MH, the patient experiences weakness and possibly disequilibrium.

A dynamometer could be used to assess grip strength objectively, but this requires the patient's cooperation. In a study of adults, the dose of dantrolene that produced maximal depression of grip strength and evoked force of thumb contraction had no significant effect on vital capacity (Flewellen et al., 1983). Similar studies have not been performed in children. Clinical experience suggests that less than 2 mg/kg of dantrolene administered intravenously to a child preoperatively can be associated with significant hypotonia in the postoperative period (Brandom and Carroll, unpublished observations). Weakness induced by dantrolene could compromise the ability to swallow and even necessitate artificial protection of the airway and mechanical ventilation, although this has never been reported in the literature (Flewellen et al., 1983). Intravenous dantrolene should be administered in settings where support of airway and ventilation can be easily provided.

CLINICAL PRESENTATION

The initial clinical signs of an impending episode of MH are non-specific. The most commonly reported initial signs are hypercarbia, sinus tachycardia, and masseter spasm or jaw rigidity (Larach et al., 2010). Arrhythmias and tachypnea may be present (Box 37-1). Increased or rapidly increasing temperature is often an early sign of MH, and metabolic acidosis is often not observed before treatment of MH (Larach et al., 2010).

Rigidity of the extremities and the entire body are signs of fulminant MH. When MH is fulminant, there is severe metabolic acidosis (base deficit often greater than 8 mEq/L), respiratory acidosis (arterial carbon dioxide tension [P_{aCO_2}] of greater than 60 mm Hg), tachycardia with arrhythmias, a rapid increase in body temperature to 39.5° C or greater, hyperkalemia, myoglobinuria, and often, but not always, a marked increase in serum CK (Gronert, 1980; Newmark et al., 2007). However, because of modern comprehensive monitoring and increased awareness of MH, fulminant MH is rarely observed. The clinical diagnosis of MH is often considered before metabolism and temperature reach these extremes (Karan et al., 1994). The

Box 37-1 Steps in Identifying and Treating Malignant Hyperthermia

CLINICAL EVENTS DURING MH

Increased oxygen consumption
 Increased minute ventilation with respiratory acidosis
 $P_{ETCO_2} > 55$ mm Hg with appropriately controlled ventilation
 Total body rigidity
 Masseter spasm
 Inappropriate sinus tachycardia
 Ventricular tachycardia or ventricular fibrillation
 Inappropriate increase in temperature; rapidly rising temperature ($>1.5^\circ$ C over 5 min) or temperature $>38.8^\circ$ C
 Profuse sweating
 Mottled, cyanotic skin
 Cola-colored urine

- If any two or more of these events occur, determine venous blood P_{CO_2} , P_{O_2} , base excess, lactate, potassium ion, creatine phosphokinase, and myoglobin and consider discontinuing trigger agents. If temperature is $>40^\circ$ C, check clotting function and serum creatinine.
- If total body rigidity is present, without a neurologic explanation, send blood for laboratory evaluation as above, discontinue trigger agents, and begin treatment for acute MH episode.

LABORATORY EVALUATION: POSITIVE FINDINGS CONSISTENT WITH MH

Venous $P_{CO_2} > 65$ mm Hg with increased minute ventilation
 Arterial $P_{CO_2} > 60$ mm Hg or 65 mm Hg with spontaneous ventilation $>$ normal
 Arterial base excess more negative than -8 mEq/L
 Arterial pH < 7.25
 Potassium ion > 6 mEq/L
 Creatine kinase $>10,000$ IU/L after anesthetic without succinylcholine
 Myoglobin in serum > 170 mcg/L
 Myoglobin in urine > 60 mcg/L

P_{ETCO_2} , End-tidal carbon dioxide tension; P_{CO_2} , partial pressure of carbon dioxide; P_{O_2} , partial pressure of oxygen.

patient's medical history and clinical course usually, but not always, help to differentiate fulminant MH from other metabolic crises such as porphyria, thyroid storm, untreated pheochromocytoma, and Ecstasy exposure (Allen and Rosenberg, 1990). Some other conditions that produce signs similar to MH are sepsis, allergic drug reactions, intracranial trauma, and hypoxic encephalitis.

Ideally, MH should be recognized and treated before it becomes fulminant. Treatment is more likely to be successful the earlier it is started, but because the signs of MH are not highly specific it is difficult for anesthesia practitioners to distinguish between early MH and many other complications. If there are only mild symptoms or signs suggestive of MH (e.g., moderate increases in heart rate, blood pressure, and temperature along with a slight metabolic or respiratory acidosis), yet evidence is later obtained that the patient is indeed susceptible to MH, this constellation of clinical findings could be called *abortive MH*. In such cases, masseter spasm may or may not occur (Ellis et al., 1990). There may be a moderate increase in CK and serum myoglobin. When considering the implications of these tests, note that myoglobin appears in the plasma within minutes of muscle injury by succinylcholine. However, CK continues to increase for 8 to 20 hours after a transient injury, even in patients who are not susceptible to MH (Florence et al., 1985). The incidence of abortive MH is as high as 1:4200 anesthetics when succinylcholine is used in combination with potent inhalation anesthetics (Ording, 1985). However, in the first decade of the 21st century, the incidence of MH cases identified by hospital discharge diagnosis codes was estimated to be about 1:100,000 anesthetics (Brady et al., 2009).

The diagnosis of MH may be mistakenly applied to patients suffering hyperkalemic cardiac arrest or sudden exacerbation of chronic rhabdomyolysis, which has occurred in pediatric patients after the administration of succinylcholine (Kovarik and Morray, 1995; Larach et al., 1997; Piotrowski and Fendler, 2007). In this condition, the sudden severe increase in plasma potassium can be fatal, but metabolic abnormalities are secondary to cardiac failure and not increased metabolism in skeletal muscle, as in MH (Delphin et al., 1987; Rosenberg and Gronert, 1992; Tang et al., 1992; Larach et al., 2001).

In a group of 48 children, 17 of whom later proved to be susceptible to MH by muscle biopsy, two or more adverse signs or abnormal laboratory findings were present in all patients with positive in vitro contracture tests (Larach et al., 1987). However, similar adverse events occurred in 83% of the children who had negative muscle-biopsy findings. Generalized muscle rigidity was the single factor significantly associated with positive biopsy findings for MH. However, generalized muscle rigidity is not an absolute predictor of MH susceptibility. Three of 24 patients, who were referred for muscle-contraction testing to evaluate MH susceptibility and had negative contraction test results, had experienced generalized muscle rigidity during induction of anesthesia. Signs consistent with abortive MH, such as tachycardia, premature ventricular contractions, elevated end-tidal carbon dioxide, and increase in tension of the masseter muscle may be observed in the normal pediatric patient who is given halothane or sevoflurane and succinylcholine (Van der Spek et al., 1987; 1988; Lanier et al., 1990). Larach and others (1987) could not identify the patient with MH susceptibility on the basis of these signs (Hackl et al., 1990). Therefore, when MH is suspected clinically, after treating the patient arrangements should be made for confirmatory testing (see related sections in this chapter).

If events during the induction of anesthesia require explanation beyond light anesthesia, transient rigidity and tachycardia during inhalation of sevoflurane, or hypoventilation, further investigation to rule out the diagnosis of MH must be undertaken immediately, before surgery begins. The anesthesiologist must document the presence of increased metabolic rate, rather than the decreased metabolic rate that usually follows induction of anesthesia. Venous or arterial blood should be obtained for measurement of partial pressure of carbon dioxide [P_{CO_2}], lactate, potassium, and CK. Mixed venous blood is most likely to show significant alterations in P_{CO_2} , but it may not be readily available (Gronert and Theye, 1976a, 1976b). During anesthesia there is increased arterial-to-venous shunting through the skin. Despite this fact, blood from a large peripheral vein, femoral or antecubital, may demonstrate increasing P_{CO_2} and worsening base deficit before these changes are found in arterial blood. Increasing end-tidal carbon dioxide concentrations, particularly with increased minute ventilation, supports the presumptive diagnosis of MH. Evidence of muscle injury, such as the presence of myoglobin in the serum and urine and elevated CK and other enzymes in the blood, may not be observed if MH is treated very quickly. With anesthesia techniques common in the 21st century, MH may not be recognized until the second or third hour of anesthesia. MH may first be recognized in the postoperative recovery room. Fatal MH can occur without exposure to anesthetics (Brown et al., 2000). Once a hypermetabolic state is recognized, appropriate actions must be taken without delay, as described later.

MASSETER SPASM

Masseter spasm (also termed *masseter muscle rigidity* or *trismus*) is a marked increase in tension of the masseter that prevents opening of the mouth when succinylcholine has produced neuromuscular blockade. Masseter spasm may be an early sign of MH. However, succinylcholine can produce increased tension in normal muscle at the same time that it produces block of neuromuscular transmission (van der Spek et al., 1987, 1988). Many anesthesiologists believe that only if the jaw cannot be forced open should this phenomenon be called masseter spasm.

Hannallah and Kaplan (1994) distinguish between masseter muscle rigidity and trismus. In masseter muscle rigidity, the mouth cannot be fully opened even with firm pressure on the incisors, but the mouth can be opened far enough to permit intubation of the trachea. In trismus, the mouth cannot be opened enough to permit intubation of the trachea. Using these definitions, Hannallah and Kaplan (1994) noted rigidity in 0.2% of 500 children anesthetized with halothane and administered succinylcholine, but none of these 500 patients experienced trismus. It may be that the several-fold greater incidence of masseter spasm noted in the 1980s included cases of incomplete jaw relaxation (i.e., the mouth opens fully with firm manual separation of the teeth), which was observed in 4.4% of these 500 pediatric patients. The 22 patients with incomplete jaw relaxation in this study continued to receive halothane anesthesia with no apparent complications. Masseter spasm has been touted as a specific early warning sign of MH. Undoubtedly, deaths from MH have occurred during anesthetic procedures in which masseter spasm was observed and in cases in which it was not observed. It may be that when masseter spasm is accompanied by rigidity of the entire body, MH is likely

to occur. However, transient increase in jaw stiffness, or resting tension of jaw muscles, is a normal response to succinylcholine (van der Spek et al., 1987, 1988; Plumley et al., 1990). Increase in masseter muscle tension occurs in normal mammals after the administration of succinylcholine with prior administration of epinephrine (Pryn and van der Spek, 1990). There is a greater increase in jaw tension after administration of succinylcholine during halothane anesthesia than in the presence of barbiturates. Jaw tension is also increased in animals that are febrile as opposed to those that are normothermic (Storella et al., 1993). Temporomandibular joint abnormalities may confuse the diagnosis of masseter spasm by interfering with jaw opening.

Although masseter spasm usually occurs after anesthesia induction with halothane and the administration of succinylcholine, it may occur with other anesthetic agents (Larach et al., 1987; Marohn and Nagia, 1992; Takamatsu et al., 1996). Masseter spasm occurs despite abolition of evoked muscle function in the extremities. Tachycardia or other nonspecific arrhythmias may accompany masseter spasm. MH may follow masseter spasm immediately; in the continued presence of anesthetic trigger agents, however, a period of 10 or more minutes often intervenes between masseter spasm and the clinical presentation of MH when the clinical presentation of MH is defined as arterial P_{CO_2} greater than or equal to 50 mm Hg, pH less than 7.25, and base deficit more negative than 8 mEq/L (O'Flynn et al., 1994).

Anesthesia with halothane has been continued after isolated masseter spasm with no increased metabolism or cardiovascular instability. Littleford and others (1991) reported on 57 such children, of whom 33% experienced transient arrhythmias intraoperatively. Most of these children also had some degree of hypercarbia or metabolic acidosis. CK levels measured 18 to 24 hours postoperatively were elevated in all but one of these children, and CK levels greater than 20,000 units/L were observed in many. However, there were 11 children who experienced generalized rigidity in combination with masseter muscle spasm. Anesthesia was aborted for four of these children and continued without inhalation agents in three of the children. None of these children developed fulminant MH in the perioperative period. The remaining four patients who developed generalized rigidity received dantrolene. Kaplan and Rushing (1992) documented a case of masseter spasm in which clinical abnormalities prompted administration of dantrolene, and postoperative CK was 40,000 IU. Nine years later, this healthy adolescent had completed extensive evaluation for neuromuscular disorders, including *in vitro* testing for MH with the caffeine-halothane contracture test (CHCT). The patient and family remained without signs, symptoms, or diagnosis of any myopathy. If this patient had been labeled as susceptible to MH, it would have been a misdiagnosis. Total body rigidity accompanying masseter muscle rigidity does not absolutely guarantee that the patient has MH (Larach et al., 1987). Anesthetic depth may have been misjudged; however, if rigidity does not abate when deep neuromuscular block was produced with nondepolarizing blockers, muscle must be abnormal. Either fulminant MH is occurring or the patient may have occult myotonia (Neuman and Kopman, 1993).

Inhalation anesthesia without succinylcholine was associated with fewer episodes of both fulminant (2 vs. 8) and abortive (17 vs. 110) MH than was succinylcholine with potent inhalation anesthetics in a Danish population (Ording, 1985). Thus, avoiding succinylcholine administration to pediatric patients

anesthetized with inhalation anesthetics not only avoids the diagnostic uncertainties associated with masseter spasm but also produces fewer episodes of MH and other adverse events (Delphin et al., 1987; Rosenberg and Gronert, 1992). Pediatric anesthesiologists may choose to administer succinylcholine only when definite, strong indications for this drug have been identified.

Management of Masseter Spasm

There is no agreement among experienced clinicians concerning the preferred management of patients with incomplete relaxation of the masseter after the administration of succinylcholine (Kaplan et al., 1993). If jaw stiffness is mild, so that the mouth can be opened with increased effort, there is no rigidity in the rest of the body, and cardiovascular function is stable, anesthesia may be continued with careful documentation of capnography and core temperature. Fluid deficits should be replaced completely so that urine output is greater than 3 mL/kg per hour. Urine should be obtained in the early postoperative period to check for the presence of myoglobin. Blood should be obtained for measurement of electrolytes and CK. It is not necessary to terminate anesthetic administration unless signs of increasing metabolic rate occur. If jaw stiffness is so great that the mouth cannot be opened, there are several reasons to terminate elective anesthetic administration, not the least of which may be the need to clear the upper airway. If trismus and extensor rigidity are present, biochemical signs of MH should be sought and treatment of MH initiated. Venous blood should be obtained for gas analysis and measurement of electrolytes, myoglobin, and CK. If rigidity persists in the presence of neuromuscular blockade either the patient has MH or a form of myotonia.

After an episode of masseter spasm, myalgia and occasionally weakness may be present for several days or longer. In patients who were not susceptible to MH and undergoing ophthalmic surgery with halothane anesthesia who received succinylcholine intraoperatively, an increase in CK level was noted 24 hours after surgery. The highest postanesthetic CK level in these otherwise healthy patients was 40 times that of normal (Inness and Stromme, 1973). Myoglobin appears quickly in the plasma after halothane anesthesia and succinylcholine administration, even in children who had no masseter spasm (Plotz and Braun, 1982). If radioimmunoassay is used to measure serum myoglobin concentrations, increases in myoglobin can be measured within the first hour after succinylcholine administration in normal children anesthetized with isoflurane or halothane.

If surgery must continue, inhalation anesthesia can be stopped and intravenous anesthetics given. Intraarterial, central venous, and bladder catheters are useful if evidence of increased metabolism is found and dantrolene is administered. Muscle tension of the rest of the body should be noted.

Postoperative renal failure has occurred in patients who had myoglobinuria after administration of succinylcholine during anesthesia. In any situation in which injury to muscle may occur, it is important to document that myoglobinuria is not present. If increased muscle stiffness is noted after administration of succinylcholine or the if child complains of muscle pain postoperatively, urine should be obtained. If there is no blood in the urine as assessed by orthotolidine (Hematest), then there is no myoglobin present (Bosch et al., 2009). If the response

to blood is positive on the dipstick, urine should be examined for the presence of red blood cells, and free hemoglobin and myoglobin should be measured. If myoglobin is present, the patient should remain in the hospital. The patient should be observed for signs of MH, evaluated for the presence of occult muscle disease, and well hydrated. Alkaline urine may reduce the risk of renal tubular injury from myoglobin (Elsayed and Reilly, 2010).

TREATMENT OF AN ACUTE EPISODE OF MALIGNANT HYPERTHERMIA

When the diagnosis of MH is strongly suspected, the most important step to take is to administer dantrolene. The other steps in management are to discontinue the triggering anesthetic agents immediately, increase minute ventilation several-fold with 100% oxygen at the highest possible flow rate, check core temperature, and alert the surgeon that the procedure must be concluded promptly. Other anesthesiologists, paramedical personnel, or both should be called in at once for assistance. If core temperature is higher than 39° C, cooling measures should be applied until temperature is below 38° C (see www.mhaus.org).

Dantrolene must be diluted with sterile, preservative-free, distilled water that should be stored in large quantities with the drug (Table 37-1). It is important to store sterile water in clearly labeled containers of a different size from those used for routine intravenous solutions and to keep a mixing system nearby. New formulations of dantrolene may go into solution faster than did dantrolene manufactured before 2008. The initial intravenous dantrolene dose should be 2.5 mg/kg, although more than 10 mg/kg may be needed to control the episode (Larach et al., 2010). Repeated dosing should be guided by clinical and laboratory signs. A flow sheet including minute ventilation, end-tidal carbon dioxide concentration, heart rate and rhythm, arterial

blood pressure, central venous pressure, core temperature, and urine output, along with arterial and venous blood gas tensions, serum electrolytes, and glucose and total fluid intake, provides a useful guide for continued therapeutic interventions. Dantrolene must be administered until respiratory and metabolic acidosis, tachycardia and stiffness have resolved. The usual upper limit of 10 mg/kg may be exceeded as necessary. The most common side effects of this drug are muscle weakness and phlebitis.

The anesthesia machine need not always be switched to a standby unit that has been kept free of inhalation anesthetics. However, because of both the increased internal gas volume of and the increased anesthetic solubility in modern anesthesia work stations, more time may be required to eliminate traces of anesthetic. For example, over 100 minutes of 10 L/min fresh gas flow (10 L/min FGF) was needed to reduce residual inhalation anesthetic to 5 ppm in the Drager Fabius anesthesia machine, whereas after 20 minutes residual sevoflurane was less than 5 ppm in the Drager Narcomed GS machine (Gunter et al., 2008; Whitty et al., 2009). Isoflurane washout can require more than 45 minutes of 10 L/min FGF in the Drager Primus machine, more than 50 minutes in the Datex-Ohmeda machine, and more than 75 minutes in the Aestiva machine (Crawford et al., 2007; Birgenheier et al., 2009). If the carbon dioxide absorber and circuit tubing are not changed, 30 minutes of 10 L/min FGF is needed to reach 2 ppm isoflurane in the Datex-Ohmeda work station (Schonell et al., 2003). In summary, replacement of all exposed elements, including the ventilator diaphragm and breathing system with autoclaved or new parts, provides the fastest preparation of the anesthetic work station without the addition of charcoal filters. Continuation of 10 L/min FGF for the duration of the anesthesia has been recommended to avoid increasing concentrations of agent (Crawford et al., 2007; Whitty et al., 2009). If MH occurs after the first hour of exposure to an inhalation anesthetic, there is a substantial volume of the anesthetic trigger agent in the patient's body. It is likely that placement of a charcoal filter on the inspiratory limb of the anesthesia circuit and administration of 10 L/min FGF could greatly speed elimination of potent anesthetic from the breathing circuit (Gunter et al., 2008; Birgenheier et al., 2009).

Procedures to cool the body should be instituted quickly. The goal is to reduce muscle metabolism and avoid exposure to a critical core temperature of greater than 40° C (Bouchama and Knochel, 2002). Furthermore, a temperature that is higher than normal may accelerate an MH episode in humans, as has been observed in animals (Chelu et al., 2006; Dainese et al., 2009). Drapes should be removed, heated humidifiers and hot air blowers should be turned off, and water mattresses should be turned to cooling temperatures. Room temperature normal saline solution should be given intravenously to maintain normal central venous pressure. The stomach can be irrigated with iced saline solution through an orogastric tube. Open body cavities can also be lavaged with iced saline solution, and ice packs can be placed in the groin and axillae where large vessels come close to the skin surface.

An arterial catheter should be inserted to observe the patient's hemodynamic status and acid-base balance. A central venous catheter is useful for obtaining cardiac filling pressures and blood gas tensions, as well as for administering intravenous fluids. A pulmonary artery catheter allows measurement of mixed venous blood gases and lactate and adjustment of cardiac filling pressures in the patient with pulmonary edema. Mixed

TABLE 37-1. Drugs and Dosages Used to Treat an Acute Episode of Malignant Hyperthermia

Dantrolene*	2.5-10 mg/kg or more (Sterile water must be available to dilute dantrolene.)
Sodium bicarbonate	2 mmol/kg as needed
Iced normal saline solution	As needed (10-12 L for 50-kg patient)
Mannitol	300 mg/kg (Note that there is 150 mg of mannitol per milligram of dantrolene in the vial.)
Furosemide	0.5-1 mg/kg
Insulin (regular)	10 units regular insulin in 50 mL of 50% dextrose titrated to produce normokalemia
Lidocaine	1 mg/kg

*Dantrolene administration should be repeated until physical and chemical signs have returned to normal. When this degree of physiologic stability has been obtained, dantrolene (1 mg/kg or more) should be repeated approximately every 6 hours until all signs of MH, including muscle stiffness, have abated and creatine kinase has decreased consistently. If the patient is metabolically stable, vital signs are normal, and muscle weakness is present, the interval between dantrolene doses can be increased to 8 hours.

venous blood is a more sensitive indicator of the patient's acid-base status than arterial blood. A blood sample should be taken to determine the blood gases and pH, potassium, glucose, CK, myoglobin, creatinine, and clotting profile as soon as feasible.

Hyperkalemia results when cell membranes are disrupted and when acidosis is severe. This is recognized on the electrocardiogram as increased T-wave amplitude in the early stages and later by widening QRS complexes, intraventricular conduction delays and blocks, and finally no organized rhythm at all. Intravenous calcium is appropriate emergency treatment of the hyperkalemia associated with MH (Gronert et al., 1986). Glucose and insulin (10 units of regular insulin in 50 mL of 50% glucose titrated to effect) can be administered to lower serum potassium temporarily. β -agonists can also be useful to move potassium intracellularly.

Large losses of intravascular volume should be anticipated; evaporative loss of fluid may be great, and edema formation may occur in muscles and in other tissues during fulminant MH. Intravenous fluids should be given to maintain normal cardiac filling pressures, as evidenced by adequate perfusion pressure, urine output, and capillary refill. Alkaline osmotic diuresis is induced by mannitol in the current formulation of dantrolene (150 mg of mannitol/mg of dantrolene in Dantrium). This protects renal tubule function in the presence of myoglobinuria and promotes acute intravascular volume loss. The management of the acute MH episode is summarized in [Box 37-2](#).

Because calcium channel blockers might interfere with excitation-contraction coupling and conserve energy reserves, it is reasonable to ask what effects such drugs might have on MH-susceptible muscle (Lynch et al., 1986). Not all calcium channel-blocking drugs have the same effects in subjects with

MH susceptibility. Diltiazem inhibits halothane-induced contracture in MH-susceptible pig muscle, thus confirming a single similar observation in human muscle (Illias et al., 1985). Verapamil, however, is not a therapeutic agent in porcine MH (Gallant et al., 1985). Furthermore, verapamil and dantrolene can interact to produce severe hyperkalemia and myocardial depression (Lynch et al., 1986; Rubin and Zablocki, 1987). Nifedipine administration has been associated with the development of MH in a child with underlying neuromuscular disease (Cook and Henderson-Tilton, 1985). At this time, it seems prudent to administer calcium channel-blocking drugs to patients with a history of MH or neuromuscular disease only with caution. Calcium channel blockers are not recommended in the management of acute MH. If dantrolene must be administered to a patient who is also receiving calcium channel-blocking drugs, invasive hemodynamic monitoring and frequent measurement of serum potassium levels have been recommended (Lynch et al., 1986; Rubin and Zablocki, 1987).

Postanesthesia Considerations

A patient who has been successfully treated for MH in the operating room requires intensive care to continue treatment and to monitor for late manifestations of the disorder. Continuation of treatment is necessary, because recrudescence of MH can occur after an episode that has apparently been successfully treated. This usually happens in the first few hours after the initial event. Patients with a muscular body type, temperature increase, or longer interval between induction of anesthesia and beginning of the MH reaction had increased risk of recrudescence (Burkman et al., 2007). As much as 12 mg/kg of dantrolene has been required to treat recurrences over 12 hours (Pollock et al., 1992). Continuous monitoring of vital signs and minute ventilation, and frequent measurement of venous lactate, blood gases, and electrolytes should detect metabolic changes. Dantrolene should be administered intravenously as necessary, not only until no evidence of metabolic acidosis remains, but also until serum myoglobin levels decrease toward normal or there is no myoglobinuria. The half-life of myoglobin in the blood is normally 1 to 3 hours. In contrast, CK peaks 24 to 36 hours after injury and usually decreases about 40% per day thereafter (Salluzzo, 1992).

After an acute episode, the patient with MH may die of a recrudescence, disseminated intravascular coagulopathy, or other nonspecific systemic injury. Disseminated intravascular coagulopathy is a common finding in fatal MH (Larach et al., 2008). The administration of dantrolene should be continued to stop the disruption of muscle, the presumed underlying cause of disseminated intravascular coagulopathy. Supportive intensive care should be given as indicated, and coagulation function must be carefully monitored during and after an episode of MH.

Late manifestations of an episode of MH range from mild muscle pain to multiorgan system failure. Cerebral edema may occur. Fulminant cases of MH may have permanent neurologic sequelae (e.g., coma or paralysis) for no apparent reason. Even satisfactory care during anesthesia may not prevent these neurologic complications (Gronert, 1980). Rehabilitation can take months after an episode of fulminant MH.

Pulmonary edema may occur because of marked shifts in intravascular volume, myocardial dysfunction, and the effects

Box 37-2 Management of the Acute Malignant Hyperthermia Episode

Follow treatment guidelines prepared by MHAUS (see www.mhaus.org).

- Stop inhalation anesthetics immediately.
- Cancel or conclude surgery as soon as possible.
- Hyperventilate with >10 L/min of 100% oxygen.
- Administer dantrolene (2.5 mg/kg) intravenously over 5 minutes and repeat as needed. Give more dantrolene if signs of MH reappear.
- Initiate cooling with intravenous cold saline solution (15 mL/kg over 10 minutes), ice packs in the axillae and groin, and lavage of body cavities with cold saline solution if the core temperature is greater than 39° C. Stop cooling when the core temperature falls to 38° C.
- Correct metabolic acidosis with 1 to 2 mEq/kg of sodium bicarbonate as an initial dose.
- Administer calcium (10 mg/kg of calcium chloride) or insulin (0.2 mcg/kg) in 50% dextrose in water (1 mL/kg) to treat the effects of hyperkalemia.
- Follow Advanced Cardiac Life Support algorithm to treat dysrhythmias. Lidocaine may be given during an MH crisis.
- Maintain urine output of 2 mL/kg per hour with additional mannitol and furosemide (1 mg/kg) if needed.
- Insert arterial and central venous catheters.
- Repeat venous blood gas and electrolyte analyses every 15 minutes until these and vital signs normalize.

of heat shock. The presence of pulmonary edema requires more careful assessment of the circulatory status to improve cardiac filling pressures and inotropic state. Areas of myocardium may have abnormal conduction, decreased contractility, or both. It is important to maintain adequate renal perfusion, because massive myoglobinuria produced by fulminant MH can cause acute renal failure. Sufficient muscle damage to produce myoglobinuria and acute renal failure can occur in the absence of pigmenturia or dramatic elevation of CK (Grossman et al., 1974). If myoglobin (or hemoglobin) is present, urine gives a positive reaction with orthotolidine (Hematest). In the presence of myoglobinuria, normal saline solution should be given to force a diuresis of at least 3 mL/kg per hour; if urine output is less than this, then mannitol (1 mL of 25% solution) and bicarbonate (1 mEq) in 5% dextrose in water (D₅W; 8 mL) should be given at twice the maintenance fluid rate. Rapidly increasing serum creatinine signals the onset of renal failure.

All cases of MH, anesthetic-related episodes of increased metabolism or rhabdomyolysis, isolated masseter spasm, and anesthetics administered to patients who have undergone a CHCT should be reported to the Malignant Hyperthermia Registry, so that the epidemiologic study of MH may have as broad a scope and as complete a collection of data as possible. Report forms may be obtained by telephone (888-274-7899) or printed from www.mhreg.org.

PROPHYLACTIC MANAGEMENT

Indications for Muscle Biopsy and Genetic Evaluation of Type 1 Ryanodine Receptor

Indications may vary depending on the particular goals being addressed. Individuals, both patients and physicians, concerned with improving the diagnostic tests for MH may urge all patients with any symptoms consistent with MH and those with a clear history of fulminant MH to undergo muscle biopsy and CHCT. Others prefer to advise that this invasive test be performed only when the predictive value of the test is likely to be helpful for patient management. The CHCT is currently the only method that can rule out MH susceptibility. The Clinical Grading Scale (CGS) was developed using the Delphi process to provide clinical definition of a case that is almost certain to be MH for the purpose of defining the diagnostic criteria of the CHCT (Larach et al., 1994). **Box 37-1** contains many of the elements of the CGS. The five processes evaluated by the CGS (rigidity, muscle breakdown, respiratory acidosis, temperature increase, and cardiac involvement) each contribute a limited number of points to the score. Scores are further divided into categories of likelihood of the patient having MH. Category 6 is almost certain MH; category 5 indicates that MH is very likely; category 4 means that MH is somewhat greater than likely; category 3 indicates that MH is somewhat less than likely; category 2 implies that MH is unlikely; and in category 1, the chance of a patient having MH is almost none. If the total score of the CGS is 50 or more, the case is category 6, almost certain to be MH. If the score is between 35 and 49 the case is category 5, very likely to be MH. The CGS must be applied with medical judgment to estimate the probability that a given anesthesia event was MH. It is important to document the adequacy of minute ventilation when interpreting carbon

dioxide tensions. Increased minute ventilation may be the only sign of MH. This produces a category 3 score on the CGS, indicating that MH is somewhat less than likely and might suggest that further testing is not warranted. However, if the anesthesiologist feels that carbon dioxide production was increased and this was reversed by elimination of potent anesthetic, the patient should be referred for testing of MH susceptibility. On the other hand, a child who has sepsis with cerebral palsy, or one of many other medical conditions, may have a high score on the CGS. Referral of a patient whose illness is explained by other processes for evaluation of MH susceptibility would be a costly waste of effort.

A new benefit of undergoing CHCT is that patients with contracture tests indicating MH susceptibility are candidates for genetic study. Initial studies of the *RYR1* gene in these subjects with MH susceptibility were limited to the three hot spots in *RYR1*. However, as a larger proportion of the *RYR1* gene is studied, the percentage of patients who have MH susceptibility with *RYR1* mutations or variants of unknown significance (VUS) has increased to 50% or more (Robinson et al., 2003; Sambughin et al., 2005; Ibarra et al., 2006; Levano et al., 2009). The process of evaluating MH susceptibility in relatives can begin with genetic evaluation in search of the familial mutation (Urwyler et al., 2001; Girard et al., 2004) after an *RYR1* mutation has been identified in the proband. Because fewer than 50% of all people who undergo contracture testing may be diagnosed as susceptible to MH by this test, if evaluation of MH status begins with screen of *RYR1*, the yield of positive diagnoses will be low (Girard et al., 2004).

A panel of 17 *RYR1* exons, encompassing all the acknowledged MH mutations, is available as a clinically useful genetic test of MH susceptibility (Sei et al., 2004) (see www.mhaus.org for the addresses of the diagnostic laboratories). It may detect a *RYR1* abnormality in about 30% of North American patients who would be diagnosed as susceptible to MH by CHCT. With this test, genetic counseling is available at the University of Pittsburgh, Center for Medial Genetics (800-54-8155). It is expected that genetic testing of MH susceptibility will be less sensitive but also less invasive and less costly than muscle biopsy and CHCT, because the genetics of MH susceptibility is not completely known (Nelson et al., 2004). Therefore, clinical genetic testing is of most value for determining affected family members in a family in which an *RYR1* mutation has been found in an individual who experienced severe MH or had a positive CHCT. The incidence of compound heterozygotes is relatively high when the entire *RYR1* gene is examined. Therefore, if an individual does not have the familial *RYR1* variant, contracture testing must be performed to prove that the patient is not susceptible to MH.

Individuals who have had positive muscle contracture tests after experiencing MH episodes should undergo genetic screening and document the result in the MH Registry (www.mhreg.org; 888-74-7899). If no abnormality is found in the *RYR1* gene in such patients, these are important subjects for experimental study of MH genetics.

The sensitivity and specificity of the CHCT have been determined; therefore, general statements about the predictive value of this test can be made (Larach et al., 1992; Larach, 1993; Ording et al., 1997; Allen et al., 1998). The clinician needs to know the predictive value of the test because the clinician can obtain the results of the diagnostic test. Before applying the test, the clinician cannot be sure whether or not the patient really has the disease.

The positive predictive value (PPV) of a test is the probability that an individual whose test result indicates that the disease is present does indeed have the disease of interest. The negative predictive value (NPV) of a test is the probability that an individual whose test result indicates that disease is absent does not have the disease in question. By definition, the predictive value depends on the probability that the individual has the disease in question before the test results are obtained, as well as the sensitivity and specificity of the test (Rosner, 1990). The sensitivity of a diagnostic test is the probability that a test result will indicate the disease is present, when in fact the individual tested has the disease in question. Specificity is the probability that a test result will indicate disease is not present, when in fact the individual tested does not have the disease in question. The definition of a positive result of the CHCT was set to make this test sensitive, so that fewer than 1% of the people who would be at risk of MH events would fail to be identified by the CHCT. Therefore, the CHCT could not also be highly specific. To apply Bayes Theorem and estimate the PPV or NPV, given the sensitivity and specificity of the CHCT, a clinician also has to make a decision about the probability that the patient is MH susceptible before the diagnostic results are known (Rosner, 1990). This probability may be thought of as the prior probability of the individual having the disease of interest or, if a population rather than an individual is considered, the incidence of the disease in the population (Box 37-3).

Rather than speculate on what a group of clinical findings suggests about the probability of MH susceptibility in an individual, it is possible to use the test characteristics (sensitivity and specificity) to calculate the predictive value of the CHCT over a wide range of prior probabilities (Fig. 37-5, A and B). For example, if a patient with a history of isolated masseter spasm is thought to have less than a 25% chance of having MH, then if the sensitivity of the CHCT is 99% and the specificity

Box 37-3 Interpretation of a Test

Sensitivity = $\Pr(T^+/D^+)$: The sensitivity of a test is the probability (\Pr) that the test result is positive (T^+) given that the disease is present (D^+).

Specificity = $\Pr(T^-/D^-)$: The specificity of a test is the probability (\Pr) that the test result is not positive (T^-) given that the disease is not present (D^-).

Predictive value of a positive test = $\Pr(D^+/T^+)$: The predictive value of a positive test, also known as the *positive predictive value (PPV)*, is the probability that the disease is present given that the test result was positive.

Predictive value of a negative test = $\Pr(D^-/T^-)$: The predictive value of a negative test, also known as the *negative predictive value (NPV)*, is the probability that the disease is present given that the test result was positive.

Prior probability and prevalence may be used interchangeably in these equations.

is 85%, the positive predictive value of the CHCT in that individual is less than 69% and the negative predictive value is greater than 99%. In other words, the chance of that individual having a false-positive result of CHCT is at least 30%, and the chance of a false-negative result is less than 1%. In contrast, if a patient with a strong family history of MH has many of the clinical signs of MH, it might be judged that the probability of that individual having MH, before obtaining the result of the CHCT, would be 80%. The positive and negative predictive values of the CHCT would be 96% and 99%, respectively, for such a patient. These statements are oversimplifications in that these calculations assume that the disease being tested for has similar manifestations in all affected individuals. Certainly this is not the case for MH. Nevertheless, appreciation of the concept of

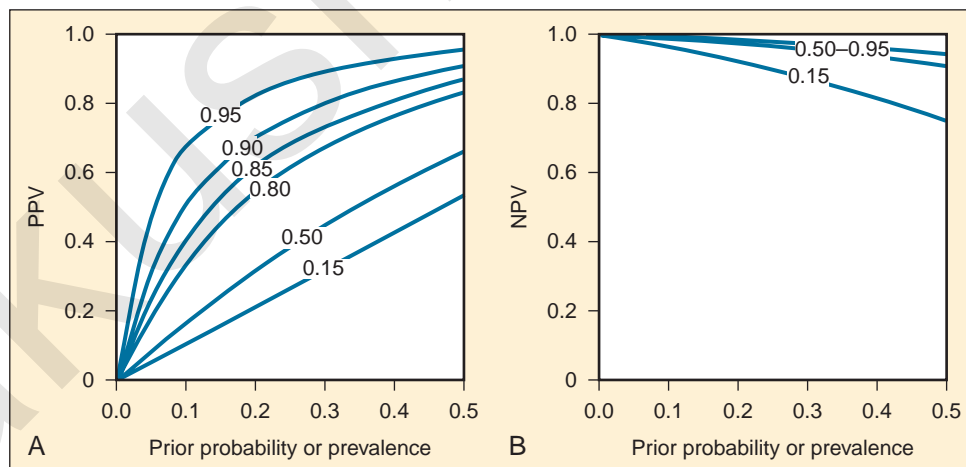

FIGURE 37-5. A, The y-axis is the PPV of the CHCT. This figure illustrates the fact that when the sensitivity is 95% and the specificity is 85%, the positive predictive value is less than 50% when the prior probability is less than 15%. **B,** The y-axis is the NPV of the CHCT. NPV is less altered by specificity than PPV when prior probability is less than 50%. Thus, the NPVs coincide for specificities from 85% to 95%. These two images illustrate the relationship between the sensitivity and specificity of a test, the prior probability of the disease, and the predictive value of that test (see definitions in Box 37-3). The probabilities on the graphs are shown as decimals between 0 and 1. In both figures, the x-axis is prior probability of MH susceptibility in the individual under consideration. This may be thought of as the probability that the individual under examination is susceptible to MH before the results of the CHCT are considered. This probability ranges from 0 to 0.5, or 50%, in these figures. In both figures, the sensitivity of the test is 0.95, or 95%. In both figures, the specificity of the CHCT varies between 0.95 (95%) and 0.15 (15%), as labeled on the dotted lines. The heavy line is the predictive value of the CHCT when sensitivity is 95% and specificity is 85%.

the predictive value of a test is important when questions arise regarding the meaning of clinical events and test results. These concepts have been used to argue that the index case should be the first person to undergo contracture testing, followed by first-degree relatives (Loke and MacLennan, 1998a; Larach and MacLennan, 1999). The same order of testing is appropriate for genetic analysis.

Currently, muscle biopsy and contracture testing of viable muscle is the only method that can confirm the diagnosis of not MH susceptible. The procedure can be viewed at www.mhaus.org. For satisfactory *in vitro* testing, 1 g of muscle must be removed from the thigh. A child weighing less than 20 kg may be too small to undergo muscle biopsy for CHCT. In general, children younger than 10 years of age are too young to undergo CHCT. Diagnostic standards were developed in adults.

Parents of an affected child may wish to have a muscle biopsy and contracture test performed (Figs. 37-6 and 37-7 and www.mhaus.org). The relatives of the parent whose findings are negative (assuming autosomal dominant inheritance) can then be reassured, without further testing, that they have no increased risk of MH. Ideally, siblings and first cousins on the affected side should be informed and offered diagnostic testing. Financial and geographic considerations often discourage families in these endeavors. However, the costs are less for genetic testing than for muscle contracture testing. Clinical genetic testing does not require travel to the location of the testing lab, as is necessary for CHCT. At the very

least, relatives of an patient with MH susceptibility should be informed about the presence of MH susceptibility in their family and its implications.

A valuable self-help resource is the Malignant Hyperthermia Association of the United States (MHAUS; PO Box 1069, 11 East State St., Sherburne, NY 13460; fax 1-607-674-7910). This organization offers information, expert consultation and referral, and many useful resources for families and health care providers. The MHAUS newsletter contains up-to-date information and reviews of the recent professional literature on topics related to MH. MHAUS maintains a 24-hour, professionally staffed telephone line to provide information on diagnosis, treatment, and referral of patients with MH (1-800-644-9737). See www.mhaus.org for addresses of the clinical laboratories at which genetic testing and muscle contracture testing are performed.

Care of Patients with a History of Malignant Hyperthermia

When a patient is referred preoperatively because of “possible MH,” the anesthesiologist should determine what led to this diagnosis. At times, patients are erroneously told that they “must have had an episode of MH” because a slight increase in temperature or transient ventricular arrhythmias occurred and no diligent effort was made to clarify the causes or to obtain

■ **FIGURE 37-6.** The muscle fiber contraction in response to an electrical stimulus and subsequent relaxation produces a black mark on the polygraph. Time is increasing from left to right. At the arrow, 3% halothane is added to the bath surrounding the fiber. The strength of normal muscle contraction (*top*) increases, but the muscle still relaxes to baseline. The MH susceptible muscle (*bottom*) does not relax back to baseline after exposure to halothane. In this case the contracture, the increase in baseline tension is over 2.5 g. (Courtesy of Dr. Muldoon and the MH Diagnostic Laboratory at the Uniformed Services of the Health Sciences.)

■ **FIGURE 37-7.** The muscle fiber contraction in response to an electrical stimulus and subsequent relaxation produces a black mark on the polygraph. Time is increasing from left to right. At the arrows increments of caffeine are added to the bath surrounding the fiber. The strength of normal muscle contraction (*top*) increases, but the muscle still relaxes to baseline until exposed to 8 mmol caffeine. The MH-susceptible muscle (*bottom*) does not relax back to baseline after exposure to low concentrations of caffeine. In this case the contracture, the increase in baseline tension is over 0.6 g in the presence of 2 mmol caffeine. (Courtesy of Dr. Muldoon and the MH Diagnostic Laboratory at the Uniformed Services of the Health Sciences.)

biochemical evidence of hypermetabolism or rhabdomyolysis. Many cases of increased jaw tension, arrhythmia, or mild elevation of myoglobin or CK after the administration of succinylcholine occur in the absence of MH susceptibility. When the issue of MH susceptibility has been raised, the personal and family history should be examined for adverse sequelae to anesthetics, sudden cardiovascular collapse suggestive of arrhythmias or heatstroke, and any evidence of musculoskeletal disorders, including cramping with exercise. A positive finding suggests that consultation with a neurologist and further testing (possibly including a muscle biopsy with *in vitro* contracture testing) may be warranted.

CK levels, at rest, are of no predictive value in the general population (Britt et al., 1976; Paasuke and Brownell, 1986). If a relative of a patient known to be susceptible to MH has an elevated CK level, that individual has an increased likelihood of susceptibility; however, this will not hold true for patients with other problems producing CK elevations (e.g., Duchenne's muscular dystrophy [DMD]). In some populations, more than 25% of the patients with elevated CK levels were not susceptible to MH on *in vitro* testing (Ellis et al., 1975).

Preoperative Care of Patients Who Are Susceptible to Malignant Hyperthermia

When it is clear that the suspected episode was MH, and especially when contracture testing has already been done and shows a typical MH pattern, several decisions must be made. If it is

at all possible, regional or local anesthesia should be chosen. Although some theoretic objections to amide-type local anesthetics exist, data in animals and humans have not shown any local anesthetic to trigger MH. Review of anesthetics during muscle biopsy suggests that nerve blocks with small volumes of amide local anesthetics do not provoke an episode of MH (Berkowitz and Rosenberg, 1985). Regional anesthesia with lidocaine, bupivacaine, ropivacaine, or another local anesthetic is an acceptable choice for the patient who is susceptible to MH.

Preoperative prophylactic dantrolene is not indicated. Because many muscle biopsies and other operations without preoperative administration of dantrolene or postoperative complications have been performed in patients with positive CHCT, it is considered acceptable to withhold preoperative dantrolene (Ording et al., 1991). These patients must be closely monitored during anesthesia with nontriggering agents (Table 37-2). If there are no signs of increased metabolism or rhabdomyolysis, and if no dantrolene was administered, then patients with MH susceptibility may be safely discharged on the day of surgery, even as soon as 2.5 hours after leaving the operating room (Yentis et al., 1992; Pollock et al., 2004, 2006).

Perioperative Care of Patients Who Are Suspected of Being Susceptible to Malignant Hyperthermia

An anesthesiologist may encounter patients who have had an anesthetic course or who have a family history that suggests susceptibility to MH but who have not had that possibility

TABLE 37-2. Malignant Hyperthermia and Drugs Used During Anesthesia

Drugs Likely to Trigger MH	Drugs that Do Not Trigger MH
Potent inhalation anesthetics:	Narcotics:
Sevoflurane	Benzodiazepines
Desflurane	Barbiturates
Isoflurane	Propofol
Halothane	Ketamine
Enflurane	Nondepolarizing (competitive) blockers
Ether	Anticholinesterases and anticholinergics
Depolarizing neuromuscular blocker succinylcholine	Local anesthetics
	Nonsteroidal antiinflammatory drugs
	Calcium

evaluated by means of muscle biopsy and in vitro contracture testing. A reasonable approach to providing anesthesia for such patients is to administer a nontriggering anesthetic and monitor the patient carefully for signs of MH (when this is consistent with safe anesthesia in that patient). It may not be possible to diagnose the underlying muscle disorder, but it is practical to watch for the processes that may hurt the patient postoperatively if an occult myopathy is present; these processes are hyperkalemic cardiac arrest, MH in the postanesthesia care unit (PACU), hyperthermia later resulting in multiorgan system failure, and myoglobinuric renal failure. Electrocardiogram can be monitored in the PACU in children. If there are no signs of MH in the first hour postoperatively, MH is unlikely to occur later (Litman et al., 2008). Rectal acetaminophen could block the increase in thermoregulatory setpoint that may produce postoperative temperature elevation and appropriate fluid replacement can promote dissipation of heat during recovery from anesthesia. Urine should be examined before discharge if a diagnosis of MH or other occult muscle disease is suspected. Dipstick of the urine with no blood demonstrates that there is no myoglobin in the urine; if there is no myoglobin in the urine, the patient has no increased risk of renal injury.

ANESTHESIA TECHNIQUES

Physiologic responses to stress may play a part in the initiation of an episode of MH in humans, as well as in pigs (Gronert and Theye, 1976a, 1976b; Gronert et al., 1980). Anesthesia for the patient who is susceptible to MH should be designed to be as stress free as possible, so that any tachycardia and arrhythmias that may occur are more likely to be associated with impending MH than with the stress of anesthetic, induction, or surgery.

There are many nontriggering techniques for general anesthesia (see Table 37-2). Local anesthetic cream can produce topical analgesia of the skin, which may facilitate intravenous catheter placement. Preoperative medication with midazolam, 0.3 to 0.7 mg/kg orally or 0.2 to 0.3 mg/kg nasally, often produces sedation adequate to facilitate the placement of an

intravenous catheter in a child. In the opinion of some anesthesiologists, preoperative sedation is an important part of the anesthetic management for patients who are susceptible to MH. After placement of an intravenous catheter, anesthesia may be induced with barbiturates or propofol, narcotics, and α_2 -agonists (e.g., dexmedetomidine), as indicated by the planned surgery and other characteristics of the patient (Raff and Harrison, 1989; Harrison, 1991). Intramuscular administration of general anesthetics may be an alternative. Prior administration of benzodiazepine can reduce chest and truncal rigidity commonly observed after the administration of a synthetic narcotic. A nondepolarizing neuromuscular blocking agent may be administered if necessary. It is helpful to use a peripheral nerve stimulator when a neuromuscular blocker is administered so that the dose of drug can be titrated to the desired effect. Similarly, an anticholinesterase should be administered as indicated by the results of peripheral nerve stimulation.

There are rare reports of changes compatible with MH occurring after the use of such “safe” general anesthetic drugs (Fitzgibbons, 1980; Pollock et al., 1992; Shukry et al., 2006). For susceptible patients, there is no absolutely safe general anesthetic technique—merely drugs that are less likely to trigger MH. It is advisable to avoid drugs that may affect temperature regulation and sympathetic tone to such an extent that it might be difficult to detect early signs of insidious MH. Furthermore, serotonergic agonists and some psychotropic drugs (e.g., Ecstasy) have produced MH episodes in susceptible pigs (Wappler et al., 1997; Fiege et al., 2003). Large doses of phenothiazines and anticholinergics are not drugs of choice for the patient who is susceptible to MH. Atropine is administered only when there is significant risk of bradycardia. However, some anesthesiologists have found ketamine to be a useful anesthetic in patients who are susceptible to MH.

Monitoring and preparedness to treat acute MH are of the utmost importance. In addition to precordial heart tones, electrocardiogram, blood pressure, minute ventilation, and oxygen saturation, end-tidal oxygen and carbon dioxide concentrations should be monitored. Core temperature should be measured. Arterial and urinary bladder catheters are not needed for all surgery in patients with susceptibility to MH, but they are convenient for repeated blood sampling and close monitoring of hemodynamic stability and urine myoglobin.

It is helpful to keep drugs and supplies to treat MH in a portable container, such as a carry-all or rolling cart that is immediately accessible in the operating room and recovery room and can easily be transported to other areas of the hospital (see Table 37-1). The necessary supplies include at least 5 to 10 mg/kg of dantrolene and liter quantities of sterile, preservative-free, distilled water in which to dissolve the dantrolene. Ice or cold packs should be available, and large volumes of normal saline solution should be available in a nearby refrigerator.

Anesthetic Management for Muscle Biopsy for Contracture Testing

The preceding recommendations for the anesthetic care of patients with MH susceptibility apply to the patient undergoing diagnostic muscle biopsy. Biopsy for CHCT can be done only in one of the four specialized centers in the United States that support the performance of this in vitro test. The list of currently active centers may be obtained from www.mhaus.org.

The child scheduled for a biopsy usually weighs more than 20 kg, and some biopsy center directors will test only children who are at least 10 years old. The patient may be mature enough to have regional anesthesia before biopsy; in a cooperative child the use of lateral femoral-cutaneous nerve block and intravenous sedation is often successful (Berkowitz and Rosenberg, 1985). If the child cannot cooperate, general anesthesia may be induced and maintained with various agents, including benzodiazepines, narcotics, propofol or barbiturates, dexmedetomidine, nondepolarizing relaxants, or nitrous oxide.

Postoperative Care of Patients Who Are Susceptible to Malignant Hyperthermia

If anesthesia has proceeded uneventfully and prophylactic dantrolene has not been administered, the patient should be transported to the recovery room for the usual monitoring of vital signs, electrocardiogram, mental status, and urine output and color. A dipstick should be used to check urine for blood. The reaction of heme with orthotolidine occurs if myoglobin, free hemoglobin, or red blood cells are present (Bosch et al., 2009). If no sign of MH appears, the patient may be transferred to the floor after an ordinary length of stay in the recovery room. After observing such a patient for 2.5 hours after the end of anesthesia without any sign of MH, the patient may be discharged from the hospital. In this way, it is possible for a child who is susceptible to MH to be treated successfully as an outpatient (Yentis et al., 1992; Pollock et al., 2004, 2006).

If there is any evidence of hypermetabolism, or if continued treatment with intravenous dantrolene is contemplated, the patient should be cared for in an intensive care area. In a patient who has MH postoperatively, the anesthesiologist should be called to evaluate fever or tachycardia; the causes are usually related to pain, dehydration, or bacteremia. Nevertheless, MH has rarely been reported to occur several hours postoperatively. The patient must be examined carefully for signs of MH or altered mental status, venous blood gas tension and lactate should be measured, and urine should be tested for myoglobin. If signs of hypermetabolism or rhabdomyolysis are present, the patient should be treated with intravenous dantrolene and transferred to an intensive care unit.

DISORDERS ASSOCIATED WITH MALIGNANT HYPERTHERMIA

A number of disorders have been thought to be related to the MH syndrome because their presence appears to increase the risk of MH during anesthesia, but solid evidence is often lacking (Table 37-3) (Davis and Brandom, 2009). A complete understanding of these syndromes could contribute to understanding the pathophysiology of MH. Although not all myopathic patients are susceptible to MH, the presence of a known or suspected myopathy should alert the anesthesiologist that there may be increased potential for MH susceptibility or anesthesia complications that may mimic MH (Heytens et al., 1992).

Many patients with DMD have received potent inhalation anesthetics without occurrence of MH, but dystrophic muscle

TABLE 37-3. Association of Various Diseases with Malignant Hyperthermia

Disease	Observed Anesthetic Complications
Duchenne's muscular dystrophy (DMD)	Rarely, chronic rhabdomyolysis increases and may result in hyperkalemic cardiac arrest.
Becker muscular dystrophy	As in DMD, and growth of new muscle increases likelihood of hyperkalemia after succinylcholine.
Noonan syndrome	Not related to MH
Osteogenesis imperfecta	Increase in temperature is common but not related to MH.
King-Denborough syndrome	Susceptible to MH
Carnitine palmitoyltransferase II deficiency	MH susceptibility plausible but unproven
Myophosphorylase B deficiency (McArdle disease)	Rhabdomyolysis is common with any stress; CHCT may be diagnostic of susceptibility to MH, but few anesthesia experiences have been recorded.
Myoadenylate deaminase deficiency	As in McArdle disease
Brodie disease	Not susceptible to MH
Asymptomatic hyperkalemia	Causes of this syndrome may be many. Patients are likely to have hyperkalemia after succinylcholine and may have normal CHCT. Alternatively, an individual with increased CK may be a patient with central core disease (CCD) who is asymptomatic. MH is likely in CCD.
Myotonia congenita	No increased risk of MH over that in the general population
Paramyotonia congenita	No increased risk of MH over that in the general population
Potassium-aggravated myotonia	No increased risk of MH over that in the general population
Myotonia fluctuans	No increased risk of MH over that in the general population
Myotonia permanens	No increased risk of MH over that in the general population
Acetazolamide-responsive myotonia	No increased risk of MH over that in the general population
Hyperkalemic periodic paralysis ± myotonia	No increased risk of MH over that in the general population
Myotonic dystrophy type I (Steinert disease)	No increased risk of MH over that in the general population

TABLE 37-3. Association of Various Diseases with Malignant Hyperthermia—cont'd

Disease	Observed Anesthetic Complications
Myotonic dystrophy type II	No increased risk of MH over that in the general population, but there is greatly increased risk of adverse respiratory events postoperatively, as well as heart block. See detailed texts on this disease.
Hypokalemic periodic paralysis	Unclear, but there may be greater risk of MH than in the general population. There is potential for dangerous stiffness after succinylcholine, but metabolism may not increase as it does in MH.
Central core myopathy (CCD)	Susceptible to MH
Multiminicore disease with <i>RYR1</i> mutation	Susceptible to MH
Multiminicore disease without <i>RYR1</i> mutation	Maybe susceptible to MH
Nemaline rod myopathy without <i>RYR1</i> mutation	Maybe susceptible to MH
Nemaline rod myopathy with <i>RYR1</i> mutation	Susceptible to MH

From Davis PJ, Brandom BW: The association of malignant hyperthermia and unusual disease: when you are hot you are hot or maybe not, *Anesth Analg* 109:1001, 2009.

is fragile and can have RYR1 dysfunction (Peluso and Bianchini, 1992; Bellinger et al., 2009). Even mild exercise in patients with DMD results in a marked egress of sarcoplasmic components into the plasma, most notably myoglobin, CK, and potassium (Florence et al., 1985). These patients can have rhabdomyolysis during anesthesia with potent inhalation anesthetics even without the administration of succinylcholine (Rubiano et al., 1987). It is not surprising that anesthetic complications with many of the qualities of MH occur in patients with abnormal dystrophin (Kleopa et al., 2000) (see Chapter 32, Systemic Disorders). Nevertheless, there has been at least one patient who had dystrophinopathy and a negative contracture test, which ruled out MH susceptibility in that patient (Gronert et al., 1992).

Less common than dystrophinopathy, enzyme deficiencies and mitochondrial disease in muscle may also produce rhabdomyolysis, which can be easily exacerbated. Nonspecific signs of MH may occur during anesthesia (Hogan and Vladutiu, 2009). If the patient has a history of recurrent rhabdomyolysis, blood-based genetic testing of carnitine palmitoyltransferase II (CTP2), myophosphorylase (PYGM; deficiency of PYGM is McArdle disease), and myoadenylate deaminase (AMPD1) may determine the cause. When these blood tests are not diagnostic, muscle biopsy may be useful for diagnosis of these enzyme deficiencies as well as deficiencies in the glycolytic pathway and mitochondrial diseases.

Several extensive family studies of central core disease (CCD) have documented morphologically abnormal muscle—i.e., central cores of oddly aligned fibers—in some patients with MH (Shy and Magee, 1956; Byrne et al., 1982; Jeong et al., 2008). CCD is the first myopathy for which a definite link to MH was shown. Multiminicore disease is a different histologic diagnosis that has also been associated with susceptibility to MH and may be related to CCD (Ferreiro et al., 2002; Jeong et al., 2008). Several mutations in *RYR1* cause both CCD and MH susceptibility; therefore, it is advisable to treat a patient with CCD as susceptible to MH (Loke and MacLennan, 1998b; Tilgen et al., 2001; Robinson et al., 2006). The risk of MH in CCD, multiminicore disease, and nemaline rod myopathy was recently reviewed by Klinger and colleagues (2009).

Another familial myopathy, the King-Denborough syndrome, is associated with MH susceptibility (King and Denborough, 1973). Affected individuals have proximal muscle weakness, postural imbalances, cryptorchidism, webbed

neck, pectus deformities, delayed development, and elevated levels of CK (Jurkat-Rott et al., 2000). Variants in the *RYR1* gene have been found in some patients with King-Denborough syndrome.

In the past, other disorders in which patients appeared to have MH susceptibility included myotonia congenita, osteogenesis imperfecta, Schwartz-Jampel syndrome (dwarfism, craniofacial and skeletal abnormalities, blepharophimosis, and muscle stiffness), and possibly arthrogyrosis (Fowler et al., 1974; Rampton et al., 1984; Baines et al., 1986). These syndromes may be associated with many of the symptoms of MH, but these symptoms are not specific for MH. Many patients with these and other muscular disorders have received inhalation anesthetics without complications. For example, a pyloromyotomy was performed in an infant with paramyotonia congenita during sevoflurane anesthesia (Ay et al., 2004). Sometimes evaluation of suspect cases has found CHCT to be negative (Hopkins et al., 1991). A recent review of myotonias concluded that with the exception of hypokalemic periodic paralysis (hypoKPP), the risk of MH in myotonic patients is not increased (Parness et al., 2009). For theoretic reasons, although there are no published case reports of MH-like adverse events in patients with hypoKPP, risk of MH may be increased in this condition. Definitive diagnosis of myotonias and other channelopathies (including MH) should be pursued, because specific treatment may be available (Lehmann-Horn et al., 2008).

The neuroleptic malignant syndrome (NMS) is a potentially fatal disorder recognized by psychiatrists that may clinically resemble MH (Cohen et al., 1985; Guzé and Baxter, 1985; Mann et al., 2003). It occurs in 1:200 patients taking neuroleptic drugs that produce dopaminergic blockade. A 24-hour consultant service is available through the Neuroleptic Malignant Syndrome Information Service (NMSIS; www.nmsis.org; 888-667-8367). Most patients with NMS are young men with schizophrenia or mania treated with the potent piperazine phenothiazines or haloperidol, but more than 25 drugs have been implicated (Heiman-Patterson, 1993). NMS may also occur when the administration of antiparkinsonian drugs is stopped. The manifestations of NMS are altered mental status, hypermetabolism with fever, tachycardia, muscle rigidity, and myoglobinuria. NMS has all of the clinical features of MH, including acute renal failure and multiorgan failure, but it progresses over hours to days rather than minutes.

The inciting events of NMS differ from those of MH. Blockade of dopamine receptors can produce hyperthermia and rigidity, and bromocriptine, (dopamine agonist) as well as dantrolene and benzodiazepines have been used to successfully treat this syndrome (Caroff, 1980; Granati et al., 1983; Heiman-Patterson, 1993). The results of CHCT in patients with a history of NMS have been inconsistent (Caroff et al., 1987; Adnet et al., 1989). Drugs that are known triggers of MH have been well tolerated in patients who have had NMS. Repeated exposure of pigs with MH susceptibility to a serotonin-2 receptor agonist can also induce typical MH symptoms without causing the same syndrome in normal animals (Gerbershagen et al., 2003). Mann et al. (2003) demonstrated that in humans the serotonin syndrome (tremor, diaphoresis, shivering, and myoclonus in the presence of serotonergic medication) could be elicited easily in individuals susceptible to MH. Dantrolene can delay serotonin-induced contractures (Wappler et al., 1997).

CONTRACTURE TEST

The CHCT is the best laboratory test available to investigate susceptibility to MH. The methods for performance of the test have been standardized in North America and slightly differently in Europe (Larach et al., 1989; Ording and Bendixen, 1992). Both tests provide consistent normal population values for comparison with diagnostic biopsies. In both North America and Europe, the CHCT is a concentration-response curve to caffeine alone and halothane alone. Unlike usual concentration-response phenomena, differences between persons susceptible to MH and those who are not do not appear as altered (median effective dose) ED_{50} or as a change in slope, but as a change in threshold. Patients must travel to the MH diagnostic center where this bioassay can be performed. The muscle strips to be tested must respond with active twitch to electrical stimulation (i.e., they must be viable). The test should be completed within 5 hours of the excision of muscle from the patient's thigh.

The North American protocol includes exposure of muscle strips to 0.5, 1, 2, 4, 8, and 32 mmol/L caffeine. A positive CHCT is often defined as an increase in tension of 0.2 g in the presence of 2 mmol/L caffeine or less. However, a cutoff of 0.3 g or 0.4 g may be preferred to increase the specificity of the test (Larach, 1989). A positive halothane contracture test is the development of more than 0.2 g to 0.7 g tension (depending on the controls in that laboratory) in the presence of 3% halothane (Larach et al., 1989). In the United States, if one muscle strip produces a positive reaction in either caffeine or halothane, the patient is said to be susceptible to MH.

Other laboratory tests have been evaluated for their diagnostic usefulness in MH; these include calcium uptake into frozen muscle, skinned fiber testing, platelet nucleotide depletion measurement, and the measurement of abnormal proteins in MH muscle. None of these is generally accepted, because none has been shown to reproduce the results of the in vitro muscle contracture tests (Lee et al., 1985; Britt and Scott, 1986; Whistler et al., 1986; Nagarjan et al., 1987). Several of the proposed tests produced inconsistent results (Ording et al., 1990; Quinlan et al., 1990).

MH is a disorder of muscle that is usually subclinical until the muscle is stressed. Tests discern MH susceptibility only if they impose a stress on the intact tissue or organism or detect a genetic difference that has been demonstrated to be causative

(Urwyler et al., 2003). MH muscle testing is generally designed to avoid false-negative diagnoses; hence, there may be false-positive results of the CHCT. Findings suggest that as with all tests, there are some rare false-negative contracture test results (Larach, 1993). However, overall MH contracture testing appears accurate, and patients with negative findings on CHCT can receive safe anesthetics with drugs that could trigger MH (Ording et al., 1991).

Failure to detect an *RYR1* mutation does not imply that the patient is not susceptible to MH. If a patient undergoes genetic evaluation before contracture testing and no MH-causative mutation is found, the patient must undergo contracture testing in order to support the diagnosis of not susceptible to MH. All patients should be monitored for signs of MH during anesthesia. Furthermore, MH can occur without the use of triggering drugs such as succinylcholine and potent inhalation anesthetics (Fitzgibbons, 1980; Pollock et al., 1992; Shukry et al., 2006).

ANESTHESIOLOGISTS' RESPONSIBILITY TO OTHER PHYSICIANS

MH has been known for more than 40 years, yet many primary care physicians, dentists, and surgeons are still unaware of its life-and-death significance. In 1986 the Malignant Hyperthermia Association of the United States published a letter from a parent:

Your information will be most helpful for my married, out-of-state, pregnant daughter who tried to explain that MH existed in our family... They told her nobody could be allergic to anesthetics, which was the same thing I was told 22 years ago when my son's tonsils were removed. We had lost many relatives to ether for minor surgery over the years. Trying to explain MH in places that don't have large amounts of it is difficult. Some won't listen...

Anonymous, 1986

Physicians who are aware of the potential seriousness of MH may ask what the implications of the diagnosis of MH susceptibility are for the patient's daily life. MH susceptibility has been associated with fourfold increases in plasma catecholamines with graded exercise and rapid exhaustion after intense exercise; however, individuals susceptible to MS have performed farm labor in the hot sun without precipitating an MH attack (Wappler et al., 2000; Rueffert et al., 2004). Early studies of metabolic responses during noncompetitive, low-intensity, steady-state exercise found no difference between control and patients with MH susceptibility (Green et al., 1987). Slower recovery of muscle pH and phosphocreatine/inorganic phosphate ratios have been observed in patients with MH susceptibility (Allsop et al., 1991; Olgin et al., 1991). Patients who are susceptible to MH should be encouraged to refrain from strenuous exercise if they experience cramps or fever under such circumstances (Davis et al., 2002). Some people with MH susceptibility are unable to sustain exercise in the heat as well as they do in cool environments, and some patients with exertional heat stroke are actually susceptible to MH (Bendahan et al., 2001; Tobin et al., 2001; Wappler et al., 2001). Dantrolene may be therapeutic when these symptoms occur (Gronert, 1980).

Sudden death from undetermined cause may be common in the history of families with MH susceptibility. In adults these sudden deaths may be the result of arrhythmias. As of yet there are no published data regarding possible changes in

muscle function with age in patients susceptible to MH, but it is noteworthy that in some families with MH susceptibility the young adults are muscular and strong, whereas the older adults may fatigue easily. CCD may be found in some individuals who are susceptible to MH.

The North American Malignant Hyperthermia Registry, now at the University of Pittsburgh Medical Center in Pittsburgh, Pennsylvania (Dr. Barbara W. Broom, Director), collects data from health care providers, affected families, and testing centers in Canada and the United States. This registry provides a database through which to define clinical MH and to study aspects of its presentation, treatment, and diagnostic methods. Because MH is a rare event, it is necessary to collect clinical reports from a large geographic area over an extended period of time to improve understanding of the clinical problem. Because MH is rare, all health care providers have a responsibility to report such cases or suspected cases to the Registry.

SUMMARY

MH is a potentially lethal pharmacogenetic syndrome. It has been of particular concern to pediatric anesthesiologists because succinylcholine and inhalation anesthetics are potent triggers of MH and may be administered often in the practice of pediatric anesthesia. With the advent of improved monitoring techniques and universal availability of intravenous dantrolene, mortality from MH has plummeted. However, the

definitive diagnosis of MH is still not simple or easy. It falls to anesthesiologists to choose anesthetic agents and adjuvants that maximize the safety of the patient, to identify as potentially susceptible to MH those individuals who experience adverse reactions consistent with MH, and to counsel and refer those individuals and families to appropriate diagnostic centers. Anesthesiologists must also make fellow physicians and other health care providers aware of the existence and the seriousness of MH and its effective treatment and prevention. When capnography, blood gas analysis, temperature monitoring, and dantrolene are available, patients with a history of MH susceptibility may safely receive routine anesthetic care with nontriggering anesthetics.

In the late 1950s, children suffering cardiac arrest during anesthesia received 1.5 minutes of knee-to-chest “artificial respiration” followed by a thoracotomy for internal cardiac massage (Rainer, 1957). In 1958, closed-chest compressions were successfully performed on a 2-year-old child (Sladen, 1984). The resuscitation of that child, along with several successful resuscitations of subsequent patients (many undergoing anesthesia) led to reporting of closed-chest compressions for cardiac resuscitation (Kouwenhoven et al., 1960). Currently, 50% to 60% of

children who have perioperative cardiac arrest are successfully resuscitated (Bhananker et al., 2007). Despite the success rate of resuscitation during anesthesia, the potential for disaster and the increased likelihood of cardiac arrests in younger children and infants require that pediatric anesthesiologists have a complete understanding of the physiology and pharmacology of cardiopulmonary resuscitation (CPR). “No more depressing shadow can darken an operating room than that occasioned by the death of a child” (Leigh and Belton, 1949).

CARDIAC ARREST DURING ANESTHESIA

Incidence of Cardiac Arrest During Anesthesia

Perioperative cardiac arrest generally refers to an event that requires chest compressions while a patient is under an anesthesiologist's care during either the intraoperative or immediate postoperative period. Cardiac arrest may be the result of factors related to anesthesia, surgical procedure, or patient comorbidities. When comparing reports of anesthesia-related cardiac arrest, definitions and timeframes vary, with some including only the intraoperative period and others including the time from premedication through 24 hours postoperatively or longer. Some studies are based on electronic databases, and others depend on voluntary reporting to registries. The inclusion of events occurring during cardiac surgery by some studies and not others further complicates this comparison.

Results of studies that examined the incidence of pediatric perioperative cardiac arrest for all types of procedures, including cardiac surgery, are listed in [Table 38-1](#). The overall incidence for pediatric perioperative cardiac arrest for all age groups undergoing all types of surgeries ranged from 7.2 to 22.9 per 10,000 procedures (Cohen et al., 1990a; Braz et al., 2006; Flick et al., 2007). Studies that excluded cardiac surgery reported a lower overall incidence, ranging from 2.9 to 7.4 per 10,000 (Murat et al., 2004; Flick et al., 2007; Bharti et al., 2009). When only anesthesia-related cardiac arrest was included, the incidence for all types of surgery (including cardiac) ranged from 0.8 to 4.58 per 10,000. The highest incidence of cardiac arrest was seen in patients undergoing cardiac surgery, ranging from 79 to 127 per 10,000 (Flick et al., 2007; Odegard et al., 2007). This information is helpful when estimating risk, but whatever the risk of pediatric perioperative cardiac arrest, the anesthesiologist must be ready and able to treat the cause and resuscitate the child.

As shown in [Table 38-1](#), risk factors for pediatric perioperative cardiac arrest were consistently found in all studies to be associated with younger patient age. The highest risk was seen in infants younger than 1 month of age, followed by those younger

than 1 year old. The Perioperative Cardiac Arrest (POCA) registry compared age groups in anesthesia-related cardiac arrests and found that between 1994 and 1997, 56% of cases were infants younger than 1 year old, whereas between 1998 and 2004, only 38% of the cases were infants younger than 1 year old. This significant decrease in the percentage of cardiac arrest in infants is attributed to the declining use of halothane and increasing use of sevoflurane, which is associated with less bradycardia and myocardial depression (Bhananker et al., 2007). Anesthesia-related cardiac arrest is reported to be higher overall for children (1.4 to 4.6 per 10,000) than adults (0.5 to 1 per 10,000), although the incidence in some studies is similar, presumably because both groups have high-risk patients at the extremes of age (Zuercher and Ummenhofer, 2008).

The patient's physical condition impacts cardiac arrest risk. Risk significantly increases when American Society of Anesthesiology (ASA) physical status (PS) is 3 or higher (Morrays et al., 2000; Murat et al., 2004; Braz et al., 2006; Bhananker et al., 2007; Flick et al., 2007). Patients at ASA PS 5 are often not included in reports of anesthesia-related events, because by definition they have a low likelihood of survival, making it difficult to determine whether events are a result of their condition or related to anesthesia. Patients with ASA PS 4 and 5 have a 30 to 300 times greater risk of cardiac arrest than patients with ASA PS 1 or 2 (Rackow et al., 1961; Newland et al., 2002). Prematurity, congenital heart disease, and congenital defects are common pediatric comorbidities that increase the risk for children (Morrays et al., 2000; Bhananker et al., 2007; Odegard et al., 2007).

The designation of emergency status to a patient's procedure was a risk factor for both cardiac arrest and mortality in some studies but not in others. Emergency surgery was associated with a significantly increased incidence of perioperative cardiac arrest, with 123 per 10,000 anesthesia procedures vs. 15 to 16 per 10,000 for nonemergent cases ($p < 0.05$) (Braz et al., 2006). In addition to a higher incidence of arrests during an emergency procedure, a poorer outcome was also reported (Vacanti et al., 1970; Marx et al., 1973; Olsson and Hallen, 1988; Morrays et al., 2000; Biboulet et al., 2001; Newland et al., 2002;

Sprung et al., 2003; Bharti et al., 2009). In contrast, several studies did not find a statistically significant trend to decreased survival as a result of emergency status (Biboulet et al., 2001; Flick et al., 2007; Zuercher and Ummenhofer, 2008). It is not clear whether emergency procedures have increased perioperative risk because of the patient's condition, the lack of optimal personnel, or both.

Etiology of Cardiac Arrest During Anesthesia

Causes of cardiac arrest during anesthesia are typically grouped either by organ systems involved or interventions applied. A summary of the etiologies and timing of cardiac arrest during anesthesia as reported in the literature is listed in [Table 38-2](#). The pediatric POCA registry uses a classification system that involved both interventions and organ systems, thus grouping cardiac arrests as being related to medication, cardiovascular factors, respiratory factors, or equipment (Murray et al., 2000; Odegard et al., 2007). Some etiologies may be difficult to classify because they fit into several grouping schemes. For example, succinylcholine-induced dysrhythmia may be classified as either a medication-related or a cardiovascular cause of cardiac arrest. A set of guidelines for reporting cardiac arrest data in children, known as the pediatric Utstein guidelines, suggested a classification based on organ systems for etiologies (Zaritsky et al., 1995). The Utstein guidelines used three groups consisting of cardiac, pulmonary, and cardiopulmonary factors for comparison of etiologies of cardiac arrest in children. The Utstein guidelines have not yet been widely incorporated into anesthesia-related cardiac arrest literature. The anesthesia literature generally groups the etiology of cardiac arrest into those related to medication, cardiovascular, or respiratory categories, as shown in [Box 38-1](#).

Previously, medication-related etiologies were the most common reasons for cardiac arrest related to anesthesia in children, representing approximately 35% of cardiac arrests (range of 4% to 54%) (Rackow et al., 1961; Salem et al., 1975; Keenan and Boyan, 1985; Olsson and Hallen, 1988; Morgan et al., 1993; Murray et al., 2000; Biboulet et al., 2001; Newland et al., 2002; Kawashima et al., 2003; Sprung et al., 2003). There has been a decrease in reports of medication-related etiologies to between 18% and 28%, and cardiac and respiratory causes are now the most commonly reported ([Fig. 38-1](#)) (Braz et al., 2006; Bhananker et al., 2007). This may be the result of a decrease in incidence of inhalation-agent overdose when use of sevoflurane replaced halothane for anesthetic induction. It is not clear whether sevoflurane is less cardiotoxic than halothane or the delivered dose of sevoflurane is lower because of vaporizer limits relative to a higher minimum alveolar concentration (MAC) for sevoflurane. Similarly, a decrease in succinylcholine-induced dysrhythmias was reported after a warning was issued related to use of succinylcholine in children. Other medication-related causes of cardiac arrest include those associated with regional anesthesia: intravenous (IV) administration of local anesthetic intended for caudal space, high spinal anesthesia, and local anesthesia toxicity. Inadequate reversal of a paralytic agent and opioid-induced respiratory depression are medication-related causes of cardiac arrest that more often present in the postoperative period.

Cardiovascular-related causes of cardiac arrest now represent approximately over 40% of cardiac arrests related to anesthesia in children (Braz et al., 2006; Bhananker et al., 2007).

Cardiac arrests caused by decreased intravascular volume are most commonly reported in this group, and causes include inadequate volume administration, excessive hemorrhage, and inappropriate volume or transfusion administration (Braz et al., 2006; Bhananker et al., 2007; Flick et al., 2007). Dysrhythmias caused by hyperkalemia are seen with succinylcholine administration, transfusion, reperfusion, myopathy, or renal insufficiency (Larach et al., 1997). Dysrhythmia or cardiovascular collapse (asystole) may have a vagal etiology as a result of traction, pressures, or insufflations of the abdomen, eyes, neck, or heart. Cardiovascular collapse can occur with anaphylaxis from exposure to latex, contrast, drugs, or dextran. Venous air embolism is another important cause of cardiovascular collapse and cardiac arrest in patients who are under anesthesia. Malignant hyperthermia is a seldom-reported cause of cardiac arrest in this group.

Respiratory-related causes are responsible for approximately 31% (range of 15% to 71%) of cardiac arrest related to anesthesia in children and adults (Rackow et al., 1961; Salem et al., 1975; Keenan and Boyan, 1985; Olsson and Hallen, 1988; Morgan et al., 1993; Murray et al., 2000; Biboulet et al., 2001; Newland et al., 2002; Kawashima et al., 2003; Sprung et al., 2003; Braz et al., 2006; Bhananker et al., 2007; Flick et al., 2007). Respiratory-related events as the primary cause of cardiac arrest have declined over the years as a source of malpractice claims, from 51% in the 1970s to 41% in the 1980s and 23% from 1990 through 2000 (Jimenez et al., 2007). Inadequate ventilation and oxygenation are broad categories often listed in this group as causes of cardiac arrest. "Loss of the airway" may involve laryngospasm or bronchospasm; an anatomy that is difficult to manage; or a misplaced, kinked, plugged, or inadvertently removed endotracheal tube (ETT). Aspiration remains a cause of respiratory-related cardiac arrest but is not often mentioned in the recent literature.

Equipment-related causes involve approximately 4% (range of 0% to 20%) of cardiac arrest related to anesthesia in children and adults (Rackow et al., 1961; Salem et al., 1975; Keenan and Boyan, 1985; Olsson and Hallen, 1988; Morgan et al., 1993; Murray et al., 2000; Biboulet et al., 2001; Newland et al., 2002; Kawashima et al., 2003; Sprung et al., 2003). Categories of equipment-related cardiac arrest most commonly described include central-venous-catheter-induced bleeding, dysrhythmias, and breathing circuit disconnection. Other etiology groups of cardiac arrest reported in some studies include multiple events (3%), inadequate vigilance (6%), or an unclear etiology (9%, range of 1% to 18%) (Olsson and Hallen, 1988; Murray et al., 2000; Biboulet et al., 2001; Kawashima et al., 2003).

Determination that a cardiac arrest is anesthesia related is subjective, as is the extent that a cardiac arrest is related to anesthesia care. Patient-related factors, procedure-related factors, and anesthesia care-related factors are the three most important determinants of etiology of operating-room cardiac arrests. Attempts to determine extent of contribution of anesthesia care in cardiac arrest has produced terms such as *anesthesia-associated* and *anesthesia-attributable* cardiac arrest. Determination of an anesthesia-related contribution is complicated by the contribution of patient- and procedure-related factors. To what extent does anesthesia care contribute to a cardiac arrest related to surgical bleeding in a patient with a coagulopathic condition? Is failing to keep up with major hemorrhage or to correct a coagulopathy related to the procedure, to the patient, or to the

TABLE 38-2. Etiology and Timing of Pediatric Perioperative Cardiac Arrest

†Flick et al. (2007) reported the results of cardiac arrest separately for cardiac and noncardiac cases. None of the cardiac arrests during cardiac procedures were considered to be anesthetic related.

Box 38-1 Causes of Cardiac Arrest During Anesthesia**MEDICATION-RELATED CAUSES**

Anesthetic overdose, or relative overdose, of inhalation or intravenous agent
 Succinylcholine-induced dysrhythmia
 Neostigmine-induced dysrhythmia
 Medication "swaps"
 Drug reactions
 Unintended intravascular injection of local anesthetic
 High spinal anesthesia
 Local anesthesia toxicity
 Inadequate reversal of a paralytic agent
 Opioid-induced respiratory depression

CARDIOVASCULAR-RELATED CAUSES

Hypovolemia
 Hemorrhage
 Inadequate or inappropriate volume administration
 Hyperkalemia as a result of succinylcholine, rapid or large-volume transfusion, reperfusion, myopathy, potassium administration, or renal insufficiency
 Hypocalcemia from citrate intoxication during rapid blood product administration
 Hypoglycemia

Vagal episodes as a result of traction, pressure, or insufflation involving the abdomen, eyes, neck, or heart
 Central venous catheter related dysrhythmia, hemorrhage or tamponade
 Anaphylaxis after exposure to latex, contrast agents, drugs, or dextran
 Embolism of air, clot, or fat
 Malignant hyperthermia
 Hypothermia
 Myocardial ischemia
 Sepsis
 Adrenal insufficiency

RESPIRATORY-RELATED CAUSES

Inadequate ventilation and oxygenation
 Inability to ventilate as a result of laryngospasm, bronchospasm, airway mass, endotracheal tube misplacement, kink, plug, or inadvertent removal
 Difficult-to-manage airway anatomy
 Residual neuromuscular weakness
 Aspiration
 Pneumothorax

FIGURE 38-1. Causes of anesthesia-related cardiac arrest in 1998 through 2004 compared with 1994 through 1997. Multiple and miscellaneous other causes (3% from 1998 to 2004 vs. 4% from 1994 to 1997) not shown.** $P < 0.01$, 1998 to 2004 vs. 1994 to 1997 by Z test. (Data for 1994 to 1997 from Morray et al: *Anesthesia-related cardiac arrest in children: initial findings of the Pediatric Perioperative Cardiac Arrest [POCA] Registry*, *Anesthesiology* 93:6, 2000.)

anesthesia care? Many studies simply use the term *anesthesia-related* to describe a cardiac arrest after an anesthesiologist has been involved in care of the patient.

Anesthesia-related cardiac arrest may be preventable 53% of the time, and anesthesia-related mortality is preventable 22% of the time (Kawashima et al., 2003). Human error may be the most important factor in deaths attributable to anesthesia and usually manifests not as a fundamental ignorance but as a failure in application of existing knowledge (Olsson and Hallen, 1988). Poor preoperative preparation and inadequate vigilance are often reported as avoidable errors. Examples of poor preoperative preparation relevant to the pediatric anesthesiologist include failure to identify patients with symptoms of an undiagnosed skeletal myopathy, coronary involvement from Williams syndrome, prolonged QT syndrome, or a cardiomyopathy. Another category of preventable causes is inadequate

vigilance, such as failure to recognize progressive bradycardia and failure to respond to persistent hypotension. In addition to improving preparation and vigilance, the use of "test doses" or divided dosing when administering medications (especially drugs that may cause hypotension in unstable patients) is suggested to minimize medication errors. Other important and preventable causes of anesthesia-related cardiac arrest include transfusion-related hyperkalemia, local anesthetic toxicity, and inhalation-anesthetic overdose (Morray et al., 2000).

Cardiac arrest that is not related to anesthesia is most often the result of the patient's underlying condition or the procedure being performed. Trauma, exsanguination, and failure to wean from cardiopulmonary bypass (CPB) are three of the most commonly reported causes of cardiac arrest that are not anesthesia related. Myocardial infarction, pulmonary embolus, sepsis, and ruptured aneurysm are other, less often observed,

patient-related causes of cardiac arrest. Procedure-related causes include technical problems, caval compression, vagal asystole related to traction or insufflation, and complications related to transplantation.

Outcomes of Cardiac Arrest During Anesthesia

What is the risk of a child dying during the perioperative period? Studies that have investigated this question have reported varied results, depending on whether they include only anesthesia-related causes or all causes of cardiac arrest. Although survival is the outcome most commonly viewed as a measure of successful resuscitation after cardiac arrest, mortality is the rate most commonly reported. Anesthesia-related mortality is currently reported to be 0.1 to 1.6 per 10,000 cases, which is down from 2.9 per 10,000 cases between 1947 and 1958 (Rackow et al., 1961; Morita et al., 2001; Morray et al., 2000; Flick et al., 2007). Some studies have even reported no anesthesia-related deaths (Tay et al., 2001; Murat et al., 2004; Braz et al., 2006). When all causes of perioperative cardiac arrest are included (i.e., anesthesia-related, surgical, and patient disease), risk of mortality is higher, ranging from 3.8 to 9.8 per 10,000 cases (Cohen et al., 1990a; Morita et al., 2001; Braz et al., 2006; Flick et al., 2007). Compared with neonates and infants, older children had a lower incidence of both cardiac arrest and mortality.

Although survival is used to describe a positive outcome for a patient who suffers a cardiac arrest, it is imprecise as to duration or quality of patient outcome. A patient may survive initial resuscitation attempts but subsequently die in the intensive care unit (ICU) from persistent hemodynamic instability or devastating neurologic injury. Initial survival from cardiac arrest after successful resuscitation efforts is defined as return of spontaneous circulation (ROSC), meaning that native heartbeat and blood pressure are adequate for at least 20 minutes. Although ROSC indicates a successful reversal of cardiac arrest, it may not be a meaningful indicator if many patients subsequently die in the ICU. The number of patients with ROSC after cardiac arrest is usually much greater than the number that has a longer, more meaningful, period of survival, such as survival to discharge from the hospital. Although survival to discharge indicates a longer survival than ROSC, surviving for a longer time does not address the quality of that outcome. An assessment of the quality of survival should acknowledge either the presence of a new neurologic deficit or a return to the patient's neurologic baseline. These terms are found in some descriptions in the anesthesia-related literature on outcomes of children who suffer cardiac arrest. Full recovery after intraoperative cardiac arrest in children is reported to range from 48% to 61% (Bharti et al., 2009; Bhananker et al., 2007; Flick et al., 2007).

It is often presumed that the duration and quality of survival from a cardiac arrest that occurred in the operating room should be good, because personnel who witness the cardiac arrest and provide resuscitation are trained and prepared. A review of the anesthesia literature reveals that cardiac arrest can be reversed in over 80% of anesthesia-related episodes (Sprung et al., 2003; Bhananker et al., 2007; Bharti et al., 2009). The likelihood of ROSC decreases to 50% or 60% if the cause of arrest includes those causes not related to anesthesia. Survival to hospital discharge after an anesthesia-related cardiac arrest appears to be approximately 65% to 68% (the range for pediatric studies of this variable is large). Survival to discharge is 30% if causes of

cardiac arrest unrelated to anesthesia are included. Comparing these data with data in literature not related to anesthesia reveals that studies of in-hospital cardiac arrest (IHCA) in children show a 23% rate of survival to discharge (range of 8% to 42%) (Gillis et al., 1986; Von Seggern et al., 1986; Davies et al., 1987; Carpenter and Stenmark, 1997; Parra et al., 2000; Suominen et al., 2000; Reis et al., 2002; Nadkarni et al., 2006; Tibballs and Kinney, 2006). This 23% survival-to-discharge rate is comparable with the 30% rate for all causes and much lower than the 65% rate for anesthesia-related causes of cardiac arrest in the operating room. The presence of anesthesiologists may account, in part, for the better survival outcomes in anesthesia-related cardiac arrests.

Outcome studies for cardiac arrest should include a determination of the presence of new neurologic injuries. Pediatric studies of IHCA show a 71% favorable neurologic outcome for the survivors (range of 45% to 90%) (Gillis et al., 1986; Davies et al., 1987; Carpenter and Stenmark, 1997; Parra et al., 2000; Suominen et al., 2000; Reis et al., 2002). Compilation of the available anesthesia-related literature indicates that 57% of children who suffer perioperative cardiac arrest survive and return to their baseline neurologic status, whereas 5% survive with a new neurologic deficit. Thus, for anesthetic-related cardiac arrest, a child has a 62% chance of surviving, and survivors have a 92% chance of having a favorable neurologic outcome. This percentage for pediatric survivors falls to 22% for those who return to neurologic baseline out of a rate of 36% for total survivors, or a 61% favorable neurologic outcome when all causes of cardiac arrest are included. The 71% favorable neurologic outcome for IHCA is comparable with the 61% rate for all causes and lower than the 92% rate for anesthesia-related causes of cardiac arrest in the operating room. It is noteworthy to mention that the number of studies and patients for these estimates are small and the ranges are large. These data indicate that both the duration and quality of survival are favorable for children who experience cardiac arrest from anesthesia-related causes.

There are many potential explanations for a higher resuscitation rate from anesthesia-related cardiac arrest. Factors such as the resuscitation skills of the anesthesiologist, preparation for emergencies by the anesthesiologist, reversible causes of cardiac arrest in the operating room, and increased monitoring during anesthesia to provide early recognition of problems may contribute to improved resuscitation rates during anesthesia care. The survival rate after cardiac arrest is affected by many factors, some of which are the same that predispose a patient to cardiac arrest: age of patient, ASA PS, and emergency procedures.

The etiology of cardiac arrest also impacts likelihood of successful resuscitation and survival. Mortality is increased if the cause of cardiac arrest is hemorrhage or is associated with protracted hypotension (both have a $P < 0.001$) (Girardi and Barie, 1995; Newland et al., 2002; Sprung et al., 2003). Resuscitation-related factors have an effect on outcome. These factors include cardiac rhythm during resuscitation, duration of resuscitation, and duration of no-flow and low-flow states during cardiac arrest and resuscitation. A no-flow state occurs when a patient is in cardiac arrest before receiving resuscitation efforts. A low-flow state occurs when a patient is in cardiac arrest and receiving resuscitation that is unable to provide adequate circulation. The longer the patient is in a no-flow or low-flow state, the worse the outcome is likely to be.

Asystole is a rhythm that, if present during resuscitation, has been associated with a decreased rate of both ROSC and survival to discharge for children with cardiac arrest outside of the operating room. Usually asystole is caused by prolonged hypoxia or myocardial ischemia and represents a terminal rhythm. Prolonged hypoxia causes the myocardium to be more resistant to resuscitation efforts and is more likely to result in neurologic injury. Thus, if the heart can be resuscitated, there is still the possibility of a poor outcome. In the operating room, continuous patient monitoring decreases the risk of prolonged periods of hypoxia or ischemia. Instead of asystole being a terminal rhythm, asystole in the operating room is often an initial rhythm that results from a vagal stimulation. As an initial rhythm, asystole is more likely to be reversed. Usually discontinuation of the vagal stimulus and chemical support of the heart rate are effective resuscitation measures. Unlike with cardiac arrests that occur outside the operating room, asystole is a commonly reported rhythm with anesthesia-related cardiac arrest and is associated with a good prognosis (Sprung et al., 2003).

The duration of the resuscitative efforts has an effect on patient outcome. Prolonged duration of CPR increases the possibility of low-flow intervals, thereby resulting in myocardial and cerebral injury. The need for CPR for more than 15 minutes has been determined to be a predictor of mortality in anesthesia-related cardiac arrests ($P < 0.001$) (Girardi and Barie, 1995). The interpretation of these data is complicated by reports of successful outcomes even after prolonged periods of resuscitation efforts. Up to 3 hours of CPR has been reported in anesthetic-related cardiac arrests, with eventual resuscitation and a good outcome (Cleveland, 1971; Lee et al., 1994). In summary, the cause of the cardiac arrest, the rhythm disturbance, and the duration of CPR can impact outcome from cardiac arrest that takes place in the operating room.

CARDIOPULMONARY RESUSCITATION

Recognition of the Need for Cardiopulmonary Resuscitation

Early recognition that a child's vital signs are inadequate and a response with rapid initiation of CPR reduces potential for injury from low-flow or no-flow intervals. It is difficult to give guidelines for the limit of each vital sign at which vital organ blood perfusion becomes inadequate for each child under anesthesia (Table 38-3). These limits depend on many factors, including the patient's general health, the patient's age, the type and depth of anesthesia, and the intensity and duration of deterioration of the vital signs. Pediatric training and experience are valuable in these uncommon but critical situations to help with the decision about when to initiate CPR.

In general, CPR including chest compressions should be initiated when it is felt that perfusion is inadequate to deliver oxygen, substrates, or resuscitative medications to the heart or brain. Extensive monitoring and continuous presence of anesthesia personnel should be optimal for early detection of inadequate perfusion or ventilation in the operating room. In the absence of adequate monitoring, health care personnel should palpate the umbilical artery in the newborn, the brachial artery in the infant, and the carotid artery in the

TABLE 38-3. Adequate Vital Signs for Children

Age	Heart Rate (bpm)*			Blood Pressure (mm Hg)
	Bradycardia	Normal PALS/HLH	Tachycardia	Hypotension
Term neonate	<60	80 to 205 95 to 180	>220	SBP <60
Infant	<60	75 to 190 110 to 180	>190	SBP <70
Child	<60	60 to 140 60 to 150	>180	SBP <70 + (2× age in years)
>10 years	<60	50 to 100 60 to 100	>150	SBP <90

Modified from Ralston M et al., editors: *Pediatric advanced life support provider manual*, American Heart Association, 2006; AHA/ILCOR Guidelines, part 12: pediatric advanced life support, *Circulation* 112(IV):167, 2005; Robertson J, Shilkofski N, editors: *Harriet Lane handbook: a manual for pediatric house officers*, ed 7, Philadelphia, 2005, Mosby, p 174.

*Bradycardia is the rate at which chest compressions should be considered; note that normal for >10 years may be below the level recommended and signs of inadequate perfusion should be assessed. Tachycardia listings are estimated rates at which symptoms usually occur.

child to detect an abnormal heart rate (Cavallaro and Melker, 1983; Lee and Bullock, 1991; AHA, 2006a). The analysis of a pulse in anesthetized and slightly hypotensive (systolic pressure lower than 70 mm Hg) infants revealed that detection of a pulse within 10 seconds was best with auscultation; brachial palpation was less successful than auscultation but better than carotid or femoral palpation by operating room nurses (Inagawa et al., 2003). Femoral palpation of pulse was more successful than carotid or brachial in anesthetized and hypotensive (systolic pressure lower than 70 mm Hg) infants in a subsequent study with personnel who had more pediatric resuscitation training (Sarti et al., 2006). Both authors agree that successful counting of heart rate over a brief time was better with auscultation.

In the operating room, monitoring is usually available to help determine vital signs of an anesthetized child. When the monitoring is unavailable or the readings are in question, having one rescuer auscultate and another palpate may increase reliability and decrease time needed to count a heart rate and determine the palpability of a pulse. Whereas either unresponsiveness or apnea is an indication to resuscitate in most situations, the administration of anesthesia masks these signs, and bradycardia by auscultation or lack of pulse by palpation may be valid indicators to start CPR.

Physiology of Cardiopulmonary Resuscitation: Reestablishment of Ventilation

The fraction of inspired oxygen (F_{iO_2}) that should be administered during CPR is important, because either too much or too little may be detrimental. A report by Elam et al. (1954) showed that exhaled air from the rescuer (16% oxygen) provided adequate oxygenation of the victim (arterial oxygen level

[Sao_2] of 90% or greater) and became the basis for ventilation during CPR when supplemental oxygen is not available. In the operating room, the anesthesiologist has the ability to administer 100% oxygen via tracheal intubation during CPR. The anesthesiologist is faced with the theoretic concern that delivery of high oxygen levels during reperfusion may increase formation of oxygen free radicals and increase cellular injury. This concern is weighed against the knowledge that CPR is less effective in restoring oxygen delivery to the brain and heart than is native circulation and that during CPR the administration of low levels of oxygen may increase the delay in restoration of oxygen delivery. Adequacy of oxygen delivery during CPR depends on many variables, including the cause of cardiac arrest, the length of decreased perfusion, the effectiveness of CPR, and the patient's metabolic demands. The complexity of the determination makes it unlikely that oxygen delivery during CPR can be measured or predicted. A review of newborn resuscitation using 21% or 100% Fio_2 found that newborns with depressed (but not arrested) cardiac function can be effectively resuscitated with either 21% or 100% oxygen and that 21% oxygen administration is associated with less markers of oxidative stress. This review also found that for cardiac arrest in newborns there is no evidence that 21% is as effective as 100% oxygen in resuscitation of circulation, and that animal studies suggest 100% oxygen administration is more effective (Ten and Matsukevich, 2009). A model of brain-tissue oxygen monitoring in piglets during CPR for cardiac arrest showed that despite administration of 100% Fio_2 , the brain-tissue oxygen levels remained either at or below the levels before cardiac arrest until after ROSC, when they became dramatically elevated (Cavus et al., 2006). This finding implies that maximal oxygen administration is needed during CPR, but that it can create hyperoxic conditions after ROSC. Without adequate data to resolve this question, it seems reasonable to continue to use 100% Fio_2 during CPR for intraoperative cardiac arrest to help maximize the oxygen delivery during this low flow-state but to reduce oxygen levels once reliable oxygen monitoring shows adequate oxygenation during the hyperdynamic phase that occurs after ROSC (see Postresuscitation Care). The exception to the use of 100% O_2 for resuscitation may be the child with a circulatory condition such as a hypoplastic left heart, whose poor systemic perfusion is the result of pulmonary over-circulation. In such a case, the anesthesiologist needs to decide whether high levels of oxygen administration would contribute to the poor systemic circulation.

The contribution of chest compressions to ventilation during CPR impacts the decision of how much ventilation to provide to victims of cardiac arrest. Early in the study of external compressions, researchers did not add ventilation during CPR because they believed that closed-chest compression alone provided adequate ventilation (Kouwenhoven et al., 1960). The findings, that chest compressions alone provide some ventilation for adult victims and that minimal ventilation is necessary shortly after a sudden fibrillatory arrest, have resulted in over-the-phone instruction for CPR with compressions alone to untrained bystanders or those unwilling to provide mouth-to-mouth ventilation. It is difficult to determine how much chest compressions contribute to ventilation; their adequacy may vary with the cause of cardiac arrest, duration of cardiac arrest, the child's age, an underlying medical condition, the efficacy of resuscitation, and the child's metabolic needs. Requirements to administer oxygen and remove carbon dioxide (CO_2) differ by type of cardiac arrest; a sudden fibrillatory arrest has little loss of oxygen reserve or accumulation of CO_2 , and a gradual asphyxial cardiac arrest has greatly depleted oxygen reserve and large accumulation of CO_2 . Asphyxial cardiac arrest derives a greater benefit from ventilation efforts. A model of asphyxial arrest in piglets shows greatest benefit with delivery of both compressions and ventilations compared with compression or ventilation alone (Berg et al., 2000). Provision of ventilation early in resuscitation from cardiac arrest may be less necessary and has the potential to cause a respiratory alkalosis, resulting in unwanted effects on brain circulation and oxygen delivery. As the duration of cardiac arrest continues, despite CPR efforts, metabolic acidosis predominates and respiratory compensation may be difficult. Lack of data usually leads the pediatric anesthesiologist to choose a rate based on recommendations for age (10 ventilations per minute in children and 30 ventilations per minute for newborns) and to adjust the rate if blood-gas analysis becomes available during resuscitation (Table 38-4).

Intubation of the trachea by the anesthesiologist is recommended for the management of ventilation during intraoperative cardiac arrest. Without intubation and positive pressure ventilation, soft-tissue obstruction may prevent adequate ventilation in some victims (Safar et al., 1961). An unprotected airway puts patients at greater risk for aspiration during CPR because of loss of the airway's protective reflexes and increased likelihood of stomach distention with positive pressure ventilation. At onset of cardiac arrest, the lower esophageal sphincter

*In the newborn there are 120 events per minute. These events include 90 compressions and 30 breaths.

competency falls from approximately 20 cm H₂O to 5 cm H₂O (Gabielli et al., 2005). The laryngeal mask airway (LMA) compares favorably with mouth-to-mouth ventilation, mask ventilation, and other airway adjuncts during CPR, but there are limited data for a comparison with tracheal intubation during CPR and non-intubation technique may be less protective of gastric distention or aspiration (Samarkandi et al., 1994; Rumball and MacDonald, 1997; Stone et al., 1998). Airway adjuncts are not recommended as a replacement for tracheal intubation during CPR in children, especially when an anesthesiologist is available (Grayling et al., 2002). Tracheal intubation is optimal to assure ventilation during CPR for pediatric anesthesiologists, because they maintain training to use this procedure.

The appropriate placement of the ETT during cardiac arrest can be verified in most instances by the presence of end-tidal CO₂ (Etco₂). The incidence of accidentally placing an ETT in the esophagus of a child is greater during cardiac arrest (19% to 26%) than during an intubation that is not involved with cardiac arrest (3%) (Bhende and Thomson, 1992; Bhende and Thomson, 1995). Demonstration of persistent Etco₂ wave forms after intubation is extremely reliable to confirm correct placement of the ETT in children with spontaneous circulation (Bhende et al., 1992). The lack of a measurable Etco₂ level in the ETT usually indicates esophageal intubation. In resuscitation from a cardiac arrest, the pulmonary blood flow is decreased during CPR and the Etco₂ level may be falsely low or absent despite a correctly placed ETT. This finding of no Etco₂ detected during CPR in children experiencing cardiac arrest was seen in 14% to 15% of correctly placed ETTs (Bhende et al., 1992; Bhende and Thomson, 1995). Continually detectable Etco₂ is proof of tracheal intubation even during cardiac arrest. The absence of Etco₂ on placement of the ETT indicates that the larynx should be visually inspected to discriminate esophageal intubation. Loss of Etco₂ during resuscitation efforts may indicate the ETT is dislodged and should be reinspected or replaced, that the ETT is plugged or kinked and a suction catheter should be passed, or that pulmonary blood flow is diminished and resuscitation efforts need to be increased. Tracheal intubation for resuscitation also offers the option of access (although limited) to the circulation for drug administration.

Interruption of chest compressions for delivery of ventilation increases the percentage of time that there is an absence of perfusion to vital organs; this percentage of CPR without perfusion is referred to as the *no-flow fraction (NFF)*. In addition to producing times with no perfusion, interruptions in the delivery of compressions result in a pooling of blood in the vasculature that causes the need for several compressions to be delivered before perfusion is back to the preinterruption level (Berg et al., 2001). Thus, there are both no-flow and low-flow problems caused by pausing compressions for ventilation or any other reason. The presence of an ETT during CPR eliminates concern for ventilation attempts contributing to the NFF. During CPR performed by bystanders compressions are held, ventilations are delivered, and then compressions are resumed. These pauses in chest compressions make it easier for ventilation provided by mouth-to-mouth or bag-mask ventilation to be delivered to the lungs, thereby improving the patient's ventilation and reducing the probability of gastric inflation. The need to interpose ventilations, thus interrupting compressions, during CPR is eliminated by placement of an ETT. A significant amount of research compares the effects of chest compression with ventilation ratios of 15:2, 30:2, and longer (continuous

compressions) with varying results for fibrillatory and asphyxial cardiac arrest in prehospital settings. These ratios become irrelevant to the anesthesiologist when an ETT is placed, and compressions can be performed without interruptions for ventilation in a 10:1 ratio, generating 100 compressions and 10 ventilations per minute. The goal for the anesthesiologist is to maintain continuous delivery of compressions with interruption only at the 2-minute intervals necessary for switching of compression providers to prevent fatigue, pulse checks to determine ROSC, and when needed, the delivery of shocks. Intubation, central line placement, and placement of adhesive pads for defibrillation are other commonly reported interruptions to chest compressions and should be minimized and compressions should be continued when possible. It is important to remember the negative impact of holding compressions during intubation attempts and to absolutely minimize the duration of procedures that require these interruptions.

It is important to understand the effect of positive-pressure ventilation on perfusion produced by chest compression. In the previous section, the importance of minimizing NFF by maintaining compressions and not interrupting for ventilations was discussed. There are other physiologic interactions that cause ventilation to influence the effectiveness of chest compressions. Factors affected by these interactions include increased intrathoracic pressure, affecting the ability of chest compressions to move blood out of the thorax; intracranial pressure (ICP), reducing perfusion of the brain; myocardial perfusion pressure (MPP), and venous return to the thorax.

A comparison of different methods of delivery of ventilation during chest compressions revealed differences in oxygenation, ventilation, and hemodynamics (Wilder et al., 1963). Delivery of ventilations independent of compressions, interposed between compressions, and synchronized with compressions allows both adequate oxygenation and ventilation, but their effects on hemodynamic pressures vary. Delivery of positive pressure ventilation has an impact on the hemodynamic variables caused by changes in intrathoracic pressure. CPR with simultaneous compression and ventilation increases intrathoracic pressure at the time of compression and yields improvement in blood flow and survival in a canine model, but it has not shown the same benefit in humans. The simultaneous increase in intrathoracic pressure may lead to increased ejection of blood from the thorax, but elevation of intrathoracic pressure also leads to increases in intracardiac and ICP. Increasing intracardiac pressure at the time of compression may result in no change in the MPP and no overall benefit to the heart. Increases in ICP occur with increases in intrathoracic pressure and may result in no change in the cerebral perfusion pressure (CPP) and no overall benefit to the brain (see section that follows, *Physiology of Cardiopulmonary Resuscitation: Reestablishment of Circulation*, for mechanism). Increasing intrathoracic pressure during the relaxation phase of chest compressions has the potential to decrease venous return and may have significant impact on the effectiveness of subsequent compressions, depending on the duration of ventilation pressure. Attention to rate, duration, and pressure used during delivery of ventilations can prevent excessive ventilation that is common during these high-stress events and the impact overventilation has on venous return. Use of the impedance threshold device, the intrathoracic pressure regulator (ITPR), and decompression during CPR are techniques used to increase venous return by lowering intrathoracic pressure and are discussed in later sections.

Overventilation or underventilation can be detrimental during CPR. As discussed previously, overventilation can have hemodynamic effects or result in hypocarbia; either of these could result in decreased perfusion of the brain. Underventilation could result in a decrease in perfusion either from reduced pulmonary blood flow during CPR secondary to the increased vascular resistance that results from atelectasis or from the systemic effects of hypercarbia in addition to metabolic acidosis. The determination of a ventilation rate during CPR depends on the age of the child, whether the airway is secured, the number of rescuers, the type of cardiac arrest, and duration of the cardiac arrest. The young child has an increased baseline metabolic activity and a greater need for an increase in the number of ventilations during CPR. Recommendations for newborns include rates of about 30 breaths per minute, whether there are 1 or 2 rescuers and whether or not the child is intubated. The infant, the child between 1 and 8 years old, the child older than 8 years, and the adult share recommendations for 8 to 10 breaths per minute with intubation (Table 38-4). The newborn has both the highest metabolic activity and baseline CO₂ production and a greater chance of having a cardiac arrest with a prolonged ischemic period, resulting in a greater need to eliminate CO₂. There may be an ideal range for ventilation during CPR; overventilation may increase intrathoracic pressure (causing reduced venous return and increased ICP) and lower arterial carbon dioxide tension (Paco₂). Causing cerebral vasoconstriction while under ventilation may allow lung collapse and atelectasis, reducing pulmonary blood flow, MPP, and CPP. The decrease in pulmonary blood flow during CPR for cardiac arrest produces higher levels of venous CO₂ and lower levels of arterial and Etco₂. Determining the adequacy of ventilation efforts during CPR is difficult, because low pulmonary blood flow impacts the CO₂ levels of both Etco₂ and blood-gas monitoring. These techniques regain their usefulness in monitoring ventilation efforts as pulmonary blood is improved with resuscitation or ROSC.

The anesthesiologist will encounter the decision of whether to use mechanical or manual ventilation during CPR for intraoperative cardiac arrest. There are no data available to use to recommend one technique or the other.

Physiology of Cardiopulmonary Resuscitation: Reestablishment of Circulation

Mechanisms of Blood Flow During Cardiopulmonary Resuscitation

Kouwenhoven et al. (1960) proposed that external chest compressions squeeze the heart between the sternum and the vertebral column, forcing blood to be ejected. This assumption about direct cardiac compression during external CPR became known as the *cardiac-pump mechanism* of blood flow. The cardiac pump mechanism proposes that the atrioventricular (AV) valves close during ventricular compression and that ventricular volume decreases during ejection of blood. During chest relaxation, ventricular pressures fall below atrial pressures, enabling the AV valves to open and the ventricles to fill. This sequence of events resembles the normal cardiac cycle and occurs with use of direct cardiac compression during open-chest CPR.

Several observations of hemodynamics during external CPR are inconsistent with the cardiac pump mechanism for blood

TABLE 38-5. Comparison of Mechanisms of Blood Flow During Closed-Chest Compressions

Proposed Mechanism	Cardiac Pump	Thoracic Pump
	Sternum and spine compress heart	General increase in intrathoracic pressure
Findings During Compression		
Atrioventricular valves	Close	Stay open
Aortic diameter	Increases	Decreases
Blood movement	Left ventricle to aorta	Pulmonary veins to aorta
Ventricular volume	Decreases	Little change
Compression rate	Dependent	Little effect
Duty cycle	Little effect	Dependent
Compression force	Increases role	Decreases role
Patient Physiology		
	Small chest	Large chest
	High compliance	Low compliance

flow (Table 38-5). First, similar elevations in arterial and venous intrathoracic pressures during closed-chest CPR suggest a generalized increase in intrathoracic pressure (Weale and Rothwell-Jackson, 1962). Second, reconstructing thoracic integrity in patients with flail sternums improves blood pressure during CPR (unexpected, because a flail sternum should allow direct cardiac compression during closed-chest CPR) (Rudikoff et al., 1980). Third, patients who develop ventricular fibrillation (VF) produce enough blood flow by repetitive coughing or deep breathing to maintain consciousness; there are examples in which no compression of the heart occurs, only an increase in intrathoracic pressure (MacKenzie et al., 1964; Criley et al., 1976; Niemann et al., 1980; Harada et al., 1991). These observations suggest a generalized increase in intrathoracic pressure may contribute to the production of blood flow during CPR. The finding that changes in intrathoracic pressure without direct cardiac compression (i.e., a cough) produce blood flow epitomizes the *thoracic-pump mechanism* of blood flow during CPR. Familiarity with the thoracic pump and cardiac pump mechanisms of blood flow during CPR help with understanding of how alternative methods of CPR might be advantageous.

Thoracic-Pump Mechanism

Chest compression during CPR generates almost equal pressures in the left ventricle, aorta, right atrium, pulmonary artery, airway, and esophagus. Because all intrathoracic vascular pressures are equal, the suprathoracic arterial pressures must be greater than the suprathoracic venous pressures for a cerebral perfusion gradient to exist. Venous valves, either functional or anatomic, prevent direct transmission of the rise in intrathoracic pressure to the suprathoracic veins (Niemann et al., 1981; Swenson et al., 1988; Paradis et al., 1989; Chandra et al., 1990; Goetting and Paradis, 1991; Goetting et al., 1991). This unequal transmission of intrathoracic pressure to the suprathoracic

vasculature establishes the gradient necessary for cerebral blood flow during closed chest CPR.

During normal cardiac activity, the lowest pressure measurement occurs on the atrial side of the AV valves, providing a downstream effect that allows venous return to the pump. The extrathoracic shift of this low-pressure area to the cephalic side of jugular venous valves during the thoracic pump mechanism implies that the heart is merely serving as part of a conduit for blood flow. Angiographic studies show that during a single chest compression, blood passes from the vena cavae through the right heart to the pulmonary artery and from the pulmonary veins through the left heart to the aorta (Niemann et al., 1981; Cohen et al., 1982). Unlike during normal cardiac activity and open-chest CPR, echocardiographic studies during closed-chest CPR have shown that AV valves remain open during blood ejection (Rich et al., 1981; Werner et al., 1981; Clements et al., 1986). In addition, unlike during native cardiac activity and open-chest CPR, aortic diameter decreases instead of increasing during blood ejection (Niemann et al., 1981; Werner et al., 1981). These findings about closed-chest CPR support the thoracic-pump theory that the chest becomes the “bellows,” producing blood flow during CPR, and that the heart is a passive conduit.

Cardiac-Pump Mechanism

Despite evidence for the importance of the thoracic-pump mechanism of blood flow during external chest compressions, there are specific situations in which the cardiac pump mechanism predominates during closed-chest CPR. First, applying more force during chest compressions (as in high-impulse CPR, see related section) increases the likelihood of direct cardiac compression and closure of AV valves (Feneley et al., 1987; Hackl et al., 1990). Second, a small chest size allows for more direct cardiac compression, causing better hemodynamics during closed-chest CPR in a canine model (Babbs et al., 1982a). Third, the compliant infant chest should permit more direct cardiac compression, as shown in a closed-chest CPR model in piglets, in which excellent blood flows are produced as compared with most adult models (Schleien et al., 1986). Transesophageal echocardiography studies have demonstrated the closing of AV valves during the compression phase of CPR in humans (Higano et al., 1990; Kuhn et al., 1991). These findings support the occurrence of cardiac compression during conventional CPR, suggesting that both mechanisms of blood flow may occur during CPR. As will be seen in a later section, varying the method of CPR may alter the contribution of each mechanism.

Efficacy of Blood Flow During Cardiopulmonary Resuscitation

The level of blood flow to vital organs produced by conventional closed-chest CPR without pharmacologic support (basic life-support models) is disappointingly low. The range of cerebral blood flow in dogs during CPR is 3% to 14% of levels before cardiac arrest (Bircher and Satar, 1981; Koehler et al., 1983; Koehler and Michael, 1985; Luce et al., 1984; Jackson et al., 1984). CPPs are also low, at 4% to 24% of levels before cardiac arrest in animals and only 21 mm Hg in humans (Bircher et al., 1981; Koehler et al., 1983; Luce et al., 1984; Goetting et al., 1991). Myocardial blood flows in this basic CPR mode are also discouragingly low at 1% to 15% of pre-cardiac arrest levels in dogs (Chandra et al.,

1981a; Voorhees et al., 1983; Koehler et al., 1985; Halperin et al., 1986a; Shaffner et al., 1990). MPPs correlate with myocardial blood flow in a one-to-one relationship between myocardial blood flow (when measured in mL/min per 100 g) and MPP (mm Hg) (Voorhees et al., 1983; Ralston et al., 1984). Several factors affect cerebral and myocardial blood flow during CPR, and these disappointing results in basic life support models can be improved with addition of pharmacologic support.

Physiologic thresholds for minimal vital organ blood flow during CPR have been described. The inability to maintain blood flow above these thresholds during CPR results in organ malfunction. A myocardial blood flow of 20 mL/min per 100 g or greater is necessary for successful defibrillation in dogs (Guerci et al., 1985; Sanders et al., 1985a). A cerebral blood flow of greater than 15 to 20 mL/min per 100 g is necessary to maintain normal electrical activity during CPR (Michael et al., 1984). Models of basic life support often do not achieve these thresholds; the addition of advanced life support measures, such as epinephrine administration, is associated with blood flow levels above these thresholds.

Maintenance of Circulation During Cardiopulmonary Resuscitation

The goal of CPR is to improve a no-flow or low-flow state by restoring and maintaining the best flow possible to the brain and heart until an adequate spontaneous circulation can be recovered. Factors related to the patient, the ventilation technique, and the compression technique contribute to restoration and maintenance of blood flow during CPR. The pediatric anesthesiologist should understand how these factors affect restoration and maintenance of blood flow during an intraoperative arrest.

Patient-Related Factors

Patient-related factors that influence the effectiveness of CPR to maintain circulation include the victim's age, the duration of CPR, the duration of preresuscitation ischemia, ICP, and volume status.

Based on limited data, young age appears related to higher cerebral blood flow during closed-chest CPR. A piglet model has substantially higher cerebral blood flow (50% of those before cardiac arrest) and slightly higher myocardial flows (17% of that before cardiac arrest) than those reported for adult models (Schleien et al., 1986). Studies on slightly older pigs yielded opposing results (Brown et al., 1987b; Sharff et al., 1984). The cerebral blood flow in the first of these two studies was markedly higher than that in adult models during closed-chest CPR, and neither of the myocardial flows was different from adult models. No human data exist with blood flows at different ages during CPR.

Age-related physical factors that affect the blood flow produced during CPR include chest wall compliance and chest wall deformability. Chest wall compliance impacts both the ability to produce anteroposterior displacement and to directly compress the heart. Young children have increased chest wall compliance that facilitates the achievement of adequate compression depth and increases the chance of direct cardiac compression, either of which can result in better blood-flow production by chest compressions. These benefits of the more compliant infant chest may account for high flows that resemble those produced

by open-chest cardiac massage in a piglet model (Schleien et al., 1986). Chest wall deformability is another factor that relates to the ability to maintain flows during prolonged periods of chest compressions. Chest deformation occurs as CPR becomes prolonged. The chest assumes a flatter shape as compressions continue, producing larger decreases in cross-sectional area at the same displacement. Progressive deformation may be beneficial if it leads to more direct cardiac compression. Unfortunately, too much deformation may result in loss of recoil of the chest wall during release of compression. Decreased chest recoil with progressive deformation limits displacement and produces less effective compression and less venous return during release of compression.

A model of conventional CPR in piglets shows a progressive decrease in the effectiveness of prolonged chest compressions to produce blood flow (Schleien et al., 1986; Dean et al., 1991). The permanent deformation of the chest in this model approaches 30% of original anteroposterior diameter. An attempt to limit deformation by increasing intrathoracic pressure during compression with simultaneous-ventilation CPR resulted in no improvement in either amount of deformation or time to deterioration of flow (Berkowitz et al., 1989). Investigators used a third mode of infant-animal CPR by using a vest to deliver compressions in an attempt to limit production of deformation. The vest distributes compression force diffusely around the thorax and greatly decreases permanent deformation (3% vs. 30%) (Schleien et al., 1986; Shaffner et al., 1990). Unfortunately, the deterioration of blood flow with time still occurs and appears to be unrelated to the amount of deformation in this model and is more likely related to the duration of prolonged CPR. There has not been a direct comparison of adult and pediatric CPR in humans. The increased compliance and deformability of the infant's chest make it likely that CPR would be more effective in children than in adults (as seen in animal models).

An increased duration of CPR has a negative effect on cerebral blood flow and seems to be most detrimental in the infant preparation (Schleien et al., 1986; Sharff et al., 1984). The length of the no-flow period before CPR begins also has a negative effect on cerebral blood flow that is produced with CPR (Shaffner et al., 1999; Lee et al., 1984). The supratentorial brain blood flow during CPR is reduced more than brain-stem flow, because the preceding ischemic interval is increased (Shaffner et al., 1998, 1999). The cause of these detrimental effects on cerebral blood flow is unclear. Tissue hypoxia resulting in loss of vascular tone that eventually becomes unresponsive to vasoconstrictors, pulmonary edema, capillary leak, and (with prolonged duration of CPR) chest wall deformity are factors that are likely to contribute. It remains obvious that a short ischemic period and quick resuscitation improve the eventual outcome.

ICP is another patient-related factor with effect on the circulation produced during CPR. ICP can represent the downstream pressure for cerebral blood flow, and if elevated it can inhibit cerebral perfusion. Increases in intrathoracic pressure with closed-chest CPR cause ICP increases (Rogers et al., 1979). This relationship is linear, and one third of the increase in intrathoracic pressure generated by chest compression is transmitted to ICP (Guerci et al., 1985). The carotid arteries and jugular veins do not appear to be involved in the transmission of intrathoracic pressure to the intracranial contents. The transmission can be partially blocked by occluding cerebrospinal fluid or vertebral vein flow (Guerci et al., 1985). The rise in ICP with chest compressions becomes more significant in

the setting of baseline increased ICP (an increase to two thirds of intrathoracic pressure is transmitted to ICP). The efficacy of CPR to perfuse the brain deteriorates markedly in the face of elevated ICP. When increased ICP is suspected (i.e., a child with hydrocephalus or head trauma) the ICP should be lowered early in the resuscitation (i.e., shunt tapped, or hematoma drained) to increase effectiveness of chest compressions to perfuse the brain.

Volume status, more specifically, hypovolemia, is another patient-related factor that can have an impact on effectiveness of chest compressions. There are little data to address the impact of volume status on blood flow during chest compression. Animal models include the administration of fluid (30 mL/kg or to a right atrial pressure of 6 to 8 mm Hg) before inducing cardiac arrest in fasted animals to improve the effectiveness of CPR (Sanders et al., 1990; Eleff et al., 1995).

Ventilation-Related Factors

Ventilation-related factors that affect compression-related blood flow during CPR have been discussed in the earlier section on the reestablishment of ventilation during CPR. These factors include the need for intubation of the trachea, avoiding interruptions of compressions to deliver ventilations, the effect of ventilation rate, the effect of ventilation pressure, and the decision to mechanically or manually ventilate, and they are discussed in detail in that section.

Compression-Related Factors

Factors related to chest compression that affect blood flow during CPR include compression rate (including NFF and number of compressions delivered), compression duty cycle, compression force, compression depth, and opportunity for full recoil (avoiding pressure during relaxation and leaning).

Compression Rate and Duty Cycle

Compression rate is the number of cycles per minute. Duty cycle is the ratio of the duration of compression phase to the entire compression-relaxation cycle, expressed as a percentage. For example, at the recommended rate of 100 compressions per minute, the total cycle for compression and relaxation is 0.6 seconds (100 compressions \times 0.6 seconds/compressions = 1 minute). A 0.36-second compression time produces a 60% duty cycle (0.36 sec/0.6 sec = 60%). The impact of duty cycle differs between the two mechanisms of blood flow (Table 38-5). In 1986 the American Heart Association Guidelines for CPR and Emergency Cardiac Care recommended increasing the rate of chest compressions from 60 to 100 per minute. This change represented a compromise between advocates of the thoracic-pump mechanism and those of the cardiac-pump mechanism (Feneley et al., 1988). The mechanics of these two theories of blood flow differ, but a faster compression rate could augment both.

In the cardiac-pump mechanism of blood flow during CPR, direct cardiac compression generates blood flow, and the force of compression determines the stroke volume per compression. Prolonging the compression (increasing the duty cycle) beyond the time necessary for full ventricular ejection fails to produce any additional increase in stroke volume in this model. Also, increasing rate of compressions increases cardiac output, because a fixed ventricular blood volume ejects with each cardiac compression.

Therefore, in the cardiac-pump mechanism, blood flow is rate sensitive and duty-cycle insensitive. In the thoracic-pump mechanism, the reservoir of blood to be ejected is the large capacitance of the intrathoracic vasculature. With the thoracic pump mechanism, increasing either force of compression or duty cycle enhances flow by emptying more of the large intrathoracic capacity. Changes in compression rate have less effect on flow over a wide range of rates (Halperin et al., 1986a). Blood flow in the thoracic pump mechanism is generally duty-cycle sensitive but rate insensitive. With an increase in duty cycle, the percentage of time in compression is prolonged, but time for relaxation becomes decreased and venous return may become inhibited. At slow compression rates, the ability to hold a compression to prolong the duty cycle becomes physically demanding. The increased ability of a rescuer to produce a 50% duty cycle at a rate of 100 (compared with 60) compressions per minute is the reason behind the compression rate change recommendation in the 1986 American Heart Association guidelines for CPR.

The no-flow fraction and measurement of compressions delivered are important factors in the continued recommendation of a rate of 100 compressions per minute. The NFF is the percentage of time that compressions are interrupted. The interruption of compressions not only produces a no-flow time but also reduces effectiveness of the initial compressions on the resumption of chest compressions. The NFF in CPR performed by bystanders during out-of-hospital cardiac arrest (OHCA) has been reported to be 48% (Wik et al., 2005). For IHCA, a NFF of 24% has been reported with a sensing monitor and defibrillator (Abella et al., 2005). Reducing the pauses for ventilations from a compression/ventilation ratio of 15:2 to 30:2 in a bystander model of CPR on a manikin reduced NFF from 33% to 22% (Betz et al., 2008). Tracheal intubation in OHCA resulted in a reduction of NFF from 61% to 41% ($p = 0.001$) (Kramer-Johansen et al., 2006). Preshock pause also contributes to the NFF. Automatic external defibrillators (AEDs) create a variable preshock pause of 5 to 28 seconds. A 5-second increase in preshock pause was associated with a decrease in shock success ($p = 0.02$), and shock success fell from 94% if the pause was for fewer than 10 seconds to only 38% if it was longer than 30 seconds (Edelson et al., 2006). Interruptions of compressions for delivery of ventilation by tracheal intubation and for AED analysis can be eliminated by using a manual defibrillator. The goal is to have only a 10-second interruption every 2 minutes (120 seconds) for compressor change and rhythm analysis, resulting in an 8% NFF.

The number of compressions delivered per minute may differ from the compression rate. The compressor (see later section on teamwork for roles assumed during intraoperative CPR) may be delivering compressions at a rate of 0.6 seconds per cycle (100 compressions per minute), but if each minute there are 10 seconds of held compressions, then the number of compressions delivered at this rate falls to 83 compressions per minute. In the analysis of a 1-minute segment in which there were 15 seconds of held compressions, this same compression rate (0.6 seconds per cycle) resulted in a decrease to 75 compressions delivered to the patient. In an OHCA study of adults, the use of a compression rate of 121 resulted in the number of compressions being delivered at 64 per minute (Wik et al., 2005). The accomplishment of 80 chest compressions per minute has been correlated with successful resuscitation in an animal model (Yu et al., 2002). Resuscitation team members in the roles of compressor and leader need to be aware of how many actual compressions

per minute are occurring and minimize interruptions to keep the rate of compressions delivered above 80 per minute. In an intubated patient, compressing at a rate of 100 per minute and only stopping for 10 seconds every 2 minutes to change compressors and perform pulse checks and rhythm analysis results in 92 compressions delivered per minute.

Compression force is the pressure and the acceleration applied to the chest. There are accelerometers available to monitor and provide feedback about the compression force applied with each compression, but they are not typically available in intraoperative resuscitation. The compression depth is the amount of anterior-posterior displacement provided by a compression and is related to the compression force applied and the compliance of the chest wall. Compression depth for adult patients is recommended as 38 to 50 mm (1.5 to 2 in) and as one third to one half of the anterior-posterior chest diameter for children and infants. Literature on adults indicates that a depth of 38 mm is not often achieved during resuscitation. Compression depths less than 38 mm occurred for 37% of compressions during IHCA on adults (mean depth 43 mm for all compressions) and for 62% of compressions during OHCA (mean depth 34 mm) (Abella et al., 2005; Wik et al., 2005). When studying the importance of adequate compression depth on the success of shocks delivered during IHCA, it was found to be that a 5-mm increase in compression depth improved first shock success ($p = 0.028$) (Edelson et al., 2006). Compression depth in a pediatric manikin model was 14 mm with the two-thumbs techniques vs. 9 mm with the two-finger technique ($p < 0.001$), indicating that the two-thumb technique is more effective for depth of compression (Udassi et al., 2009). In the operating room, the leader and recorder can assess the depth of compressions provided by the compressor and remind the compressor to achieve the suggested depth. The improvement in EtCO_2 production should be noted when increasing compression depth with a goal of maximizing EtCO_2 levels, which should correlate with blood flow through the lungs and vital organs.

Full recoil of the chest and avoiding any pressure during the release of compression (avoiding leaning on chest) is a key concept in the performance of chest compressions. The native chest recoil leads to increased negative intrathoracic pressure that augments venous blood return and blood ejection with subsequent compression. An animal model of incomplete recoil during active compression-decompression CPR resulted in increased intrathoracic pressure and reduced systemic arterial pressure, MPP, and CPP. The decrease in cerebral perfusion was related to the decrease in systemic arterial pressure rather than an increase in ICP (Yannopoulos et al., 2005b). In humans the effect of incomplete recoil on intrathoracic pressure can be similar to the use of excessive rates or durations of ventilation and is likely to result in less effective CPR because of poor venous return (Aufderheide and Lurie, 2004). In a study of pediatric IHCA, a feedback device alerted the compressor to leaning. Leaning was present in 97% of nonfeedback compressions and 89% of feedback compressions when defined as force applied to the chest of more than 0.5 kg and present in 83% of the nonfeedback compressions and 71% of the feedback compressions when defined as depth applied to the chest of more than 2 mm (Niles et al., 2009). It is interesting that a feedback device during CPR was effective in causing a lower rate of leaning, but the majority of compressions still resulted in this complication in their patients despite feedback. The importance of this concept, that venous return and blood flow are

related to chest recoil, has led to the development of alternative methods of providing compressions or ventilations to improve chest recoil during release of compression (active decompression CPR and some other techniques are discussed in a later section). Prevention of leaning on the chest during release of compression is difficult and may require the use of both visual and audio feedback devices and alternative methods of CPR. A team approach can be tried during an intraoperative cardiac arrest with the recorder and leader assessing the compressor and advising if full recoil appears to be inhibited by leaning on the chest between compressions.

Distribution of Blood Flow During Cardiopulmonary Resuscitation

Overall blood flow to tissues is decreased during CPR as compared with the normal physiologic state. A redistribution of blood flow during CPR favors perfusion to the heart and brain. This redistribution toward vital organs should enhance outcome. Maintenance of myocardial blood flow during CPR is necessary for ROSC, and maintenance of cerebral blood flow determines quality of neurologic outcome.

Distribution of blood flow to both the heart and brain during CPR is influenced by the development of regional gradients. Distribution of blood flow to the brain depends on development of three regional gradients: the intrathoracic-suprathoracic gradient, the intracranial-extracranial gradient, and the caudal-rostral gradient. The intrathoracic-suprathoracic gradient provides flow of oxygenated blood from the chest to the upper extremities and head. Either venous collapse secondary to elevated intrathoracic pressure or closure of anatomic valves in the jugular system prevents the transmission of intrathoracic pressure to the suprathoracic venous system (Rudikoff et al., 1980; Niemann et al., 1981; Fisher et al., 1982). When CPR is effective, arterial collapse does not occur and elevated intrathoracic pressure results in a gradient that promotes suprathoracic blood flow. The intracranial-extracranial gradient directs blood to the brain away from extracranial suprathoracic vessels and toward intracranial vessels. α -Adrenergic agonists constrict extracranial vessels but have little effect on intracranial vessels, resulting in increased intracranial blood flow. Use of the vasoconstrictor epinephrine increases intracranial blood flow while decreasing flow in the extracranial structures of skin, muscle, and tongue (Schleien et al., 1986). The caudal-rostral gradient occurs within intracranial vessels. The relatively low-flow state of CPR seems to increase the distribution of flow to caudal areas of the brain. Ischemia preceding CPR significantly increases the distribution of flow to these areas (Michael et al., 1984; Shaffner et al., 1998, 1999). This pattern of caudal redistribution of flow also occurs in other models of global ischemia and provides preferential perfusion of the brain stem (Jackson et al., 1981). Although brain-stem resuscitation is necessary for survival, this propensity for sparing of caudal circulation after either prolonged ischemia or prolonged CPR raises the concern for producing a victim who survives with only brain-stem function.

Myocardial blood flow does not have the advantage of a large extrathoracic pressure gradient that augments cerebral flow. The thoracic pump generates equal increases in all intrathoracic structures. This lack of a gradient can result in poor myocardial blood flow during external chest compressions. Several studies have shown much lower blood flow to the myocardium compared with the cerebrum during closed-chest CPR (Ditchey

et al., 1982; Michael et al., 1984; Schleien et al., 1986). The type of CPR influences the production of myocardial blood flow. Methods that are more likely to cause direct cardiac compression, such as high-impulse CPR, result in increased myocardial blood flow (Ditchey et al., 1982; Maier et al., 1984). Myocardial blood flow may be present only during relaxation of chest compression, correlating with a diastolic pressure, or in other methods seen during compressions correlating with a systolic pressure (Cohen et al., 1982; Maier et al., 1984; Michael et al., 1984; Schleien et al., 1986). Regional flow within the heart also changes during CPR, with a shift in the ratio of subendocardial/subepicardial blood flow from the normal 1.5:1 to 0.8:1 (Schleien et al., 1986). This ratio reverts to normal with epinephrine administration.

Conventional Cardiopulmonary Resuscitation

Conventional CPR includes closed-chest compressions delivered manually with ventilations interposed after every fifth, fifteenth, or thirtieth compression (see Table 38-4 for basic life support procedures). This method of CPR can be delivered in any setting without additional equipment and with a minimum of training. No large randomized study exists to demonstrate the superiority of any alternative method of CPR over conventional CPR.

Rescuer fatigue is a major problem with manual CPR in the field. Individual variation among rescuers performing manual CPR is another problem both in the field and in the laboratory. Mechanical devices are available to deliver chest compressions to prevent fatigue and to standardize compression delivery. Mechanical devices are presently limited to adult CPR and are not recommended for children (AHA, 2006a). The overall low efficacy of conventional CPR has led to investigations of multiple CPR modalities. The methods usually reflect attempts to enhance the contribution of the thoracic pump or cardiac pump to blood flow during CPR (Table 38-5). For example, the use of both hands to encircle the chest of an infant while using the thumbs to apply sternal compression attempts to both raise intrathoracic pressure and compress the heart (Todres and Rogers, 1975; David, 1988). This two-thumb encircling technique of CPR generates higher blood pressures and is recommended over the two-finger technique for infants (Dorfsman et al., 2000).

Blood flow to other organs during CPR is usually reduced compared with flow to the brain and heart. The lack of valves in intrathoracic veins causes retrograde transmission of venous pressure and decreases the gradient for blood flow below the diaphragm in animals (Brown et al., 1987b). Regional blood flows for intrathoracic organs (e.g., small intestine, pancreas, liver, kidneys, and spleen) during CPR are usually less than 20% of arrest rates before cardiac arrest and often close to zero (Koehler et al., 1983; Voorhees et al., 1983; Michael et al., 1984; Sharff et al., 1984). The addition of abdominal compressions does not alter the intrathoracic organ blood flow (Koehler et al., 1983; Voorhees et al., 1983). Administration of epinephrine during closed-chest CPR almost eliminates flow to the subdiaphragmatic organs, with the exception of the adrenal glands (Ralston et al., 1984). There are little data available regarding blood flow to the lungs during CPR. Pulmonary blood flow occurs primarily at times of low intrathoracic pressure during closed-chest CPR (Cohen et al., 1982). High extrathoracic venous pressure builds up during compression and results in pulmonary filling during relaxation as intrathoracic pressure falls. Resuscitation

methods that lower intrathoracic pressure may augment pulmonary vascular filling. Leaning on the chest during relaxation of compression and maintenance of increased ventilation pressures may prevent the fall in intrathoracic pressure between chest compressions and decrease pulmonary venous return and blood flow.

Alternative Methods of Cardiopulmonary Resuscitation

Simultaneous Compression-Ventilation Cardiopulmonary Resuscitation

Simultaneous compression-ventilation CPR (SCV-CPR) represents a technique designed to augment conventional CPR by increasing the contribution of the thoracic pump mechanism to blood flow. Delivering ventilation simultaneously with every compression (instead of interposed after every fifth compression) adds to intrathoracic pressure and potentially augments blood flow produced by conventional chest compressions. This method is felt to increase the perfusion gradient to the brain but has little effect on the myocardial perfusion gradient to the heart. Animal models suggested that SCV-CPR increases carotid blood flow compared with conventional CPR and show an advantage of SCV-CPR in large canine models (Koehler et al., 1983; Luce et al., 1983). No advantage is seen over conventional CPR in infant pigs and small dogs, perhaps because in small animals the compliance of the chest allows more direct cardiac compression and higher intravascular pressure than with conventional CPR (Babbs et al., 1982a, 1982b; Sanders et al., 1982; Schleen et al., 1986; Dean et al., 1987, 1990; Berkowitz et al., 1989). Human studies comparing SCV-CPR with conventional CPR show minimal improvement or detrimental effect on the coronary perfusion pressure (Harris et al., 1967; Martin et al., 1986). Survival is worse in both animals and humans when SCV-CPR is compared with conventional CPR (Sanders et al., 1982; Krischer et al., 1989). No study has shown an increased survival with this CPR technique despite the potential for increased brain perfusion.

Intraoperative arrest should be managed with endotracheal intubation, and compressions should be delivered at a 10:1 ratio with ventilations. Compressions do not have to be held for ventilations once the patient is intubated. The delivery of a ventilation breath that occurs simultaneously with a chest compression mimics SCV-CPR and may have some benefit on cerebral perfusion but is unlikely to help myocardial perfusion. The team members in the roles of airway, monitor, and leader should be careful that the rate and duration of ventilations do not significantly increase the percentage of time with increased intrathoracic pressure and inhibit venous return.

High-Impulse Cardiopulmonary Resuscitation

High-impulse CPR involves the application of force that is greater than usual during chest compression. This increase in force can be in the form of greater mass, greater velocity, or both. It is hypothesized that the larger impulses result in greater chest deflection, causing more contact with the heart (Kernstine et al., 1982). Direct cardiac compression is more likely with this form of closed-chest CPR. High-impulse CPR can generate myocardial blood flows as high as 60% to 75%

of values before cardiac arrest (Maier et al., 1984). In humans, high-impulse CPR generates increased aortic pressures (Swenson et al., 1988). An outcome study in dogs compared high-impulse CPR with conventional closed-chest CPR and found no significant improvement in resuscitation, survival, or neurologic outcome (Kern et al., 1986). The application of this benefit of greater force is the same for an intraoperative cardiac arrest, resulting in an increased likelihood of cardiac compression, which then results in higher myocardial and cerebral blood flow; however, the risk is that there is potential for increasing chest deformation and trauma.

Negative Intrathoracic Pressure Methods

Active compression-decompression CPR (ACD-CPR) requires a device that attaches to the chest and allows the rescuer to pull up on the sternum and decompress the thorax between compressions. The theoretical advantages of decompressing the chest between compressions include restoring chest wall shape and creating a negative intrathoracic pressure that pulls gas into the lungs and pulls blood into intrathoracic vessels. These characteristics allow for more effect from the subsequent compression, because more intrathoracic pressure can be generated and more blood is available to be ejected. Preliminary studies in humans have shown that after advanced cardiac life support failed, ACD-CPR was more effective than standard CPR at improving hemodynamic variables (Cohen et al., 1992). After IHCA, more patients had ROSC, survival at 24 hours, and a better Glasgow coma score when they received ACD-CPR than when standard CPR was given (Cohen et al., 1993). A larger study of IHCA victims failed to show any difference in resuscitation or outcomes between patients receiving ACD-CPR or standard CPR (Stiell et al., 1996). Several large studies of patients who suffered an OHCA did not find a difference in effectiveness of ACD-CPR or standard CPR for improving ROSC incidence, hospital admission, hospital discharge, or short-term neurologic outcome (Lurie et al., 1994; Schwab et al., 1995; Mauer et al., 1996; Stiell et al., 1996; Nolan et al., 1998).

Complication rates were not different after ACD-CPR or standard CPR in most studies (Lurie et al., 1994; Schwab et al., 1995; Mauer et al., 1996). It is interesting that the same study that showed that ACD-CPR had more complications than standard CPR (hemoptysis and sternal dislodgment) was also one of the few large studies that found ACD-CPR more effective than standard CPR for OHCA (Plaisance et al., 1997). ACD-CPR has been combined with an airway device to increase negative intrathoracic pressure—the impedance threshold device (ITD; see the next paragraph)—and has been mechanized to allow continuous application without the need to change rescuers and ease use during transport (see the section on mechanical methods). ACD-CPR is considered an optional technique for adults, and there are no data on which to base a recommendation for children.

The ITD is a device on the ETT or face mask that impedes inflow of inspiratory gas during chest reexpansion between CPR compressions when rescuers are not actively ventilating the patient. Impedance of gas inflow promotes negative intrathoracic pressure development during chest reexpansion. This increase in the negative intrathoracic pressure facilitates, by chest recoil, blood return to the thorax before the next chest compression (Lurie et al., 2002). The use of an ITD has been shown to improve coronary perfusion pressure and vital organ

blood flow with both standard and ACD-CPR in adult and pediatric animal models (Langhelle et al., 2002; Voelckel et al., 2002). Improved levels of EtCO₂, diastolic pressure, and coronary perfusion pressure occurred in a prospective, randomized controlled trial in adults undergoing ACD-CPR with ITD compared with ACD-CPR without ITD. A decrease in time to achieve a ROSC was also seen with ACD-CPR with ITD (Plaisance et al., 2000). A prospective controlled trial comparing standard CPR without an ITD and ACD-CPR with an ITD found significantly improved short-term survival (24 hours) in adult patients in the group that had ACD-CPR and an ITD (Wolcke et al., 2003). The use of an ITD with standard CPR in an OHCA trial adult of adults failed to show significant improvements in outcome for ITD vs. a sham ITD except in a subgroup with pulseless electrical activity (PEA) (Aufderheide et al., 2005). A separate study showed an improvement in short-term survival for standard CPR with an ITD vs. historical controls (Thayne et al., 2005). A no-ventilation study showed hypoxemia developing in animals that received either standard CPR with ITD or ACD-CPR with ITD but not in the animals that received standard CPR alone (Herff et al., 2007). Standard CPR with and without ITD in a ventricular-fibrillation cardiac arrest (VFCA) model in pigs showed no effect on MPP and no effect on survival in one study and worse survival with ITD in another study (Menegazzi et al., 2007; Mader et al., 2008). Further studies are needed to determine the effectiveness of the use of an ITD for pediatric resuscitation.

The ITPR combines an ITD with a vacuum to maintain a negative intratracheal gradient (-10 cm H₂O) during CPR while allowing positive pressure ventilation. An ITD relies on chest elastic properties such as outward recoil of thorax and proper CPR technique (no leaning during relaxation) to allow full recoil and generation of a negative intrathoracic pressure, whereas ITPR overcomes these limitations. An ITPR in a porcine model of VFCA was able to maintain negative intrathoracic pressure with ACD-CPR; the result was improved hemodynamic measurements and survival with no effect on ventilation (Yannopoulos et al., 2005a, 2006). ITPR has not been evaluated on asphyxial cardiac arrest or a pediatric model.

Abdominal Methods

Abdominal binding and military antishock trousers (MASTs) have been used to augment closed-chest CPR. Both methods apply continuous compression circumferentially below the diaphragm. Abdominal binding theoretically augments CPR by decreasing the compliance of the diaphragm that results in increased intrathoracic pressure, forcing blood out of the subthoracic structures to increase the circulating blood volume (an autotransfusion effect), and increasing the resistance in subdiaphragmatic vasculature, which increases suprathoracic blood flow. The increases in intrathoracic pressure and blood volume lead to increases in aortic pressure and carotid blood flow in both animals and humans (Chandra et al., 1981b; Lilja et al., 1981; Lee et al., 1981; Koehler et al., 1983; Niemann et al., 1984). Unfortunately, as the aortic pressure increases, the right atrial diastolic pressure increases to a greater extent, resulting in a decrease in the coronary perfusion pressure (Sanders et al., 1982; Niemann et al., 1984). This deterioration of coronary perfusion pressure is coincidental with a decreased myocardial blood flow (Niemann et al., 1984). This technique also decreases CPP because transmission of the intrathoracic pressure to the

intracranial vault raises the ICP (Guerci et al., 1985). Use of abdominal binders or MASTs to augment CPR does not increase survival in clinical studies (Sanders et al., 1982; Mahoney and Mirick, 1983; Niemann et al., 1990). Liver laceration from CPR performed with an abdominal binder has been reported but is no more common than with conventional CPR (Harris et al., 1967; Redding, 1971; Rudikoff et al., 1980; Mahoney and Mirick, 1983; Niemann et al., 1984). A recent study using a contoured abdominal cuff in a VFCA model in pigs found that at pressures over 200 mm Hg, abdominal binding increased MPP over standard CPR and urges a reconsideration of this technique (Lottes et al., 2007). The potential benefits over vasoconstrictor medications are that there is no need for access to the circulation, and a brisk withdrawal is possible when spontaneous circulation returns, avoiding the postresuscitation issues typical of vasoconstrictor administration. There is a lack of data in children to support the use of these techniques clinically during CPR, and potential for complications would discourage their application.

Only abdominal compression CPR (OAC-CPR) is a new method that uses only rhythmic compressions of the abdomen during resuscitation efforts to avoid the rib fractures that occur with standard chest compressions. A VFCA model in pigs comparing OAC-CPR to standard CPR showed 60% greater myocardial perfusion than did standard CPR (Geddes et al., 2007). Further evaluation is needed of the potential benefits of this technique in situations in which chest compressions need to be held, such as in the postsurgical cardiac patient when the chest is reopened during resuscitative efforts. This technique could potentially provide some brain and heart perfusion during the no-flow state while initial or subsequent sternotomy takes place (Adam et al., 2009).

Combined Abdominal and Chest Compression Methods

Interposed abdominal compression CPR (IAC-CPR) is the delivery of an abdominal compression during the relaxation phase of chest compression. IAC-CPR may augment conventional CPR by increasing venous return to the chest during the abdominal compression-chest relaxation phase and “priming the pump”; increasing intrathoracic pressure during abdominal compression, adding to the duty cycle of the chest compression; and sending blood retrograde to the carotids or coronaries because of abdominal compression on the aorta (Ralston et al., 1982; Voorhees et al., 1983; Einagle et al., 1988). Several studies have shown hemodynamic improvements secondary to IAC-CPR. In animals, cardiac output and cerebral and coronary blood flow improved when IAC-CPR was compared with conventional CPR in adult models but not in an infant swine model (Ralston et al., 1982; Voorhees et al., 1983; Walker et al., 1984; Einagle et al., 1988; Eberle et al., 1990). Studies in humans have also shown an increase in aortic pressure and coronary perfusion pressure during IAC-CPR compared with conventional CPR (Berryman and Phillips, 1984; Howard et al., 1984, 1987; Ward et al., 1989; Barranco et al., 1990; Chandra et al., 1990). Although one study reports a 10% aspiration rate, most report no aspiration or liver lacerations (Voorhees et al., 1983; Berryman and Phillips, 1984; Walker et al., 1984; Mateer et al., 1985; Einagle et al., 1988; Ward et al., 1989; Barranco et al., 1990; Sack et al., 1992). Clinically, IAC-CPR requires extra manpower or equipment and remains experimental. Outcome studies have mixed results, showing no increase in survival with OHCA but increased survival with

IHCAs (Mateer et al., 1985; Sack et al., 1992). Whereas IAC-CPR may serve as an alternative technique for in-hospital CPR in adults, a lack of data prevents a recommendation for the use of IAC-CPR in children.

Phased chest abdominal compression-decompression CPR (PCACD-CPR) is another manual method that combines chest and abdominal compressions (Tang et al., 1997). PCACD-CPR resembles a combination of ACD-CPR and IAC-CPR. It requires a device (Lifestick) that attaches to both the abdomen and chest and alternately compresses and reexpands both structures. It offers the theoretic advantages of both methods, because the chest shape is restored and blood and gas are pulled into the thorax during active chest decompression and blood flow is augmented because of compression and active decompression of the abdomen. MPP, ROSC, short-term survival, and neurologic outcome were improved in a porcine model of VFCA with resuscitation using PCACD-CPR (Tang et al., 1997). The use of the Lifestick proved safe and feasible in adults with cardiac arrest in the emergency room (Havel et al., 2008). Further information is required before these methods can be recommended for pediatric patients.

Mechanical Methods

Mechanical methods of producing chest compressions have continued interest, with the focus on minimizing interruption of compressions (to change compressors who fatigue) and reducing the NFF. Mechanical devices that provide compressions would not have pauses every 2 minutes to replace the compressor team member, would provide consistent quality of compressions, and improve the quality of compressions during patient transport. Compressions during radiation exposure for interventional procedures would be less hazardous. Several mechanical devices are currently being used for CPR.

Vest CPR uses an inflatable bladder that is wrapped circumferentially around the chest and is cyclically inflated. This method of delivering chest compressions by diffuse application of pressure has two unique characteristics. First, the increase in intrathoracic pressure occurs with only minimal change in chest dimensions, making direct cardiac compression unlikely (an almost pure thoracic-pump technique). Second, the diffuse distribution of pressure decreases the likelihood of trauma. Vest CPR in dogs improves cerebral and myocardial blood flows as well as survival when compared with conventional CPR (Luce et al., 1983; Criley et al., 1986; Halperin et al., 1986a, 1986b). In a pediatric model of vest CPR, only 3% permanent chest deformation occurred after 50 minutes of vest CPR compared with almost 30% deformation produced by an equivalent period of conventional CPR (Schleien et al., 1986; Shaffner et al., 1990). In humans, vest CPR increases aortic systolic pressure but does not significantly increase diastolic pressure compared with conventional CPR (Swenson et al., 1988). In a preliminary study of vest CPR in victims of OHCA, increased aortic and coronary perfusion pressure were demonstrated, and there was a trend toward a greater ROSC compared with standard CPR (Halperin et al., 1993). Clinically, use of vest CPR depends on sophisticated equipment, and the technique remains experimental at this time.

Load-distributing band CPR (LDB-CPR) is a modification of vest CPR that uses an automated device to provide compressions with a self-adjusting band across the anterior chest. Less equipment is required than with the use of the vest, making this technique better for OHCA. Both the vest and LDB-CPR provide compressions over a broader area of the chest than standard CPR,

reducing potential for inducing trauma during compressions. An initial study with LDB-CPR for adult OHCA showed an increase of ROSC vs. historical controls receiving standard CPR (Casner et al., 2005). LDB-CPR showed improved survival to discharge vs. standard CPR with historical controls for adult OHCA (Ong et al., 2006). A randomized study of LDB-CPR vs. standard CPR was halted for worse neurologic outcome and a trend toward worse survival than manual CPR (Hallstrom et al., 2006).

The Lund University Cardiopulmonary Assist System (LUCAS) is a mechanical device developed in Sweden to provide active compression-decompression CPR. In adult OHCA with LUCAS for CPR, the 30-day survival was 25% when it was applied within 15 minutes for witnessed cardiac arrests and 0% when applied after 15 minutes of cardiac arrest (Steen et al., 2005). The incidence and patterns of injury with the LUCAS are similar to those with manual CPR (Smekal et al., 2009). A report of five patients with IHCA showed that LUCAS ensured effective uninterrupted compressions during transport and during procedures in the cardiac catheterization laboratory (Bonnemeier et al., 2009).

Periodic acceleration CPR (pGz-CPR) is a method that produces rapid motion of the supine body in a headward-footward pattern that produces both circulation and ventilation with a decreased risk of rib fractures compared with standard CPR. In a VFCA model in pigs, pGz-CPR produced superior neurologic outcome compared with standard CPR (Adams et al., 2003). In an asphyxial cardiac arrest model in pigs, pGz-CPR produced equivalent outcomes with no broken ribs compared with standard CPR, during which 25% of animals received rib fractures (Adams et al., 2008).

In summary, multiple models of mechanical CPR are available and have the potential to provide continuous high quality compressions in many situations that would make compressions difficult (transport) or risky (fluoroscopy). None is sufficiently studied to deserve recommendation for intraoperative use in children.

Monitoring the Effectiveness of Resuscitative Efforts

The brain and heart are the organs most likely to suffer irreversible damage if resuscitation efforts do not provide adequate blood flow and oxygen delivery. The table below lists several methods that can be used during resuscitation to determine whether efforts are effective in the restoration of adequate perfusion to these vital organs (Table 38-6). It is important to determine whether restoration of perfusion by these efforts is adequate to prevent neurologic injury and to allow ROSC. The determination that resuscitation efforts are ineffective can prompt attempts to improve resuscitation or, if improvement attempts fail, to decide that resuscitation is futile and terminate efforts. If resuscitation efforts are determined to be inadequate, then interventions can be made to improve effectiveness and eventual patient outcome. These interventions include improving performance of compressions (i.e., increasing depth or replacing the fatigued compressor), administering fluid to improve intravascular volume, or administering vasoconstrictors to improve vascular tone. When the resuscitation efforts are determined to be ineffective and unable to be improved (as in prolonged cardiac arrest before CPR) this information aids in the decision that continued resuscitation is futile and efforts should be stopped.

TABLE 38-6. Techniques for Monitoring Cardiopulmonary Resuscitation Effectiveness

Technique	Monitoring Device	Goal
Level of consciousness	Examination	Consciousness
Return of spontaneous circulation	Examination, arterial catheter, EtCO_2	Spontaneous circulation
Pulse during compressions	Examination	Arterial pulsation
EtCO_2	Quantitative EtCO_2	>10 mm Hg
Arterial diastolic (relaxation) pressure	Arterial catheter	>15 mm Hg
Mixed venous saturation	Central venous catheter	>30%
Venous-arterial CO_2 difference	Arterial and central catheter	Decreased difference
Amplitude of VF	Electrocardiogram	Increased amplitude
Frequency of VF	Electrocardiogram	Decreased frequency
AMSA	ECG and software for analysis	>13 mV Hz
Transthoracic impedance	AED and software for analysis	Decreased by compression

EtCO₂, End-tidal carbon dioxide; *CO₂*, carbon dioxide; *VF*, ventricular fibrillation; *AMSA*, amplitude spectrum area; *ECG*, electrocardiogram; *AED*, automated external defibrillator; *mm Hg*, millimeters of mercury; *mV*, millivolts; *Hz*, hertz.

The level of consciousness can improve if resuscitation efforts are effective. Occasionally, a patient with a nonperfusing rhythm regains consciousness during chest compressions only to become unresponsive when compressions are held and perfusion falls. This may recur repeatedly until a perfusing rhythm is restored. Return of consciousness is evidence of highly effective resuscitative efforts, but it is rare that the level of perfusion required for this to occur can be accomplished. Additionally, in the operating room the victim of cardiac arrest may have the evaluation of their level of consciousness masked by the use of anesthetic agents. This technique is unlikely to be helpful in most intraoperative arrests.

The restoration of spontaneous circulation is another indicator of adequate resuscitative efforts. This is usually a sign that perfusion to the heart muscle is adequate to allow effective contractions. The temptation is often to hold resuscitation efforts when spontaneous ejection occurs, but spontaneous circulation may not be adequate or sustained, and continued resuscitation efforts may be required. Compressions must be continued if spontaneous circulation does not adequately perfuse vital organs.

The palpation of a pulse during chest or cardiac compressions may be a sign that significant arterial pressure is being generated. Unfortunately, the palpable pulse may represent only peak arterial pressure during compression and be accompanied by a lack of significant relaxation (diastolic equivalent) pressure necessary for coronary perfusion. Because significant coronary perfusion occurs during relaxation, a palpable peak pulse may not represent effective CPR. Additional concerns about the reliance on palpation to determine the effectiveness of resuscitation are

that the palpated artery is usually next to a large vein and that retrograde venous pulsations may occur in the absence of significant arterial blood flow. There are no data on when, or if, palpation of pulsations during chest compressions correlates with ROSC or outcome.

One of the most useful ways to measure the effectiveness of chest or cardiac compressions to generate blood flow is the use of quantitative EtCO_2 monitoring. These monitoring devices are readily available in areas where anesthesia is administered. The detection of EtCO_2 during compressions demonstrates that venous blood is being moved through the lungs in sufficient quantity that CO_2 is available for measurement with ventilation. The level of EtCO_2 increases as compressions are more effective in increasing the pulmonary blood flow and the delivery of carbon dioxide in the venous blood to the lungs.

Low levels of EtCO_2 generated during compressions correlate with decreased levels of blood flow and decreased likelihood of ROSC. EtCO_2 levels measured during CPR that are less than 10 mm Hg predict an inability to restore spontaneous circulation in adults (Callaham and Barton, 1990; Wayne et al., 1995; Levine et al., 1997). Levels of EtCO_2 during CPR that are greater than 15 mm Hg predict ROSC in adults and children (Sanders et al., 1989; Bhende and Thomson, 1995; Barton and Callaham, 1991). EtCO_2 levels lower than 10 to 15 mm Hg during CPR indicate a decreased likelihood of success and should prompt institution of methods to improve resuscitation (i.e., better compressions and fluid or vasoconstrictor administration).

The measurement of EtCO_2 during CPR has also been used to detect low levels of cardiac output during PEA, ROSC during compressions, and the presence of spontaneous circulation during CPB (Garnett et al., 1987; Barton and Callaham, 1991; Gazmuri et al., 1991).

The technique of using EtCO_2 measurement during CPR does not require an ETT. EtCO_2 levels measured during CPR with bag mask or laryngeal mask ventilations also correlate with the likelihood of achieving ROSC (Nakatani et al., 1999). Another important consideration when using this technique is that the administration of bicarbonate to the victim causes a transient elevation in EtCO_2 without an elevation in blood flow that may be misinterpreted as improving CPR. Epinephrine administration has been associated with a transient drop in EtCO_2 despite an increase in MPP and may be misinterpreted as a worsening of CPR (Martin et al., 1990b). The cause of cardiac arrest may influence the initial EtCO_2 levels during resuscitation; higher levels of EtCO_2 are found with asphyxial arrest than with fibrillatory arrest (Grmec et al., 2003).

Invasive monitoring may be in use at the time of a cardiac arrest and may be helpful to determine the effectiveness of resuscitative efforts. An arterial catheter is necessary to determine aortic diastolic pressure during the relaxation phase of compressions. If an arterial catheter is present, arterial diastolic pressure (relaxation pressure) represents the MPP, and levels greater than 15 mm Hg are necessary for, but do not guarantee, ROSC in adult patients (Paradis et al., 1990). A central venous catheter is another invasive monitor that, if present, may be used to determine the central venous oxygen saturation during resuscitative efforts. The level of venous blood oxygen saturation correlates with effectiveness of resuscitation to produce blood flow and correlates with likelihood of ROSC (Snyder et al., 1991; Rivers et al., 1992). Patients with a mixed-venous oxygen saturation of less than 30% were unlikely to have ROSC (Rivers et al., 1992). The presence of

both arterial and venous catheters allow sampling of simultaneous gases. The venous-arterial CO_2 difference is approximately 5 mm Hg during native circulation, and this difference increases significantly as perfusion falls. During hypoperfusion tissue CO_2 increases, venous CO_2 increases, pulmonary blood flow falls, and ventilation removes a greater percentage of CO_2 , resulting in lower arterial CO_2 . As CPR is made more effective, this venous-arterial gradient decreases again.

The amplitude and frequency of VF can be determined from the electrocardiogram (ECG) or specific software built into AEDs and used to determine effectiveness of resuscitation. Typically, the VF waveform is initially coarse (high amplitude, low frequency) and deteriorates over time during ineffective CPR or prolonged cardiac arrest to fine (low amplitude, high frequency) VF. As blood flow perfusing the heart during CPR improves, VF reverts back to a coarse pattern that indicates that the heart is more readily converted by shock to allow ROSC. An index of amplitude and frequency-amplitude spectral area (AMSA) has been correlated with the use of the MPP, EtCO_2 , and likelihood of ROSC in a porcine model of VF arrest (Li et al., 2008). This index is calculated by software built into the AED, and a value of at least 13 mV Hz has been regarded as a critical threshold for defibrillation success.

The transthoracic impedance (TTI) is measured between the gel-coated pads applied to the chest during CPR by the use of an AED. The TTI can be continuously measured by these devices, and impedance decreases during compression in relation to the amount of blood movement through the chest. The potential exists to use this technique to monitor the amount of blood flow generated by compressions and determine whether there is continued effectiveness or if deterioration of compressions occurs with rescuer fatigue.

Analysis of the TTI waveform using an investigational monitor or defibrillator has been used to detect ROSC in adults. Like a sudden spike in EtCO_2 during CPR, changes in the TTI waveforms can signify ROSC. These methods can lead to earlier detection of ROSC, potentially eliminate the need to pause compressions to check pulse to determine ROSC, and eliminate the simultaneous no-flow state if ROSC has not yet occurred (Losert et al., 2007). Similar impedance measurements have been shown to detect the difference between pulsatile and pulseless rhythms during pulse checks that occur with in-hospital resuscitation (Risdal et al., 2008). The rapid determination of a pulseless rhythm would prompt resumption of compressions and reduce the no-flow interval during pulse checks. A brisk fall in EtCO_2 during pulse check would be another indication that a no-flow state is occurring and compressions should be restarted.

An additional monitoring benefit of TTI during CPR is the detection of ventilation or the loss of ventilation. Entry of gas into the lungs with ventilation causes an increase in TTI. The sudden loss of the cyclic decreases in TTI with ventilation may indicate displacement of the ETT during CPR (Pytte et al., 2007). Although loss of EtCO_2 is also used to indicate displacement of the ETT, EtCO_2 levels may be markedly diminished by low pulmonary blood flow during CPR. There is potential that the disappearance of impedance changes related to the failure of air entry with ETT displacement may be more reliable in situations of very low EtCO_2 . The use of TTI to indicate loss of ventilation or ETT displacement might also eliminate the need to stop compressions to perform auscultation when ETT displacement is suspected. TTI also can be used as a training technique to review the number of compressions and

ventilations delivered over the course of resuscitation at post-resuscitation feedback sessions.

The anesthesiologist may have many methods to choose from to determine the effectiveness of intraoperative resuscitation efforts. The equipment for quantitative determination of EtCO_2 is the most likely to be available in the majority of perioperative situations. In fibrillatory arrest, the restoration of a coarse pattern demonstrates effective CPR and when defibrillation attempts are most likely to be successful (Hayes et al., 2003). In the near future, TTI measurements by the defibrillator or AED may be available to monitor the amount of blood flow produced by resuscitative efforts, recognize ETT displacement, recognize ROSC or pulseless rhythms, and serve as training tools for feedback during debriefing sessions.

Vascular Access for Drug and Fluid Administration

Peripheral and Central Vascular Access

Vascular access is crucial to the effective administration of drugs and fluids for resuscitation, but it may be difficult to achieve in pediatric patients. During cardiac arrest, attempts to obtain peripheral venous access in infants and children should be limited, and if they are unsuccessful an intraosseous (IO) needle should be placed and or the administration of drugs may be started in the ETT. The American Heart Association (AHA) and the International Liaison Committee on Resuscitation (ILCOR) recommendations prioritize IO drug administration over endotracheal administration because of variable blood concentrations if a drug is given endotracheally (AHA, 2006b; ILCOR, 2006). Central venous access may be attempted during cardiac arrest by skilled providers, but attempts should not delay administration of life-saving medications via the peripheral IV or IO route.

The ideal placement of an intravascular catheter during CPR provides ready access to the anesthesiologist and minimizes interruption of resuscitation efforts. Peripheral venous access, IO access, and femoral venous access can usually be accomplished without interruption of airway management or chest compressions. The use of a saline flush for medications administered in peripheral IV access, IO access, and central lines with the catheter tip below the diaphragm improves medication delivery to the heart in the low-flow state of CPR. A flush with 5 to 20 mL of normal saline should drive the medication into the central circulation (0.25 mL/kg was effective in an animal model) (Orlowski et al., 1990). For most instances of CPR, peripheral IV access should be adequate for administration of resuscitation medications (Table 38-7).

Intraosseous Access

IO cannulation provides a rapid and safe route to vascular access via the bone marrow; this space is a noncompressible venous plexus and therefore reliably available when peripheral venous access is limited as a result of dehydration or peripheral vasoconstriction. Trained providers can obtain IO access within 30 to 60 seconds with a first-attempt success rate of approximately 80% (Brunette and Fischer, 1988; Guy et al., 1993; Fiorito et al., 2005). All drugs, crystalloids, colloids, and blood can be administered via this route. The onset and duration of action of emergency medications are the same when given by IO, central, or peripheral access during native circulation in dogs (Orlowski et al., 1990).

TABLE 38-7. Vascular Access During CPR

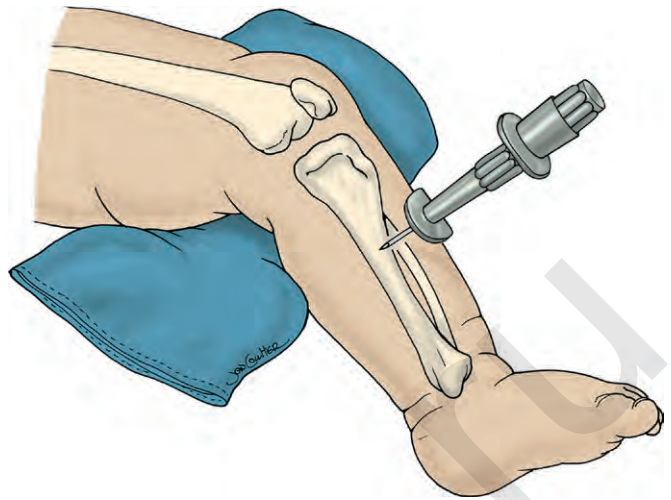

Route	Characteristics
Peripheral venous access (IV)	Route of first choice if vascular access not present Rapidly and easily placed Any drug or fluid may be administered Flush each drug with 0.25 mL/kg normal saline (20 mL in adults)
Intraosseous access (IO)	Easier to obtain in <6-year-old, can use for any age Any drug or fluid may be administered Flush with 0.25 mL/kg normal saline (20 mL in adult)
Endotracheal route (ETT)	Use only if no IV or IO access Only administer naloxone, atropine, vasopressin, epinephrine, and lidocaine (NAVEL) drugs by ETT Note: ETT drug delivery requires 2-10 times IV dose Use 5 mL of normal saline in ETT to increase distribution into distal bronchial tree (10 mL in adults)
Central venous catheter	Central access is first choice if already in place Place if no IV or IO is obtained Requires flush if catheter tip is below diaphragm
Cut-down saphenous	Use when other options have failed Requires special skill, high complication rate

CPR, Cardiopulmonary resuscitation; IV, intravenous; IO, intraosseous; ETT, endotracheal tube.

The preferred site for an IO needle in a child is the anterior tibia. Alternative sites include the distal femur, medial malleolus, and iliac crest. In older children and adults, the distal radius, distal ulna, proximal humerus, and the sternum (risk of cardiac laceration) are also considered appropriate sites (Fig. 38-2) (Glaeser et al., 1993; Guy et al., 1993; Waisman and Waisman, 1997; Calkins et al., 2000). Specially designed IO needles should be readily available to the pediatric anesthesiologist for such emergencies. Rapid deployment devices for IO needles have been developed and may increase ease of IO placement (Horton et al., 2008; Schwartz et al., 2008). The most common complication from IO access is displacement of the needle and extravasation of fluid and medication (12%) (Piorito et al., 2005). Other rare complications include bone fracture, compartment syndrome, osteomyelitis, and fat embolism (Orlowski et al., 1989).

Intratracheal Medication Administration

The intratracheal route may be used for administration of lipid-soluble resuscitation medications. Because most anesthetized children have this route available, it should be considered early, particularly if vascular access is a problem or access to

■ **FIGURE 38-2.** IO needle in proximal tibia.

extremities is limited. Concerns related to variable delivery of medication and duration of effect make IO administration preferable to endotracheal administration in situations where IV access is not available.

Medications that can be administered via the ETT include the “NAVEL” drugs (naloxone, atropine, vasopressin, epinephrine, and lidocaine) (Wenzel et al., 1997; Efrati et al., 2003a). Studies suggest that similar doses given via the trachea achieve lower serum concentrations than when given by IV route (McDonald, 1985; Quniton et al., 1987; Jørgensen and Ostergaard, 1997; Kleinman et al., 1999). Lower serum concentrations of epinephrine may produce predominately β_2 -adrenergic effects, causing vasodilation and decreased coronary perfusion pressures (Vaknin et al., 2001; Efrati et al., 2003b). Because of this concern, the recommended intratracheal dose of epinephrine is 10 times the intravascular dose, with a maximum dose of 2 to 2.5 mg (Manisterski et al., 2002). Recommended intratracheal doses of atropine and lidocaine are two times the intravascular dose; there is no optimal dose recommendation for naloxone or vasopressin. Drugs administered via the endotracheal route may have prolonged effect because of the reservoir of drug in the pulmonary tree (Hornchen et al., 1989). Prolonged effects of resuscitative medications can be detrimental in the patient after cardiac arrest because of sustained afterload and myocardial oxygen demand.

The technique for tracheal administration is to flush the medication with 2 to 5 mL (2 mL in children, 5 mL in adolescents) of normal saline into the ETT and provide five manual ventilation breaths to deliver medication into distal airways and alveoli. This technique is favored over delivery via catheter or feeding tube because of ease and practicality (Jasani et al., 1994).

DRUGS FOR RESUSCITATION

Vasoactive Drugs

Adrenergic Agonists

Epinephrine has been the drug of choice during CPR since the 1960s. Redding and Pearson (1963) first described the use of adrenergic agonists during CPR and demonstrated that early

administration of epinephrine during cardiac arrest improved the resuscitation success rate. The increase in diastolic pressure from increased systemic vascular resistance was shown to be responsible for the success of resuscitation when using adrenergic agents (Pearson and Redding, 1965).

In order to investigate the relative importance of α -adrenergic and β -adrenergic agonist actions during resuscitation, Yakaitis et al. (1979) used a canine model of cardiac arrest and found they could resuscitate only one in four animals that received both the pure β -adrenergic agonist, isoproterenol, and an α -adrenergic antagonist. In contrast, all the dogs treated with both an α -adrenergic agonist drug and a β -adrenergic antagonist were successfully resuscitated (Yakaitis et al., 1979). These data suggest that the α -adrenergic agonist action of epinephrine is responsible for successful resuscitation after cardiac arrest. Support for this theory was reported by Michael et al. (1984) who demonstrated that the effects of epinephrine during CPR are mediated by selective vasoconstriction of peripheral vessels, excluding those supplying the brain and heart. Epinephrine infusions maintain a higher aortic pressure and result in a higher perfusion pressure to both the heart and brain (Michael et al., 1984). Even with increases in both mean and diastolic aortic pressure, the flow to other, nonvital organs, such as the kidneys and small intestine, becomes compromised with intense vasoconstriction of their blood supply (Schleien et al., 1986; Michael et al., 1984; Koehler et al., 1985).

Effects on Coronary Blood Flow

The increase and maintenance of aortic diastolic pressure associated with administration of α -adrenergic agonists during CPR are critical for coronary blood flow and ultimately successful resuscitation. In the beating heart, the contractile state of the myocardium is increased by β -adrenergic receptor agonist action. During CPR, β -adrenergic drugs may stimulate spontaneous myocardial contractions and increase intensity of VF, but this inotropic effect can result in increasing intramyocardial wall pressure, decreased coronary perfusion pressure, and diminished myocardial blood flow (Livesay et al., 1978). In addition, β -adrenergic stimulation increases myocardial oxygen demand by increasing cellular metabolism and oxygen consumption. The superimposition of an increased oxygen demand on the low myocardial blood flow available during CPR probably contributes to ischemia.

The increase in and maintenance of aortic diastolic pressure associated with administration of α -adrenergic agonists during CPR are critical for coronary blood flow and ultimately successful resuscitation. Drugs that are pure α -adrenergic agonist drugs (such as methoxamine and phenylephrine) have been used successfully during CPR. The absence of direct β -adrenergic stimulation avoids an increase in myocardial oxygen uptake, resulting in a more favorable oxygen demand-to-supply ratio in the ischemic heart. These nonepinephrine, α -adrenergic agonists have been reported to be used in successful resuscitation and to maintain myocardial blood flow during CPR as effectively as epinephrine (Redding and Pearson, 1963; Pearson and Redding, 1965; Yakaitis et al., 1979; Schleien et al., 1989). Schleien et al. (1989) found that high aortic pressures can be sustained in a canine model of CPR with phenylephrine, a pure α -adrenergic agonist. The long-standing debate continues about the merits of pure α -adrenergic agonist drugs for resuscitation because of

confusion regarding benefit vs. detriment of the β -adrenergic effects of epinephrine (Holmes et al., 1980; Brown et al., 1987a, 1987c).

Effects on Cerebral Blood Flow

During CPR, the generation of cerebral blood flow, similar to coronary blood flow, depends on the vasoconstriction of peripheral vessels, and this vasoconstriction is enhanced by administration of α -adrenergic agonists. Epinephrine and other α -agonist drugs produce selective vasoconstriction of noncerebral peripheral vessels, supplying areas of the head and scalp (i.e., tongue, facial muscle, and skin) without causing cerebral vasoconstriction models of CPR in adults and infants (Koehler et al., 1983; Schleien et al., 1986; Beattie et al., 1991). Infusion of either epinephrine or phenylephrine maintained cerebral blood flow and oxygen uptake at prearrest levels for 20 minutes in a canine model of CPR. There were no differences in neurologic outcome 24 hours after resuscitation when either epinephrine or phenylephrine was administered 9 minutes after VF (Brillman et al., 1985). Other investigators found epinephrine to be more beneficial medication in generating vital organ blood flow (Brown et al., 1986b, 1987a, 1987c). This may have been because of the use of drug dosages that were not equipotent in generating vascular pressure and subsequent blood flow. In addition, epinephrine may have either a vasoconstriction or vasodilation effect on cerebral vessels, depending on the balance between α - and β -adrenergic actions (Winquist et al., 1982).

Cerebral oxygen uptake may be increased by a central β -adrenergic receptor effect if sufficient amounts of epinephrine cross the blood-brain barrier (BBB) during or after resuscitation (Carlsson et al., 1977; MacKenzie et al., 1976). When cerebral ischemia is brief and the BBB remains intact, epinephrine and phenylephrine have similar effects on cerebral blood flow and metabolism (Schleien et al., 1989). Catecholamines may cross the BBB when mechanical disruption occurs or when enzymatic barriers to vasopressors (i.e., monoamine oxidase inhibitors) are overwhelmed during tissue hypoxia (Edvinsson et al., 1978; Lasbennes et al., 1983). During CPR, the BBB may be disrupted by the generation of large fluctuations in cerebral venous and arterial pressures during chest compressions. In addition, permeability of the BBB may increase because of arterial pressure surge that occurs in a maximally dilated vascular bed after resuscitation (Arai et al., 1981). An increase in cerebral oxygen demand when cerebral blood flow is limited could affect cerebral recovery adversely. In an infant model of 8 minutes of cardiac arrest with CPR, disruption of the BBB was present 4 hours after defibrillation (Schleien et al., 1991). In similar protocols involving 8 minutes of cardiac arrest, endothelial vacuolization has been shown, with extravasation of protein through the BBB (Schleien et al., 1992a). These theoretic effects of catecholamines on cerebral circulation need to be further clarified and do not represent a contraindication to administration of epinephrine during cardiac arrest.

Dosage

High-dose epinephrine (0.1 mg/kg) is not recommended for resuscitation because of lack of evidence for benefit over standard dosing (0.01 mg/kg) and concern for harm (AHA, 2006b). Although early animal models of cardiac arrest and clinical

studies indicated that high-dose epinephrine may be beneficial through increased cerebral and coronary blood flow (Brillman et al., 1985; Berkowitz et al., 1991; Brown et al., 1986a), other studies in animal models suggested that high-dose epinephrine is associated with a disproportionate rise in myocardial oxygen consumption (Maier et al., 1984; Jackson et al., 1984; Brown et al., 1988a, 1988b; Ditchey and Lindenfeld, 1988). Initial case series in adults reported increased diastolic blood pressure and successful ROSC when high-dose epinephrine was administered (Gonzalez et al., 1988, 1989; Paradis et al., 1990; Martin et al., 1990a; Cipolotti et al., 1991). In a nonrandomized, unblinded study, Goetting and Paradis (1989) reported on seven pediatric patients treated successfully with 0.2 mg/kg of epinephrine; three survived. Several large randomized controlled studies of high-dose and standard-dose epinephrine showed no benefit of high dose on survival or neurologic outcome (Brown et al., 1992; Callahan et al., 1992; Stiell et al., 1992). A prospective, randomized, double-blinded trial in children comparing high-dose epinephrine (0.1 mg/kg) with standard-dose epinephrine (0.01 mg/kg) for inpatient cardiac arrest after failure of initial standard epinephrine dose found that whereas the high-dose and standard-dose arms had equal ROSC (21 out of 34 vs. 20 out of 34), there was significantly better survival at 24 hours (7 out of 34 vs. 1 out of 34, $p = 0.05$) and discharge (4 out of 34 vs. 0 out of 34) in the standard dose patients (Perondi et al., 2004). Finally, a meta-analysis of these and other randomized, double-blinded studies found that whereas high-dose epinephrine may have benefit for the endpoint of ROSC, there was no improvement in survival to discharge; in fact, there was a trend toward negative impact on this endpoint (Vandycke and Martens, 2000). High-dose epinephrine may account for some of the adverse effects that occur after resuscitation by worsening myocardial ischemia that results in arrhythmias, hypertensive crisis, pulmonary edema, digitalis toxicity, hypoxemia, and cardiac arrest (Brown et al., 1992; Schleien et al., 1992b).

The 2005 AHA guidelines recommend epinephrine at 0.01 mg/kg IV or IO as the first and subsequent doses for pulseless cardiac arrest: asystole, PEA, ventricular tachycardia (VT), and VF. A dosing interval of 3 to 5 minutes is usually recommended; more frequent dosing may result in increased side effects similar to those with the use of high doses. Dosing every 4 minutes is within the recommendations and can be timed with every other 2-minute break for change in compressor and rhythm analysis. When IV or IO access is unavailable, epinephrine may be administered via the ETT at 0.1 mg/kg, although the 2005 guidelines emphasize IV and IO dosing over ETT dosing because of more reliable drug absorption and effect. The high dosage of epinephrine (0.1 mg/kg) may be considered in clinical situations refractory to standard dosing, such as β -blocker or calcium channel overdose, severe anaphylaxis, or septic shock (AHA, 2006b) (Table 38-8).

Other Adrenergic Agents

Dopamine and dobutamine are additional agents used for vasopressor support after cardiac arrest in infants and children. Guidelines for postresuscitation support advocate their use, because they cause less tachycardia, myocardial ectopy, and hypertension than epinephrine in the patient who has experienced cardiac arrest. Dopamine hydrochloride is administered as an infusion of 2 to 20 mcg/kg per minute. At higher doses (more than 10 mcg/kg per minute), α -adrenergic activity

TABLE 38-8. Epinephrine Administration During CPR

Actions	Decreases perfusion to nonvital organs (α -adrenergic effect) Improves coronary perfusion (aortic diastolic pressure) (α -adrenergic effect) Increases intensity of ventricular fibrillation (β -adrenergic effect) Stimulates cardiac contractions (β -adrenergic effect) Intensifies cardiac contractions (β -adrenergic effect)
Indications	Bradycardia with hemodynamic compromise Asystole or pulseless arrest
Dosage	Bradycardia: 0.01 mg/kg intravenous or intraosseous or 0.1 mg/kg ETT Repeat every 3-5 min at the same dosage Pulseless First dose: 0.01 mg/kg intravenous or intraosseous or 0.1 mg/kg ETT Repeat every 3-5 min

TABLE 38-9. Vasopressor Infusions in the Post-Arrest Period

Agent	Dosage	Comments
Epinephrine	0.05-1.0 mcg/kg/min	Inotrope, chronotrope
Dopamine	2-20 mcg/kg/min	Inotrope, chronotrope; dilates the splanchnic vasculature at lower doses, pressor effect at higher doses
Dobutamine	2-20 mcg/kg/min	Inotrope, decreased SVR
Milrinone	Load: 50-75 mcg/kg Infusion: 0.5-1 mcg/kg/min	Inotrope, improve diastolic relaxation, decreased SVR

SVR, Systemic vascular resistance.

is dominant. Dobutamine hydrochloride is another adrenergic agent used for inotropic support. Infusions rates range from 2 to 20 mcg/kg per minute. Decreases in systemic vascular resistance can be seen as a result of β -adrenergic effects (Table 38-9).

Phosphodiesterase Inhibitors

Milrinone is commonly used as an inotrope to support myocardial function during the perioperative period in children undergoing congenital heart surgery and may be useful in the postresuscitation period. The benefits of this agent are: increased inotropy (force of left ventricular contraction), increased dromotropy (speed and efficiency of myocardial conductive pathways) and increased lusitropy (left ventricular diastolic relaxation). There is no effect on chronotropy (rate of contraction); thus, minimal impact on myocardial oxygen consumption and the risk of arrhythmias is low. The side effects of milrinone are predominately thrombocytopenia and a decrease in systemic vascular resistance. Milrinone is usually loaded with a dose of 50 mcg/kg over 30 minutes followed by an infusion of

0.5 to 1 mcg/kg per minute. In an animal model of CPR during VFCA, a loading dose and maintenance infusion of milrinone improved stroke volume and sustained rhythm after arrest (Niemann et al., 2003).

Vasopressin

Vasopressin is a pituitary hormone that binds to specific receptors located throughout the vasculature (V1 receptors) that are responsible for vasoconstriction and in renal tubules (V2 receptors) that facilitate water reabsorption. L-arginine vasopressin is the exogenously administered compound traditionally used to treat diabetes insipidus and gastric hemorrhage. More recent indications for vasopressin include vasoplegic shock and cardiac arrest. Both endogenous and administered vasopressin are cleared and inactivated from plasma during passage through the liver and kidneys. This results in an elimination half-life of about 10 to 20 minutes.

In cardiac arrest, vasopressin has a theoretic advantage compared with epinephrine, because it causes vasoconstriction without adrenergic activity; it does not increase myocardial oxygen demand at a time when oxygen delivery is limited. In addition, vasopressin may result in less ventricular ectopy and tachycardia in the postresuscitation period. These advantages may be offset by intense vasoconstriction after ROSC, potentially worsening myocardial ischemia (Prengel et al., 1996, 1998; Wenzel and Lindner, 2002).

A meta-analysis of animal studies of vasopressin in cardiac arrest found that vasopressin increases ROSC compared with placebo (93% vs. 19%, $p < 0.001$) or adrenaline (84% vs. 52%, $p < 0.001$) (Biondi-Zoccai et al., 2003). However, data in humans are not as strong. Wenzel et al. (2004) performed a large randomized trial of vasopressin and epinephrine for the treatment of OHCA and found no difference between the two drugs in hospital admission for patients with VF or PEA but did show improved hospital admission rate and survival discharge in patients with asystole treated with vasopressin. Additionally, there was improved hospital admission (25.7% vs. 16.4%, $p = 0.002$) and survival to discharge rate (6.2% vs. 1.7%, $p = 0.002$) among patients treated with vasopressin and then epinephrine vs. epinephrine alone (Wenzel et al., 2004). However, other large, randomized controlled trials have failed to demonstrate the beneficial effect of vasopressin alone or in combination with epinephrine vs. epinephrine alone for survival to discharge (Lindner et al., 1997; Stiell et al., 2001; Callaway et al., 2006; Gueugniaud et al., 2008).

The pediatric literature concerning the use of vasopressin during CPR is limited. A pediatric animal model of asphyxia cardiac arrest found that ROSC was significantly more likely in animals treated with epinephrine than with vasopressin (Voelckel et al., 2000). In a retrospective review, Mann showed that four of six children experiencing cardiac arrest had ROSC after administration of vasopressin (0.4 units/kg). Two patients survived to 24 hours, and one patient survived to discharge (Mann et al., 2002). An additional case series reported the use of terlipressin, a vasopressin analogue in seven children with asystole. ROSC was achieved in five children, and four children survived to discharge (Matok et al., 2007). A retrospective review of the National Registry of CPR (NRCPR) database of vasopressin use during pediatric IHCA from 1999 to 2004 showed only 5% of children received vasopressin during the management of cardiac arrest. Children who received vasopressin had a lon-

ger duration of cardiac arrest than those who did not (median 37 vs. 24 minutes, $p = 0.004$) and were more commonly in an intensive care setting (77%). After multivariate analysis, vasopressin was associated with worse ROSC and no difference in 24-hour or discharge survival (Duncan et al., 2009). Thus, the role of vasopressin in pediatric cardiac arrest is indeterminate and requires further study.

Indication and Dosage

AHA guidelines do not recommend for or against the use of vasopressin for pediatric cardiac arrest, but they do recommend the administration of two doses of 40 units of vasopressin intravenously for refractory VF in adults. Vasopressin may have an advantage over epinephrine in the resuscitation of a child with prolonged QTc syndrome, because epinephrine may potentiate ventricular dysrhythmias in this disease. The few reports of vasopressin use in pediatric cardiac arrest, or pediatric models of cardiac arrest use a 0.4 to 0.5 units/kg dose, with an adult dose of 40 units (Mann et al., 2002). There are insufficient data on which to base suggestions for repeating the dose for pediatric cardiac arrest.

Adverse Effects

The most common side effects seen with vasopressin treatment in children receiving treatment for diabetes insipidus and gastric hemorrhage are nausea, vomiting, and abdominal pain. These may be related to vasoconstriction of the splanchnic vasculature. Rare adult reports of bowel ischemia, skin necrosis, and myocardial ischemia have been made that may be related to the vasoconstrictive effects of vasopressin. Anaphylactic and other allergic reactions have also been reported but also are rare (Wenzel and Lindner, 2002).

Antiarrhythmic Drugs

Atropine

Atropine is a parasympatholytic agent that reduces vagal tone to the heart, resulting in an increased discharge rate of the sinus node, enhanced atrioventricular conduction, and activated latent ectopic pacemakers (Gillette and Garson, 1981). Atropine has minimal effects on systemic vascular resistance, myocardial perfusion, and myocardial contractility (Gilman et al., 1990).

Indications

Atropine is indicated for treatment of bradycardia associated with hypotension, second- and third-degree heart block, and slow idioventricular rhythms (Goldberg, 1974; Scheinman et al., 1975). Atropine is a useful drug for clinical states associated with excessive parasympathetic tone. Pediatric patients who experience cardiac arrest commonly have bradycardia or asystole as initial rhythms, making atropine a first-line drug for such patients. During the perioperative period, laryngoscopy or manipulation of viscera may result in severe bradycardia or even asystole secondary to enhanced parasympathetic tone, particularly in infants. Bradycardia as a result of the oculocardiac reflex during ophthalmologic surgery can occur in a child of any age. Although the first line of treatment is cessation of

the precipitating stimuli, atropine has been shown to be helpful when given intravenously or intraglossally (Arnold et al., 2002)

Dosage

The pediatric dose for atropine is 0.02 mg/kg, with a minimal dose of 0.1 mg and a maximal total dose of 1 mg. The minimal dose is recommended because of the potential for paradoxical bradycardia caused by a primarily central stimulating effect on the medullary vagal nuclei with low doses (Kottmeier et al., 1968). Atropine may be given via many routes: IV, endotracheal, IO, intraglossal, intramuscular, or subcutaneous. However, the intramuscular and subcutaneous routes may not have adequate perfusion and absorption during cardiac arrest or CPR. Onset of action occurs within 30 seconds, and peak effect occurs 1 to 2 minutes after an IV dose. The adult dose of atropine is 0.5 mg IV given every 5 minutes until a desired heart rate is obtained or to a maximal dose of 2 mg. Full vagal blockade occurs in adults who receive a dose of 2 mg. Dosages larger than recommended may be required in special circumstances, such as organophosphate poisoning or nerve gas exposure.

Adverse Effects

Atropine should not be used in patients in whom tachycardia is undesirable. After myocardial infarction or ischemia with persistent bradycardia, atropine should be administered in the lowest dose possible that increases heart rate. Tachycardia, which increases myocardial oxygen consumption and can lead to VF, can occur after large doses of atropine in patients with myocardial ischemia. Caution should also be used when administering atropine to patients with pulmonary or systemic outflow tract obstruction or idiopathic hypertrophic subaortic stenosis, because tachycardia can decrease ventricular filling and lower cardiac output (Table 38-10). Electrical pacing may be a safer means of maintaining a desired heart rate in these patients.

Adenosine

Adenosine is a purine nucleoside that is a first line treatment for supraventricular tachycardia (SVT) for children and adults. Adenosine acts by binding directly to adenosine receptors in the myocardium and peripheral vasculature. Receptor binding initiates intracellular signaling via G proteins and results in prolonged AV-node refractory period and slowed conduction. This action of adenosine breaks the reentrant circuit responsible for most SVT (Crosson et al., 1994).

Indications

Treatment of narrow complex QRS tachyarrhythmia (fewer than 0.08 seconds) with adenosine results in conversion to sinus rhythm in 72% to 77% of patients with few side effects (Till et al., 1989; Losek et al., 1999). Adenosine can be used diagnostically to differentiate between VT and SVT, because the temporary AV block allows observation of isolated atrial node electric activity. The half-life is less than 10 seconds because of rapid uptake by red blood cells and endothelial cells and metabolism by adenosine deaminase on the red-cell surface. Adenosine is completely cleared from the plasma in less than 30 seconds, giving it rapid onset and short duration of action (Losek et al., 1999).

TABLE 38-10. First Line Antiarrhythmic Administration During CPR

Atropine	
Indications	Symptomatic bradycardia with AV node block Vagal bradycardia during intubation attempts After epinephrine for bradycardia with poor perfusion
Dosage	0.02 mg/kg IV or intraosseous after ensuring oxygenation (2.5 times dose if given ETT) Repeat every 3-5 min at the same dose Maximum single dose 0.5 mg in a child and 1.0 mg in an adolescent Maximum total dose 1.0 mg in a child and 2.0 mg in an adolescent
Adenosine	
Indications	First line after vagal maneuvers fail for supraventricular tachycardia
Dosage	First dose, 0.1 mg/kg rapid IV bolus; second dose, increase to 0.2 mg/kg rapid IV bolus (maximum single dose: 12 mg) Note: must be followed with 0.5-1 mL/kg normal saline flush over 1-2 seconds to have effect.
Amiodarone	
Indication	Supra-ventricular and ventricular tachyarrhythmias
Dosage	5 mg/kg IV over 30 minutes (push if pulseless).

Data from American Heart Association.

CPR, Cardiopulmonary resuscitation; AV, atrioventricular; ETT, endotracheal tube; IV, intravenous.

Dosage

A rapid bolus of 100 mcg/kg (to a maximum of 6 mg) is given. If SVT resumes or no electrical response is seen, another higher bolus of 200 mcg/kg (to a maximum of 12 mg) is given and may be repeated if no response is seen or there is a limited duration of effect. The technique of administration of adenosine is critical for success of therapy. Each dose should be followed by rapid injection of 10 mL of saline flush to allow the drug to reach the heart before plasma clearance. This can be achieved with a two-stopcock technique connecting both the adenosine and flush to the patient in series. Central administration is preferable when available. Effectiveness is improved when adenosine is given by central venous access. When administering adenosine, the ECG may be helpful in determining the source of the arrhythmia.

Adverse Effects

Reported complications are rare and include hypotension, bradycardia, and brief AV block. Less likely complications are bronchospasm, facial flushing, headache, dyspnea, chest pain, nausea, lightheadedness, complete AV block, and ventricular standstill. If complications do occur they are often short in duration secondary to the short duration of action of adenosine. Dosages may need to be increased for patients receiving methylxanthines (i.e., theophylline), because these agents are adenosine antagonists (Table 38-10).

Amiodarone

Amiodarone hydrochloride is a diiodinated benzofuran derivative containing a diethylated tertiary amine chain. It is strongly lipophilic and has extensive tissue distribution. The drug is metabolized by the liver with mainly bile elimination; there is little renal elimination. Amiodarone has a long elimination half-life that ranges from 20 to 47 days (Chow, 1996). Amiodarone has pharmacologic effects of all four antiarrhythmic classes (Singh et al., 1989). It blocks potassium channels, blocks inward sodium current, is a noncompetitive β -blocker, and has calcium-channel blocking properties. Interestingly, its major electrophysiologic effect is dependent on the route (and duration) of administration (Bauman, 1997). With long-term oral treatment, amiodarone's predominant activity is to increase the duration of the action potential in most cardiac tissue, a class III effect. When used intravenously, amiodarone increases AV node refractoriness and intranodal conduction interval time, a class II antiadrenergic effect, or a calcium-channel blocker effect (Nattel, 1993). Additionally, amiodarone causes both coronary and systemic vasodilation (Coté et al., 1979). It does have phosphodiesterase inhibition and is a selective inhibitor of thyroid hormone metabolism (Singh et al., 1989; Harris et al., 1993).

Indications

Amiodarone has been studied as both a prophylactic long-term medication for patients with high arrhythmogenic potential caused by organic heart disease and for use in acute life-threatening arrhythmias. Amiodarone has been shown to be most effective for VT or VF when compared with lidocaine and bretylium in over 15 adult studies (Bauman et al., 1987; Helmy et al., 1988; Roberts et al., 1994; Podrid, 1995; Chow, 1996). When IV amiodarone was compared with placebo in a randomized trial (ARREST trial), there was significant improvement in the number of patients surviving to the emergency department after OHCA (Gonzalez et al., 1998). Amiodarone was shown to improve survival to admission when given to adults with OHCA and shock-resistant VF (Kudenchuk et al., 1999). A study comparing the efficacy of lidocaine to amiodarone for shock-resistant VF in OHCA demonstrated a 15% vs. 27% survival of adult patients to admission (Dorian et al., 2002). These adult studies support the superior performance of amiodarone for ventricular arrhythmias.

Amiodarone has been studied in children with generally favorable outcome. Perry et al. (1993) showed arrhythmia resolution in six of 10 children (mean age of 6.8 years) who had not responded to multiple other antiarrhythmic drugs. Figa et al. (1994) studied 30 infants and children with life-threatening arrhythmias, including SVT and VT and showed amiodarone eliminated arrhythmias in 71% of patients; an additional 23% experienced a significant improvement in clinical status and rhythm. Burri et al. (2003) treated 23 infants with hemodynamically unstable tachycardias with amiodarone; dosages ranged from 5 to 26 mcg/kg per minute (mean dosage of 15 mcg/kg per minute). He found only one infant to be unresponsive and adverse effects in four infants. A review of amiodarone use entered in the NRCPR database from 2000 to 2005 revealed that approximately 20% of children with VF while hospitalized and pulseless VT received amiodarone (October et al., 2008). The 2005 AHA guidelines recommend

amiodarone for treatment of VF or VT without a pulse. It may also be considered in the treatment of stable SVT and VT.

Dosage

There are limited data of amiodarone pharmacokinetics in children. IV administration for active arrhythmias is common practice, and it is often followed by a continuous infusion or transition to oral medication if ongoing treatment is indicated. An initial IV dose of 5 mg/kg may be followed by additional doses or a continuous infusion of 5 mcg/kg per minute. Increases in the infusion can occur up to maximum of 10 mcg/kg per minute or 20 mg/kg per 24 hours (Perry et al., 1996). Caution should be taken in the rate of administration of amiodarone, because cardiovascular collapse can occur with rapid administration, particularly in the patient with arrhythmias who may already have hemodynamic instability. For patients in a state of cardiac arrest, amiodarone is administered via bolus. For patients not in a state of cardiac arrest, administration should be over 30 to 60 minutes to avoid further hemodynamic instability. Pretreatment with calcium may help prevent hypotension during administration, especially if the patient is hypocalcemic.

Adverse Effects

All of the adverse effects of amiodarone appear to be less common at lower dosages (Singh, 1996). Cardiovascular effects appear to be the most common and include hypotension caused by acute vasodilation and negative inotropic effects. Bradyarrhythmias, congestive heart failure, cardiac arrest, and VT have all been reported. Proarrhythmias, although possible, are seen less often than with other class III antiarrhythmics. The incidence is thought to be approximately 2%. Torsades de pointes occurs in one third of these cases (Perry et al., 1993). The most common noncardiovascular toxicities are pulmonary complications. Interstitial pneumonitis is the most common, usually associated with long-term oral treatment. A hypersensitivity pneumonitis can occur early in the course of treatment. Symptoms include cough, low-grade fever, dyspnea, weight loss, respiratory associated chest pain, and bilateral interstitial infiltrates. These symptoms are usually reversible on cessation of the drug (Jessurun et al., 1998). Hepatotoxicity can occur and is more common with oral use. Thyroid dysfunction may occur in as many as 10% of patients, resulting in either hypothyroidism or hyperthyroidism. Optic neuritis or neuropathy resulting in decreased acuity or blurred vision can progress to permanent blindness. Neurologic symptoms include ataxia, tremor, peripheral neuropathy, malaise or fatigue, sleep disturbance, dizziness, and headache. Dermatologic reactions include allergic rash, photosensitivity, and blue-gray skin discoloration (Hilleman et al., 1998) (Table 38-10).

Lidocaine

Lidocaine, a class IB antiarrhythmic, depresses the fast inward sodium channel, which results in an increased refractory period and shortening of the total action potential. The drug is metabolized primarily in the liver by the microsomal enzyme system (Collingsworth et al., 1974). Up to 10% of lidocaine is excreted unchanged in the urine. The amount excreted unchanged increases in acidic urine. There is no biliary excretion or intestinal absorption in humans.

During CPR, lidocaine clearance is decreased because of inherent decrease in cardiac output and low hepatic blood flow. During conventional CPR in dogs who had a blood pressure of 20% of control values, an IV lidocaine bolus of 2 mg/kg resulted in elevated blood and tissue concentrations. Lidocaine distribution, which is usually complete in 20 minutes, was still not complete after 1 hour. Lidocaine clearance and distribution may also be altered as a result of changes in protein binding and metabolism during CPR (Chow et al., 1983). In humans, high peak blood and tissue concentrations of lidocaine occur during CPR, with a delay in time to peak concentration. Comparison of peripheral, central, and IO routes of administration of lidocaine during open-chest CPR in dogs showed no difference in time to peak serum concentration (Chow et al., 1981).

Electrophysiology

Lidocaine causes a decrease in automaticity and in spontaneous phase 4 depolarization of pacemaker tissue. The drug increases VF threshold, whereas it has essentially no effect on ventricular diastolic threshold for depolarization. It decreases action potential duration of Purkinje fibers and ventricular muscle and increases the effective refractory period of these fibers. Lidocaine does not affect conduction time through the AV node or intraventricular conduction time. By decreasing automaticity, lidocaine prevents or terminates ventricular arrhythmias caused by accelerated ectopic foci. Lidocaine abolishes reentrant ventricular arrhythmias by decreasing action potential duration and conduction time of Purkinje fibers, thus reducing the nonuniformity of activity. The effect on ischemic tissues in which lidocaine delivery may be limited is unknown (Collingsworth et al., 1974).

Hemodynamic Effects

In animal models, rapid IV delivery of lidocaine causes a decrease in stroke work, blood pressure, systemic vascular resistance, left ventricular contractility, and a slight increase in heart rate (Austen and Moran, 1965; Constantino et al., 1967). In healthy adults, the drug does not appear to cause any change in heart rate or blood pressure, but patients with cardiac disease have a slight decrease in ventricular function (Jewitt et al., 1968; Schumacher et al., 1969). In most patients, even in those who have sustained a recent myocardial infarction, a 1- to 2-mg/kg bolus of lidocaine does not alter cardiac output, heart rate, or blood pressure (Jewitt et al., 1968). Excessive doses of lidocaine given by rapid infusion may decrease cardiac function in patients with cardiac disease, especially in those suffering an acute myocardial infarction. Therefore, slow IV administration, no faster than 50 to 100 mg/min in adults, is recommended (Collingsworth et al., 1974).

Antiarrhythmic Effects

Lidocaine is effective in terminating ventricular premature beats and VT in humans during the perioperative period of general or cardiac surgery, after an acute myocardial infarction, and in patients with digitalis intoxication. Lidocaine is also effective in preventing and treating ventricular arrhythmias during cardiac catheterization. The drug is a secondary line of therapy for VF, especially when VF or tachycardia recurs. Lidocaine is not effective in the treatment of atrial or AV junctional arrhythmias.

Dosage

To achieve and maintain therapeutic levels of lidocaine, a bolus dose should be given at the initiation of a constant infusion. In patients with normal cardiac and hepatic function, an initial IV bolus of 1 mg/kg lidocaine is given, followed by a constant infusion at a rate of 20 to 50 mcg/kg per minute. If the arrhythmia recurs, a second bolus of the same dose can be given (Greenblatt et al., 1976). When a bolus administration is used without an infusion, the ventricular arrhythmias often return within 15 to 20 minutes because of its rapid clearance (Bartlett et al., 1984). If an infusion is begun without an initial bolus, approximately five half-lives are required to approach a plateau serum concentration (half-life of 108 minutes) (Collingsworth et al., 1974).

Patients with severe diminution of cardiac output should receive a bolus no greater than 0.75 mg/kg followed by an infusion at a rate of 10 to 20 mcg/kg per minute. In patients with hepatic disease, dosages should be decreased to 50% of normal. Patients with chronic renal disease who are receiving treatment through hemodialysis have normal lidocaine pharmacokinetics.

Drug interactions with lidocaine are common. Phenobarbital increases lidocaine metabolism, requiring increased doses. Isoniazid and chloramphenicol decrease lidocaine metabolism, so a decreased dosage should be used. Any drug that decreases cardiac output increases the serum concentration of lidocaine, and drugs that increase cardiac output and hepatic blood flow cause the serum concentration to be lower than predicted.

Adverse Effects

Lidocaine toxicity with a serum concentration of greater than 7 to 8 mcg/mL occurs most commonly in patients with severe hepatic disease or severe congestive heart failure. Decreased cardiac output results in decreased hepatic blood flow, which leads to decreased lidocaine clearance.

The toxic effects of lidocaine generally involve the central nervous system and include seizures, psychosis, drowsiness, paresthesias, disorientation, muscle twitching, agitation, and respiratory arrest. Treatment for seizures and psychosis includes benzodiazepines or barbiturates. True allergic reactions to lidocaine are rare. Cardiovascular side effects (discussed previously) are usually observed in patients whose myocardial function is already decreased. Conversion of second-degree to complete heart block has been described (Lichstein et al., 1973). Further slowing of sinus bradycardia has also been observed. These effects are uncommon and occur with large-dose administration. These potential side effects do not prohibit the use of lidocaine in these patients (Table 38-11).

Magnesium

Only two clinical scenarios are indications for emergent magnesium therapy in children: hypomagnesemia and polymorphic VT (torsades de pointes VT). Magnesium is an intracellular cation with less than 1% of the body's store available in the serum. The ionized fraction is physiologically active, much like calcium, and serves as a cofactor in enzymatic reactions. Low serum magnesium levels often develop in critically ill patients and patients who have had CPB surgery.

TABLE 38-11. Second-Line Antiarrhythmic Administration During CPR

Lidocaine	
Indications	Ventricular arrhythmias (not ventricular escape rhythm) Suppress ventricular ectopy Raise threshold for fibrillation
Dose	1 mg/kg intravenous or intraosseous bolus (2.5 times dose if ETT) 30-50 mcg/kg/min intravenous or intraosseous infusion Reduce infusion rate if low cardiac output or liver failure
Magnesium	
Indications	Torsades de pointes Hypomagnesemia
Dose	25-50 mg/kg intravenous or intraosseous (maximum: 2 g/dose)

Data from AHA: 2005 American Heart Association (AHA) guidelines for cardiopulmonary resuscitation (CPR) and emergency cardiovascular care (ECC) of pediatric and neonatal patients: pediatric advanced life support. American Heart Association, *Pediatrics* 117:e1005, 2006b.
CPR, Cardiopulmonary resuscitation, ETT, endotracheal tube.

Magnesium has been shown to be effective in children with torsade de pointes VT that is associated with acquired or congenital long QT interval (Tzivoni et al., 1988; Hoshino et al., 2006). Other situations such as myocardial ischemia, premature ventricular contractions, and atrial arrhythmias have been studied; however, the benefits of magnesium administration are controversial. Treatment with magnesium (whether by bolus or infusion) prevented falls in magnesium levels and resulted in a lower incidence of hemodynamically unstable arrhythmias than was found in a placebo group in children after surgery for congenital heart disease (Dorman et al., 2000; Dittrich et al., 2003). However, amiodarone may be more effective in dealing with these same postoperative arrhythmias, and other studies have not found an association between hypomagnesemia and postoperative arrhythmias (Hoffman et al., 2002; Batra et al., 2006a). The exact mechanism of magnesium on the conduction pathways of the heart is not known. Studies have demonstrated antagonism of calcium channels. Such antagonism of calcium has been shown to block the rise of intracellular calcium during periods of hypoxia.

Dosage

Treatment with magnesium sulfate is 25 to 50 mg/kg per dose (with a maximum of 2 g/dose) given intravenously over 20 to 30 minutes in nonurgent situations; it may be bolused if a patient has polymorphic VT. Serum levels should be monitored, with some controversy regarding the utility of monitoring ionized levels. Of note, 1 g of magnesium sulfate is equivalent to 4 mmol, 8 mEq, or 98 mg of elemental magnesium. Magnesium sulfate can be administered by the IV, IO, and oral routes.

Adverse Effects

A rapid rate of administration can cause a fall in systemic vascular resistance by as much as 30%. This hypotension can be treated

by either slowing or stopping the dose. Apnea and weakness are possible complications but are not routinely seen until toxic levels that have reached more than 4 mmol/L. Potentiation of neuromuscular blockade and neuromuscular weakness has been reported at lower serum levels (Table 38-11).

Other Drugs

Sodium Bicarbonate

Sodium bicarbonate causes an acid-base reaction in which bicarbonate combines with hydrogen ion to form water and carbon dioxide, resulting in an elevated blood pH:

Because sodium bicarbonate generates CO_2 , adequate alveolar ventilation must be present before its administration. As respiratory failure is the leading cause of cardiac arrest in children, caution should be taken before sodium bicarbonate administration in the face of preexisting respiratory acidosis. Sodium bicarbonate use during CPR is one of the most controversial issues in the literature related to cardiac arrest. This stems from lack of evidence of benefit during CPR in animals and humans, as well as the potential adverse effects associated with sodium bicarbonate administration.

Literature on sodium bicarbonate use in CPR dates back to the 1960s, but there are little data demonstrating a beneficial impact on human survival (Levy, 1998). In animal models of resuscitation from cardiac arrest, sodium bicarbonate has been associated with increased survival in few studies and with no difference in survival in many studies (Andersen et al., 1967; Redding and Pearson, 1968; Kirimli et al., 1969; Lathers et al., 1989; Bleske et al., 1992; Neumar et al., 1995; Vukmir et al., 1995). Administration of sodium bicarbonate to humans experiencing cardiopulmonary arrest has been associated with increased mortality in retrospective reviews and nonblinded prospective studies (Suljaga-Pechtel et al., 1984; Skovron et al., 1985; Deloos and Lewi, 1989).

Several studies in both humans and animals document deleterious effects on physiologic endpoints such as myocardial performance, arterial blood pressure, and partial pressure of venous CO_2 (Pco_2) after sodium bicarbonate administration during CPR (Wang and Katz, 1965; Bishop and Weisfeldt, 1976; Weil et al., 1985; Adroque et al., 1989; Kette et al., 1991; Eleff et al., 1995). This literature is difficult to interpret because of large variations in dosage, timing, blood sampling, and testing conditions. Animal data and a retrospective review of OHCA in adults indicate improved outcomes in cardiac arrest when sodium bicarbonate is administered early in cardiac arrest (Vukmir et al., 1995; Bar-Joseph et al., 1998; 2005; Leong et al., 2001). Dybvik et al. (1995) conducted the only randomized control trial of sodium bicarbonate administration in humans during CPR. Researchers found no survival benefit, but the study may have been underpowered because survival from OHCA is low and a large cohort would be required to detect a difference. Overall, there are insufficient data to assess the impact of sodium bicarbonate administration on survival during CPR.

Indications

The AHA's 2005 guidelines for CPR recommend that sodium bicarbonate be considered in cases of prolonged cardiac arrest only after effective ventilations and chest compressions are

established and after epinephrine administration. Sodium bicarbonate is used for correction of significant metabolic acidosis. Acidosis depresses myocardial function by decreasing spontaneous cardiac activity, electrical threshold for VF, myocardial inotropic state, and cardiac responsiveness to catecholamines, and by prolonging diastolic depolarization (Pannier and Leusen, 1968; Cingolani et al., 1970; Orłowski, 1980; Steinhart et al., 1983). Acidosis also decreases systemic vascular resistance and blunts the vasoconstrictive effects of catecholamines (Wood et al., 1963). In addition, pulmonary vascular resistance increases with acidosis in patients with a reactive pulmonary vasculature (Rudolph and Yuan, 1966). Therefore, correction of acidosis may be of help in resuscitating patients who have potential for right-to-left shunting.

Sodium bicarbonate is also indicated in hyperkalemic arrest, because the increase in pH drives potassium intracellularly, resulting in a lowered serum potassium concentration. Hypermagnesemia, tricyclic antidepressant overdose, and overdose from sodium-channel blocking medications including cocaine, β -blockers, and diphenhydramine are other indications for sodium bicarbonate (Kilecki et al., 1997; Donovan et al., 1999; Mullins et al., 1999; AHA, 2006b).

Dosage

When the partial pressure of arterial CO_2 (Paco_2) and pH are known, the dose of sodium bicarbonate needed to correct the pH to 7.40 can be calculated from the following formula:

$$(0.3 \times \text{Weight [kg]} \times \text{Base Deficit}) = \text{mEq Bicarbonate}$$

Because of the possible side effects of sodium bicarbonate and the large arterial-to-venous carbon dioxide gradient that develops during CPR, giving half the dose based on a volume of distribution of 0.6 is recommended. If blood gases are not available, an initial dose of 1 mEq/kg, followed by 0.5 mEq/kg every 10 minutes of ongoing arrest has been proposed (Martinez et al., 1979). Adequate alveolar ventilation is important to eliminate the CO_2 produced during bicarbonate administration (Table 38-12).

Adverse Effects

Multiple adverse effects occur with administration of sodium bicarbonate, including metabolic alkalosis, hypernatremia, hypercapnia, and hyperosmolarity; all are associated with an increased mortality rate (Mattar et al., 1974; Worthley, 1976). Metabolic alkalosis causes a leftward shift of the oxyhemoglobin dissociation curve that impairs release of oxygen from hemoglobin to tissues at a time of low cardiac output and low oxygen delivery (Bishop and Weisfeldt, 1976). Hypernatremia and hyperosmolarity may decrease organ perfusion by increasing interstitial edema in microvascular beds.

Various theoretic adverse effects are also created by administration of sodium bicarbonate. The marked hypercapnic acidosis in both systemic venous and coronary sinus blood that develops during cardiac arrest may be worsened by administration of sodium bicarbonate (Grundler et al., 1986; Weil et al., 1986). Hypercapnic acidosis in the coronary sinus may cause decreased myocardial contractility (Pannier and Leusen, 1968; Cingolani et al., 1970; Deshmukh et al., 1986). Falk et al. (1988) measured the mean venoarterial difference of Paco_2 as 23.8 ± 15.1 mm Hg in five patients during CPR. In one patient,

TABLE 38-12. Sodium Bicarbonate Administration During CPR

Indications	Hyperkalemia Preexisting metabolic acidosis Long CPR time without blood-gas availability Pulmonary hypertensive crisis
Dosage	1 mEq/kg intravenous or intraosseous empirically, or calculated from base deficit Ensure adequate ventilation when administering bicarbonate
Complications	Metabolic alkalosis Impairs O_2 delivery by shift of oxyhemoglobin dissociation Decreases cardiac contractility Increases possibility for fibrillation Decreases plasma K^+ and Ca^{2+} by intracellular shift Hypernatremia Hyperosmolarity Hypercapnia Paradoxical intracellular acidosis

CPR, Cardiopulmonary resuscitation; O_2 , oxygen; K^+ , potassium; Ca^{2+} , calcium.

the difference increased from 16 mm Hg to 69 mm Hg after administration of sodium bicarbonate.

An additional theoretic concern is intracellular acidosis from CO_2 diffusion across cell membranes despite increased serum pH with sodium bicarbonate administration. In the central nervous system, intracellular acidosis probably does not occur unless overcorrection of the pH occurs. After administration of two doses of bicarbonate of 5 mEq/kg to neonatal rabbits recovering from hypoxic acidosis, the arterial pH increased to 7.41 and the intracellular brain pH increased to prehypoxic levels (Sessler et al., 1987). A paradoxical intracellular acidosis did not develop. In a study in rats the intracellular brain adenosine triphosphate (ATP) concentration did not change during 70 minutes of extreme hypercarbia, despite a decrease in the intracellular brain pH to 6.5 (Cohen et al., 1990b). After hypercarbia, these animals could not be distinguished from normal controls, and their brains were not morphologically different from those of control animals. Eleff et al. (1995) used magnetic resonance spectroscopy to measure cerebral pH during cardiac arrest and CPR in a dog model where CPP was maintained and Pco_2 was normalized with controlled ventilation. In that model, cerebral pH paralleled blood pH; administration of sodium bicarbonate did not cause a paradoxical intracerebral acidosis and instead prevented cerebral acidosis that occurred in the control group.

Calcium

The calcium ion is essential in myocardial excitation-contraction coupling and myocardial contractility, and it enhances ventricular automaticity during asystole (Greenblatt et al., 1976). Ionized hypocalcemia leads to decreased ventricular performance, peripheral vasodilation, and blunting of the hemodynamic response to catecholamines (Bristow et al., 1977; Scheidegger et al., 1977; Drop and Scheidegger, 1980; Marquez et al., 1986; Urban et al., 1986).

Based on its role in myocardial function, calcium should be of benefit in cardiac arrest, particularly PEA and asystole. However, limited retrospective and prospective adult studies have failed to demonstrate a benefit of calcium in these conditions (Harrison and Amey, 1983; Stueven et al., 1983, 1985a, 1985b). As a result of this data and others like it, the AHA's 2000 guidelines limited recommendations for calcium administration to cardiac arrest associated with electrolyte abnormalities and toxic ingestions (Guidelines 2000 for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, 2000).

Calcium administration during CPR has been associated with poor survival and neurologic outcomes in pediatric patients. In a single center trial, de Mos et al. (2006) reviewed 91 cardiac arrests in critically ill children over 5.5 years. In a multivariate analysis, patients who received one or more calcium boluses during cardiac arrest were 5.4 times more likely to suffer hospital mortality. In a large review of pediatric IHCA in the NRCPR database, Srinivasan et al. (2008) found that calcium was used in 45% of CPR events, despite guidelines limiting calcium use in CPR. After controlling for confounding variables, calcium administration was independently associated with decreased survival to discharge and poor neurologic outcome. However, for children with electrolyte- or toxin-associated cardiac arrest, calcium administration was not associated with worse event-survival or survival to discharge.

Neonates have low intracellular calcium stores and are more dependent on serum calcium levels. Calcium administration to this population, particularly after cardiac surgery, theoretically seems indicated and has been postulated to be beneficial (Peddy et al., 2007). Srinivasan et al. (2008) analyzed calcium administration during cardiac arrest in infants after cardiac surgery as part of a large review of NRCPR (spanning 2000 to 2004); after adjusting for confounding variables, calcium administration was associated with worse event-survival but not reduced rates of survival to discharge or unfavorable neurologic outcome. However, adjusted odds ratios were low (0.4 to 0.6), and this was a subgroup analysis only.

Calcium's association with poor outcomes may be related to its role in cellular apoptosis. In the setting of ischemia-reperfusion injury, calcium administration may worsen postischemic hypoperfusion and hasten development of intracellular events that lead to cell death. Intracellular calcium overload occurs in many pathologic conditions, including ischemia, and may be a part of the common pathway of cell death (Katz and Reuter, 1979; White et al., 1983).

Indications

The few firm indications for calcium use during CPR include cardiac arrest secondary to total or ionized hypocalcemia, hyperkalemia, hypermagnesemia, or an overdose of a calcium channel blocker (AHA, 2006b). Hypocalcemia occurs with a number of conditions that predispose to low total-body calcium stores, including the long-term use of loop diuretics. Ionized hypocalcemia may coexist with a normal total plasma calcium concentration. This occurs in the presence of severe alkalosis, which may be seen in the operating room secondary to iatrogenic hyperventilation. Ionized hypocalcemia also follows massive or rapid transfusion of citrated blood products into patients during surgery. The degree of hypocalcemia caused by citrated products depends on the rate of administration, the total dose, and the hepatic and renal function of the patient.

Administration of 2 mL/kg per minute of citrated whole blood causes a significant but transient decrease in the ionized calcium in patients who have been anesthetized (Denlinger et al., 1976).

Intraoperative cardiac arrests are more likely to be caused by electrolyte abnormalities than pediatric cardiac arrests in other situations. Electrolyte imbalance, particularly hyperkalemia, caused 5% of pediatric perioperative cardiac arrests in the 2007 review of the POCA registry (Bhananker et al., 2007). Despite the limited recommendations for calcium during CPR, intraoperative cardiac arrest is more likely to have a cause for which calcium administration is beneficial.

Dosage

The dosage of calcium chloride solution is 20 mg/kg. Calcium gluconate is as effective as calcium chloride in raising ionized calcium concentration during CPR (Heining et al., 1984). However, calcium chloride is more effective than calcium gluconate in supporting blood pressure in the hypotensive child (Broner et al., 1990). Calcium gluconate can be given as a dose of 30 to 100 mg/kg, with a maximum dosage of 2 g in pediatric patients (Table 38-13). Equally rapid increases in ionized calcium levels seen in patients with anhepatic jaundice after administration of calcium chloride and gluconate suggest that hepatic function is not necessary for either drug to be effective (Martin et al., 1990a).

Adverse Effects

Calcium should be given slowly through a large-bore, free-flowing IV line, preferably a central venous catheter. Severe tissue necrosis can occur when calcium infiltrates into subcutaneous tissue. When administered too rapidly, calcium may cause severe bradycardia, heart block, or ventricular standstill.

Glucose

Glucose administration during and after CPR should be restricted to documented hypoglycemia because of the detrimental effects of hyperglycemia during brain ischemia. Myers (1979) first hypothesized that hyperglycemia worsens the neurologic outcome after cardiac arrest. Siemkowitz and Hansen (1978) confirmed this finding when they found that after 10 minutes of global brain ischemia, neurologic recovery of hyperglycemic rats was worse than in normoglycemic control animals. Hyperglycemia exaggerates ischemic neurologic injury by increasing lactic acid production in the brain by anaerobic metabolism. During ischemia under normoglycemic conditions, brain lactate concentration plateaus. However,

TABLE 38-13. Calcium Chloride Administration During CPR

Indications	Hyperkalemia
	Hypocalcemia

Dosage	20 mg/kg intravenously or intraosseously

CPR, Cardiopulmonary resuscitation.

when hyperglycemia is present, lactate concentration in the brain continues to rise for the duration of the ischemic period (Siesjo, 1984). The severity of intracellular acidosis during brain ischemia is directly proportional to the preischemic plasma glucose concentration.

Clinical studies have shown a direct correlation between the initial glucose concentration after cardiac arrest and a poor neurologic outcome (Pulsinelli et al., 1983; Longstreth and Inui, 1984; Woo et al., 1988; Ashwal et al., 1990). Longstreth et al. (1986) suggested that a higher plasma glucose concentration at admission may be an endogenous response to severe stress and not the cause of more severe brain injury. Losert et al. (2008) retrospectively examined blood glucose levels in adults 12 hours after ROSC and found that after controlling for confounding variables, normoglycemia and even mild hyperglycemia were associated with survival 6 months after arrest and good neurologic outcome. They concluded that glucose control goals after cardiac arrest need not be strict normoglycemia. Despite a lack of evidence in children, given the likelihood of additional ischemic events during the postresuscitation period, it seems warranted to maintain serum glucose in the normal range.

Voll and Auer (1988) showed that administration of insulin to hyperglycemic rats after global brain ischemia improved the neurologic outcome. Similarly, Katz et al. (1998) found that insulin and glucose administration after asphyxial cardiac arrest in rats improved neurologic outcome and histologic findings; the combination of insulin and glucose had superior outcomes as compared with either drug individually or saline placebo. The effect of insulin may be independent of its glucose-lowering properties, because an additional study by Voll and Auer (1991) found that normoglycemic-treated rats had a better outcome than placebo-treated controls. Infants, patients with hepatic disease, and debilitated patients with low endogenous glycogen stores are prone to hypoglycemia when energy requirements rise. In these patients, bedside monitoring of serum glucose level is critical during the perioperative period and cardiac arrest episodes.

Dosage

To treat hypoglycemia, an IV dose of 1 mL/kg of 50% dextrose for adults, 2 mL/kg of 25% dextrose in children, or 3 to 5 mL/kg of 10% dextrose for infants can be administered.

ELECTRICAL INTERVENTIONS IN CARDIOPULMONARY RESUSCITATION

Defibrillation

Defibrillation is the delivery of an untimed electrical shock for pulseless VT or VF. It is a life-saving intervention for children and adults, and AHA guidelines for 2005 place emphasis on the skill and timeliness of defibrillation (AHA, 2006b). This skill is particularly important to the anesthesiologist. As team leader of perioperative arrest, the anesthesiologist is expected to have a mastery of skills associated with resuscitation, including defibrillation.

VF is not an uncommon rhythm during cardiac arrest; it occurs in 27% of pediatric cardiac arrests at some point during resuscitation (Nadkarni et al., 2006). Intraoperative cardiac arrests seem more likely to have arrhythmias as part of the

presentation, because arrest causes are most commonly caused by cardiovascular problems, such as hypovolemia, blood loss, and electrolyte disorders (Bhananker et al., 2007). Timeliness of defibrillation is crucial, because likelihood of successful defibrillation from ventricular defibrillation degrades by 5% to 10% with each minute of delay, and a graded association is seen between increasing time to defibrillation and lower survival to discharge for each minute of delay during in-hospital ventricular arrhythmias (Larsen et al., 1993; Chan et al., 2008). In adult studies, survival rates higher than 50% can be achieved if VF is defibrillated in fewer than 3 minutes (Valenzuela et al., 2000). Despite these facts, in a survey of anesthesiologists' knowledge of CPR guidelines, only 49% of anesthesiologists who care for children routinely knew the correct sequence of defibrillation for VT (Heitmiller et al., 2008). Similarly, only 51% of senior pediatric residents were able to provide a successful defibrillation on the first attempt in a simulation model of pulseless VT (Hunt et al., 2009). The only variable independently associated with time to defibrillation in Hunt's study was previous experience discharging a defibrillator, highlighting the importance of hands-on training and simulation in learning and practicing psychomotor skills such as defibrillation.

Monophasic vs. Biphasic Current

Monophasic waveforms deliver current of one polarity (direction), whereas biphasic waveforms deliver current in two directions (Fig. 38-3). Neither monophasic nor biphasic waveforms have been associated with higher ROSC or survival to discharge; however, the biphasic waveform variant appears to be more effective at producing defibrillation and cardio version at lower dosages, as well as potentially less tissue damage (White et al., 1999; Clark et al., 2001; Tang et al., 2002). The advantages of lower dose and potentially less risk of injury have made biphasic defibrillators appealing. Monophasic waveform defibrillators are no longer manufactured, although many are in use.

Energy Dosage

The optimum dosage of electrical energy to defibrillate the heart of an infant or child is not conclusively established for either monophasic or biphasic current. The recommended dose of 2 to 4 J/kg for external defibrillation was derived from an animal model and a retrospective review of 57 children with in-hospital VF using monophasic current (Geddes et al., 1974; Gutgesell et al., 1976). In a swine model of pediatric fibrillation, biphasic current was superior to monophasic current at terminating VF at lower dosages; the biphasic dosage

■ **FIGURE 38-3.** Monophasic and biphasic defibrillator waveforms. (From Philips Healthcare, Andover, Mass.)

that was required for 50% defibrillation success with first shock was 3 J/kg (Clark et al., 2001). Other data in both swine and children suggest that 2 J/kg is often ineffective at terminating fibrillation, particularly if the fibrillation is of longer duration (Berg et al., 2005a, 2005b). In a review of pediatric OHCA that received shocks for VF, a wide dosage range was documented, and 75% of children received more than the recommended dose; 45% of children received more than 6 J/kg energy doses (Rossano et al., 2006). The AHA guidelines for defibrillation dose in children are 2 J/kg initial dose and 4 J/kg subsequent doses with monophasic or biphasic current, but there is a lack of evidence to support that dosing regimen, and there is some evidence that required doses may be higher than what is recommended (AHA, 2006b). The biphasic dosage recommendations for adults are 150 to 200 J for the initial dose and equal or higher energy levels for subsequent doses (AHA, 2006b).

Paddle or Pad Type and Position

Correct paddle or self-adhesive pad size and position are important to the success of defibrillation. Two paddle sizes are available for external defibrillation: 8 to 13 cm in diameter for adults and children who weigh more than 10 kg, and 4.5 cm for infants and children who weigh less than 10 kg. Self-adhesive pads come in adult and pediatric sizes and are preferred to paddle defibrillation, because they have the correct gel interface prepackaged and are “hands-free,” allowing for rapid return to chest compressions after defibrillation (Estes, 2005). The largest paddle or pad size that can be used without causing the paddles to touch should be used; large surface area reduces the density of current flow, TTI, and myocardial damage (Atkins and Kerber, 1994). Care should be taken that the entire paddle rests firmly on the chest wall; otherwise, a high-density current will be delivered to a small contact point on the skin. The paddles should be positioned on the chest wall with most of the myocardium included between them. If two paddles cannot be placed on the anterior chest, an alternate approach is to place one paddle anteriorly over the left precordium and the other paddle posteriorly between the scapulae; this technique works well in small infants (Garcia et al., 1998).

When providing defibrillation to patients with permanent pacemakers or automatic internal cardiac defibrillators (AICDs), care should be taken not to position paddles or pads over the device generators. The defibrillator current may cause device malfunction, and the device may block some current from reaching the myocardium. Pacemakers and AICDs should be checked for proper function after defibrillation.

The interface between the paddle and chest wall can be gel pads, electrode cream, paste, soap, or self-adhesive, monitoring defibrillation pads. The cream produces lower impedance than paste. Care should be taken not to allow the substance from one paddle to touch that from the other paddle, because electrical current follows the path of least resistance. This is especially important in infants, in whom the distance between electrodes is short.

Defibrillation Sequence and Technique

When the onset of VF or pulseless VT is observed, defibrillation should be attempted as soon as possible. AHA guidelines have changed to reflect the emphasis on reducing the time

spent with the patient in a no-flow state; algorithms for ventricular arrhythmias no longer call for three rapidly administered shocks and multiple rhythm and pulse checks. Instead, with the onset of ventricular arrhythmia, CPR should be administered immediately while preparing for defibrillation. As soon as possible, defibrillation at 2 J/kg should be attempted with immediate return to CPR without a pulse or rhythm check. Epinephrine is administered during CPR, and a rhythm check can be performed after 2 minutes of CPR. If ventricular arrhythmia persists, additional defibrillation with 4 J/kg energy and return to CPR should be performed. Additional shocks at 4 J/kg are interspersed between CPR and antiarrhythmic medications (Fig. 38-4). The resuscitation should be seen as a continuous period of CPR with as brief as possible interruptions for defibrillation and rhythm checks (Fig. 38-5).

Although no studies compare the previously recommended three stacked shocks to the one-shock protocol, it has theoretic basis in multiple studies. Biphasic defibrillation has an initial-shock success rate of 90% in adults, and further shocks may not provide added benefit (Martens et al., 2001). Increased interruption of CPR for rhythm checks and defibrillation attempts (increasing no-flow time) is associated with lower coronary perfusion pressures and lower defibrillation success (Berg et al., 2001; Edelson et al., 2006).

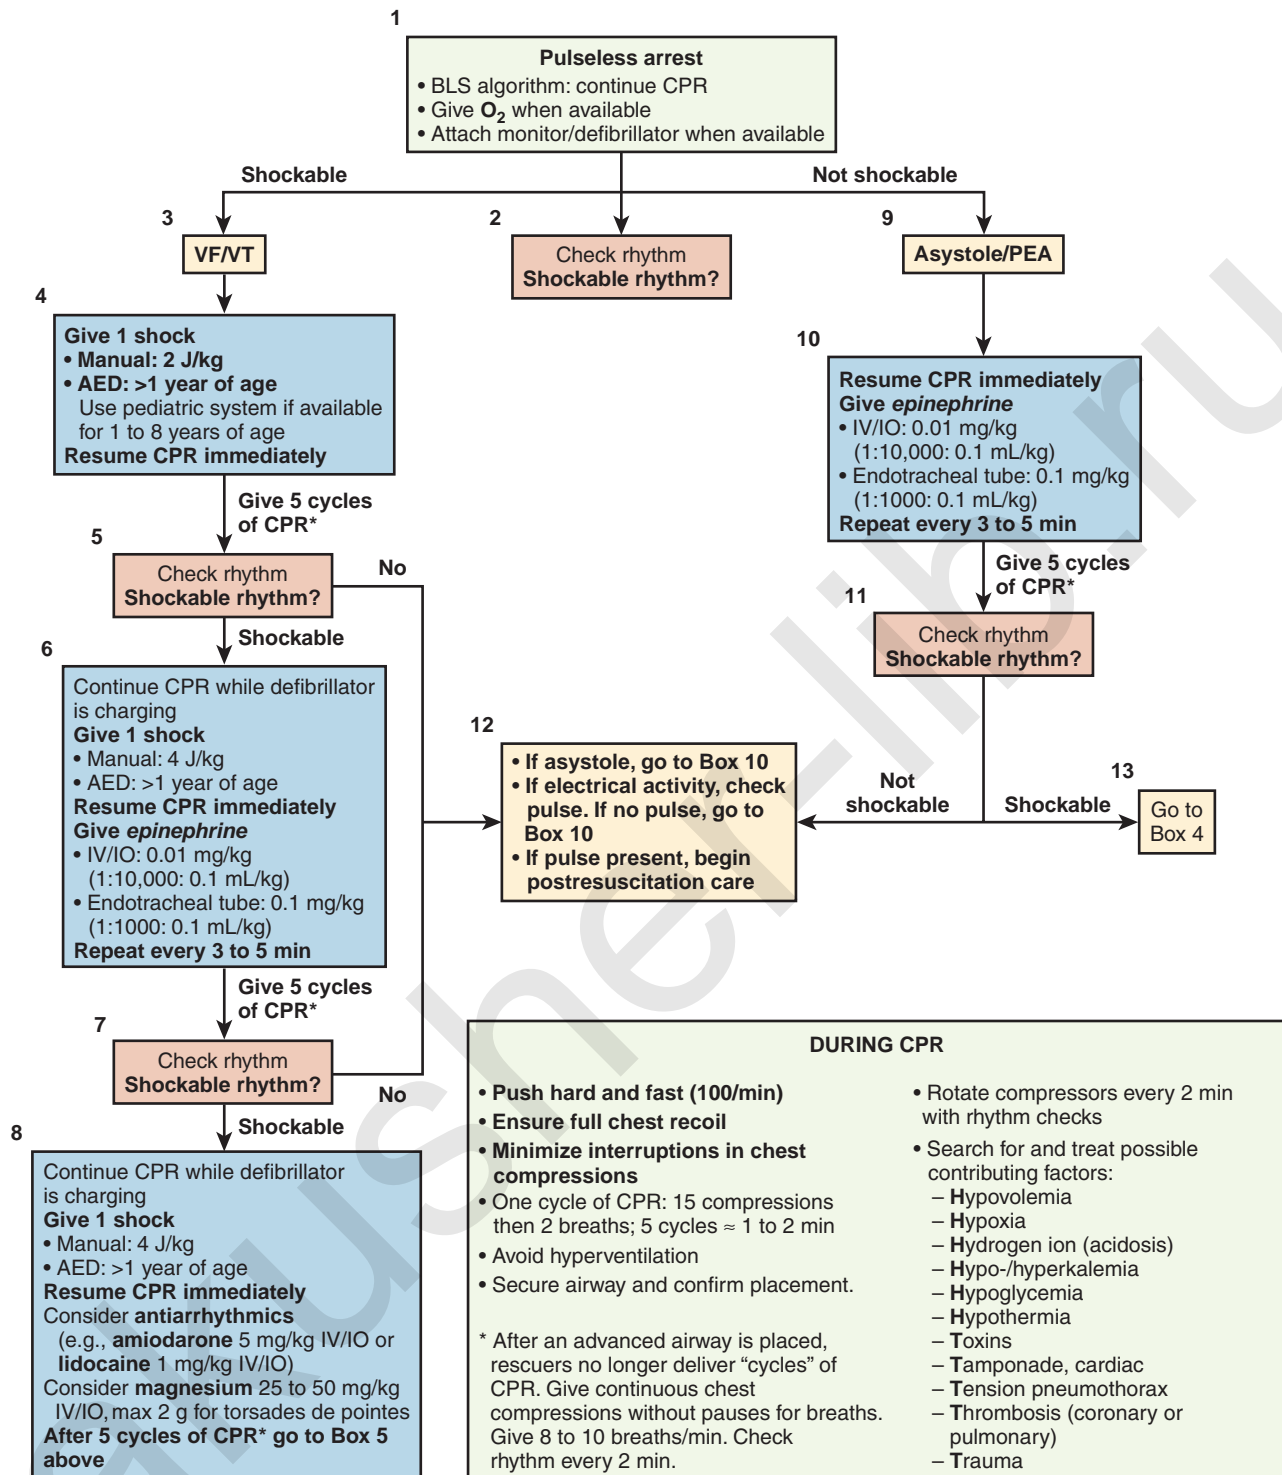

Open-chest or internal defibrillation should be performed when the sternum is already open during surgery or is reopened after surgery. Paddles made specifically for this purpose are applied directly to the heart. Internal paddles have diameters of 6 cm for adults, 4 cm for children, and 2 cm for infants. The handles should be insulated. One electrode is placed behind the left ventricle, and the other is positioned over the right ventricle on the anterior surface of the heart, with saline soaked pads as conducting material. A dose 1 J/kg to a maximum of 10 J of delivered energy should be used, beginning with the lowest energy level available on the defibrillator.

Risk of Defibrillation

Skin erythema or first-degree burns have been documented after defibrillation; use of biphasic waveforms may decrease this complication (Ambler and Deakin, 2006). Reports exist of fire associated with defibrillation, particularly in an oxygen-rich environment (Miller, 1972; Theodorou et al., 2003). Care should be taken to remove disconnected oxygen tubing from the patient's immediate area during defibrillation. A review of the literature found no reports of life-threatening injury or long-term disability to rescuers and caregivers who were inadvertently shocked with a defibrillator, but defibrillation to the chest wall of a healthy individual can be life-threatening (Hoke et al., 2009).

Automated External Defibrillation

AEDs are preprogrammed defibrillators that analyze the ECG signal to distinguish shockable and nonshockable rhythms and direct providers to deliver shock when indicated. The devices are common in public settings where large numbers of people congregate and have been shown to increase the rate of survival from sudden cardiac arrest (MacDonald et al., 2002; Hallstrom et al., 2004). In a large, prospective randomized trial in public settings, lay-rescuer CPR combined with AED programs doubled survival

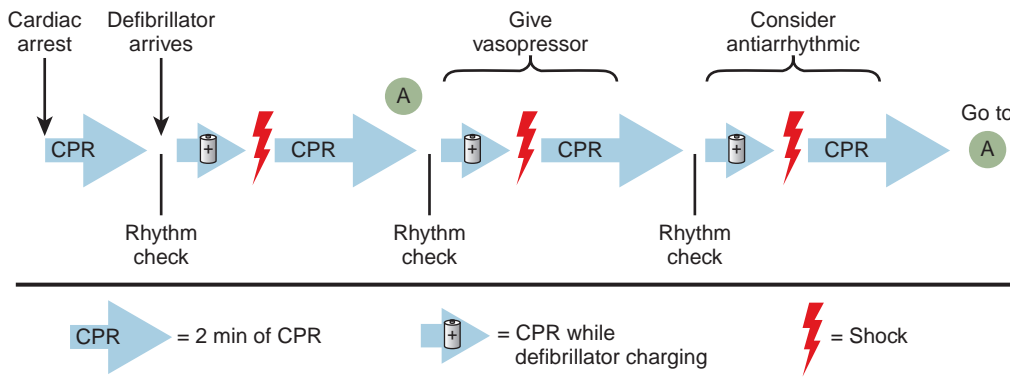

■ **FIGURE 38-4.** PALS pulseless arrest algorithm, 2005. (From Ralston M et al., editors: Pediatric advanced life support provider manual, Dallas, 2006, American Heart Association, p 168.)

from out-of-hospital VF when compared with programs that provided early emergency medical services and CPR (Hallstrom et al., 2004).

Recommendations support the use of AEDs for early rhythm identification in children as young as 1 year of age. The algorithms are highly sensitive and specific for pediatric rhythms (Atkinson et al., 2003; Atkins et al., 2008). The energy dosage for AED use in adults is standardly set at 150 to 360 J and

often can be attenuated with a pediatric cable and pads for children younger than 8 years old (Berg, 2004). Attenuated pediatric energy doses range from 35 to 50 J for the initial dose and 80 to 90 J for subsequent doses. No adjustments are made for patient size or weight. Recommendations are to use pediatric attenuation cables and pads if they are available; if not, a standard AED should be used. AHA guidelines do not recommend for or against use of AED in infants younger than 1 year

■ **FIGURE 38-5.** Continuum of CPR, 2005. (From Ralston M et al, editors: Pediatric advanced life support provider manual, Dallas, 2006, American Heart Association, p 175.)

of age, although termination of VF has been reported in infants with attenuated pediatric pads (Atkins and Jørgenson, 2005). A drawback of AED use in the operating room is that the time for rhythm recognition and delivery of shock needed by the AED may delay resuming chest compressions. This delay may be less with manual defibrillation by a trained provider.

Synchronized Cardioversion

Synchronized cardioversion involves timing the delivery of a shock with the cardiac cycle to treat organized arrhythmias such as atrial fibrillation and flutter or SVT. Delivery of low-dose, unsynchronized shocks in these rhythms may result in VF. Synchronized cardioversion is indicated for patients who have tachyarrhythmias but are hemodynamically stable; patients who are unstable should be defibrillated as described above.

The defibrillator or cardioversion device should be set in the synchronous mode (“sensing” on) to permit coordination of the countershock with electrical activity of the heart. Once a patient is adequately sedated (if necessary), paddles are positioned for optimal contact as described for defibrillation. The monitor should indicate adequate sensing and charge set to deliver 0.5 to 1 J/kg. Repeated dosing with up to 2 J/kg is sometimes required with the same technique. These energy dosages were developed for monophasic waveform defibrillators. Lower energies may be used with biphasic defibrillators (Batra et al., 2006b; Liberman et al., 2006).

After successful cardioversion, a follow-up ECG should be obtained and the rhythm strip should be reviewed to identify the resulting rhythm. Other antiarrhythmic therapy can be initiated if the rhythm is only transiently responsive to the cardioversion. For resistant tachycardias, hypoxemia, acidosis, hypoglycemia and electrolyte abnormalities should be sought and corrected, because they can interfere with success of cardioversion.

Transcutaneous Pacing

Most modern defibrillator and cardioversion units have capability for cardiac pacing. For transcutaneous pacing, external pacing electrodes should be positioned anteriorly on the left-sternal border and posteriorly between the scapulae. For most resuscitative efforts, asynchronous pacing should be selected. Initial settings should be set at the desired age-appropriate rate, and the output should be set at zero. Output should then be increased rapidly until capture and pacing occurs. Note that required output is

usually relative and not in a defined milliamperage (mA), as with epicardial or transvenous pacer units. Once electrical capture is seen on the monitor, mechanical association should be assessed by palpation of a pulse (Beland et al., 1988).

Transvenous Pacing

When transcutaneous pacing fails to provide results, transvenous pacing may be attempted. Experience with transvenous-pacing techniques in children has primarily occurred in the catheterization lab. Limited data are available using this technique in children during CPR. One study retrospectively reviewed experience with five children who had various causes for cardiac arrest. Four of the patients had restoration of cardiac output and stability for 10 to 60 minutes with subsequent cardiac arrest and death (Greissman et al., 1995). The pacing wire can be placed via a vascular introducer into the right atrium or right ventricle. The technique for setting output and sensitivity are the same as for epicardial pacing leads.

Epicardial Pacing

Many infants and children undergoing cardiac surgery have atrial and ventricular epicardial pacing wires placed during the procedure for postoperative management. During resuscitation, if both atrial and ventricular leads are available, ventricular leads should be used to maintain cardiac output. Note that most pacemaker generators can sense as well as pace, depending on the mode. It may be necessary to adjust the sensitivity and output to produce ventricular depolarization with every paced beat. Pacing in an asynchronous, ventricular, fixed-rate, or ventricular-inhibited pacing mode assures the most consistent cardiac output. Electrical activity should be monitored for electrical association, and pulses or arterial waveform should be monitored to evaluate mechanical capture and cardiac output.

ARRHYTHMIAS IN CARDIOPULMONARY RESUSCITATION

Bradycardia

Bradycardias are common complications in children during the perioperative period. Bradycardia is the rhythm seen most often before cardiac arrest in pediatric patients. Most

bradycardic events are precipitated by hypoxemia, vagal stimuli, or side effects of medication. A sufficiently slow heart rate in an infant or child that results in hemodynamic instability should prompt CPR, diagnosis, and treatment. If resolution does not occur with ventilation, oxygenation, atropine, epinephrine, and chest compressions, then electrical pacing is indicated. The probability of successfully pacing after cardiac arrest decreases with increasing duration of CPR (Quan et al., 1992; Beland et al., 1988). If a bradyarrhythmia persists despite resuscitative and electrical support, other forms of cardiovascular support should be sought (e.g., extracorporeal membrane oxygenation). This therapy, although not curative, can provide time needed for diagnosis, treatment, and recovery.

Sinus Bradycardia

Great variability exists in infant and pediatric heart rates (Table 38-3). Lower limits of heart rates serve as guidelines but may not be indicative of pathology. Sinus bradycardia results from slowed or suppressed sinoatrial node depolarization. However, other pathologic causes can occur and should be considered in the settings of trauma, cardiac surgery, and structural heart disease. Diagnosis of sinus bradycardia implies that a normal P wave is visible on evaluation of a 12-lead ECG. Hemodynamic instability may or may not be present and is not essential for the diagnosis. Underlying causes, such as increased vagal tone, elevated ICP, hypoxia, metabolic abnormalities (hypokalemia or hypercalcemia), hypothermia, and drug effects, should be sought.

Sinus and Atrioventricular Block

Sinus block or sinus node arrest is characterized by absence of P waves from the ECG and is usually related to toxic ingestion or underlying cardiac disease. This can also present as asystole. In the absence of sinus node activity, the heart generates “escape” beats that originate from the atria, AV node, or ventricle. Atrial escape beats are characterized by P waves of varying morphology and timing associated with narrow QRS complexes. Junctional escape beats originate from the AV node and are narrow and complex; P waves from retrograde conduction may or may not be present. Ventricular escape rhythm is a wide, complex slow rate of approximately 30 to 40 beats per minute. Recognition and prompt initiation of transcutaneous pacing is crucial and can be lifesaving (Beland et al., 1988).

Varying degrees of heart block appear as a bradyarrhythmia (Fig. 38-6, A). Often a 12-lead ECG is needed to diagnose changes in the PR interval and potential conduction delays. First-degree heart block is the prolongation of the PR interval beyond normal for age. PR intervals vary but are usually less than 0.16 seconds. Such prolongation can be normal or a sign of underlying disease or medication effects. Most patients with first-degree heart block are hemodynamically stable and require monitoring for progression to other forms of heart blockage. No emergency intervention is required.

Second-degree AV block is characterized by the occurrence of a P wave without a QRS complex, where some but not all atrial impulses are conducted to the ventricle. Progressive lengthening of the PR interval until a P wave occurs alone and the QRS complex is “dropped” is called a *Wenckebach (Mobitz type I)* rhythm (Fig. 38-6, B). If the QRS complex is repeatedly absent without a change in the PR interval, it is termed a *Mobitz type*

II rhythm (Fig. 38-6, C). Both are forms of second-degree heart block caused by delayed or absent conduction through the AV node. Some medications, hypoxia, and myocarditis can create this problem. If the ventricular rate maintains adequate perfusion, no immediate treatment is necessary and determining and eliminating the causative factor is curative. However, if hemodynamic instability exists, attempts to increase conduction by increasing the heart rate with atropine or epinephrine may be useful, and a pediatric cardiologist should be consulted.

Third-degree AV block, or complete heart block, is characterized by consistent electrical and mechanical dissociation between the atrial and ventricular rates (Fig. 38-6, D). ECG analysis shows P waves at one rate and wide QRS complexes at a separate rate. As with other forms of heart block, finding and eliminating the causative agent are curative. If hemodynamically stable, observation is often suitable. However, if the rhythm deteriorates or the patient's condition becomes unstable, some form of supportive pacing is required. If the third-degree heart block is congenital in origin or is persistent from surgical correction of a congenital heart lesion, a permanent pacemaker is often required.

Treatment of Bradycardia

Therapy for all causes of bradycardia should focus on hemodynamic support and treatment of underlying causes. If the patient's condition is unstable, airway support and CPR should be initiated and immediate measures should be taken to improve the heart rate. In the operating room, potentially deleterious medications and exposures, including surgical stimulus, should be discontinued as therapy for bradycardia is initiated. The first line of therapy is administration of a vagolytic agent. The POCA registry has demonstrated that epinephrine with or without atropine is most successful in returning a stable heart rate and circulation (Murray, 2002). Potentially reversible causes of bradycardia that should prompt acute therapy can be recalled using the “H’s and T’s” mnemonic device (Box 38-2). If a patient is hypoxic, improved oxygenation and oxygen delivery often result in improvement in heart rate. Bradycardia secondary to vagal stimulus can be treated by the removal of the stimulus and the administration of a vagolytic agent. Further treatment with adrenergic agents, such as epinephrine, is reasonable and effective. Epinephrine may be the first choice treatment for bradycardia if it is associated with severe hypotension and causing inadequate cerebral or myocardial perfusion. Earlier recommendations have included the use of isoproterenol, a potent β -selective adrenergic agent, to provide chemical pacing. However, because of its tendency to vasodilate, resulting in inadequate coronary and cerebral perfusion, it is no longer recommended and the next line of therapy is electrical pacing (Fig. 38-7). Figure 38-8 shows additional algorithms that include pediatric advanced life support (PALS) guidelines as well as an emphasis on intraoperative factors and interventions, including evidence-based endpoints for quality care during cardiac arrest.

Tachycardia

Tachycardias include a variety of rhythms that occur at a rate greater than normal for age (Table 38-3). Analysis of a tachyarrhythmia must discriminate between sinus, supraventricular,

junctional, or ventricular origins. The source of tachycardia, whether it is the sinus node, excitable focus, or reentrant pathway, creates variations of wide or narrow QRS complexes. Those tachycardias with narrow complexes (less than 0.08 seconds) are often atrial or high-junctional (between the atria) in origin. SVT, atrial fibrillation, atrial flutter, and junctional ectopic tachycardia (JET) present with narrow QRS complex. Wide-complex tachycardias originate from the ventricle or are SVTs with aberrant ventricular conduction. VT, often surprisingly well tolerated by pediatric patients, is the most common wide-complex tachycardia.

A patient with tachycardia may vary from showing no symptoms to being hemodynamically unstable, depending on underlying cause, other coexistent conditions, and duration and type of tachycardia. Increased myocardial oxygen consumption combined with reduced coronary perfusion caused by shortened diastolic time in rapid heart rates may cause myocardial failure when tachycardia persists or presents in an already diseased myocardium, such as cardiomyopathy.

■ FIGURE 38-7. PALS bradycardia with a pulse, 2005. (From Ralston M et al., editors: Pediatric advanced life support provider manual, Dallas, 2006, American Heart Association, p 123.)

Evaluation should include assessment of hemodynamic stability and end-organ perfusion. A 12-lead ECG is often required to evaluate tachycardia. Treatment is directed at support of hemodynamics and diagnosis and treatment of tachycardia.

Sinus Tachycardia

Sinus tachycardia is the most common tachycardia seen in the pediatric patient who is under anesthesia. Common causes are pain, hyperthermia, light anesthesia, hypovolemia, anemia, hypercarbia, hypoxia, and hypoglycemia. Generally, these conditions are easily diagnosed and treated (Fig. 38-8). It is not uncommon to have a child with a heart rate that is 20% to 30% above baseline in the postoperative period because of

these factors. Sinus tachycardia has a heart rate that is not fixed; it varies with activity and intervention.

Supraventricular Tachycardia

SVT is the most common tachyarrhythmia in all ages. It is the most common nonarrest arrhythmia in children and the most common arrest arrhythmia in infancy (Fig. 38-9). The cause is often a reentrant mechanism that produces a rapid and narrow QRS complex (less than 0.08 seconds) on ECG. Rates are more than 220 beats per minute in infants and more than 180 beats per minute in children. The ability of a pediatric patient to tolerate SVT depends on coexistent pathology, possible initiating factors, and duration of arrhythmia.

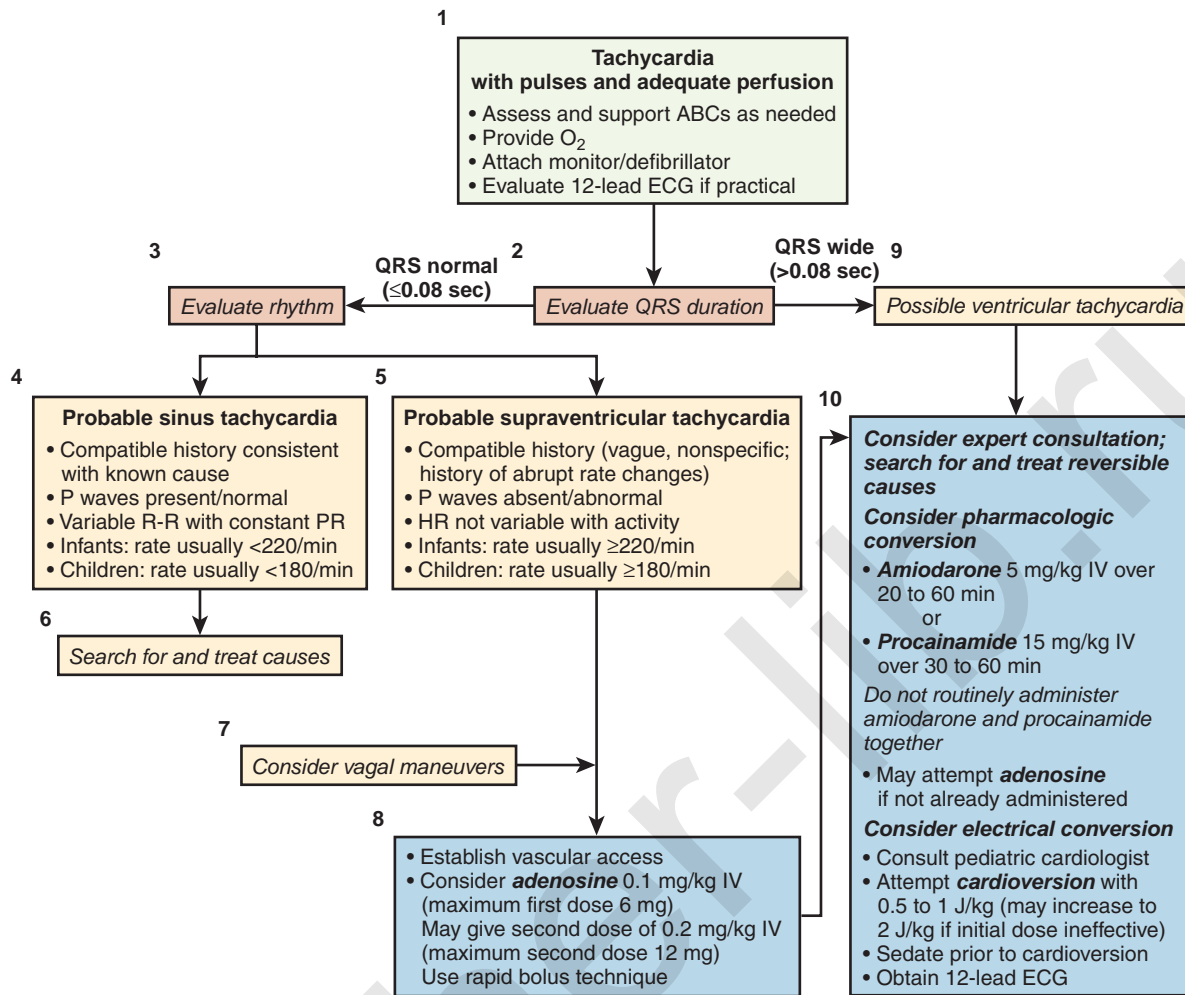

FIGURE 38-9. ECG of supraventricular tachycardia.

In infants, signs of SVT may be irritability and poor feeding. Older children often complain of lightheadedness, fatigue, and sometimes chest discomfort. Uncommonly, SVT can originate from an atrial focus that depolarizes faster than

the intrinsic sinoatrial node rate. This tachycardia is termed *ectopic atrial tachycardia (EAT)*, or *automatic tachycardia*, and is typically associated with cardiac surgery or congenitally acquired.

In patients who are under anesthesia, differentiating SVT from sinus tachycardia can be challenging. Lack of variability in the SVT rate compared with sinus tachycardia can be a clue. Additionally, most SVT has abrupt onset and offset, whereas sinus tachycardia tends to gradually increase and decrease. P waves in sinus tachycardia are normal and may be absent or abnormal in SVT. Ruling out possible causes of sinus tachycardia, such as fever, pain, hypovolemia, hypoxia, hypercarbia, and myocardial failure is helpful (Fig. 38-10).

■ **FIGURE 38-10.** PALS tachycardia with adequate perfusion algorithm, 2005. (From Ralston M et al., editors: Pediatric advanced life support provider manual, Dallas, 2006, American Heart Association, p 141.)

SVT generally has a narrow, complex QRS appearance, but when ventricular aberrant conduction is present, the widened QRS complex and rapid rate can mimic VT. An ECG to evaluate P waves and the QRS complex can be helpful. SVT with aberrant conduction is quite rare, and in a patient whose condition is unstable, a wide-complex tachycardia should be assumed to be ventricular in origin.

If the patient is hemodynamically unstable, synchronized cardioversion is the treatment of choice at an initial dose of 0.5 to 1 J/kg. If SVT persists or recurs after countershock, additional synchronized cardioversion can occur with the dose increased to 2 J/kg. If both vascular access and adenosine are readily available, adenosine (see the related section on adenosine) can be attempted for hemodynamically unstable SVT; no delays for vascular access should occur (Figs. 38-11 and 38-12).

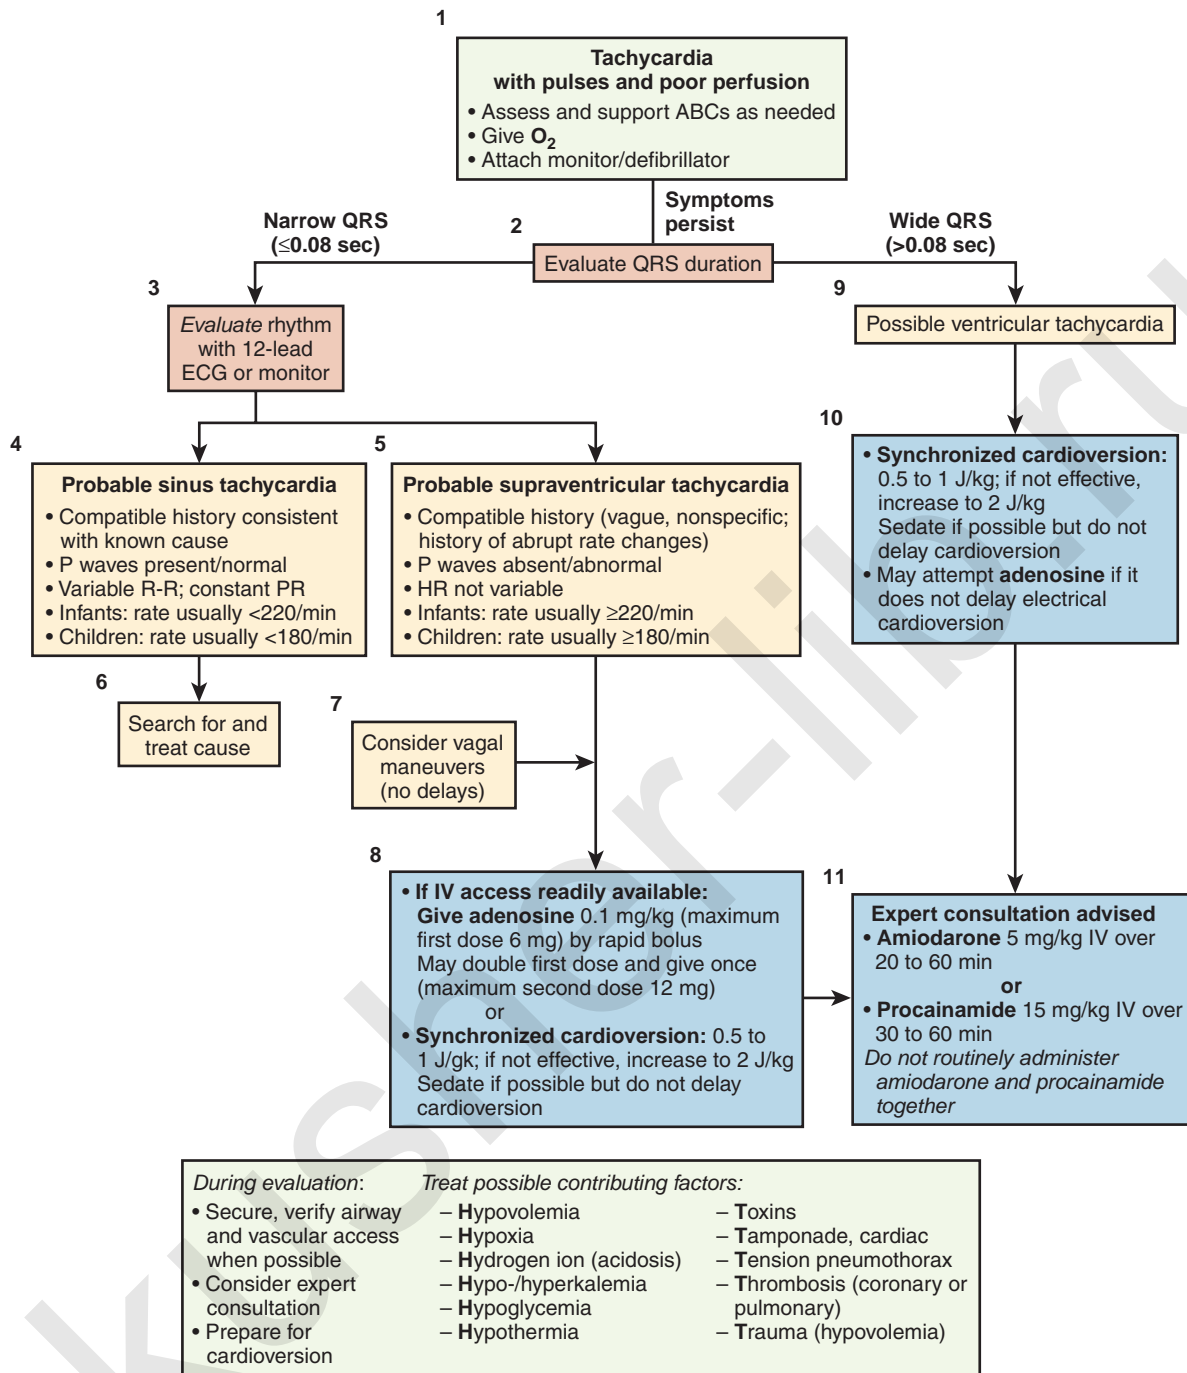

In a child with SVT whose state is hemodynamically stable, vagal maneuvers such as the gag and diving reflexes can be attempted as the first line of therapy. Ocular rubs are no longer recommended because of the risk for ocular trauma. Intraoperatively, some of these maneuvers will be unavailable. Ice to the face, Valsalva maneuvers, and carotid sinus massage have potential benefit and may be attempted until adenosine dosing is prepared. Failure of the above methods may indicate

a more complex arrhythmia and necessitate consultation with a pediatric cardiologist. Overdrive pacing with an esophageal or epicardial lead is an additional possible therapy in consultation with a pediatric cardiologist (Fig. 38-10).

Atrial Fibrillation and Atrial Flutter

Atrial flutter and fibrillation are extremely rare in children (Figs. 38-13 and 38-14). Atrial flutter is a rapid and regular rhythm, and in children it is often associated with structural heart disease. The underlying physiology is a macroreentry phenomenon creating a rapid, regular tachycardia. Atrial rates of 200 to 500 beats per minute are usually present and a “saw-toothed” wave or flutter waves are present on the ECG.

Atrial fibrillation is a rapid, irregular, tachycardia. Atrial rates can be as high as 600 beats per minute. The rhythm occurs because of multiple microreentrant circuits in the atria that create a variable ventricular response and irregular atrial rate. Treatment options are variable and depend on the underlying structural cause. If the rhythm is sustained and stable, consultation with a pediatric cardiologist should be sought. If it is unstable, synchronized cardioversion with 0.5 to 2 J/kg is the treatment of choice.

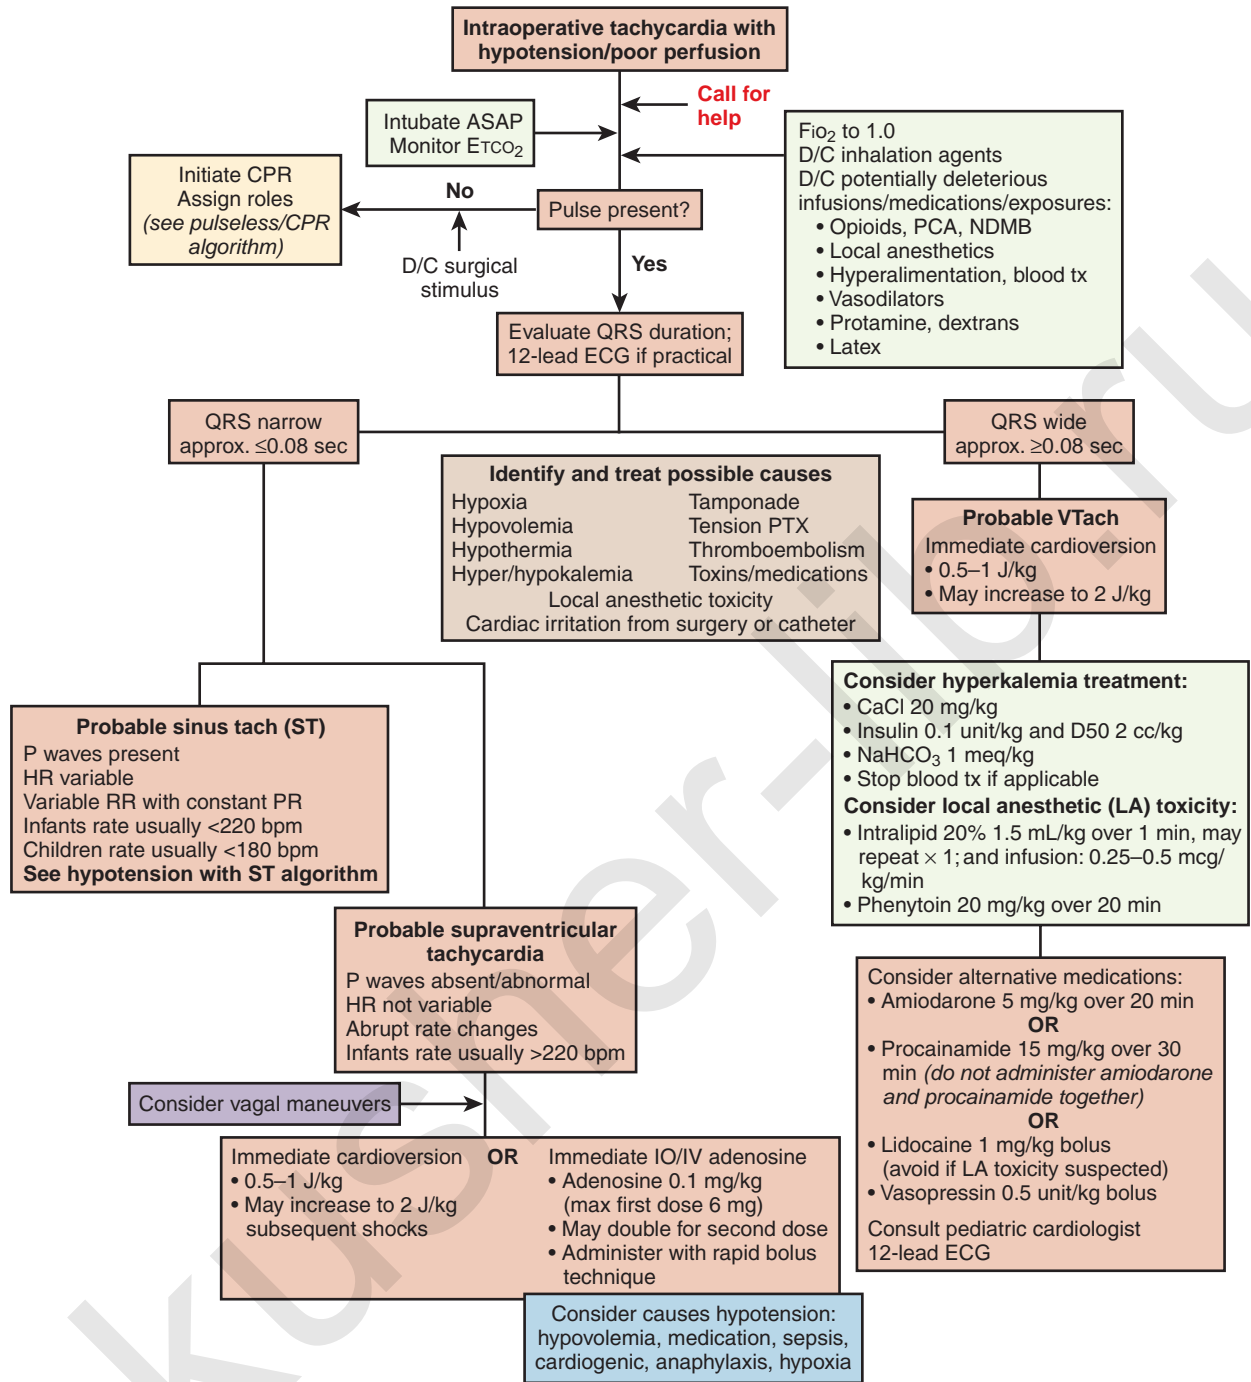

■ **FIGURE 38-11.** PALS tachycardia with pulses and poor perfusion algorithm, 2005. (From Ralston M et al., editors: Pediatric advanced life support provider manual, Dallas, 2006, American Heart Association, p 145.)

Junctional Ectopic Tachycardia

JET is most commonly seen after cardiac surgery for congenital heart disease. It is a narrow, complex, rapid rhythm with complete AV dissociation resulting in a ventricular rate that is more rapid than the atrial rate. Many describe the arrhythmia as a narrow complex SVT brought on by increased automaticity of the AV node or bundle of His. Occasional atrial beats are conducted through to the ventricles, depending on timing of the electrical pulse. Hemodynamic instability depends on heart rate

and degree of AV dissociation. If there is no instability, treatment is not needed. However, as cardiac output diminishes, more aggressive treatment is warranted. Therapy involves elimination of painful stimuli, metabolic acidosis, electrolyte abnormalities, endogenous and exogenous catecholamines, and fever. Further interventions involve cooling the child, IV amiodarone, and pacing the atria at a rate higher than the JET rate to provide improved AV synchrony. These efforts are supportive until the JET rhythm resolves over 2 to 4 days (Hoffman et al., 2002).

Ventricular Tachycardia

VT is defined as a rapid, wide complex QRS tachycardia (Fig. 38-15). The origin of the tachycardia is below the bifurcation of the bundle of His. This can result from either a reentrant phenomenon or from increased automaticity. At minimum, there are three wide QRS complexes with no evident P wave. When wide complex beats persist in runs of 30 seconds or more, sustained VT is present.

■ **FIGURE 38-15.** ECG of ventricular tachycardia.

If the patient has no pulse, defibrillation should be administered immediately at 2 J/kg followed by chest compressions. Changes in the 2005 AHA recommendations for the pulseless VT algorithm reflect the emphasis on sustained chest compressions and decreasing time when no cardiac output occurs (i.e., a no-flow state). Three stacked shocks are no longer recommended for pulseless VT; instead, recommendations are for a single defibrillation attempt followed by 2 minutes of chest compressions without pulse check (see Fig. 38-4; Fig. 38-16). Pharmacologic therapy in the algorithm includes epinephrine and in cases refractory to defibrillation and epinephrine, amiodarone or lidocaine.

VT with a pulse but poor perfusion should be treated as an emergency with synchronized cardioversion. Countershock should start with 0.5 to 1 J/kg and increase to 2 J/kg with subsequent countershocks (see Figs. 38-11 and 38-12). If the patient's condition is stable, then pharmacologic cardioversion can be attempted with the slow administration of IV amiodarone (see Fig. 38-10). The cause of VT should always be considered, and therapy should be instituted in parallel with the AHA PALS algorithms. The use of the H's and T's mnemonic device provides a method to recall likely causes (see Box 38-2). During anesthesia, electrolyte abnormalities, particularly hyperkalemia associated with rapid blood transfusion or succinylcholine, as well as other medication causes such as toxicity to local anesthetic should be considered. Surgical stimulus or venous air embolism can also cause ventricular arrhythmias (see Fig. 38-12).

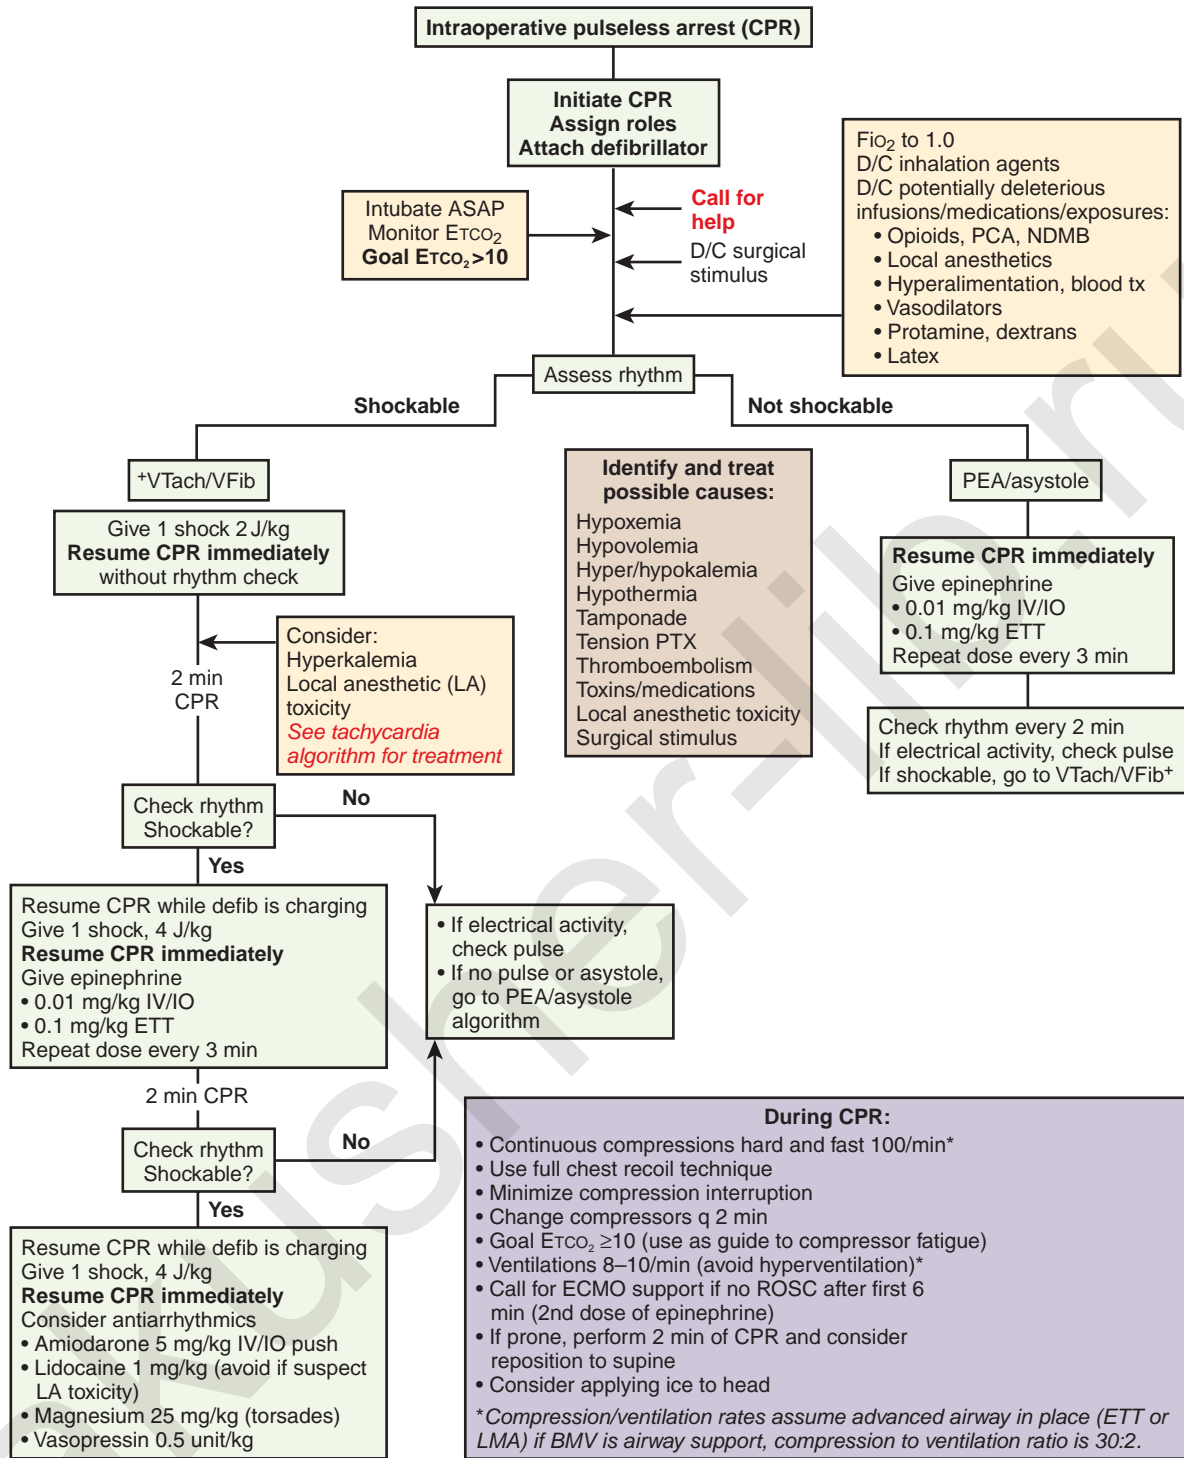

After initial stabilization, electrolytes should be measured, medications should be reviewed for possible toxic or adverse effects, and potential structural or conductive abnormalities should be explored. Myocarditis and myocardial ischemia, although rare in pediatrics, should always be in the differential diagnosis.

Although most VT is monomorphic, VT can be polymorphic in nature when the QRS complexes vary in appearance. Torsades de pointes VT is a distinctive form of polymorphic VT in which the complexes increase and decrease in amplitude, seemingly undulating around the ECG isoelectric line (Fig. 38-17). Causes of torsades de pointes VT include long QT syndrome, hypomagnesemia, and drug toxicities. Torsades de pointes VT is an unstable, pulseless, preterminal rhythm, and treatment follows the pulseless algorithm with the addition of IV magnesium to treat presumed hypomagnesemia (Fig. 38-16).

Ventricular Fibrillation

VF is a sustained burst of multiple, uncoordinated, regional ventricular depolarizations and contractions that result in an ineffective cardiac output and cessation of myocardial blood flow. (Fig. 38-18). Reentrant impulses, generated within the ventricles with multiple shifting circuits, maintain VF. Several physiologic conditions lower the threshold for fibrillation, including hypoxia, hypercapnia, myocardial ischemia, hypothermia, metabolic acidosis, and electrolyte disturbances (such as imbalances of potassium, calcium, sodium, and magnesium). In addition to these causes of VF, surgical stimulus can trigger VF in the operative environment.

A review of outcomes of in-hospital VF arrests in children found that VF or pulseless VT was the presenting rhythm in 10% to 14% of patients and occurred at some point during the cardiac arrest in an additional 15% of patients. When VF or pulseless VT is the presenting rhythm in cardiac arrest, survival to hospital discharge is approximately 30% to 35%. Survival is significantly better in patients whose cardiac arrest presented with VF or VT than for those who developed it subsequently (35% vs. 11%, odds ratio = 2.6; 95% confidence interval 1.2 to 5.8). Additionally, survival to hospital discharge for patients with either VF or VT that developed subsequently during cardiac arrest was worse than for those patients with asystole or PEA. Presumably, VT or VF that develops later in cardiac arrest occurs as a result of other triggers, such as myocardial reperfusion injury (Samson et al., 2006; Nadkarni et al., 2006).

■ **FIGURE 38-18.** ECG of ventricular fibrillation.

Treatment and causes of VF is the same as it is for pulseless VT—rapid single defibrillation and chest compressions (see Figs. 38-4 and 38-16).

Pulseless Electrical Activity

PEA is a clinical state characterized by the presence of electrical activity in the absence of detectable cardiac output. This is a preterminal condition that often leads to asystole. Typically, it is characterized by a slow, wide-complex rhythm in a child without a pulse who has experienced a prolonged period of hypoxia, ischemia, or hypercarbia. If the condition occurs rapidly, then it may result from a reversible cause. PEA was previously described as electromechanical dissociation (EMD). A review of the NRCPR data found that PEA is the presenting rhythm in 24% of pediatric cardiac arrests and has a rate of 27% for survival to hospital discharge. Over half of those cases of survival had good neurologic outcome (Nadkarni et al., 2006).

PEA should be managed according to the pulseless cardiac arrest algorithm (see Figs. 38-4 and 38-16).

During CPR for PEA, treatable causes of PEA should be considered; the H's and T's mnemonic device can be used to recall causes (see Box 38-2). In the setting of the operating room, many episodes of PEA in children are related to reversible causes that if promptly recognized and treated, result in survival.

Asystole

Asystole occurs when no electrical activity or mechanical contractions are present in the heart. Asystole is a presenting rhythm in 40% of IHCA's, and survival to hospital discharge from in-hospital asystolic cardiac arrest is 18% to 22% (Nadkarni et al., 2006). However, this rate includes patients who came to the emergency department in cardiac arrest and who were unmonitored on hospital medical or surgical floors. Although data are unavailable, perioperative cardiac arrest would be presumed to have a lower percentage of an asystolic presentation, because asystole more commonly occurs as other rhythms deteriorate, treatments fail, and patients are closely monitored in this setting. Asystole is treated according to the pulseless arrest algorithm (see Figs. 38-4 and 38-16).

In all arrhythmias that cause pulseless cardiac arrest, care should be taken to perform high-quality CPR while diagnosing and treating the rhythm and cause (see the inset boxes of Fig. 38-16). Compressions should be hard and fast, at 100 beats per minute, using full-chest-recoil technique, and minimizing compression interruption. ETCO_2 should be monitored with a goal of pressure higher than 15 mm Hg; hyperventilation should be avoided to improve venous return and cerebral

blood flow. Mechanical support, such as extracorporeal membrane oxygenation (ECMO), should be considered if ROSC is not achieved within the first 5 minutes.

ANESTHESIA-ASSOCIATED CONSIDERATIONS DURING CARDIOPULMONARY RESUSCITATION

Open-Chest Cardiopulmonary Resuscitation

Open-chest CPR involves a thoracotomy and application of direct compression of the heart to generate blood flow. The use of this technique requires a high level of preparation and training, as well as special equipment and facilities. These requirements limit open-chest CPR to certain hospital settings.

Open-chest CPR represents a model of the cardiac pump mechanism for generation of blood flow. In theory, this model eliminates production of intrathoracic pressure which, if transmitted, could reduce gradients for blood flow. This enhanced gradient combined with directly applied compression can result in near-normal blood flows. In experimental models, open-chest CPR produces cardiac outputs of 25% to 61% of values before cardiac arrest (Weiser et al., 1962; Bircher et al., 1981; Bartlett et al., 1984). These studies and others demonstrate cardiac outputs two to three times larger than with conventional closed-chest CPR (Weiser et al., 1962; Del Guercio et al., 1965; Bircher et al., 1980, 1981; Bartlett et al., 1984). Increases in CPP have been significant in some studies but not in others (Bircher et al., 1980, 1981; Del Guercio et al., 1965). MPPs are significantly increased compared with closed-chest CPR (Bircher et al., 1980; Sanders et al., 1984b). In dogs, cerebral blood flow of 150% of values before cardiac arrest can be produced with open-chest CPR (Jackson et al., 1984). Cross-clamping the descending aorta during open-chest CPR further increases carotid blood flow.

Survival in dogs can be improved by using of open-chest CPR after inadequate closed-chest CPR (Sanders et al., 1984a). Dogs with MPP of less than 30 mm Hg after 15 minutes of closed-chest CPR received 2 to 4 minutes of either open-chest or closed-chest external CPR before defibrillation was attempted. Dogs that received open-chest CPR had significantly greater MPPs and survival rates.

The length of time of preceding closed-chest CPR affects the success of subsequent open-chest CPR (Sanders et al., 1985b). After 20 and 25 minutes of closed-chest CPR, the success rate of open-chest CPR drops to 38% and 0%, respectively. This implies that the benefits from open-chest CPR are limited by time and that early application is crucial. There are no data to recommend routine use of open-chest CPR in the pediatric patient. Postoperative cardiac patients with a recent sternotomy may

benefit from open-chest CPR. They have easier access, can be inspected for tamponade, and suture lines can be inspected and avoided.

Conventional Cardiopulmonary Resuscitation in the Prone Position

Conventional CPR is usually performed with sternal compressions applied to a supine patient. Prone positioning for surgical procedures provides an extra complication when cardiopulmonary arrest occurs. Patients who are prone and undergoing posterior cranial or spine surgery and suffer a cardiac arrest may not be able to be quickly repositioned to the supine position. An unstable spine, protruding stabilizers, and ongoing blood loss are factors that may delay turning the patient and necessitate starting CPR in the prone position. Additionally, repositioning the prone patient into a supine position requires multiple people, taking drapes down, and caution against dislodging tubes or lines. The time it takes to reposition delays life-saving CPR and defibrillation; therefore, resuscitation may be attempted before repositioning. Two methods for delivering posterior chest compressions to a patient in the prone position have been suggested. The first uses two hands with one hand spread over each scapula, and the second uses the heel of one hand on the spine with the second hand on top of the first, similar to the method for sternal compressions (Sun et al., 1992; Tobias et al., 1994; Dequin et al., 1996). Counter pressure under the sternum with another rescuer's hand or fist or a sand bag has also been suggested (Sun et al., 1992; Dequin et al., 1996; Mazer et al., 2003). In a high-fidelity simulation model of CPR with the patient in the prone position and using midline compressions with a counter pressure pad, effective or partially effective compression depth was able to be achieved 75% of the time (Atkinson, 2000). Prone CPR using a spine compression technique compared favorably with supine CPR in six intensive-care patients (Mazer et al., 2003). When possible, patients should be turned supine for CPR, but effective CPR may be able to be performed when a patient is in the prone position.

In addition to chest compressions, defibrillation may be necessary in a prone patient. Prone defibrillation may be attempted if the patient cannot be turned immediately. Placement of self-adhesive defibrillation pads is advised, because intraoperative placement of paddles may be difficult and require time. Gel pads placed on the back on either side of the surgical incision in the left midaxillary line and inferior to right scapula have been successful for defibrillation in a prone patient (Miranda and Newton, 2001).

Consideration of Etiology of Cardiopulmonary Arrest During Cardiopulmonary Resuscitation

Cardiopulmonary arrest in the perioperative period is likely to be caused by either surgical intervention or anesthesia in isolation or in combination with patient comorbidity. Therefore, the anesthesiologist is faced with the unique situation in which causes of cardiac arrest are diagnosed and treated in parallel with the delivery of standard resuscitation care. When possible, other skilled providers should be called to assist with CPR and the rapid processing of multiple algorithms and data that is required (see the section about roles in the operating room).

The most recent review of the POCA Registry found 193 perioperative cardiac arrests over 6 years. The most common causes of arrest include hypovolemia (15%), electrolyte imbalance including hyperkalemia (5%), and laryngospasm (6%). Other causes of cardiac arrest that require consideration perioperatively include venous air embolus, medication overdose, intravascular local anesthetic injection, anaphylaxis, and surgical stimulus (Bhananker et al., 2007). In addition to CPR, resuscitation for the patient in the perioperative period should include interventions targeted at likely causes for the cardiac arrest. There are algorithms that are based on the AHA guidelines for PALS but are focused on intraoperative management (see Figs. 38-8, 38-12, and 38-16).

Patients with Congenital Heart Disease and Cardiopulmonary Resuscitation

Pediatric anesthesiologists care for children with atypical cardiac anatomy and physiology that can have an effect on the cause of cardiac arrest, effectiveness of CPR, and the interventions required for resuscitation. Patients with congenital heart disease who are in or near cardiac arrest require thorough knowledge of patient-specific anatomy, physiology, and ECG. Patients with congenital heart disease have a higher likelihood of arrhythmia rather than respiratory insufficiency or failure as the primary cause of arrest (Peddy et al., 2007).

For patients with shunt-dependent pulmonary blood flow, occlusion of shunt flow is an emergency that may require urgent surgical intervention or mechanical support in addition to CPR. $EtCO_2$, typically a marker for CPR effectiveness, should be evaluated in context of the patient's anatomy and potential for altered pulmonary blood flow. For example, the patient with shunt-dependent physiology and occluded shunt flow could have low $EtCO_2$ even when adequate CPR is being performed. $EtCO_2$ during CPR may not have the same prognostic value in patients with altered cardiac anatomy and pulmonary blood flow.

EXTRACORPOREAL SUPPORT AS ADJUNCTIVE THERAPY DURING CARDIOPULMONARY RESUSCITATION

The primary goal of CPR is to provide cerebral and coronary perfusion that is adequate to preserve organ function in anticipation of resumed circulation. Intuitively, extracorporeal support could aid in that goal by increasing oxygenation and blood flow in the low-flow and no-flow states of cardiopulmonary arrest. Additionally, extracorporeal support could prolong reliable organ perfusion while reversible causes of cardiac failure are treated.

CPB was the original model for extracorporeal support; its utility was documented in animal studies (Safar et al., 1990). In dogs, CPB increases 72-hour survival, recovery of consciousness, and preserves myocardium better than conventional CPR (Levine et al., 1987; Pretto et al., 1987). Additionally, CPB results in better neurologic outcome than continued conventional CPR after a 4-minute ischemic period in a canine model (Levine et al., 1987; Pretto et al., 1987). Survival for 24 hours is possible for at least 90% of dogs after 15 or 20 minutes of cardiac arrest but for only 10% of dogs after 30 minutes of cardiac

arrest with CPB stabilization during defibrillation (Reich et al., 1990). In a model involving coronary artery occlusion, it was found that CPB decreases myocardial infarct size compared with conventional CPR (Angelos et al., 1990). Clinical use of CPB for CPR in humans is limited by equipment and technical constraints.

Improvements in gas-exchange apparatus permitted extracorporeal support to go beyond a few hours and allowed CPB techniques to move from the operating room into the intensive care unit. Because the gas-exchange portion of the circuit was very different than CPB, prolonged extracorporeal life support became known as extracorporeal membrane oxygenation (ECMO). Bartlett et al. (1976) first used of ECMO for neonatal cardiac failure after a mustard operation in 1972 and later published his case series about neonates with respiratory failure who were supported with ECMO.

Similar to CPB, ECMO removes deoxygenated blood from the venous system and returns oxygenated blood to the aorta using a mechanical pump and gas-exchange apparatus. In contrast to CPB, ECMO is designed for longer usage (days or weeks vs. hours). ECMO provides a gas-exchange apparatus—a membrane between the oxygen and blood interface—that causes less hemolysis than CPB. CPB is used intraoperatively to facilitate cardiac surgery by emptying the heart and supporting organ function during cardiac surgery; cannulae are typically placed directly in the heart or great vessels through sternotomy incision. ECMO can provide longer support to failing respiratory or cardiac systems when recovery is anticipated; arterial and venous cannulae can be placed percutaneously in large vessels more distal to the heart. Lower heparin dosages may be used in ECMO than in CPB, decreasing hemorrhagic risk over time.

The first use of ECMO for rescue in a pediatric patient receiving extracorporeal CPR (ECPR) was reported by Dalton in 1993. She reported the use of ECMO for cardiac failure in 29 patients with acquired or congenital heart disease after repair or transplantation; 11 of those were receiving CPR during cannulation. Survival to discharge in this group was six cases out of 11 (55%) despite CPR duration of 42 to 110 minutes (Dalton et al., 1993).

Since that time, multiple case series and reviews of ECMO data have replicated Dalton's findings. The majority of the reported cases concern patients with congenital or acquired heart disease and are inpatients that are younger than 1 year of age (Morris et al., 2004; Shah et al., 2005; Thourani et al., 2006; Alsoufi et al., 2007; Huang et al., 2008). Survival to hospital discharge in the series with larger numbers of patient is generally 33% to 41% (Morris et al., 2004; Shah et al., 2005; Alsoufi et al., 2007; Huang et al., 2008).

Few studies report neurologic outcomes or long-term follow-up issues; those that do have mixed results. Using the Pediatric Cerebral Performance Category Scale, Huang et al. (2008) reported normal or only mild disability in 10 of 11 survivors of ECPR in a population of pediatric patients 1 to 4 years after hospitalization. Morris et al. (2004) reported that 24% (five out of 21) of survivors of ECPR had significant neurologic impairment that was noted at the time of discharge.

Increased duration of CPR before ECMO cannulation has been found to increase the risk of mortality in two studies and to have no impact on survival in others (Dalton et al., 1993; Morris et al., 2004; Alsoufi et al., 2007; Huang et al., 2008; Tajik and Cardarelli, 2008). Notably, there are also reports of patients surviving nearly 2 hours of CPR before ECMO initiation with-

out neurologic injury (Morris et al., 2004; Thourani et al., 2006; Alsoufi et al., 2007).

In the few studies that look at survival for noncardiac patients separately, outcomes may be much lower than for patients with cardiac disease. Alsoufi et al. (2007) reported nine patients without cardiac disease in his cohort of 80 patients; only one of those nine (11%) survived to discharge. Similarly, Morris et al. (2004) reported on 64 patients from a single institution who had received ECPR from 1995 to 2002. Only two of 21 (9.5%) noncardiac patients survived to discharge. The largest series of ECPR in noncardiac patients was reported by MacLaren in 2007. He reported on the use of ECMO in 45 pediatric patients with sepsis; 18 patients had CPR at the time of cannulation. In contrast to the findings of Morris and Alsoufi, 11 out of 18 (55%) survived to discharge (MacLaren et al., 2007).

Two large reviews of the Extracorporeal Life Support Organization (ELSO) database have demonstrated increased use of ECMO during CPR with stable survival outcomes. Cengiz et al. (2005) reviewed the ELSO database from 1981 to 2002 and found 161 reports of ECPR in children with and without cardiac disease, with survival to discharge in 64 of 161 (40%) patients. In a more recent review of the same database with overlapping dates with the Cengiz review, Thiagarajan et al. (2007) found 682 reports of ECPR in the ELSO database from 1992 to 2005; 499 were patients with heart disease. The median age was 0.25 years, and survival to discharge was 261 of 682 (38%). Patient age, weight, gender, or site of cannulation (thoracic vs. peripheral) did not impact survival. The duration of CPR before ECMO was not reported (Thiagarajan et al., 2007). Neither study reported neurologic outcomes.

Given that survival of prolonged IHCA (longer than 15 to 30 minutes) has been reported as low and that survival after ECPR may be as high as 33% to 41%, ECPR could provide an incremental increase in survival compared with refractory cardiac arrest that is treated with CPR alone (Suominen et al., 2000; Morris et al., 2004). Considering that this population would likely be deceased otherwise, ECMO is a potent and life-saving therapy.

ECPR perhaps has the greatest potential application for the intraoperative patient. Because patients are closely monitored by providers who are skilled in resuscitation at the time of cardiac arrest, the no-flow interval is minimal. Additionally, surgical staff is present at the time of cardiac arrest to assist with cannulation. There are multiple causes of reversible cardiac dysfunction in the operating room, including but not limited to hyperkalemia, local or general anesthetic overdose, and airway emergency. Dialysis to treat hyperkalemia and other drug or toxin overdose can be readily performed during ECMO; dialysis cannot be performed while CPR is in progress.

Survival from pediatric anesthesia-related cardiac arrest is reported to be 72%, but this number only represents survival from acute cardiopulmonary arrest; survival to discharge is not reported (Bhananker et al., 2007). A review of 91 cardiac arrests in the pediatric ICU (PICU) over 5 years similarly found an 82% survival rate for an acute cardiopulmonary arrest event but only 25% survival to discharge. Notably, use of ECMO in the first 24 hours after cardiac arrest in this population was associated with reduced hospital mortality (mortality reduced from 78% to 63%) in multivariate logistical regression analysis (odds ratio of 0.18; 95% confidence interval of 0.04 to 0.76) (de Mos et al., 2006). Data from the PICU patient population have mixed application to perioperative patients. Although the patients in the PICU are similar to those in the operating room in that the cardiac arrest

is witnessed and acted on immediately by skilled providers, the PICU patients likely have significant comorbidities and may be an overall sicker population than operative patients. However, ECMO usage in the operating room would likely reduce mortality from perioperative cardiac arrest in select patients, similar to results seen in the PICU data.

There are issues and contraindications to ECMO that must be considered, however. ECMO is expensive, requires considerable technical support and experience, and is not universally available. ECMO provides support while reversible causes of CPA are treated and is not a therapy for CPA in itself. Contraindications to ECMO include nonreversible pathology or disability that precludes quality of life after ECMO. Heparinization is required, and bleeding can be a significant, but not insurmountable, problem after surgery. The anesthesiologist and surgeon should assess the cause of cardiac arrest, the potential reversibility of the etiology, and patient comorbidities before ECMO initiation.

The 2005 AHA recommendation regarding ECPR states: “Consider ECPR for IHCA refractory to initial resuscitation attempts if the condition leading to the arrest is reversible or amenable to heart transplantation, if excellent conventional CPR has been performed after no more than several minutes of no-flow cardiac arrest, and if the institution is able to rapidly perform ECMO” (AHA, 2006b). Because surgical and resuscitative staff members are present at the time of cardiac arrest, the no-flow period of cardiac arrest is virtually eliminated. If support for ECMO exists and can be rapidly mobilized, intraoperative cardiac arrests appear to be an ideal application for ECPR in children without contraindication to ECMO.

TEAMWORK DURING INTRAOPERATIVE CARDIAC ARREST

Complex, high-stake events that occur rarely, such as an intraoperative cardiac arrest in a child, often require multiple simultaneous interventions performed as rapidly as possible during a time of high stress. The response can be more effective and efficient, and the stress can be divided and reduced by using a well-organized team with the appropriate skills. Teamwork principles that can be applied to these situations are derived from airline industry’s response to aviation disasters and referred to as *crew resource management (CRM)*. Application of these same principles to anesthesia-related emergencies led to the development of crisis-resource management (also CRM). The low incidence of intraoperative cardiac arrests makes it difficult to evaluate the application of CRM training on outcome. Simulation can be used to determine the effect that CRM training has on the improvement of attitudes or behaviors of the team (Cooper, 2004). Multiple reviews describe CRM in the fields of anesthesia and pediatrics (Sundar et al., 2007; Eppich et al., 2008; Weinstock and Halamek, 2008; Manser, 2009). Many of the principles and concepts of CRM are applicable to teams involved in responding to a cardiac arrest involving a child undergoing anesthesia for a procedure (Box 38-3).

A shared mental model is the concept that, without need for overt communication, all team members understand the organization and purpose of the team. It is difficult to develop this concept on an *ad hoc* basis. Even if they have not previously worked together, the individuals that will become the team in the event of an intraoperative arrest should have the same mental model for the team. Discussion and exploration of this

Box 38-3 Principles of Crew Resource Management that Apply to Teams Involved in Intraoperative Cardiac Arrests

SHARED MENTAL MODEL

- Team composition
- Individual roles
- Team goal

TEAM-ORIENTED BEHAVIOR

- Mutual respect
- Mutual trust
- Mutual performance monitoring
- Back-up behavior
- Conflict avoidance and resolution

CLARITY OF ROLES AND RESPONSIBILITIES

- Effective leadership
- Effective followership

RESOURCE MANAGEMENT

- Access to equipment or staff needed
- How to get it
- Who will get it
- When to get it

EFFECTIVE COMMUNICATION

- Assertive
- Directed
- Closed-loop

SUPPORT MANAGEMENT

- When to call for help
- Who to call for help

REGULAR FEEDBACK AND DEBRIEFINGS

- Team evaluation as opposed to evaluation of individuals

concept among individuals likely to be involved should occur before the event that will require the team formation.

Team-oriented behavior describes the willingness of individuals to work as members of a team and to accept the other members of that team. In the event of an intraoperative cardiac arrest, team members should treat the other members with respect due individuals who are willing to work hard under pressure to save the life of a child. A lack of respect that leads to the impression that offering suggestions will receive a condescending response could prevent the transfer of vital information. Team members should be observant of how the other team members are performing. If it is perceived that another team member is overwhelmed, other team members should be willing to offer assistance if they are able. If they have a conflict with another team member, they should postpone comments or actions that do not contribute to team performance until after the child is stabilized and the tension is decreased.

Having clarity of roles and responsibilities is a critical concept in the event of an intraoperative cardiac arrest. In the cardiac operating room, it is clear that the surgeon will compress the heart and deliver shocks for defibrillation, while the anesthesiologist will provide medications and fluids and manage ventilation. In this situation, in which the cardiac arrest is usually related to the surgical efforts, the surgeon initiates and leads the resuscitation. In contrast, when the cardiac arrest is related to problems with patient’s response to anesthetics or difficulty with ventilation, the anesthesiologist becomes the leader.

The combination of a small number of pediatric cardiac surgeons and anesthesiologists at an institution and the common occurrence of cardiac arrests in their patients result in more opportunity to clarify their roles and responsibilities. In a surgery center during a hyperkalemic response (e.g., to the administration of succinylcholine for laryngospasm in a child with undiagnosed muscular dystrophy), it may not be clear who is best qualified to perform compressions, who should go for the defibrillator, who should perform IO access, who should administer defibrillation shocks, and who should record therapeutic interventions and responses while the anesthesiologist continues involvement in maintaining a secure airway, providing ventilation, and administering medications. Calling for help in these situations can complicate the situation by having the distraction of unnecessary staff who are unfamiliar with team roles during resuscitation and by causing roles or responsibilities to be missed or duplicated.

Clarity of roles and responsibilities is one of the team training concepts emphasized by the AHA in the PALS course. Six roles are recommended in the PALS course for pediatric arrests, the titles *Leader*, *Airway*, *Compressor*, *Access*, *Monitor*, and *Recorder*. These roles can be applied to the pediatric operating room environment, depending on the setting and available resources (Table 38-14). In the cardiac operating room the necessary resources (e.g., defibrillator, vasoactive medications, blood products, and CPB equipment) are available, and in this setting multiple roles are assumed by a few individuals. For example, the anesthesiologist performs the Airway, Access (medication), and Recorder roles while the surgeon performs Compressor and Monitor (defibrillator) roles, and either could be the Leader. In a general or ambulatory operating room, the necessary resources (e.g., code cart and defibrillator) often need to be brought to the room, and multiple roles may need to be assigned. It is a good idea to predetermine who will assume the Leader role in this setting; the anesthesiologist may have more

information about the cause of arrest, making it easier for him or her to solve problems in the Leader role. If enough staff is available, an additional anesthesiologist can assume the Airway role and maintain ventilation, allowing the primary anesthesiologist to focus on leadership. An otolaryngology surgeon may need to be in the Airway role during airway surgery. The Compressor role might need to be part of the surgical staff if the chest needs to be in the sterile field. The Access role is usually assumed by an anesthesiologist, ideally not the Leader or Airway designee, although combinations of roles may need to occur if an insufficient number of staff are available to provide all for all six roles. The Monitor role may require the participation of a surgeon if sterility is required, or it may be filled by an anesthesiologist if adhesive gel pads are to be applied under the surgical drapes. The Recorder role often falls to the anesthesiologist, who is already recording intraoperative events, but a circulating nurse performing this role could free the anesthesiologist for leadership or other roles. The Recorder role can also be expanded to include a list of desired goals, and the Recorder can use it to remind the Leader what has been accomplished and what needs to be completed and when (See the section on documentation). Predetermining which roles are likely to be empty and which could be combined may save time and confusion during an actual event. In the event of insufficient staff, the primary anesthesiologist may be able to assume the Leader and Airway roles and delegate the Access and Monitor roles to additional responding anesthesiologists.

The principles of leadership and followership are very important in high-stress situations involving complex responses. It is important to have a clearly defined Leader who remains separate from resuscitative efforts, is able to assess the whole picture, determines the goals of resuscitation efforts, keeps focus on goals, monitors team effectiveness, redistributes work load for members who are overwhelmed or underused, frequently reassesses the situation, and makes clear decisions about the needs for resources and support. Followers need to be willing to assume their roles and responsibilities, act under the Leader's direction, offer feedback and ideas in a supportive manner, and own (and stick with) their assigned roles. The principles of leadership during resuscitation may not have received the proper focus in medical training. Residents in the field of internal medicine report not feeling qualified to lead a resuscitation team, and residents in pediatrics inadequately demonstrated leadership skills during mock pediatric arrests (Hayes et al., 2007; Hunt et al., 2008). Understanding and practicing the principles of leadership and followership should be incorporated into the goals of training for the management of intraoperative cardiac arrests.

Resource management may be one of the most important principles to apply to the situation of an intraoperative cardiac arrest. It is crucial to know what equipment, supplies, or information is needed and whether they are available when an intraoperative cardiac arrest is likely or occurring (Table 38-15). To have the code cart brought early requires that the team know where it is kept, whose responsibility it is to bring it, and what it contains. Pediatric anesthesiologists seldom use a defibrillator or AED, and issues often occur with paddle-size selection, switching to pediatric paddles, charging and discharging efficiently, understanding biphasic and monophasic dosing, and understanding defibrillator and AED differences (especially AED analysis and response time) (Heitmiller et al., 2008). Instruction in defibrillator use has a greater impact when the

TABLE 38-14. Roles and Responsibilities During Intraoperative Arrest

Role	Responsibility
Leader	Assigns roles Directs resuscitative efforts Monitors the performance of tasks
Airway	Equipment and oxygen preparation Airway and gastric intubation Ventilation
Compressor	Delivers chest compressions
Access (medication)	Obtains intravascular or intraosseous access Fluid and medication preparation and administration
Monitor (defibrillator)	Establishes and operates monitors and defibrillator Performs pulse checks
Recorder	Records resuscitative efforts Compares recorded efforts to goals of resuscitation list Reviews record as needed by the Leader/team

Modified from Ralston M et al., editors: *Pediatric advanced life support course guide*, Dallas, 2006, American Heart Association, p 31.

TABLE 38-15. Resources that May Be Needed During a Pediatric Intraoperative Cardiac Arrest

Resource	Indication
Backboard	Patient on stretcher or mattress
Stool	Improve compressor performance and endurance
Stretcher	Patient in prone position or on equipment that decreases CPR effectiveness
Code cart	Arrest is likely or in process
IO needles	Difficult access
Defibrillator	Shockable rhythm
Pacemaker	Dysrhythmia
Cognitive aids	Help with resuscitation algorithms
Blood products	Blood loss or coagulopathy
Ice, cooled IV fluids	Malignant hyperthermia or therapeutic hypothermia
Dantrolene	Malignant hyperthermia
Lipid emulsion	Local anesthetic toxicity
Emergency airway tools	Difficult airway

trainees are required to demonstrate their use by having gone through the steps themselves rather than watching an instructor (Hunt et al., 2009). Cognitive aids may be attached to the code cart, so the Leader can review resuscitation algorithms if needed. Ice, cooled IV fluids, and dantrolene may be needed if malignant hyperthermia is encountered, as well as a small inflatable pool that may be placed under the patient to contain large quantities of ice. Keeping instructions with lipid emulsion can be helpful in the rare event of a toxic response to a local anesthetic. These and other issues of resource management during a resuscitation event can have a big effect on the response time and thus on outcome. It should be a goal of team training to have multiple (or all) members familiar with the resources needed and how they will be deployed in the event of intraoperative arrest.

Effective communication is another skill that is emphasized by the AHA in PALS training. Several CRM communication principles can be applied to team management during intraoperative resuscitation (Box 38-4). Assertive communication is important to ensure that all necessary information is communicated to the Leader and other team members. Failing to

Box 38-4 Important Principles of Effective Communication that Apply to Resuscitation

Be assertive.
Use direct communication to the appropriate team member using names and eye contact.
Deliver clear messages.
Use a closed-loop style of communication to show message has been received and understood as intended.

report necessary information because of concern about a condescending response may cost a child's life. Direct communication helps prevent information from being ignored because of not having the intended member's attention. Ideas should not be delivered in a general manner but instead directed to appropriate members after obtaining their attention. Team members should introduce themselves if they are not familiar with each other's names. The establishment of eye contact helps determine that the speaker has the attention of the appropriate members. Names of the appropriate members and eye contact should be used before information is delivered. The information should be delivered as clearly as possible. In the use of closed-loop style of communication, recipients should acknowledge and repeat the message to demonstrate that the information was received and understood as intended.

Support management is another team-training concept that is important to apply to pediatric intraoperative resuscitation. Support management involves knowing what help is available, how to access that help, and when to activate that help. The concept of activating "incremental help" means requesting only the necessary help rather than a broad request for all help, which may result in the chaos that can accompany too large of a response. In the setting of an intraoperative cardiac arrest, the concept of support management applies to many situations (Table 38-16).

Debriefing is the final team-management concept that should be applied to teams that respond to intraoperative arrests. Regular feedback and debriefing can be used to improve team performance for subsequent responses. It is recommended that feedback sessions be used to evaluate the team's performance and not that of an individual. Nontechnical skills improve with debriefing, and oral feedback alone may be sufficient and not enhanced by the use of accompanying video (Savoldelli et al., 2006).

One of the major differences between floor or operating-room resuscitations is that in the operating room there is rarely a team that responds with preconceived roles and responsibilities. In a code on a hospital ward, a senior resident responds as Leader, an anesthesiologist and respiratory therapist respond as Airway, a pharmacist and ICU nurse administer medications, a junior resident is responsible for the defibrillator (Monitor role),

TABLE 38-16. Support that May Be Needed During a Pediatric Intraoperative Cardiac Arrest

Support Needed	Situation
Additional resuscitation help	Unfilled team roles (any anesthesiologist call)
Otolaryngologist	Difficult airway management
General or thoracic surgeon	Vascular access or chest tube placement
PICU staff	Need for additional resuscitation support
Cardiologist	Arrhythmia management
ECMO or CPB	Failure to achieve return of circulation

PICU, Pediatric intensive care unit; ECMO, extracorporeal membrane oxygenation; CPB, cardiopulmonary bypass.

a ward nurse serves as Recorder. In noncardiac pediatric operating rooms there are individuals who have little experience with each other during resuscitation efforts who are suddenly put together in a critical high-stress situation. Discussing and practicing the concepts of CRM help teams perform better in simulated events and can be applied to the management of pediatric intraoperative cardiac arrest.

Documentation During a Pediatric Intraoperative Cardiac Arrest

The Recorder mentioned in the preceding section is tasked with documentation of resuscitative efforts performed during an intraoperative cardiac arrest. In addition to providing documentation for the patient's medical record, the information can be used by the Recorder to review for the Leader and team what has been accomplished and what has not been done that may still be of benefit to the patient. This documentation can also be used after the cardiac arrest for feedback and debriefing, and the documentation tool used by the Recorder should be designed with consideration of this potential use.

A potential additional use of the documentation tool that the Recorder uses may be as a cognitive aid to list resuscitation goals. A cognitive aid is a tool that can be used by the resuscitation team during a cardiac arrest to review the sequence of interventions described in a resuscitation algorithm. The design of the documentation used by the Recorder could be such that it incorporates a cognitive aid that allows the Recorder to review the resuscitative efforts against the suggested algorithms. The design of the documentation in this way would allow the Recorder to provide the Leader and team with time lines for interventions during resuscitation. For example, documentation could be designed in 2-minute intervals so that it reminds the Recorder when it is recommended to switch Compressors to prevent fatigue and to check for ROSC. A space for recording the initials of the Compressor and another for noting the state of the circulation every 2 minutes would serve to remind the Recorder of the need for these interventions. Every other 2-minute interval (every fourth-minute interval) could be designated to record the administration of epinephrine that is normally given every 3 to 5 minutes during resuscitation, again prompting the Recorder to note when epinephrine is due or overdue. A check-box at the 6-minute interval could be added to the documentation, asking whether resuscitation continues and if so whether ECMO has been activated. It takes time to assemble the necessary resources for ECMO; however, it is most effective when applied early. If it is forgotten until late in resuscitation, the benefit may be diminished. Six minutes into resuscitation is an appropriate time to consider the activation of ECMO, because it is long enough to show that initial resuscitation and the first dose of epinephrine have failed to have resuscitated the victim, but early enough to allow ECMO to be applied within the first hour of cardiac arrest. Additional check-boxes can be added for reminders of other significant tasks, such as bringing the code cart into the room or notifying the PICU. The design of the documentation tool should include a checklist of important tasks to accomplish that prompt the Recorder to make sure they are done on time. The Recorder can discuss these prompts with the Leader as necessary. Although this discussion with the Leader may be redundant in some cases, redundancy might help prevent

important tasks from being missed during the stress of an intraoperative resuscitation.

POSTRESUSCITATION CARE

Close monitoring of vital-organ perfusion remains a priority in the postresuscitation period. Care should be taken that celebration of the team's success in resuscitation of the child does not interfere with patient care in the postresuscitation period. It is important to ensure that the patient is closely monitored during this postresuscitation period for several reasons.

First, the primary cause of the cardiac arrest may recur. For example, pulseless VT secondary to hyperkalemia from blood products is treated with medications that drive the potassium intracellularly. However, most of these acutely administered therapies do not actually remove potassium from the body (i.e., as opposed to furosemide, sodium polystyrene, and hemodialysis) and thus a rebound phenomenon, recurrence of VT, is not uncommon. It is essential that the team focus on how to fully reverse the primary cause of the event in order to decrease the chance of recurrence. Another example would be if a patient suffered a tension pneumothorax and a PEA cardiac arrest that was successfully treated with needle decompression. In this case, it is essential that the patient then have a chest tube placed to prevent recurrence of the event.

Second, invasive tubes and lines may have been disrupted during the cardiac arrest. In addition, lines placed during a cardiac arrest may not have been placed with the best technique (i.e., not truly sterile or placement not confirmed) because of the complexity of the event. It is essential that the anesthesiologist assess each of these tubes and lines to make sure they are in the location of choice (i.e., the central venous line is venous, not arterial, and in a safe location). Whereas it may not be appropriate to replace a line that was placed without fully using sterile technique in the immediate postresuscitation period, the details of the line placement should be shared with the intensivist who will manage the child later so a risk-benefit analysis about replacing the line and when it is safe to do so can be made.

Third, during reperfusion the patient is likely to be in a state that is more unstable than before the cardiac arrest, especially if it was a prolonged cardiac arrest. If the patient received multiple doses of vasoconstrictors or has elevated levels of endogenous catecholamines, the patient may be hypertensive and have increased cardiac ectopy. On the other hand, such a patient may be hypotensive, have a profound metabolic acidosis, or have developed disseminated intravascular coagulation (DIC) with bleeding. The patient may need interventions to maintain adequate metabolic supply, requiring attention to blood pressure, ventilation, and glucose levels. Avoiding increased metabolic demand involves prevention of hyperthermia and seizures. In the postresuscitation period, blood pressure should be maintained adequate for vital organ perfusion and may require the administration of fluids, vasoactive medication, or pacing. Ventilation should be normocapnic, avoiding hyperventilation and hypoventilation. Blood-glucose levels should also be normalized, avoiding hyperglycemia and hypoglycemia. Whereas it may not be feasible or necessary for the anesthesiologist to start an insulin infusion, particularly if the child is going to be rapidly transferred to the ICU, it is important to check a dextrose stick and remove any glucose-containing fluids that would exacerbate the situation if the child has developed hyperglycemia.

Postresuscitation hyperthermia is common, because patients are often excessively rewarmed. This overwarming can increase metabolic demands, thus worsening outcome, and overwarming should be avoided. In fact, hypothermia may be neuroprotective and has recently been recommended for adult victims of cardiac arrest. The International Liaison Committee on Resuscitation recommends that unconscious adult patients with spontaneous circulation after OHCA be cooled to 32° to 34° C for 12 to 24 hours when the initial rhythm was VF (Nolan et al., 2003). Consideration to cooling should also be given for other rhythms or IHCA. These recommendations are based on the results from two prospective randomized clinical studies that compared hypothermia with normothermia in comatose survivors of cardiac arrest (Hypothermia Study Group, 2002; Bernard et al., 2002). These European and Australian studies excluded children and patients who had cardiac arrests of non-cardiac origin. Animal models of asphyxial arrest are reporting protective effects of hypothermia in rats and piglets (Xiao et al., 1998; Hicks et al., 2000; Hickey et al., 2000; Hachimi-Idrissi et al., 2001; Agnew et al., 2003). A recent multicenter, retrospective cohort study of 79 children who suffered cardiac arrests revealed that hypothermia was disproportionately applied to children at greater risk of a poor outcome, but adjusted analysis found no differences in outcomes based on the use of hypothermia (Doherty et al., 2009). There is currently insufficient evidence to make a recommendation on the use of therapeutic cooling for children resuscitated from cardiac arrest, and randomized controlled trials are ongoing. Thus, at this point, a primary goal of the anesthesiologist should be to avoid hyperthermia.

Finally, a very important issue to address is the role of the anesthesiologist in reporting information about the cardiac arrest to the surgeon, the family, and intensivist who will be caring for the child in the postresuscitation period. Each of these parties will be trying to determine the prognosis for the child. With regard to the intensivist, he or she will want a clear history of the child's baseline neurologic status and how the child was doing medically before the cardiac arrest. They will need details about all of the items on the following list:

1. How the event started
2. The proposed etiology of the event
3. The quality of basic life support and PALS delivered
4. The length of the cardiac arrest

5. The neurologic examination (i.e., pupils, breathing, movement, and drugs that may affect the examination, such as atropine or scopolamine),
6. Procedures that were performed during the event and whether any lines or tubes need to be checked or changed
7. Issues related to postresuscitation care
8. Information that was communicated to the family members (or patient) about the event

It is important to recall that little can be said about a patient's prognosis based on the neurologic examination that takes place immediately after the event. A patient can be fixed and dilated and in status epilepticus but make a full recovery. A patient may receive 90 minutes of compressions, receive ECMO during the event, make a full neurologic recovery; yet there are occasionally patients who have cardiac arrests of short duration who never wake up. Thus, it is important that the anesthesiologist avoid making comments about prognosis when talking to family about the likelihood of recovery.

CPR is not a definitive treatment for cardiac arrest but rather a means of maintaining respiration and circulation until the underlying pathology can be corrected. Because of the limited efficacy of CPR, it is important to identify the underlying pathology as early as possible and correct it so that spontaneous circulation can be restored.

Preparation for cardiopulmonary arrest during anesthetic management begins with an understanding of the surgical and patient-related risk factors and knowledge of the most current CPR recommendations. The anesthesiologist must also have at his or her disposal the appropriate medications and devices, as well as the skills to lead the operating room team in resuscitation. Because pediatric intraoperative cardiac arrest is a rare event, regular education and hands on practice will increase a team's confidence and effectiveness. A patient's chance for survival from intraoperative cardiac arrest will be maximized with thorough education, preparation, and practice.

	Summary: The Role of the Intensivist 1271

In the 1960s and 1970s, pediatric anesthesiologists played a major role in the development of the pediatric intensive care unit (PICU), in part because the applied cardiopulmonary physiology in the operating room experience is similar to the initial resuscitation of patients with rapidly evolving illness such as multiple trauma and septic shock. With modern critical care, the job of the intensivist continues for days and weeks beyond the initial resuscitation.

Critical illness occurs in stages. The acute illness is followed by a plateau phase, which may be prolonged and is poorly understood. The biphasic response to stress exhibited by the hypothalamic pituitary adrenal axis is also poorly understood. In critically ill patients, an initial surge in adrenocorticotropic hormone (ACTH) and cortisol is followed by a prolonged state of decreased ACTH levels and persistently elevated cortisol (Beishuizen and Thijs, 2004). Persistent hypercortisolism may benefit the patient by promoting the availability of fuel substrates and minimizing inflammation, or it may be harmful, causing hyperglycemia, delayed wound healing, immune suppression, and myopathy. The immune or inflammatory response to injury follows a similar pattern (Hotchkiss and Karl, 2003).

An increasing number of studies have focused on long-term functional outcomes, and these are likely to change critical care practice in coming years. For example, although tolerance of relative hypoxia has become the norm for treating patients with acute respiratory distress syndrome (ARDS), outcome

studies show that duration of saturation less than 90%, less than 85%, and less than 80% correlated with impairment in memory, attention, and processing speed, respectively (Hopkins et al., 1999). Pediatric patients undergoing arterial switch, a procedure that should leave them with normal long-term heart function, had a higher than expected incidence of neurodevelopmental disabilities at school age (Mehta and Arnold, 2004). As more information about how to promote good long-term functional outcomes becomes available, our practice will evolve.

The therapies we deliver in the ICU can be inherently dangerous, and the unintended consequences of the care constitute a large part of critical illness. The side effects of critical illness may be short term, merely prolonging ICU stay, or may last a lifetime. An important part of the discipline of critical care is anticipating these consequences. Prompt discontinuation of unnecessary therapies and the timely institution of prophylactic therapies can make a significant difference in the long-term outcomes of critically ill patients.

This chapter is organized by organ systems. In each section, the relevant pathophysiologic processes and support modalities are discussed, with a focus on recent discoveries and current controversies. The goal is to describe practices unique to intensive care, review some well-established protocols, and discuss the scientific foundation for some emerging therapies, as well as to provide a framework for the anesthesiologist who ventures into the ICU for extended periods.

RESPIRATORY SYSTEM

Actual or impending respiratory failure is a common reason for admission to the PICU, and one in six patients admitted requires mechanical ventilation (Epstein, 2009). Although some patients with healthy lungs require mechanical ventilation for nonrespiratory reasons, the majority have acute respiratory failure due to lung parenchymal disease. The treatment of acute respiratory failure remains primarily supportive. The goal of treatment is to avoid further damage to the lungs and other organ systems during the period required for the lungs to heal.

Modes of Mechanical Ventilation in the PICU

Ventilators commonly used in the PICU are capable of sophisticated measurements and analysis of airway pressure, gas flow, and carbon dioxide. All ventilator modes may be understood by identifying the variables that are controlled. In almost all cases, a preset rate is provided. The size of the breath delivered may be controlled either by setting a tidal volume to be delivered or by setting an airway pressure to be achieved.

Volume Control

In volume-control modes, the size of the breath is controlled by targeting a volume to be delivered. The ventilator senses air flow and calculates the volume as a product of flow and time. Most sophisticated volume ventilators measure and adjust the gas delivery on the basis of exhaled tidal volumes. When air leaks from the chest by routes other than the gas delivery circuit (e.g., a bronchopleural fistula or a leak around the endotracheal tube), volume delivery may be inaccurate. When compliance of the respiratory system is poor, a percentage of the tidal volume is lost in the circuit because of expansion of the ventilator tubing. The loss of tidal volume may be estimated using a compliance factor that is specific to the diameter of the ventilator tubing. The most sophisticated ventilators (the Servo 300i, Siemens Medical Solutions, Stockholm, Sweden) can adjust for this inaccuracy if that setting is selected. The most accurate measures of tidal volumes are obtained at the endotracheal tube using an in-line respiratory profile monitor (CO₂SMO Mainstream, Respironics). When the size of the breath is controlled by volume delivered, decreasing compliance in the lung will result in higher pressures achieved. An inspiratory pause gives the pressure in the circuit time to equilibrate between the proximal airway and the alveoli, and will help to determine if the alveoli are being distended by high pressures. In the setting of noncompliant, diseased lung, the duration of inhalation or inspiratory time will affect the pressures achieved in volume control modes.

Pressure Control

In pressure-control modes, the size of the breath delivered is determined by the target pressure and the inspiratory time. Pressure-control modes were developed for use in small infants before sophisticated methods existed to control delivery of very small tidal volumes. The volume delivered at a given airway pressure will depend on the compliance of the lungs. As the patient's disease process resolves and compliance improves, tidal volumes may become large, placing the patient at risk for

ventilator-induced lung injury (VILI). The very high initial flow rates necessary to achieve a given pressure for the duration of the inspiratory time can result in turbulence in a constricted airway, which results in decreased dynamic compliance and smaller tidal volumes delivered.

Pressure-Regulated Volume Control

Pressure-regulated volume control (PRVC) is a volume-controlled mode with a flow pattern similar to a pressure-controlled breath. A target tidal volume is set, and the ventilator applies constant pressure throughout inspiration to achieve that target volume. Volume delivered is measured on exhalation, and the pressure is adjusted in subsequent breaths to deliver the target tidal volume. Because exhalation volume is used to calculate the pressure needed for the next breath, PRVC may not be used when there is significant air leak outside the ventilatory circuit.

PRVC shares with pressure control the advantages of a larger area under the pressure-time curve, leading to higher mean airway pressure (MAP) and improvement in oxygenation. PRVC shares with volume control the safety of a controlled tidal volume that cannot increase as compliance improves or decrease as compliance worsens. This mode is particularly useful when dramatic improvement in compliance is expected, such as after the administration of surfactant. When PRVC is not available as a synchronized mode, significant inspiratory effort may result in breath stacking or extreme variability in tidal volumes delivered. For this reason, PRVC is usually used with very heavy sedation or neuromuscular blockade (or both), except with the Servo 300i, which can provide synchronized intermittent mandatory ventilation with PRVC.

Support Modes

Effort above a preset rate may or may not be supported. The most common form of support is pressure support. Pressure support has been shown to facilitate weaning, and it may also improve patient comfort. Pressure support is frequently used to recondition weakened respiratory muscles while still providing mandatory breaths to prevent atelectasis; however, data to support this approach do not exist (Turner and Arnold, 2007).

Positive End-Expiratory Pressure

All ventilation modes generate inhalation pressures above a set positive end-expiratory pressure (PEEP). The application of PEEP improves functional residual capacity and minimizes shearing forces that result from repeated opening and closing of lung units. Increasing PEEP also increases MAP, which improves ventilation/perfusion (V/Q) matching and oxygenation. High levels of PEEP may impair venous return to the thorax and thus cardiac preload. When there is significant resistance to exhalation, as in status asthmaticus, the patients may have an increase in intrinsic PEEP, which increases the resting lung volume and decreases inspiratory capacity. Intrinsic PEEP can be measured with an expiratory pause pressure.

Noninvasive Positive Pressure Ventilation

Over the past few years, there has been an increase in the use of noninvasive ventilation to prevent or delay endotracheal intubation. Noninvasive positive pressure ventilation (NPPV)

includes continuous positive airway pressure (CPAP), which is used to increase functional residual capacity (FRC) and to overcome inspiratory airway collapse, and biphasic positive airway pressure, which also supports respiratory effort with positive inspiratory pressure. Studies in adults have shown clear benefit to NPPV, especially when endotracheal intubation can be avoided, with no decrement when endotracheal intubation is merely delayed (Pagano and Barazzone-Argiroffo, 2007). NPPV has been demonstrated successfully in pediatric patients with neuromuscular disease, upper airway obstruction, status asthmaticus, and cystic fibrosis (Deis, 2008).

There are many delivery devices for noninvasive ventilation, but most are poorly adapted to infants and toddlers. Skin breakdown under the mask or nasal delivery device is common, so strict attention to skin care is necessary when noninvasive ventilation goes on for more than a few hours. It is ideal to have more than one delivery device (e.g., nasal prongs and a mask) when NPPV is used for more than a few days, as rotation between devices can avoid skin breakdown. These devices are commonly used in the long term at home for children with neuromuscular disease.

Successful use of NPPV requires careful patient selection and close monitoring for signs of response or failure. NPPV should be used in patients with normal mental status and normal airway protective reflexes. Patient cooperation is necessary, and NPPV for a severely anxious patient is unlikely to succeed. It is also not very likely to succeed for patients with poor mask fit, copious secretions, or significant acid-base disturbances. NPPV should not be used in patients with upper gastrointestinal (GI) bleeding, recent upper airway or GI tract surgery, or hemodynamic instability.

Patients on NPPV should be carefully monitored for synchrony between patient and ventilator. A decrease in respiratory rate is a fairly reliable sign of effective response and is usually seen within 1 hour of initiation of therapy. In a patient with severe hypoxemic respiratory failure, converting to endotracheal intubation from a high level of support with NPPV can result in severe desaturations. The decision to intubate should be considered when the patient's fraction of inspired oxygen (FiO_2) requirement rises above 60%.

Ventilator-Induced Lung Injury

Ventilator-induced lung injury is caused by prolonged exposure to high FiO_2 , by alveolar stretch from excessive tidal volumes (volutrauma), and by opening and closing of alveoli (shear stress trauma). Although hyperoxic inspired gas is essential for patients with lung injury, exposure to FiO_2 greater than 95% for 24 to 48 hours causes lung injury similar to ARDS and causes death within 48 to 72 hours due to oxygen toxicity (Adams et al., 2003).

Mechanical trauma from ventilation causes injury both through physical disruption of the architecture of the lung and through release of inflammatory mediators. Atelectrauma, which is thought to occur when PEEP is set below the lower inflection point of the lung hysteresis curve, is particularly problematic in lung disease states associated with surfactant dysfunction, such as ARDS. Patients with heterogeneous lung disease are at increased risk for volutrauma. Transpulmonary pressure is not uniformly distributed to alveoli, and collapsed alveoli adjacent to inflated

alveoli may be subject to extreme shearing forces. Mechanical trauma leads to release of inflammatory mediators, which may spill over to systemic circulation and play a role in the development of multiorgan failure (Plötz et al., 2004; Harris, 2005; Tremblay and Slutsky, 2006).

Use of Lung Hysteresis Curves

More sophisticated ventilators can calculate pressure-volume loops showing the difference in the pressure-volume relationship between the inspiratory and expiratory limbs of the respiratory cycle (Fig. 39-1). The sigmoidal shape of the hysteresis curve reflects differing compliance at different lung volumes. The lower inflection point represents the point during inspiration at which compliance improves. Below this point, the majority of alveoli are closed. The upper inflection point represents another change in compliance. Above a certain volume, more pressure is required to further distend alveoli, and the upper inflection point is thought to represent the beginning of a zone in which further pressure causes significant alveolar strain. The curve is steepest and nearly linear between these points, reflecting maximal compliance. Lung injury is thought to be minimized by keeping PEEP above the lower inflection point to maintain recruitment, and keeping tidal volumes below the upper inflection point by minimizing peak inspiratory pressure (Tremblay and Slutsky, 2006).

FIGURE 39-1. Pressure-versus-volume curve of the respiratory system. **A**, The inflation limb of the curve. **B**, The deflation limb of the curve. The point at which the curve touches the y-axis (zero pressure) is the functional residual capacity (FRC). The lower inflection point (LIP) represents the point during inspiration at which compliance improves. The upper inflection point (UIP) represents the point at which alveolar overdistention leads to worsening compliance. The curve is steepest between these points, reflecting the zone of best compliance. Lung injury is thought to be minimized by keeping positive end-expiratory pressure (PEEP) above the lower inflection point to maintain recruitment, and by keeping tidal volumes below the upper inflection point by minimizing peak inspiratory pressure. Alternative Modes of Ventilation

High-Frequency Oscillatory Ventilation

Despite conventional ventilation strategies to reduce VILI, about one third of patients with ARDS die, and many of the survivors experience a significant decrement in function. The object of high-frequency oscillatory ventilation (HFOV) is to accomplish oxygenation and ventilation with less injury to the lung. HFOV uses laminar flow at high MAPs to maintain the lung open, and it uses an oscillating piston to create pressure displacement above and below the MAP to deliver very small tidal volumes in the range of the volume of the patient's anatomic dead space (Stawicki et al., 2009) (Fig. 39-2). The result, ideally, is ventilation only on the steep and linear part of the hysteresis curve. Compliant alveoli, which might receive an excessively large share of the delivered tidal volume in conventional ventilation, are protected from volutrauma. With this strategy, noncompliant alveoli—those with time constants long enough to preclude opening with conventional ventilation—may be recruited. Recruitment of new lung units may improve V/Q matching. A crossover trial comparing HFOV with conventional ventilation in children with severe lung disease showed that HFOV was associated with improved oxygenation and, despite higher MAPs, a reduced need for supplemental oxygen at 30 days (Arnold et al., 1994).

In HFOV, the variables controlled on the ventilator are frequency of respiration, (measured in cycles per second, or Hertz), amplitude of ventilation (power), and MAP. Frequency is measured in cycles per second. A frequency of 10 is 600 “breaths” per second, and a frequency of 3 is 180 breaths per second. A lower frequency functionally creates a longer inspiratory time and therefore a larger breath. The frequency is initially set at 10 for infants, and somewhat lower for older children. Amplitude, also referred to as *power*, is measured in centimeters of water. There is no standard starting pressure. The amplitude is initially set to produce a visible wiggling motion of the patient's

body to the level of the lower abdomen or groin. MAP is initially set to 5 cm H₂O greater than the last MAP on conventional ventilation (Stawicki et al., 2009). A chest radiograph performed within an hour or two after initiating HFOV should confirm an appropriate MAP setting by showing approximately nine visible ribs from the top of the thorax to the diaphragm.

Oxygenation can be improved by increasing Fio₂, MAP, or bias flow. Bias flow is an auxiliary flow of gas that crosses the oscillating gas flow to provide fresh gases and clear CO₂. Increasing MAP to the point where alveolar distention causes collapse of perialveolar vessels may result in hypotension or hypoxemia that may be responsive to administration of intravascular volume. Lung recruitment often allows a decrease in MAP within the first 24 hours. When the MAP can be weaned to near the last MAP recorded from conventional ventilation, conversion back to conventional ventilation should be considered.

Ventilation can be improved by increasing the amplitude and decreasing the frequency. As the frequency of breaths decreases, a higher percentage of the set amplitude will be delivered. This is like increasing the tidal volume in a conventional ventilator; decreasing frequency is a way to increase ventilation, thereby decreasing P_aCO₂. Frequencies less than 3 (180 cycles per minute) may increase the risk for volutrauma (Stawicki et al., 2009).

Patients on HFOV are usually treated with sedation and neuromuscular blockade. Because they are subject to a constant distending pressure, which may impede venous return, it is important to be attentive to maintaining a good intravascular volume and right ventricular filling pressure. Many patients require intravascular volume loading at the initiation of HFOV. Although nursing staff may be reluctant to suction patients on HFOV, secretions in the endotracheal tube can dramatically attenuate amplitude and should be removed. Finally, the appearance of a patient on HFOV, with the loud noise of the machine's diaphragm and the absence of tidal movement of the chest, can be disconcerting to patient's families. It is best to inform them of what to expect.

■ **FIGURE 39-2.** High-frequency oscillatory ventilation (HFOV). Both graphs depict pressure versus time in HFOV. The graph on the left depicts the ventilator cycle over only a fraction of a second, to illustrate the key variables that are controlled in HFOV. The graph on the right shows the pressure-versus-time curve of HFOV, with conventional ventilation superimposed for comparison. The y-axes are different, reflecting airway pressures in HFOV on the left and pressures in conventional ventilation on the right. The exhalation pressure in HFOV is actually negative, making expiration an active process. (Reprinted with permission from Stawicki SP, Goyal M, Sarani B: High-frequency oscillatory ventilation [HFOV] and airway pressure release ventilation [APRV]: a practical guide, J Intensive Care Med 24:215, 2009.)

For a more complete treatment of the mechanics of HFOV, see Stawicki and colleagues (2009).

Airway Pressure-Release Ventilation

Airway pressure-release ventilation (APRV) cycles between a high- (P_{high}) and a low-pressure level (P_{low}) in a high-flow CPAP circuit (Fig. 39-3). The continuous high flow allows spontaneous breathing throughout the ventilatory cycle, and it may reduce the need for heavy sedation and neuromuscular blockade. Spontaneous breathing is necessary to realize the benefits of this mode of ventilation (Stawicki et al., 2009).

Most of the respiratory cycle is spent at P_{high} , and pressure is briefly released to P_{low} several times per minute. Ideally, time spent at P_{high} will maximize recruitment and, by placing the lung on the steep part of the hysteresis curve, make spontaneous breathing easier. The time spent at P_{low} allows ventilation, but it is believed to be brief enough to prevent atelectasis of alveoli with long time constants (Stawicki et al., 2009).

Initially, P_{high} is set at the plateau pressure measured from an inspiratory pause on conventional ventilation and adjusted to allow weaning of FiO_2 . P_{low} is set at zero to maximize the velocity of exhalation. The time (T) of T_{high} is initially set between 4 to 6 seconds and adjusted to maintain adequate oxygenation and ventilation. T_{low} is set at 0.4 to 0.5 seconds and adjusted to maintain a tidal volume of about 5 mL/kg, or such that expiration ends when the flow reaches 50% to 75% of the measured maximal expiratory flow. T_{low} is the critical variable that affects bulk air flow and thus ventilation. Oxygenation is increased by increasing FiO_2 or by increasing P_{high} or T_{high} , both of which will increase MAP. Ventilation is increased by encouraging spontaneous respiration or increasing T_{low} (Stawicki et al., 2009).

Although it was described in 1987, APRV is relatively new in pediatrics and has not been thoroughly studied. Case reports of APRV in pediatric patients have shown improvement in oxygenation with the ventilation strategy (Krishnan and Morrison, 2007; Kuruma et al., 2008). With a crossover design, the one randomized controlled trial of APRV in children demonstrated comparable ventilation at lower peak inspiratory and plateau pressures (Schultz et al., 2001). The potential advantages of decreasing mechanical ventilatory pressures and allowing spontaneous breathing and a reduced need for sedation and

neuromuscular blockade in patients with severe lung disease make it worth considering despite the paucity of data. APRV may be contraindicated in patients with severe obstruction to exhalation, such as status asthmaticus.

Adjuncts to Mechanical Ventilation for Patients with Severe Lung Disease

Helium-Oxygen Mixtures (Heliox)

Helium is a low-density, biologically inert gas that can be safely mixed with oxygen. When air flow through a tube is turbulent, the flow rate depends on the density of the gas. With high helium concentrations, heliox can flow more rapidly through narrowed airways than nitrogen-oxygen mixtures. Additionally, carbon dioxide diffuses through helium faster than through air. The FiO_2 required by the patient may limit the use of heliox, as minimal benefit is believed to occur from heliox concentrations of less than 60%. When used with a spontaneously breathing patient, efforts should be made to prevent entrainment of room air with a well-fitting nonrebreather mask. Heliox can be delivered through the ventilator but may interfere with tidal volume measurements. This difficulty can be overcome with in-line monitors of respiratory mechanics (Myers, 2006).

Heliox may improve the delivery of nebulized medications. It improves dyspnea and peak expiratory flow in spontaneously breathing asthmatics, and it may limit peak inspiratory pressure in ventilated patients with status asthmaticus (Gupta and Cheifetz, 2005; Kissoon et al., 2008). Heliox improves respiratory distress associated with upper airway obstruction and improves the work of breathing in patients with bronchiolitis (Gupta and Cheifetz, 2005). No adverse effects of heliox have been reported. Despite a widespread belief that early application of heliox can prevent the need for intubation in select patients, there are no studies of heliox directed at patient outcomes.

Prone Positioning

In a supine patient, the dependent lung is underventilated and at risk for collapse, and the antidependent lung is aerated and at risk for overdistention. The mechanism by which prone

■ **FIGURE 39-3.** Airway pressure-release ventilation (APRV). In the pressure-versus-time curve for APRV, spontaneous breaths are present throughout the respiratory cycle. (Reprinted with permission from Stawicki SP, Goyal M, Sarani B: High-frequency oscillatory ventilation [HFOV] and airway pressure release ventilation [APRV]: a practical guide, J Intensive Care Med 24:215, 2009.)

positioning can improve oxygenation is not completely clear, but it may improve V/Q matching by improving the aeration of the dependent lung (Ryu et al., 2008). Prone positioning can also improve lung mechanics by decreasing thoracoabdominal compliance. In adult patients, a protocol of prone positioning for 7 hr/day improved oxygenation but did not alter ventilator-free days or mortality (Gattinoni et al., 2001). In pediatric patients, a protocol of prone positioning for 20 hr/day improved efficiency of oxygenation but did not improve ventilator-free days or organ failure-free days (Curley et al., 2005).

Nitric Oxide

Inhaled nitric oxide (iNO) has been a mainstay of treatment for both primary and secondary pulmonary hypertension of the newborn since its introduction. In these patients, it causes a rapid and sustained improvement in efficiency of oxygenation by preferentially vasodilating ventilated lung units (Konduri and Kim, 2009). Because it is rapidly inactivated by hemoglobin, the effect of iNO is limited to the pulmonary vasculature (Adhikari et al., 2007).

Because the pathophysiology of ARDS and acute lung injury (ALI) involves V/Q mismatching, there has been interest in using iNO for patients outside the neonatal age range. In adult studies, iNO improved oxygenation (i.e., the ratio of pulmonary arterial oxygen pressure [P_{aO_2}] to F_{iO_2} , and the oxygenation index) but did not improve mortality. There has been some concern in adult patients that iNO may be associated with an increase in the need for new renal replacement therapy (Adhikari et al., 2007). In a randomized trial in children, iNO improved oxygenation without harmful side effects from methemoglobinemia at dosages up to 20 parts per million. The study was not powered to detect a difference in mortality (Tang et al., 1998).

Nitric oxide is commonly used at a level of 20 ppm. Very high concentrations of NO may paradoxically worsen V/Q matching by diffusing into nonventilated areas and improving the perfusion there. High concentrations also carry a significantly increased risk for methemoglobinemia. Methemoglobin should be monitored daily while therapy with iNO is used. If methemoglobin becomes elevated, it is usually sufficient to decrease the concentration of iNO. For very high methemoglobin levels, a scavenger, such as methylene blue, may be used. Exposure to NO for even a brief period can sensitize the pulmonary vasculature to its effects. Rapid weaning to low levels (5 ppm) is usually well tolerated, but thereafter, iNO should be weaned slowly to prevent rebound vasoconstriction (Adhikari et al., 2007).

Surfactant

Surfactant deficiency has been described in ARDS and ALI, particularly in the acute phase of the illness. The best-studied application of surfactant is in meconium aspiration syndrome, where significant clinical improvement is reported after surfactant instillation (Willson et al., 2008). Surfactant instillation in infants mechanically ventilated for respiratory syncytial virus disease leads to improvement in oxygenation and decrease in duration of mechanical ventilation (Tibby et al., 2000; Luchetti et al., 2002).

Trials of endotracheal instillation or aerosolization of surfactant in adults have shown little or no benefit. In children, treatment with calfactant, a natural preparation relatively rich in surfactant specific protein B, has been associated with

improved oxygenation and mortality, with particular benefit seen in patients younger than 12 months (Willson et al., 2005). Although this trial generated significant interest in the use of calfactant for pediatric ARDS and ALI, an independent analysis of the data noted that the placebo arm of the trial had more immunocompromised patients, and that statistical significance was lost when controlling for immune status (Czaja, 2007). Surfactant therapy for ARDS/ALI in patients outside of the neonatal age range remains controversial.

Surfactant is administered by direct endotracheal instillation through an endotracheal tube or bronchoscope at a dosage of 100 mg/kg body weight. The total volume of the drug preparation is significant. Complications of surfactant instillation include volume-responsive hypotension and transient hypoxia. Most authors cite pulmonary hemorrhage as a relative contraindication (Willson et al., 2008). Surfactant is probably best used early in the course of mechanical ventilation. Administration of surfactant in patients with severe hypoxia can provoke severe desaturation. In patients with severe hypoxia, surfactant may be safely given while the patient is supported with extracorporeal therapies.

Weaning and Extubation

Mechanical ventilation causes VILI, frequently necessitates invasive monitoring and heavy sedation, and predisposes patients to complications such as ventilator-associated pneumonia and gastric ulcer, so it should be discontinued as soon as the patient is capable of spontaneous breathing. The most common approach to weaning is gradual reduction of mechanical ventilatory support, often using pressure-support modes combined with mandatory breaths. Optimal sedation is crucial to weaning success. Oversedation may decrease respiratory drive, whereas undersedation may increase thrashing and the risk for airway injury, particularly in young children.

Not all patients require gradual weaning. An alternative approach is to perform a daily test of extubation readiness, such as a spontaneous breathing trial, and give higher amounts of support to provide periods of rest for the respiratory muscles between these tests. A third approach is to provide periods of rest interspersed with periods of lower support designed to exercise or train the muscles of respiration. Several adult studies have shown that protocolized weaning results in earlier extubation without an increase in complications (Newth et al., 2009). Studies of weaning protocols in children are ongoing. Pediatric studies have corroborated adult data showing that spontaneous breathing trials with a T-piece (i.e., a tracheotomy tube collar) or pressure support can predict successful extubation (Newth et al., 2009). A negative inspiratory force of -30 correlates with extubation success in adults but has not been validated in children.

Despite weaning and careful testing, 8% to 20% of patients fail extubation. Extubation failure is independently associated with a fivefold increased risk for mortality in children, and upper airway obstruction accounts for or contributes to 25% to 40% of extubation failures (Newth et al., 2009). Testing for a leak around the endotracheal tube may predict post-extubation stridor, particularly in patients with uncuffed endotracheal tubes and those whose intubation has been prolonged. The absence of a leak at 30 cm H_2O does not accurately predict extubation failure, but it is commonly a trigger for the use of steroids.

Dexamethasone given 24 hours in advance of extubation may reduce the inflammation associated with airway injury from the endotracheal tube (Randolph, 2009).

Specific Disease Processes Requiring Mechanical Ventilation

Asthma

Children who are ventilated for status asthmaticus are among the most difficult ventilated patients to manage. Resistance to exhalation may cause intrinsic PEEP, which can profoundly decrease the available inspiratory volume. In severe asthmatics, exhalation is an active process; under neuromuscular blockade, the loss of patient participation in exhalation almost always results in significant worsening of hypercarbia. The most important strategy for mechanical ventilation of the patient with status asthmaticus is to prevent the need for positive pressure ventilation with aggressive bronchodilator and steroid therapy. Helium-oxygen mixtures and intravenous magnesium can be useful adjuncts to these therapies.

NPPV, if applied early in patients with status asthmaticus, can take advantage of patient's respiratory efforts and prevent the muscle fatigue that leads to the need for intubation (Stather and Stewart, 2005). There is evidence that NPPV prevents hospitalization in patients presenting to the emergency department with status asthmaticus. Mental status changes, anxiety, exhaustion, or refractory hypoxemia preclude the use of NPPV, and it is these clinical changes rather than arterial blood gas analysis results that should guide the decision to intubate.

Once the patient is intubated, the primary strategy is to limit gas trapping, which causes intrinsic PEEP and forces the lung to operate on the less compliant portion of the hysteresis curve. Gas trapping is evident in flow-versus-time graphs, where inspiration is seen to start before flow returns to zero, or in graphs of end-tidal CO_2 versus time, where CO_2 fails to reach a plateau before the next inspiration begins (Stather and Stewart, 2005).

Significant controversy exists as to the best method for ventilating asthmatics. There are advocates for both pressure- and volume-control ventilation. Because of the high air-flow rates required to achieve targeted pressure in pressure-control ventilation, this mode may cause more turbulence in the airways of ventilated asthmatics. Volume-control modes may require higher set pressures to deliver adequate tidal volumes; however, because much of the pressure is lost in overcoming proximal airway resistance, alveolar hyperinflation may not occur. Alveolar pressure can be measured with an inspiratory pause pressure; complications are rare when this pressure does not exceed 30 cm H_2O (Stather and Stewart, 2005).

Intrinsic PEEP can be measured with an expiratory pause pressure in a muscle-relaxed patient. Because complete exhalation is the goal, some authors recommend minimizing PEEP with an initial setting from 0 to 5 cm H_2O . Others, acting on the theory that PEEP will stent airways open and ameliorate gas trapping, recommend setting PEEP at or slightly higher than the measured intrinsic PEEP. If a higher-PEEP strategy is used, intrinsic PEEP should be measured frequently, and the ventilator settings should be adjusted accordingly (Stather and Stewart, 2005).

There is general agreement that exhalation time should be as long as possible. Low respiratory rates and short inspiratory

times give maximum exhalation time, but often at the expense of minute ventilation. Permissive hypercapnia (see Acute Respiratory Distress Syndrome and Acute Lung Injury, next) has been successfully used in the ventilation of asthmatics (Stather and Stewart, 2005). With permissive hypercapnia, patient ventilatory dyssynchrony is common. Neuromuscular blockade with adequate sedation is often necessary until severe bronchospasm resolves, usually within 24 hours. Weaning and extubation should be prompt, because spontaneous respiration is favorable for asthmatics. There are no generally agreed on criteria for extubating asthmatics, except that it should be performed as soon as possible. Negative inspiratory pressure with active exhalation is more effective than positive pressure in obstructive lung disease. Blood gas and ventilatory parameters that suggest the patient with asthma is improving include a normalizing partial pressure of CO_2 and pH, and a peak inspiratory pressure that begins to approach the inspiratory pause pressure. The difference between peak inspiratory pressure and inspiratory pause pressure correlates with airway resistance.

Acute Respiratory Distress Syndrome and Acute Lung Injury

The clinicopathologic picture of ARDS and ALI is diffuse alveolar damage, and four clinical parameters are involved: acute onset, severe arterial hypoxemia resistant to supplemental oxygen, bilateral infiltrates, and absence of left atrial hypertension. A $\text{PaO}_2/\text{FiO}_2$ ratio of less than 200 mm Hg defines ARDS, and a ratio of less than 300 mm Hg defines ALI (Randolph et al., 2003).

The most common cause of ARDS and ALI is lower respiratory tract infection, but it can be precipitated by a variety of systemic inflammatory conditions, including infection outside the respiratory tract, pancreatitis, and tissue necrosis. Overall mortality for children ranges between 8% and 15%, which is lower than that for adults (Randolph et al., 2003). Patients with bone marrow transplantation may have a significantly higher mortality. Because of the low mortality in children, duration of mechanical ventilation or number of ventilator-free days are both considered acceptable endpoints for studies of ARDS and ALI.

Although not a predictor of mortality in adults with ARDS, multiple single-center and multicenter studies of the epidemiology of ARDS and ALI in pediatric patients confirm that the ratio of the alveolar oxygen pressure (PAO_2) to FiO_2 at the onset of ARDS or ALI is an independent predictor of mortality (Flori et al., 2005; Erickson et al., 2007). Mortality rates for children with ARDS or ALI from studies in the past 10 years range from 8% to 35% (Willson et al., 2008; Randolph et al., 2003). A recent prospective multicenter observational study of 320 children with ARDS or ALI found that mortality in patients with a $\text{PAO}_2/\text{FiO}_2$ ratio of less than 200 is nearly twice the mortality in those with a ratio between 200 to 300 (26% versus 13%) (Erickson, 2007). The $\text{PAO}_2/\text{FiO}_2$ ratio also predicted the number of ventilator-free days (Flori et al., 2005). The severity of hypoxia is also sometimes measured by the oxygenation index, defined as $(\text{MAP} \times \text{FiO}_2)/\text{PaO}_2$ (Randolph, 2009).

Treatment of ARDS and ALI

Control of a persistent trigger of the inflammatory cascade is critical to eliminating the stimulus for ongoing lung injury. Because inflammation with capillary leak is part of the

pathophysiology of ARDS, patients may benefit from a restrictive fluid strategy (Wiedemann et al., 2006). Fluid restriction should be initiated only after a patient with shock has been adequately resuscitated. Treatment of hypoproteinemia with albumin and furosemide may also be beneficial (Randolph, 2009).

Intensive care unit (ICU) stays for patients with ARDS or ALI may be prolonged, so is important to be attentive to other organ systems and to the prevention of iatrogenic injury. Strategies to avoid ICU-related pneumonia, critical care myopathy, central line infection, deep venous thrombosis, and gastritis, will be discussed later (see Prophylaxis).

Mechanical ventilation strategies for ARDS and ALI are designed to minimize VILI while protecting the patient from profound hypoxia. A P_{aO_2} target of 55 to 80 mm Hg (i.e., an arterial oxygen saturation as measured by pulse oximetry [SpO_2] of 88% to 95%) is commonly recommended for adult patients but may be too low for children, as the effect of prolonged marginal oxygenation on the developing brain is unknown. Most authors recommend an SpO_2 target of greater than 90% for children (Randolph, 2009).

In patients with ARDS and ALI, parenchymal lung damage occurs heterogeneously. The relatively normal aerated lung, which may be a relatively small proportion of the total lung volume, is at risk for overdistention. In 2000, the Acute Respiratory Distress Syndrome Network (ARDSNet) trial, in adults, a strategy aimed at reducing overdistention decreased mortality. The authors recommended reducing plateau pressure to 30 cm H_2O or less by targeting tidal volumes to 6 mL/kg or less. These data have not been replicated in children. Adoption of the target values from the adult study is controversial, particularly for younger children, as their more compliant chest wall and smaller airways may predispose them to atelectasis.

Alveolar collapse is possible with a low tidal volume strategy. Recruitment maneuvers with such a strategy include application of a sustained increase in airway pressure (i.e., a pressure of 40 mm Hg for 40 seconds) with a goal of opening the collapsed lung. After recruitment, PEEP is optimized to maintain the open lung (Randolph, 2009).

Permissive Hypercapnia

If the mode of ventilation that maintains ideal oxygenation and minimizes VILI is not capable of adequate CO_2 exchange, a lower pH and a higher P_{CO_2} may be tolerated. Patients in whom hypercapnia is being tolerated to minimize lung stretch will exhibit increased air hunger and anxiety and will require increased sedation. Hypercapnia is accompanied by acidosis in the acute phase, until renal compensation can buffer the pH. Hypercapnic acidosis (HCA) may benefit patients with ARDS or ALI apart from its association with ventilator strategies designed to decrease lung stretch. HCA increases cardiac output and organ blood flow (Rogovik and Goldman, 2008). It has antiinflammatory effects and attenuates free radical production. It may thus function to attenuate further lung injury from mechanical ventilation and from evolving infection.

HCA may have deleterious effects in select populations. Decreases in neutrophil chemotaxis and in the bactericidal activity of neutrophils and macrophages seen with HCA may be harmful, particularly in patients with sepsis (Curley et al., 2010). HCA increases pulmonary vascular resistance, and therefore it may not be appropriate for patients who are anticipated to

have reactive pulmonary vasculature, particularly those in the neonatal age range (Curley et al., 2010). The increase in organ blood flow with HCA can cause increased intracranial pressure (ICP) in at-risk patients. Higher levels of CO_2 are not believed to damage the brain, but rigorous long-term outcome studies in children have not been done (Curley et al., 2010).

Extracorporeal Membrane Oxygenation

Despite all the innovative therapies, deterioration of lung function in patients with acute respiratory failure may lead to a requirement for 100% oxygen and high ventilatory pressures. In some of these patients, extracorporeal membrane oxygenation (ECMO) can ensure adequate oxygenation and ventilation without high F_{iO_2} and without potentially injurious airway pressures, allowing time for the lungs to heal. ECMO has been a particularly effective treatment for neonates with persistent pulmonary hypertension of the newborn: the use of ECMO reduced mortality in this group from between 80% and 85% to about 20% (Roy et al., 2000). Although older trials had suggested that ECMO for acute respiratory failure in adults was futile, the Extracorporeal Life Support Organization registry reports a survival rate of 53% for the small number of adult patients treated with ECMO for respiratory failure (Zapol et al., 1979; Conrad et al., 2005). A recent randomized trial of ECMO for adults with acute respiratory failure found the therapy effective in terms of improving survival without disability, and in terms of cost effectiveness (Peek et al., 2009). The use of ECMO was associated with an improved survival in pediatric patients with respiratory failure (Green et al., 1996). In pediatric patients, the mortality reported by the Extracorporeal Life Support Organization registry was 56% (Conrad et al., 2005). A randomized controlled trial of ECMO in pediatric patients was attempted but failed because of an overall decrease in mortality, probably resulting from lung-protective ventilation strategies.

The general indication for ECMO is reversible lung disease that prevents adequate oxygenation with conventional therapy, or shock refractory to medical treatment in a patient who is believed to have reversible disease (see ECMO for Circulatory Support of the Patient with Shock, later).

It is difficult to precisely identify the indications for ECMO for the patient with respiratory failure. The issue is clearer in neonates, who may be expected to have a relatively rapid resolution of pulmonary hypertension and a good outcome with extracorporeal therapy. Before the advent of high-frequency oscillating ventilation and nitric oxide, an oxygenation index of 40 was the criterion for considering ECMO. A recent review of 174 newborns with respiratory failure suggested that using a lower oxygenation index (the authors suggested 33.2) as the criterion for ECMO resulted in a lower mortality rate and a lower rate of chronic lung disease (Bayrakci et al., 2007). As mechanical ventilation becomes more sophisticated, it becomes more difficult to identify its moment of failure. With continuous innovation, it is also difficult to collect historical data for criteria that would identify patients in whom mortality with conventional ventilation exceeds the expected mortality with ECMO.

ECMO should be considered in a patient with high airway pressures and high F_{iO_2} , who may be expected to require a long course of mechanical ventilation, or when the clinician believes that the probability of chronic lung disease induced by mechanical ventilation outweighs the risk of ECMO. The best

outcomes are seen in patients with single-organ dysfunction and viral pneumonia. Mortality is highest in patients with trauma, immune suppression, or multiple-organ dysfunction syndrome (MODS) at the time of ECMO initiation. Most authors consider prolonged ventilatory course (>10 to 14 days) with high pressures and high F_{iO_2} to contraindicate ECMO, because significant VILI has already occurred (Frenckner and Radell, 2008). Survival to hospital discharge is less likely in patients who have been ventilated longer than 10 days (Nehra et al., 2009). Absolute contraindications to ECMO include conditions that make cannulation impossible, including severe prematurity or small size (e.g., infants <34 weeks old and weighing <2 kg), any condition that would preclude systemic heparinization (e.g., major coagulopathy, active hemorrhage, or recent intracranial hemorrhage), or conditions amenable to surgical repair (e.g., total anomalous pulmonary venous return and lethal anomalies).

Once the need for ECMO is identified, the route of cannulation must be determined. Venoarterial ECMO, usually performed through the jugular vein and carotid artery, is used to provide both respiratory and cardiac support. In patients with respiratory failure who lack a significant component of cardiac insufficiency, venovenous ECMO may be preferable. Venovenous ECMO eliminates the risk for arterial embolic events and preserves the carotid artery, but, because of the inevitable recirculation, it may not allow complete oxygenation.

When ECMO is initiated, the ventilator is adjusted to settings that allow the lung to rest. Generally, this means reducing the F_{iO_2} to 21% and the airway pressures to the minimal settings that allow some lung inflation. In patients older than neonates, it can be very difficult to reopen lungs that have completely collapsed on ECMO.

The pulmonary hypertension that leads to neonates requiring ECMO resolves in a few days, but the lung damage that leads to pediatric patients requiring ECMO is much slower to heal. For pediatric patients, the mean time on ECMO is almost 2 weeks (Frenckner and Radell, 2008; Nehra et al., 2009). A recently published 8-year experience with ECMO from Massachusetts General Hospital described an average duration of ECMO for respiratory failure of 274 hours (11.4 days), with a range of 1 to 1154 hours (48 days) (Nehra et al., 2009). The duration of a course of ECMO should be considered on a case-by-case basis. In general, it is reasonable to continue ECMO support for a pediatric patient with respiratory failure until there is clear evidence that pulmonary disease is irreversible, or until complications preclude survival.

Every day on ECMO increases the risk for complications. Bleeding occurs in up to 16% of pediatric patients on ECMO, and it is most commonly seen at surgical sites, at cannula sites, and in the GI tract. Complications related to the ECMO circuit (e.g., oxygenator failure, cannula dysfunction, tubing rupture, pump malfunction) occur for 14% of pediatric patients (Frenckner and Radell, 2008). During prolonged ECMO runs, attention to the support and preservation of extrapulmonary organ systems becomes paramount. Patients who may require ECMO should be sent to a center with expertise in the procedure before the severity of lung disease prevents safe transport.

For a thorough review of management of the patient on ECMO, see Frenckner and Radell (2008). For the most complete resource on ECMO management, see Van Meurs and colleagues (2005).

CARDIOVASCULAR SYSTEM

Treatment of shock is the mainstay of emergent support of the cardiovascular system in the pediatric ICU. It is difficult to determine what percentage of shock seen in pediatric patients presenting to the PICU is septic shock, because nearly three fourths of children admitted to the PICU meet the criteria for systemic inflammatory response syndrome (SIRS) (Carvalho et al., 2005; Wessel and Laussen, 2006). Therefore, recommendations for treatment of shock are skewed toward SIRS, probably the most common cause of shock in the PICU. Despite their disparate causes, the various types of shock share a common pathophysiology and treatment, and classifying shock by etiology is not particularly useful in children. Pediatric patients with septic shock present with elements of hypovolemic, cardiogenic, and distributive shock (Zanotti-Cavazzoni and Dellinger, 2006).

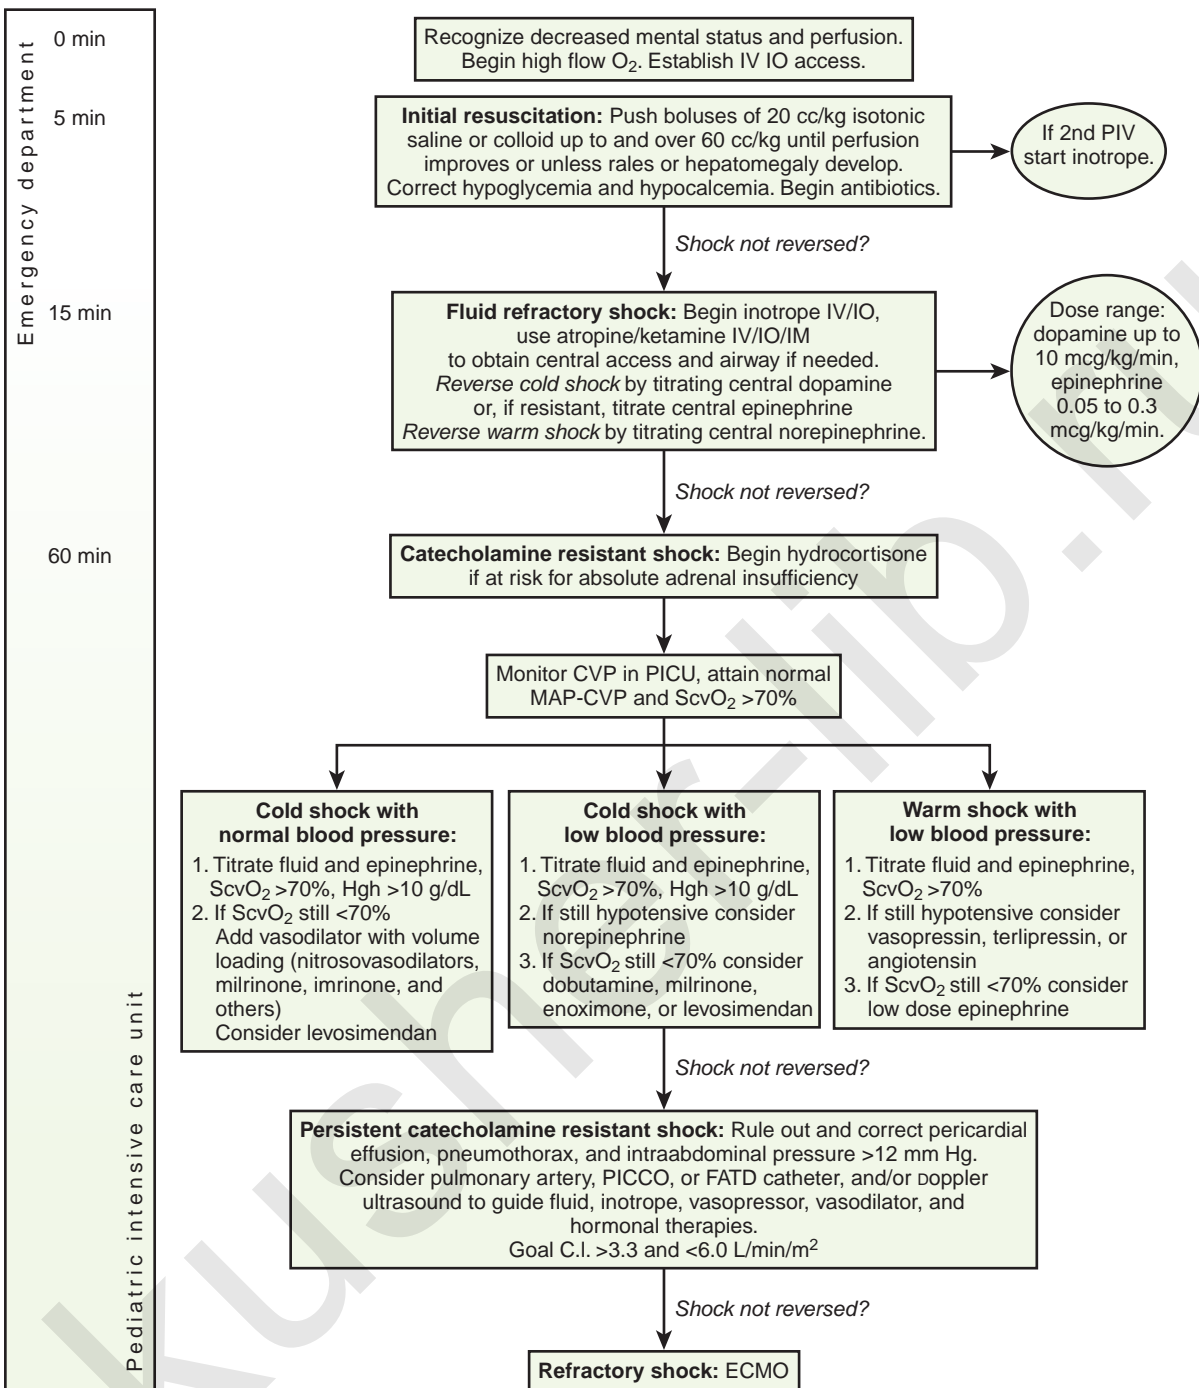

Rapid resuscitation and management of shock are critical to the treatment of children with shock, and diagnosing the type of shock is secondary to initiating resuscitation (Brierley et al., 2009). Aggressive fluid resuscitation and initiation of inotropes and antibiotics should be accomplished within the first hour after presentation. In adults, an early and aggressive protocol for septic shock has proved vastly more effective than any pharmacologic intervention (Rivers et al., 2001). Pediatric shock resuscitation protocols call for symptomatic treatment of shock using clinical signs as endpoints. The guidelines are divided into specific tasks to be accomplished in the first 5 minutes, the first 15 minutes, and the first hour (Fig. 39-4). The guidelines from the American College of Critical Care Medicine (ACCM) have resulted in improved outcomes for children with septic shock (Han et al., 2003; de Oliveira et al., 2008).

Recognition of Shock and Initial Resuscitation

Outcomes are improved if shock is recognized by its early signs, before the onset of arterial hypotension (Han et al., 2003). Because of children's capacity to increase systemic vascular resistance, they may be normotensive in shock. Tachycardia is a sensitive but nonspecific indicator. Prolonged capillary refill in a central location, particularly when combined with tachycardia, is a more specific indicator of shock. Once the diagnosis of shock has been made, resolution of tachycardia is a useful indicator of successful treatment. Severe tachycardia (>180 beats/min in a child younger than 1 year, or >140 bpm in a younger child) in a severely ill child may be rapidly followed by a precipitous decline in blood pressure (Dabrowski et al., 2000). Treating shock in a timely manner, before hypotension develops, may prevent circulatory collapse.

The two distinct clinical presentations of shock are warm shock (characterized by full, bounding pulses, warm skin, and hypotension) and cold shock (characterized by hypotension and delayed capillary refill). Warm shock is more common in adults, but it is present in only 20% of children who present with septic shock (Zanotti-Cavazzoni and Hollenberg, 2009). Particularly in patients with cold shock, tissue hypoperfusion begins to occur long before compensatory mechanisms fail and hypotension develops (Dabrowski et al., 2000).

Shock resuscitation should begin with assessment of the airway, breathing, and circulation. All children with suspected shock should receive supplemental oxygen. Pulse oximetry is

■ **FIGURE 39-4.** American College of Critical Care Medicine guidelines for resuscitation of pediatric patients with septic shock. (From Brierley J, Carcillo JA, Choong K, et al: *Clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock: 2007 update from the American College of Critical Care Medicine*, Crit Care Med 37:666, 2009.)

useful, not only to monitor adequacy of oxygenation but also because a poor signal indicative of poor perfusion may prompt a more aggressive resuscitation. Children with shock and severely increased work of breathing, or a Glasgow Coma Scale of less than 8, are at high risk for respiratory arrest, and the airway should be secured. Although etomidate as an induction agent favors hemodynamic stability, it impairs steroidogenesis and has been associated with increased mortality in patients with septic shock (Hildreth et al., 2008; Cuthbertson et al., 2009).

Ketamine, because of its favorable effects on hemodynamics and its antiinflammatory properties, may be the drug of choice for intubating patients in shock (Lois and De Kock, 2008).

Vascular access should be established as quickly as possible. Clinicians should have a low threshold for using the intraosseous route. Central venous access is recommended for fluid refractory shock, but resuscitation should begin via intravenous or intraosseous access (Brierley et al., 2009). Anything that can be given through an intravenous line can be given via

the intraosseous route. For a child with impaired perfusion, the time to central circulation for drugs administered via the intraosseous route may be shorter than for drugs given through a peripheral intravenous line. A bedside glucose test is appropriate for any acutely ill child, as high metabolic rates and limited glycogen stores predispose infants and small children with sepsis to hypoglycemia. Hypocalcemia is an easily reversible contributor to myocardial dysfunction. An ionized calcium level should be obtained, and hypocalcemia should be treated in the initial phase of resuscitation (Brierley et al., 2009).

Fluid resuscitation should be accomplished as quickly as possible. No consensus exists with regard to the use of crystalloid versus colloid (Brierley et al., 2009). The most common initial resuscitation fluid is normal saline. Crystalloid resuscitation should be delivered in 20 mL/kg aliquots to most patients in 15 minutes or less (Brierley et al., 2009). Because it is impossible to administer large volumes rapidly via a standard intravenous pump, resuscitation fluids need to be pushed by hand in children larger than 10 to 15 kg. Children with shock may require large volumes of fluid resuscitation, often in excess of 100 mL/kg, and increased fluid requirements may persist for several days (Carcillo and Fields, 2002). Children can develop severe hypovolemia before presenting with obvious shock. They may also have significant ongoing losses from the intravascular space as a result of capillary leak. Outcomes are improved when at least 60 mL/kg are given within the first hour of resuscitation (Carcillo et al., 1991). Large volumes of fluid given to pediatric patients with shock have not been shown to increase the rate of ARDS (Carcillo et al., 1991). Fluid resuscitation should continue until there is clinical improvement, with normalization of heart rate, perfusion, and mental status, or evidence of a hypervolemic state. Smaller fluid boluses (5 to 10 mL/kg) should be considered in some patients, particularly neonates and patients with suspected heart disease. The relatively thick right ventricle of the newborn may be less compliant and therefore less able to tolerate larger fluid boluses.

Fluid Refractory Shock

Vasoactive agents are an important adjunct to the stabilization of children in shock, but they should not be considered a replacement for adequate fluid resuscitation. Current ACCM guidelines recommend beginning with an inotrope (dopamine, up to 10 mcg/kg per minute, or lower-dosage epinephrine, beginning at 0.05 mcg/kg per minute). Mortality increases with delay in initiation of inotropes. Inotropes may be given through peripheral venous access (with close monitoring of the access site) or through an intraosseous line (Carcillo et al., 1991). In patients who require vasoactive medications, central venous access should be established. Warm shock should be treated with norepinephrine delivered via a central line (Carcillo et al., 1991).

Catecholamine-Resistant Shock

When shock is not reversed by the addition of centrally delivered inotropes or vasopressors, adrenal insufficiency should be considered (Carcillo et al., 1991). The diagnosis of relative adrenal insufficiency in patients with septic shock is controversial. Hypothalamic pituitary adrenal axis suppression can occur in patients with sepsis by a variety of mechanisms, as a result of dysfunction at any point along the hypothalamic pituitary

adrenal axis. A landmark study by Annane and colleagues (2002) found an improvement in mortality rates when septic patients with relative adrenal insufficiency were treated with steroid replacement. This study found a high incidence of relative adrenal insufficiency, which was probably related to a high rate of etomidate exposure in these patients, leading the author to recommend abandoning the use of etomidate (Annane, 2005). A subsequent multicenter randomized controlled trial failed to find a mortality benefit, although corticosteroid replacement did *hasten* reversal of shock in patients when shock could be reversed (Sprung et al., 2008). Exogenous corticosteroids have been shown to improve the vascular response to exogenous catecholamines in patients with shock (Oppert et al., 2005). The definition of an adequate circulating cortisol level is a subject of debate and probably depends on the severity of the illness. The most widely accepted definition in adults is a serum cortisol level of less than 15 mcg/dL, or an increase of less than 9 mcg/dL after ACTH stimulation (Annane et al., 2000). Because the dosage used in the ACTH stimulation test is supraphysiologic, some question its usefulness in identifying patients who could benefit from steroid replacement. Current recommendations for adult sepsis recommend use of low-dosage steroids (<300 mg/day of hydrocortisone) for shock that is resistant to fluid resuscitation and catecholamines without use of ACTH stimulation test (Dellinger et al., 2008; Marik et al., 2008). Because the P450 cytochrome system, which is responsible for steroidogenesis, matures to an adult level of functioning by about 1 year of age, infants and young children are at higher risk for adrenal insufficiency (Bartelink et al., 2006; Masumoto et al., 2008; Fernandez and Watterberg, 2009).

Adrenal insufficiency should be suspected in patients with fluid- and catecholamine-resistant shock who have risk factors for adrenal insufficiency, including a history of systemic steroid use, with a rapidly evolving purpuric rash, a history of panhypopituitarism, or exposure to etomidate (Brierley et al., 2009). The ACCM guidelines recommend hydrocortisone replacement for children with risk factors for adrenal insufficiency and catecholamine-resistant shock and for those with shock and inadequate response to the corticotropin stimulation test (peak cortisol, <18 mcg/dL after stimulation) (Brierley et al., 2009). A cortisol level should be drawn before the first dose of hydrocortisone. It is not always possible to wait for results of a stimulation test before initiating steroid replacement therapy. The recommended dosage for hydrocortisone ranges from 2 mg/kg per day (stress dosage) to 50 mg/kg per day (shock dosage) (Brierley et al., 2009). The dosage may be titrated to resolution of shock. Results of serum cortisol, when available, may lead to discontinuation of replacement hydrocortisone. The patient should be weaned from steroid therapy as soon as hemodynamics allow, because the impact of exogenous stress-dosage steroids on sensitive elements of the immune system is not fully understood. Prospective randomized controlled trials in children have not been done.

Increasing Oxygen Delivery and Normalizing Perfusion

The 2007 clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock from the ACCM recommend use of clinical goals to direct shock resuscitation in the first hour. Shock resuscitation should be continued until therapeutic endpoints are reached (Box 39-1). Adult studies have shown improved outcomes when therapies for shock are titrated

Box 39-1 Therapeutic Endpoints for the Resuscitation of Shock

FIRST HOUR

- Maintain airway, oxygenation and ventilation
- Maintain hemodynamic variables
 - Heart rate below the 98th percentile of normal
 - Blood pressure above the 5th percentile of normal
- Maintain clinical indices of perfusion
- Capillary refill < 2 seconds
- Normal pulses, with no differential between central and peripheral pulses
- Warm extremities
- Urine output > 1 mL/kg per hour
- Normal mental status

BEYOND THE FIRST HOUR

- All of the above, plus the following:
- Perfusion pressure (mean arterial pressure and central venous pressure appropriate for age)
- Venous oxyhemoglobin saturation (Svo₂) > 70%
- Cardiac index > 3.3 L/min per square meter; < 6 L/min per meter-squared

Adapted from Brierley J, Carcillo JA, Choong K, et al: Clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock: 2007 update from the American College of Critical Care Medicine, *Crit Care Med* 37:666, 2009.

to maximize oxygen delivery, using venous oxyhemoglobin saturation (Svo₂) as a surrogate (Rivers et al., 2001). After the first hour of resuscitation in children, shock management should be directed to generating an Svo₂ of greater than 70% and, when pulmonary artery (PA) catheters are used, a cardiac index of 3.3 to 6.0 L/min per square meter (Brierley et al., 2009). A low Svo₂ may be treated with increasing inotropes or with blood transfusion, aiming for a hemoglobin level of about 10 mg/dL.

In adults, the use of PA catheters has not been shown to improve mortality, but comparable studies have not been done in children. PA catheters have been shown to identify incorrect assessment of hemodynamic status made on the basis of clinical parameters in children (Ceneviva et al., 1998). PA catheters may be useful in children when therapy directed by central venous pressure and Svo₂ is inadequate to reverse shock (Carcillo and Fields, 2002).

Children with cold shock and with poor perfusion often benefit from a reduction in cardiac afterload. Phosphodiesterase inhibitors such as milrinone are useful adjuncts to adrenergic agonists in these patients. Many of these children already have maximal adrenergic stimulation of the myocardium (whether exogenous or endogenous) and can benefit from the alternative pathway to increased inotropy provided by milrinone. As phosphodiesterase inhibitors are initiated, many patients will require further volume expansion. Loading dosages of phosphodiesterase inhibitors (e.g., milrinone) should not be used in pediatric patients with shock. Continuous intravascular monitoring is necessary when afterload reducers are used for patients with shock.

Vasopressin has been used in catecholamine refractory shock, particularly in the setting of decreased vascular tone. Children with severe shock often have high levels of endogenous catecholamines and some degree of catecholamine resistance.

This, coupled with the fact that catecholamines have some unfavorable effects on immune function and catabolism, have led investigators to consider other biochemical pathways to reverse shock. Vasopressin is a powerful vasoconstrictor, but at low dosages it has organ-specific vasodilatory effects (Holmes et al., 2003). Vasopressin deficiency has been described in vasodilatory shock states in both adults and children (Landry et al., 1997; Lodha et al., 2006). Studies in adults have shown that vasopressin improves blood pressure and urine output and allows lowering of the dosage of norepinephrine; however, a recent large randomized controlled trial of low-dosage vasopressin infusion found a good safety profile but no impact on mortality when compared with norepinephrine alone (Russell et al., 2008).

Vasopressin and its synthetic analogue, terlipressin, have been used in children in two ways: as a rescue therapy for severe shock, and as a catecholamine-sparing hormone replacement. Case series of the use of vasopressin in patients with refractory shock have described the use of dosages in the range of 0.0001 to 0.08 units/kg per minute (Matok et al., 2005; Choong and Kissoon, 2008; Yildizdas et al., 2008). When vasopressin is used as a hormone replacement, it is not titrated to clinical effect but used as a low-dosage continuous infusion. The only pediatric randomized controlled trial so far used a dosage of 0.0005 units/kg per minute, as in adult trials, and found an increase in MAP but no differences in time to hemodynamic stability or other clinical outcomes (Choong et al., 2009).

Reassessment of Fluid Balance and Hemodynamic Profile

Serial reassessments of patients admitted with shock are critical to good outcomes, and require continuous and meticulous attention to the maintenance of optimal preload, contractility, and afterload. Shock in neonates and children is more variable than in adults. Children who present in warm shock with an increased cardiac output and low systemic vascular resistance often progress to cold shock with myocardial dysfunction within 24 hours. Shock that is refractory to fluid resuscitation and vasoactive agents should prompt review of volume status. A high percentage of patients who have persistent shock after volume resuscitation have an underfilled ventricle, seen by echocardiography (Jardin et al., 1999). It should also raise the possibility of alternative diagnoses, including acquired cardiac disease, obstructive etiologies, toxins, occult blood loss, and inborn errors of metabolism.

Other Causes of Shock

Once shock resuscitation is initiated, the clinician should begin to consider the causes. Septic shock is the most common etiology of shock in the PICU. In patients with persistent shock, mechanical obstruction to flow in the form of pericardial effusion or elevated intraabdominal pressure should be considered. Other causes of shock, including occult hemorrhage, toxicologic causes, and acquired heart disease, should be addressed.

Causes of shock in the neonatal age range include congenital heart disease, particularly ductal-dependent lesions. An infusion of prostaglandin E₂ should be started immediately in neonates with shock until a ductal-dependent congenital heart lesion can be ruled out. Prostaglandin may cause apnea at higher dosages. Very young infants still transitioning from fetal to neonatal circulation are also at high risk for pulmonary hypertension and right-sided heart failure. Acidosis from

shock and hypoxia can trigger this pathophysiology. Therapies that reduce pulmonary arterial pressure, including supplemental oxygen, sedation, maintenance of an alkalotic pH, and nitric oxide, are commonly needed for neonates with fluid-refractory shock and may be started empirically if necessary (Carcillo and Fields, 2002). Particular attention should be paid to maintenance of adequate temperature and glucose level in neonates with shock.

Early antibiotic administration is a high priority in patients presenting with septic shock. In adults with septic shock, a delay in antibiotic therapy is associated with worse survival, with mortality rates increasing by 7% for every 30 minutes that passes without delivery of appropriate antibiotic therapy (Kumar et al., 2006). Cultures are extremely important, but antibiotics should not be delayed if it is difficult to secure appropriate samples. In particular, lumbar puncture should be deferred until the patient is more stable and an evaluation of the coagulation system can be performed.

ECMO for Circulatory Support of the Patient with Shock

Shock that is refractory to medical interventions may be treated with extracorporeal support. ECMO for pediatric circulatory support was used in 29% of all cases in 2004, but most of these were cardiac patients requiring perioperative support (Conrad et al., 2005). Shock related to acute fulminant myocarditis has been successfully treated with extracorporeal support, with survival rates approaching 80% for patients on ECMO (Duncan et al., 2001). ECMO may be a bridge to myocardial recovery or to heart transplantation in these patients. It may be more effective in the support of shock characterized by inadequate cardiac output than of shock with a prominent component of vasoplegia or failure of oxygen extraction.

The use of ECMO for other causes of shock is uncommon and poorly studied. Historically, sepsis was considered a contraindication to ECMO because of concerns that the circuit would become irreversibly contaminated, but today, sepsis causing pulmonary hypertension is a standard indication for ECMO in neonates. Randomized controlled trials of ECMO for refractory septic shock are not possible, because the condition is rare and the options for treatment are few. A recent single-center report of 45 pediatric patients treated with ECMO for refractory circulatory failure due to sepsis, collected over 18 years, is the largest study published to date. These authors reported a 47% survival to hospital discharge despite the fact that 91% of the patients had three or more organ failures (Maclaren et al., 2007). Estimates of mortality without ECMO in case series of patients in which ECMO was used for this indication support the idea that ECMO as a treatment for septic shock significantly improves mortality rates (Bartlett, 2007). The reported average durations of ECMO for sepsis-related circulatory failure are 137 hours and 76 hours in case series of 9 and 12 patients, respectively (Beca and Butt, 1994; Goldman et al., 1997).

ECMO should be used for refractory shock when the clinician believes that other options are exhausted and the patient is unlikely to survive without it. In the treatment of septic shock, ECMO provides the treating team time to identify and treat the infectious agent, and it eliminates the problems of high dosages of vasoactive drugs and the toxicities associated with treatment of patients with ALI related to systemic inflammation.

Cardiac Arrest in Children

Management of the Patient after Cardiac Arrest

Protocols for the management of pediatric cardiac arrest have been developed by the American Heart Association and are covered in Chapter 38, Cardiopulmonary Resuscitation. The focus here is on the care of children after the return of spontaneous circulation.

The most important treatment for pediatric cardiac arrest is prevention. Because pediatric cardiac arrest is not usually sudden in onset, a window of opportunity exists in the period before it occurs. Medical emergency teams designed to respond to patients in danger of decompensation have been shown to decrease hospital mortality rates and the frequency of more serious codes (Topjian et al., 2009). In addition to early recognition of impending cardiac arrest, extracorporeal cardiopulmonary resuscitation (ECPR) has been used in an attempt to improve these outcomes. Intact survival from isolated respiratory arrest is the rule, but outcomes from in-hospital pediatric cardiac arrest remain poor. Return of spontaneous circulation is established in one half to two thirds of cases of in-hospital arrest, but less than 18% of patients survive with good neurologic outcome (Nadkarni et al., 2006). Survival rates and neurologic outcomes for out-of-hospital cardiac arrest are much poorer (Young et al., 2004). Cold-water submersion for cardiac arrest, even for relatively long duration, may be associated with a much higher rate of intact survival.

Extracorporeal Cardiopulmonary Resuscitation

Multiple physicians have examined the application of extracorporeal therapy as a rescue therapy during cardiac arrest before the return of spontaneous circulation. Survival to hospital discharge in these case series is surprisingly high—35%—despite a relatively long median duration of cardiopulmonary resuscitation (CPR) before the establishment of flow on ECMO (mean duration of 50 minutes) (Morris et al., 2004). With ECPR, survival to hospital discharge does not correlate with duration of CPR before ECMO. Neurologic outcomes have been encouraging: good neurologic outcomes are reported in greater than 75% of patients (Huang et al., 2008; Prophan et al., 2009). It is important to select patients who have a reversible disease process for use of ECPR.

Management of Hypoxic-Ischemic Brain Injury after Resuscitation

Strategies aimed at preservation of brain function after cardiac arrest have been reported in adults and are under investigation in children. There is no single measure to decrease the impact of cardiopulmonary arrest on the brain.

Postischemic cytotoxicity occurs in animal models, so eliminating pathologic states known to increase active cerebral metabolism, such as seizure or hyperthermia, may be beneficial. The majority of cell injury may occur during the initial hypoxic ischemic event. However, cell death from apoptosis and as a result of reperfusion continues after the initial insult. After the event, an initial period of hyperemia is followed by a period of delayed postischemic hypoperfusion. Therapeutic strategies aimed at controlling this delayed cell death include maintenance of normoglycemia; avoidance of oxygen toxicity;

control of states characterized by increased cerebral metabolic rate, such as seizures and hyperthermia; and the application of therapeutic hypothermia.

Controlled hypothermia is associated with improved mortality rates and improved functional outcome after cardiac arrest in adults and in neonates with birth asphyxia (Bernard et al., 2002; Hypothermia after Cardiac Arrest Study Group, 2002; Gluckman et al., 2005; Shankaran et al., 2005). It is difficult to extrapolate these findings directly to children, because the circumstances surrounding cardiac arrest in children are different from those in adults. Ventricular fibrillation is the most common cause of cardiac arrest in adults, but cardiac arrest in children is predominately caused by asphyxia. Asphyxial arrest occurs after a period of hypoxia, and the total duration of cerebral insult (hypoxia plus anoxia) may be very long. Ischemic injury may be seen in brain cells after relatively short periods of interrupted circulation if they are preceded by a period of hypoxia (Vaagenes et al., 1997).

Clinical trials of therapeutic hypothermia after cardiac arrest in children are ongoing. Although there are not yet randomized controlled data supporting controlled hypothermia for pediatric patients after cardiac arrest, it is being used in the United States “consistently” by 9% of the pediatric intensivists surveyed and “sometimes” by 38% (Haque et al., 2006). Target temperatures vary widely, with most using temperatures of 32° to 35° for 12 to 24 hours (Haque et al., 2006). It is relatively labor intensive to rapidly achieve and maintain hypothermia. Neuromuscular blockade may be necessary to control shivering. Slow and controlled rewarming (0.5° C every 2 hours) is an important part of this therapy. Vigilance during the rewarming phase is necessary to avoid hyperthermia, which is known to exacerbate ischemic brain injury, but also to allow careful monitoring of the blood pressure and electrolyte disturbances that are common with rewarming (Wang et al., 2009; Fink et al., 2010a, 2010b). In a retrospective analysis of children after cardiac arrest, there was no increase in the number of hypothermia-associated adverse events in patients who received this therapy (Doherty et al., 2009).

Hypoglycemia has a synergistic, deleterious effect when coupled with neonatal asphyxia (Lubchenco and Bard, 1971). Hyperglycemia has been shown to be detrimental after near-drowning and traumatic brain injury, and, in general, glucose-containing solutions are not used in the first 48 hours after brain injury in older children (Ashwal et al., 1990; Chiaretti et al., 2002). Both hypotension and hypertension during reperfusion have been shown to have deleterious effects in animal models (Miller and Myers, 1972; Bleyaert et al., 1980).

Oxygen toxicity is posited to play a role in postischemic reperfusion injury. The brain is susceptible to oxygen free-radical damage (Siesjö et al., 1989). On the basis of this, there has been some interest in using room air to resuscitate newborns, particularly those with preserved circulation (Ten and Matsiukevich, 2009). In older patients, avoidance of hyperoxia may be beneficial.

Seizure activity increases cerebral metabolic rate and may worsen ischemic injury. Subclinical seizure activity is common after cardiac arrest, particularly in patients treated with therapeutic hypothermia, because of the requirement for neuromuscular blockade. Prophylactic use of antiepileptic drugs in patients who require paralysis is reasonable (Abend et al., 2009).

Prediction of Outcome after Cardiac Arrest

Attempts to use variables such as duration of cardiac arrest, initial pH, or early neurologic examination to predict neurologic outcome after cardiac arrest in children have been misleading. Electroencephalography can provide some prognostic information. The burst suppression pattern seen on the electroencephalogram after cardiac arrest is sensitive and specific for poor outcome (Wijdicks et al., 2006). No single test has been validated to predict outcome with a high sensitivity and specificity. High-quality CPR, and well-established ventilation and oxygenation in the period before the return of spontaneous circulation or the establishment of ECMO flow, may be the best predictors of outcome (Topjian et al., 2009).

RENAL SYSTEM

Fluid Balance and Renal Replacement

Fluid overload and renal insufficiency are common in critically ill patients because of requirements for fluid resuscitation, medications, and blood products. Fluid overload is associated with increased incidence of multiorgan failure in critically ill adults and children (Schuller et al., 1991; Rosenberg, 2003; Goldstein et al., 2005). Decreased fluid overload is associated with improved outcomes in neonates on ECMO, adults with ARDS, and children requiring continuous hemofiltration (Kelly et al., 1991; Foland et al., 2004; National Heart, Lung and Blood Institute, 2006). Diuretics and fluid restriction are routinely used to ameliorate the fluid overload accumulated with initial resuscitation. Fluid restriction may be necessary when fluid excretion is limited by kidney injury, but over time it may impair caloric intake.

Acute Kidney Injury

Acute kidney injury is fairly common in pediatric ICU patients and is independently associated with mortality (Plötz et al., 2008). The definition of acute renal failure is not mutually agreed on: it is described as a change from baseline in serum creatinine, or an elevation in blood urea nitrogen level, or urine output inadequate to match required intake (Plötz et al., 2008). A uniform definition of renal injury is important for research, but it does not yet inform clinical decision making. The RIFLE criteria (risk, injury, failure, loss, end-stage renal disease) have been proposed to classify renal injury in adult patients (Kellum et al., 2002). A pediatric modification of the adult RIFLE criteria has been proposed and independently evaluated (Table 39-1) (Akcan-Arikan et al., 2007). Among children requiring mechanical ventilation for less than 4 days, 58% met pediatric RIFLE criteria for acute kidney injury, most on the first day of admission. Patients with acute kidney injury according to the pediatric RIFLE scoring system had a mortality rate that was five times higher than patients without acute kidney injury (Akcan-Arikan et al., 2007; Plötz et al., 2008).

The primary treatment of acute kidney injury and failure is to remove the causative agent, if possible. The use of nephrotoxic medications should be reassessed; when they are deemed necessary, dosages should be based on drug levels and or creatinine

TABLE 39-1. Pediatric Modified RIFLE Criteria

	Estimated Creatinine Clearance Index	Urine Output
Risk	eCCI decreased by 25%	<0.5 mL/kg per hr for 8 hr
Injury	eCCI decreased by 50%	<0.5 mL/kg per hr for 16 hr
Failure	eCCI decreased by 75% or eCCI <35 mL/min per 1.73 square meter	<0.3 mL/kg per hr for 24 hr, or anuric for 12 hr
Loss	Persistent failure > 4 wk	—
End-stage renal disease	End-stage renal disease (persistent failure > 3 mo)	—

From Akcan-Arikan A, Zappitelli M, Loftis LL, et al: Modified RIFLE criteria in critically ill children with acute kidney injury, *Kidney Int* 71:1028, 2007. eCCI, Estimated creatinine clearance index; RIFLE, risk, injury, failure, loss, and end-stage renal disease.

clearance. Consultation with a pharmacist, when one is available, can be invaluable for making these adjustments. Although acute kidney injury is associated with mortality, renal function usually returns in survivors, provided the offending agent is removed and attention is paid to preventing new medication and perfusion-related injury. While the kidney is healing, maintenance of appropriate fluid balance may require renal replacement therapy (RRT).

Renal Replacement Therapy

Criteria for Initiating Renal Replacement Therapy

There are no nationally published guidelines for the initiation of RRT, and there is wide variation among practitioners as to its timing of initiation and discontinuation. Absolute indications for renal replacement therapies include life-threatening electrolyte abnormalities and anuria. However, RRT is more commonly used for the relative indication of fluid overload with inadequate urine output (Gibney et al., 2008). The guidelines used at the Children's Hospital of Pittsburgh (University of Pittsburgh Medical Center) are shown in **Box 39-2**. There is increasing evidence that fluid overload contributes to mortality, particularly in children. Observational studies suggest that increasing severity of fluid overload before or at initiation of RRT is an independent predictor of mortality after controlling for severity of illness. RRT should be considered when accumulated fluid overload reaches 10% (Ricci and Ronco, 2008; Sutherland et al., 2010).

Practical Aspects of Renal Replacement Therapy

Continuous renal replacement therapy (CRRT) is the preferred mode of renal replacement therapy in ICU patients with hemodynamic instability. The advantages of CRRT over intermittent hemodialysis are that it allows correction of metabolic acidosis, provides temperature control, and provides constant fluid

Box 39-2 Indications for Continuous Renal Replacement Therapy

- Fluid overload (defined as >10% weight gain from baseline) and acute renal dysfunction (defined as urine output <1 mL/kg per hour, unresponsive to diuretics infusion within 24 hours) and at least one of the following:
 - A change from baseline of >50% of serum creatinine, or
 - Elevated serum creatinine greater than 1.5 times the age-based normal value, or
 - A blood urea nitrogen level >40 mg/dL.
- Oliguric or anuric renal failure in patients who require administration of additional intravascular volume or whose nutritional status could be improved by increased fluid administration.
- Oliguric or anuric renal failure in patients with hepatic failure (continuous venovenous hemofiltration may remove hepatically cleared toxins).
- Electrolyte abnormalities requiring renal replacement (especially potassium and phosphorus).
- Metabolic derangements in which the production of noxious metabolic products is continuous, such as hyperammonemia
- Acute respiratory distress syndrome, defined as $F_{iO_2}/P_{aO_2} < 200$, or oxygenation index > 10 in bone marrow transplantation patients. In this patient population, a high rate of clearance may be beneficial.

hemostasis with better avoidance of intracerebral fluid shifts. Its main drawback is the need for anticoagulation. Although CRRT shows no survival benefit over intermittent therapy, it may predict renal recovery in survivors (Uchino et al., 2007).

CRRT can be accomplished with ultrafiltration alone (i.e., continuous venovenous hemofiltration [CVVH]) or with dialysis. With CVVH, both water and high-molecular-weight substances pass across the membrane because of a pressure gradient that creates convective flow. Convection, or passive movement of solute across a membrane along with water, allows phosphates and molecules such as urea and creatinine to clear at similar rates. Profound hypophosphatemia can easily develop, and patients on CVVH require phosphate replacement. Larger molecules such as heparin, insulin, and vancomycin, cleared in only negligible amounts during dialysis, are cleared more efficiently by CVVH.

With dialysis, blood flows along one side of a semipermeable membrane as a crystalloid solution is pumped along the other side of the membrane, countercurrent to the blood flow. Through the process of *diffusion*, molecules cross the membrane. The larger the molecule, the more slowly it moves across the membrane. Urea, a small molecule, is cleared efficiently, whereas creatinine, a larger molecule, is cleared less well. Phosphate ions have very low rates of clearance across the membrane.

Clinical Changes When Initiating CRRT

Clinicians should be alert to the risk for hypotension when CRRT is initiated. Hypotension may occur as a result of inadequate intravascular volume, hypocalcemia, or bradykinin release syndrome, particularly when patients are acidotic at the time of CRRT initiation. Once CRRT is begun, therapies aimed at preventing fluid overload should be discontinued. Diuretics

should be decreased or stopped. Nutrition should be increased if it had been limited by fluid restriction. The amount of protein in parenteral nutrition should be increased to 1.5 to 4 mg/kg per day, because hemofiltration results in significant amino acid loss across the membrane (Maxvold et al., 2000). A low blood urea nitrogen level in a patient on RRT reflects inadequate nitrogen balance. A patient on CRRT requires additional potassium and phosphorus to replace that lost to the circuit. When CRRT is discontinued or interrupted, diuretics, fluid rate, TPN prescription, and electrolyte infusions should be returned to normal. The removal of medications across the CRRT membrane is difficult to predict. Consultation with a pharmacist is recommended with initiation of CRRT.

High-Clearance CRRT for Treatment of Sepsis

It is conventional to speak of the *dosage* of CRRT, meaning the quantity of blood purified per unit time. Higher-clearance CRRT (at least 35 mL/kg per hour versus 20 mL/kg per hour) is associated with improved survival in adults, with the greatest improvement seen in septic patients (Ronco et al., 2000). There has been some interest in using extremely high clearance CRRT to remove cytokines and modulate inflammation. This approach has shown some promise in patients with ARDS after bone marrow transplantation (DiCarlo et al., 2003). The pore size in most filters used for hemofiltration and dialysis admit passage of proteins whose size is in the range of 30 to 40 kDa, which is more than adequate for removal of interleukins 1, 6, 8, and 10, and tumor necrosis factor. Studies of high-clearance CRRT in septic patients have not shown significant and sustained decreases in cytokine levels, and high-clearance CRRT has not been conclusively shown to improve outcome (Joannidis, 2009).

Contraindications to CRRT

There are no absolute contraindications for the use of CRRT. Patients at risk for life-threatening bleeding with systemic heparinization may be put on CRRT with a citrate anticoagulation protocol. Citrate is added to the CRRT circuit, generating a level of hypocalcemia in the circuit sufficient to prevent clotting. Calcium must be infused centrally to replace the calcium lost in the circuit. Most of the citrate is removed in the circuit, and the liver metabolizes what remains. When citrate is used for anticoagulation, patients with liver failure who are unable to metabolize citrate are at risk for citrate lock, manifested by an increased ratio of total to ionized calcium (Morgera et al., 2004). Risks and benefits should be weighed carefully when considering the use of citrate CRRT in patients with liver failure.

Nutritional Support

Premorbid, protein-energy malnutrition is associated with poor immune function and wound healing, multiorgan failure, longer hospital stays, and poor outcomes, and the nutritional status of children deteriorates while they are in the PICU (Pollack et al., 1982; Pollack et al., 1985; Hulst et al., 2004). It can be difficult to assess the nutritional needs of PICU patients. Adults have a hypermetabolic response to critical illness. Calculations of resting energy expenditures and correction factors for a variety of critical illness states in children have been proposed, but, with the exception of burn injury,

for which the hypermetabolic state is well documented, these have not been validated. There are factors that both increase and decrease metabolic needs during critical illness. Resting energy expenditure may be higher than normal, but the energy used by muscle activity is much lower for healthy children. Metabolic calculations in critically ill children demonstrated that energy expenditure was lower than predicted by common formulas and was lowest in patients with multiple-organ dysfunction syndrome (Turi et al., 2001). Both overfeeding and underfeeding have deleterious consequences in critically ill children (Skillman and Wischmeyer, 2008). Optimal energy intake during the acute phase and the recovery phase of critical illness remains uncertain.

The recommended daily calorie requirements for healthy children are a reasonable starting target for critically ill children. A general estimate of calorie requirements by age is presented in Table 39-2 (Agus and Jaksic, 2002).

Enteral Feeding

Enteral feeding is usually withheld until cardiovascular stability is established, because generalized hypoperfusion and vasoactive agents limit intestinal blood flow. However, early enteral feeding may preserve gut mucosal integrity, may decrease septic episodes, and may decrease the incidence of ventilator-associated pneumonia (Jeejeebhoy, 2001; Kompan et al., 2004). Aspiration is thought to be a risk factor for ventilator-associated pneumonia (VAP), but enteral nutrition decreased the risk for VAP in adults. Similar studies have not been done in children. The frequent interruptions to enteral feeding (for many reasons, including perceived intolerance, procedures, diagnostic tests, medication administration) may result in inadequate nutrition delivery (de Neef et al., 2008). Attention should be given to calories *delivered*, not just calories *prescribed*. Feeding protocols may limit the impact of these factors on the delivery of adequate nutrition (Meyer et al., 2009). When complete enteral nutrition is impossible, low-dosage enteral nutrition in combination with parenteral nutrition is probably preferable to parenteral nutrition alone (Heidegger et al., 2008).

Transpyloric feeding may help to avoid unnecessary feeding interruptions, particularly in patients with gastroparesis or those who are at increased risk for aspiration, but it does not prevent aspiration of gastric contents (Meert et al., 2004). Because infants and children are at higher risk for malplacement of enteral feeding tubes, tube placement should be confirmed radiographically before use. Enteral formulas exist for special situations such as renal failure, general malabsorption, fat malabsorption, and pancreatitis. Although it is generally accepted that enteral nutrition is superior to parenteral nutrition, studies in pediatric patients are lacking.

TABLE 39-2. Estimated Calorie and Protein Requirements of Children During Critical Illness

Age	Calories	Protein (g/kg per day)
Premature infant	120	3.5
Term infant	100	2.5-3
Child, 1 to 12 years	70	1.5-2
Child, >12 years	70	1.5

Parenteral Nutrition

Total parenteral nutrition (TPN) is indicated for patients with contraindications to enteral feeding. TPN is associated with a number of complications, including intestinal mucosal atrophy with increased bacterial translocation, metabolic abnormalities including hyperglycemia and hypertriglyceridemia, and immune dysfunction and infection. With long-term therapy, hepatic steatosis, cholestasis, and irreversible liver failure can occur. When there is risk for liver injury, TPN is often cycled to mimic the postabsorptive state (Kelly, 2006). Timing of initiation of parenteral nutrition is controversial. A recent review suggested starting it when enteral nutrition could not be used for 3 to 5 days (Skillman and Wischmeyer, 2008). In patients at high risk for malnutrition, it may be appropriate to initiate parenteral nutrition sooner.

In TPN, carbohydrates provide 60% to 75% of nonprotein calories. Carbohydrate concentrations are increased gradually to avoid hyperglycemia. The glucose infusion rate is calculated according as follows:

$$\text{Glucose infusion rate (mg/kg per minute)} = \frac{\text{Volume (mL/kg per day)} \times \text{Glucose concentration (as a decimal)}}{1.44}$$

The glucose infusion is typically started at 5 to 6 mg/kg per minute and increased by 0.5 to 1 mg/kg per minute per day for preterm infants, or 2 to 4 mg/kg per minute per day for older children. For patients with sepsis, the ACCM guidelines recommend at least 8 mg/kg per minute for neonates, 5 mg/kg per minute in children, and 2 mg/kg per minute in adolescents (Brierley et al., 2009). Glucose control may be important in critically ill patients (see later). Some of the negative effects of parenteral nutrition seen in studies done in the past two decades may be related to carbohydrate overfeeding and poor glycemic control.

Provision of adequate protein intake prevents negative nitrogen balance and skeletal muscle wasting and supports growth and wound healing. To prevent protein from being used as a calorie source and to preserve its availability for growth and repair, adequate nonprotein calories must be provided (see Table 39-2). In renal failure, it may be necessary to decrease the amount of protein delivered. When CRRT is initiated, protein delivery should increase to compensate for protein lost across the membrane.

Fats serve as an energy source and a source of essential fatty acids. About 30% to 40% of TPN calories are delivered as fat, providing both an energy source and a source of essential fatty acids. At least 3% to 4% of calories should be given as fat to prevent free fatty acid deficiency. If too much fat is given, the lipoprotein lipase system is overloaded and lipemia occurs. TPN fats are delivered as a 20% emulsion, which is low in osmolality and thus safe for peripheral veins.

It is routine to provide a pediatric multivitamin in TPN. Other minerals, such as selenium, iodide zinc, and iron, may not be provided by standard TPN solutions but are available as additives.

Intensive Insulin Therapy in Critically Ill Patients

Hyperglycemia is common in critically ill patients. In children, hyperglycemia is associated with organ dysfunction and poor outcomes (Kyle et al., 2010). Maintenance of normal fasting blood glucose values (80 to 100 mg/dL) conferred a survival advantage over maintenance blood glucose values (180 to 200

mg/dL) in critically ill adult surgical patients and was associated with a shorter ICU and hospital stay, a shorter period of mechanical ventilation, and less renal injury in adult medical patients (van den Berghe et al., 2001, 2006). In a recently published trial of tight glucose control using age-stratified glucose targets in critically ill children, tight control was associated with improvement in morbidity and mortality over a glucose target of 180 to 214 mg/dL, despite episodes of hypoglycemia occurring in 25% of the treatment group. More than two thirds of the children in this study were postoperative cardiac surgery patients; this may hamper the study's generalizability to medical patients (Rouette et al., 2010).

The appropriate target for glycemic control in critically ill pediatric patients remains to be determined. Adoption of a tight glucose control strategy requires frequent monitoring and familiarity with glycemic control protocols at all levels of care. The long-term impact of hypoglycemia in the PICU is not known. These issues have prevented the widespread adoption of tight glycemic control in critically ill children.

NEUROLOGIC SYSTEMS

The special sensitivity of the brain to inflammation and the catastrophic effects of herniation generally lead physicians to prefer ICU monitoring for new neurologic impairment. Neurologic problems that are common in the ICU include status epilepticus and prolonged seizures leading to respiratory failure; meningitis and other intracranial infections; spontaneous vascular accidents including stroke and hemorrhage; and traumatic brain injury. Sensitivity to the possibility of adding to existing brain injury and to the possibility of herniation should guide ICU treatment of the patient with suspected intracranial pathology. General strategies to limit brain injury are similar to the treatments to limit worsening of hypoxic injury in cardiac arrest patients (see earlier) and include maintaining adequate blood pressure and oxygenation, avoidance of states that increase cerebral metabolic rate (e.g., fever and seizure), preservation of blood oncotic pressure with normal to high sodium levels, avoidance of hyperglycemia and hypoglycemia, and avoidance of preventable causes of increased ICP, such as hypercarbia and unsedated laryngoscopy.

Traumatic Brain Injury

See Adelson and colleagues (2003) for a thorough review of traumatic brain injury in infants, children, and adolescents. See Chapter 22, Anesthesia for Neurosurgery, for perioperative treatment of the pediatric trauma patient. Here, the focus is on the critical care management of traumatic brain injury (TBI).

Physiology of Traumatic Brain Injury

In the injured brain, there is an area of primary injury that cannot be ameliorated, a penumbra of brain tissue that is at risk for further injury, and normal brain distant from the site of initial injury. The goal of critical care after TBI is to keep that penumbra as small as possible and to protect the normal brain from further injury. Only part of the injury sustained in TBI occurs with the initial injury. The most important causes of secondary injury include hypoxia, hypotension, hyperglycemia

and hyperthermia, seizures, and intracranial hypertension. The mechanisms for secondary brain injury, including excitotoxicity, have been reviewed by Kochanek and coworkers (2008).

Initial Management of the Brain-Injured Patient

Early management of airway, breathing, and circulation should take into account the devastating effect of even transient hypoxia and the impact of hypercarbia on ICP. Prevention of hypoxia by intubation is strongly associated with improved outcomes (Franschman et al., 2009; Zebrack et al., 2009). The initial management of TBI is presented in **Box 39-3**. The examiner should always be sensitive to signs of intracranial hypertension or impending herniation, including pupillary dilation, Cushing’s triad, and extensor posturing. The Glasgow Coma Scale has been adapted for use in children and should be calculated for all patients with TBI on arrival and in subsequent examinations (**Table 39-3**). Brain injuries evolve over time, and the initial computed tomography scan might not reflect the current state of brain edema or intracranial hemorrhage. A sustained change in ICP or in the neurologic examination should prompt repeat imaging.

Minimizing Secondary Injury

Once the initial assessment and resuscitation are complete, further management is aimed at preventing and treating causes of secondary brain injury. The goals are to preserve delivery of fuel substrates, to prevent increases in cerebral metabolic needs, and to minimize ICP. The management for minimizing secondary injury is presented in **Box 39-4** (Chiaretti et al., 2002; Adelson et al., 2003; Davis, 2008). Therapeutic hypothermia is under investigation for children with TBI, and although there are no data to support broad application of this therapy, it might be considered for severe refractory intracranial hypertension.

Box 39-3 Initial Management of Traumatic Brain Injury

AIRWAY (INDICATIONS FOR INTUBATION)

- Absence of protective reflexes
- Glasgow Coma Scale (GCS) < 8

BREATHING

- Maintain normal $Paco_2$ (35 to 40 mm Hg)

CIRCULATION

- Blunt sympathetic response to intubation with medication (lidocaine, 1 mg/kg)
- Maintain normal blood pressure
- Avoid nasogastric tube placement until cribriform plate injury is ruled out

INTRACRANIAL PRESSURE (ICP) MANAGEMENT

- Calculate pediatric GCS on arrival
- Head computed tomography scan
- Place ICP monitor for GCS < 8

Modified from Franschman G, Peerdeman SM, Greuters S, et al: ALARM-TBI investigators: Prehospital endotracheal intubation in patients with severe traumatic brain injury: guidelines versus reality, *Resuscitation* 80(10):147, 2009; Zebrack M, Dandoy C, Hansen K, et al: Early resuscitation of children with moderate to severe traumatic brain injury, *Pediatrics* 124(1):56, 2009.

TABLE 39-3. Glasgow Coma Scale for Children and Adults

	Infants and Young Children	Older Children and Adults
Eye Opening		
4	Spontaneous	Spontaneous
3	To voice	To voice
2	To pain	To pain
1	None	None
Verbal		
5	Coos, babbles	Oriented
4	Irritable	Confused
3	Cries to pain	Inappropriate words
2	Moans to pain	Incomprehensible sounds
1	None	None
Motor		
6	Normal spontaneous movements	Obeys commands
5	Withdraws to touch	Localizes pain
4	Withdraws to pain	Withdraws to pain
3	Abnormal flexion	Abnormal flexion
2	Abnormal extension	Abnormal extension
1	Flaccid	None

Box 39-4 Minimizing Secondary Injury

- Treat hypotension with isotonic intravenous fluids.
- Do not treat hypertension in the presence of increased intracranial pressure.
- Maintain $Pao_2 > 60$ mm Hg.
- Maintain $Paco_2$ at 35 to 40 mm Hg.
- Maintain normal plasma glucose. Hyper/hypoglycemia worsen outcome.
- Hyponatremia may contribute to cerebral edema. Use isotonic intravenous fluids.
- Treat fever aggressively with antipyretics.
- Early (1–7 days) prophylactic anticonvulsant medication is recommended.

Modified from Chiaretti A, Piastra M, Pulitanò S, et al: Prognostic factors and outcome of children with severe head injury: an 8-year experience, *Childs Nerv Syst* 18(3–4):129, 2002; Adelson PD, Bratton SL, Carney NA, et al; American Association for Surgery of Trauma; Child Neurology Society; International Society for Pediatric Neurosurgery; International Trauma Anesthesia and Critical Care Society; Society of Critical Care Medicine; World Federation of Pediatric Intensive and Critical Care Societies: Guidelines for the acute medical management of severe traumatic brain injury in infants, children, and adolescents. Chapter 5. Indications for intracranial pressure monitoring in pediatric patients with severe traumatic brain injury, *Pediatr Crit Care Med* 4(3 Suppl):S1, 2003; Davis DP: Early ventilation in traumatic brain injury, *Resuscitation* 76(3):333, 2008.

Management of Intracranial Hypertension

Intracranial hypertension may impair cerebral blood flow and is associated with poor outcome. It results from osmolar shifts, cellular edema, vasogenic edema (blood-brain barrier breakdown),

Box 39-5 Management of Intracranial Hypertension

- Cerebral perfusion pressure should be maintained at 40 mm Hg or greater.
- Intracranial pressure (ICP) should be treated if greater than 20 mm Hg.
 - Consider ICP monitor for GCS < 8.
 - Head in midline position, and head of bed at 30 degrees.
 - Provide sedation and analgesia.
 - Use neuromuscular blockade to decrease metabolic demands.
 - Hyperosmolar therapy (3% normal saline, mannitol)
 - Hyperventilation for impending herniation
 - CSF drainage
 - Surgical evacuation of intracranial blood
 - Decompressive craniectomy

Adapted from Davis DP: Early ventilation in traumatic brain injury, *Resuscitation* 76(3):333, 2008; Adelson PD, Bratton SL, Carney NA, et al; American Association for Surgery of Trauma; Child Neurology Society International Society for Pediatric Neurosurgery; International Trauma Anesthesia and Critical Care Society; Society of Critical Care Medicine; World Federation of Pediatric Intensive and Critical Care Societies: Guidelines for the acute medical management of severe traumatic brain injury in infants, children, and adolescents. Chapter 5. Indications for intracranial pressure monitoring in pediatric patients with severe traumatic brain injury, *Pediatr Crit Care Med* 4(Suppl 3):S1, 2003.

mass lesions, and intracranial hemorrhage. Protocols exist for the management of intracranial hypertension, but they should not be seen as a surrogate for cooperative management with a neurosurgical team (Adelson et al., 2003). Therapies aimed at controlling intracranial pressure are applied in a stepwise fashion, beginning with the least invasive measures (Box 39-5).

HEMATOLOGY AND IMMUNOLOGY

Red Blood Cell Transfusion in the PICU

Critically ill patients are prone to anemia as a result of hemodilution, phlebotomy, and suppression of hematopoiesis by, for example, inflammation and malnutrition. Red blood cell transfusions are associated with significant risks related to immune suppression, transfusion reactions, transfusion associated lung injury, infection. Changes in the red blood cell that occur during storage may decrease oxygen delivery, negating the benefit expected from transfusion (Tinmouth et al., 2006). Adult studies have shown that setting a conservative threshold for transfusion (i.e., a hemoglobin level of 7 mg/dL) is safer than a threshold of 10 mg/dL. A conservative threshold reduced the number of transfusions and decreased the incidence of organ failure, cardiac complications, and mortality (Hébert et al., 1999).

Pediatric studies support that it is safer to use a conservative (7 mg/dL) than a liberal (9.5 mg/dL) threshold for stable critically ill children and postsurgical pediatric patients. This restrictive strategy reduces the number of transfusions per patient and dramatically reduces the number of patients who receive transfusions without worsening organ dysfunction (Lacroix et al., 2007; Rouette et al., 2010). The optimal transfusion threshold for unstable patients is unknown. It is probably appropriate to

target the normal range in children with profound hypoxemia and shock (Carcillo and Fields, 2002; Randolph, 2009).

Sepsis and Multiple Organ Dysfunction Syndrome

No treatment improves outcomes in pediatric patients with sepsis besides providing appropriate antibiotic therapy and rapidly and aggressively treating shock (for discussions on the latter, see Cardiovascular System, p. 1258). Administration of appropriate antimicrobial therapy should be considered urgent, as a delay of even 30 minutes has been shown to increase mortality in adults. It is appropriate to start with broad coverage, using local antimicrobial resistance patterns to guide antibiotic choice. The most common bacterial causes of sepsis vary by age and immunization status, with group B *Streptococcus* and *Escherichia coli* predominating in newborns, and *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Neisseria meningitidis* predominating in older children. Viruses and fungi can also cause sepsis, particularly in immunocompromised hosts. The pathophysiology of sepsis is complex and incompletely understood (but see Hotchkiss and Karl, 2003).

Activated protein C, which held some promise in adult patients with sepsis, is not recommended in children. In a randomized controlled trial of activated protein C in pediatric patients with sepsis, no difference in organ failure or mortality was found between groups, but there was an increase in central nervous system bleeding in the treatment group (Nadel et al., 2007).

Multiple organ dysfunction syndrome represents a continuum of physiologic abnormalities rather than a dichotomous state of organ function or failure. MODS develops quickly in children, with a maximum number of organ failures seen at 72 hours in most children (Proulx et al., 1994). Diagnostic criteria for organ failures are useful for comparing patients in research studies and evaluating outcome in clinical trials (Wilkinson et al., 1987; Leteurtre et al., 2003). Because overall mortality is lower in critically ill children than in adults, organ failure scores and time to resolution of organ failure are considered appropriate endpoints for clinical trials in pediatric intensive care. Children with MODS have a better chance of a good outcome than adults. Six months after discharge from the PICU, 60% of survivors of MODS have a normal quality of life, and 32% have ongoing health, emotional, or cognitive problems (Ambuehl et al., 2002). The number and severity of organ failures are associated with mortality, but it is rarely the case that failure of a specific organ can be implicated as a cause of death. Children with severe MODS usually die when the decision to withdraw support is made in response to an increasingly grim prognosis.

MODS is associated with shock states, including cardiogenic shock, sepsis, SIRS states not associated with infection, ARDS without systemic infection, and solid organ or bone marrow transplantations. The etiology of MODS is not completely understood, but it is almost certainly multifactorial and probably differs for different patients. The pathophysiology that is thought to contribute to MODS is worth reviewing, as it underscores the importance of many of the therapies already discussed here.

Shock states may cause relative hypoperfusion to abdominal organs, as sympathetic stimulation preferentially diverts blood flow from the periphery and the splanchnic circulation and toward the myocardium and the brain. This is particularly true in children, for whom the most common hemodynamic profile is cold shock. Elevated levels of both proinflammatory

and antiinflammatory cytokines are associated with severity of MODS (Doughty et al., 1998; Whalen et al., 2000). Breakdown of the barrier function of intestinal mucosa has been postulated to contribute to MODS by initiating or exacerbating the inflammatory cascade (Proulx et al., 2009). Increased prothrombotic and antifibrinolytic activity in plasma is associated with severity of MODS. Dysregulation of normal clotting and fibrinolytic mechanisms may lead to microvascular thrombosis, impairing organ perfusion locally and perpetuating the inflammatory state (Proulx et al., 2009). Nitric oxide, which is present in increased amounts in the blood during shock states, may combine with superoxides to produce peroxynitrites. Peroxynitrites can damage lipid membranes and DNA and alter mitochondrial function (Wong et al., 1995; Burney et al., 1999).

Mechanical ventilation causing excessive stretch of poorly compliant lungs leads to the release of inflammatory mediators and has been implicated in the development of multiorgan failure in ARDS patients (Tremblay and Slutsky, 2006). The abnormalities of metabolism and neuroendocrine response noted in patients with multiorgan failure may represent other organ failures or may contribute to the syndrome (Proulx et al., 2009). Impairments in the immune response have also been noted in these patients. Failure of antigen presentation (i.e., immunoparalysis) and depletion of lymphoid elements predispose patients with MODS to secondary infection and may contribute to mortality (Peters et al., 1999; Felmet et al., 2005). Finally, mitochondrial dysfunction has been posited to be a part of the final common pathway of MODS and may some day be treatable (Singer, 2007).

The treatment of MODS is supportive. Treatments discussed earlier and later in this chapter are intended to minimize the development and severity of organ dysfunction. Treatments that have been associated with a decrease in the incidence or severity of MODS in adults include use of ventilator strategies that avoid excessive stretch or atelectrauma, aggressive shock resuscitation, control of source of infection or inflammation, early enteric feeding to prevent intestinal mucosal atrophy, tight glycemic control, and a conservative transfusion threshold (Proulx et al., 2009).

PROPHYLAXIS

Gastritis

The association between severe stress and GI ulceration is well established. The incidence of clinically important GI bleeding in both adult and pediatric patients with critical illness is low (Quenot et al., 2009; Reveiz et al., 2010). The mechanism of stress ulcer formation is incompletely understood, but it includes impairment of blood flow to the intestinal mucosa and circulation of proinflammatory cytokines (Quenot et al., 2009). Direct damage to the epithelium by hydrogen ions is preventable to some degree, but this is only one of many factors. Options for prophylaxis include antacids, sucralfate, histamine type 2 (H_2) receptor antagonists (H_2 RAs), and proton pump inhibitors (PPIs).

Sucralfate works by improving the neutralization capacity of the mucous layer of the gastric lining. It may decrease the absorption of concomitantly administered medications. Because it is not systemically absorbed, it may not be administered via duodenal or jejunostomy tubes. H_2 RAs decrease gastric acid secretion through competitive inhibition of histamine-stimulated

acid secretion. PPIs irreversibly inhibit the final step in acid production (the transport of hydrogen), providing long-lasting acid suppression. PPIs inhibit both vagally mediated and histamine-induced acid secretion. Both PPIs and H_2 RAs are superior to placebo in suppressing clinically significant stress-ulcer-related bleeding (Reveiz et al., 2010).

Stress-ulcer prophylaxis is not routinely indicated for ICU patients but should be reserved for patients at risk for stress ulcer-related bleeding. These include patients with sepsis, coagulopathy, or a history of ulcer or GI bleeding within the past year, and patients requiring mechanical ventilation for longer than 48 hours, a prolonged ICU stay, or high-dosage corticosteroids (Reveiz et al., 2010). A recent meta-analysis failed to find convincing evidence that PPIs are superior to H_2 RAs in terms of preventing stress ulcer-related bleeding (Lin et al., 2010). Many clinicians discontinue stress ulcer prophylaxis when the patient begins an oral diet, begins a complete enteral diet, or discontinues steroid therapy.

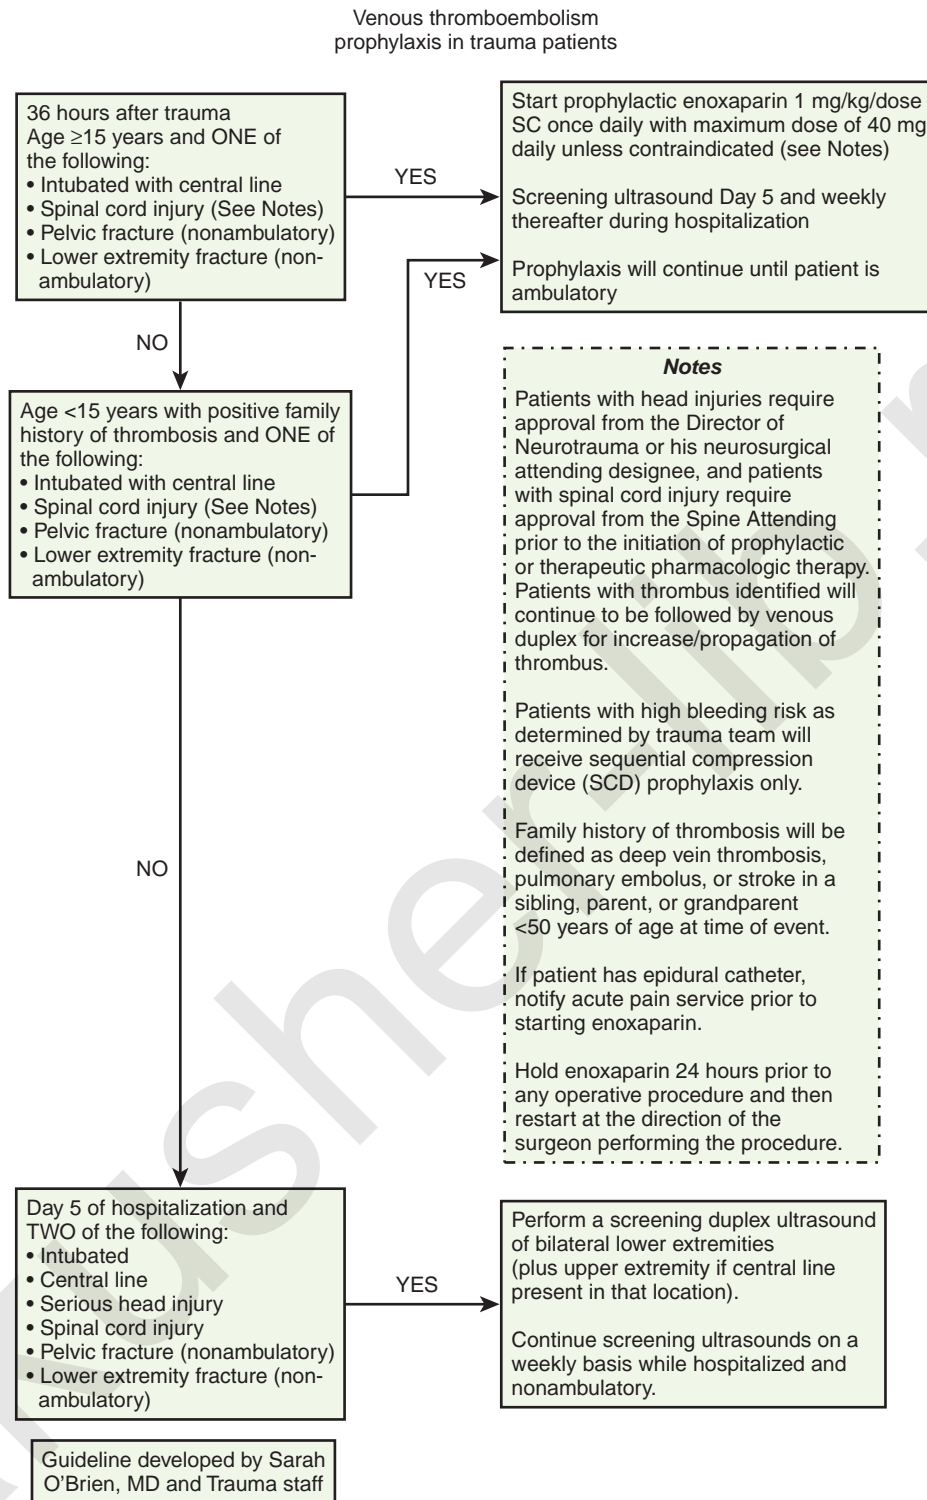

Deep Venous Thrombosis

Among adult trauma patients, the risk for deep venous thrombosis (DVT) is greater than 50% without venous thromboembolism (VTE) prophylaxis. Prophylaxis reduces the incidence of new DVT in the adult medical and surgical ICU to between 10% and 33% (Cook et al., 2005). The incidence in pediatrics is much lower, but comprehensive screening studies have not been done. The reported incidence of DVT among pediatric trauma patients is 0.2 to 3.3 per 1000 trauma discharges. Older adolescents and young adults may be at higher risk than younger pediatric patients (O'Brien et al., 2008). For children who are critically ill after trauma, the incidence of symptomatic DVT is reported to be much higher (6.2%). The presence of central venous lines, poor perfusion and immobility, and a family history of thrombosis are risk factors. Studies screening for asymptomatic VTE found central venous line-associated VTE rates in critically ill children ranging from 8% to 35% (Hanson et al., 2010).

An algorithm for the use of VTE prophylaxis in pediatric trauma patients has been proposed (Fig. 39-5) (O'Brien et al., 2008). In critically ill pediatric patients without trauma, mechanical prophylaxis and vigilance for signs of DVT may be appropriate. Pulmonary embolus is rare in children, with about 40 per year occurring in the United States. The nonspecific symptoms of pulmonary embolus may be responsible for its underrecognition in critically ill patients. Massive pulmonary embolus in children is most often described at autopsy (Baird et al., 2010).

Ventilator-Associated Pneumonia

The frequency of VAP in pediatric patients is 2.9 episodes per 1000 ventilator days (Principi and Esposito, 2007). The presence of an endotracheal tube is the most important risk factor, and shortening the duration of ventilation is the most important preventative. Organisms responsible are typically *S. aureus* and gram-negative bacteria (Grohskopf et al., 2002). Early VAP may involve organisms commonly associated with community-acquired pneumonia. Specific measures for VAP prevention recommended in adult patients include raising the head of the bed by 30 to 45 degrees, instituting a daily sedation holiday with an extubation readiness trial, stress-ulcer prophylaxis, and DVT

■ **FIGURE 39-5.** Deep venous thrombosis (DVT) prophylaxis for pediatric trauma patients. (From O'Brien SH, Haley K, Kelleher KJ, et al: Variation in DVT prophylaxis for adolescent trauma patients: a survey of the Society of Trauma Nurses, J Trauma Nurs 15:53, 2008.)

prophylaxis (Grohskopf et al., 2002). It is essential to identify the causative agent. Because of antimicrobial resistance in hospital-acquired organisms, initial therapy should be broad and should be tailored once sensitivities are known. Compared with placebo, sucralfate and H₂ blockers do not alter the incidence of VAP or upper airway colonization in children (Lopriore et al., 2002).

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is an immune response to platelet factor–heparin complexes that results in platelet activation and thrombocytopenia. These signs appear 4 to 5 days after initial heparin exposure, or more abruptly after reexposure. The primary complications are mostly thrombotic,

although bleeding may occur, often as a postthrombotic complication. The diagnosis of HIT depends on demonstration of antibodies to platelet factor 4 (PF4)-heparin complexes, and on the appearance of the syndrome's clinical features, including a 50% fall in platelet count with appropriate timing and absence of a more likely cause of thrombocytopenia. Demonstration of PF4 heparin antibodies is necessary but not sufficient for diagnosis, as only a small fraction of patients with the antibody have the syndrome (Hassell, 2008).

Treatment consists of removal of all forms of heparin and using of alternative anticoagulants. Low-molecular-weight heparin has been used when platelet aggregation is not demonstrated. Warfarin and aspirin have been used in pediatric patients. Direct thrombin inhibitors such as argatroban, and anti-Xa agents such as fondaparinux have been used in adult patients. These drugs have been used in pediatric patients, but the efficacy and safety have not been well established (Rayapudi et al., 2008; Dhillon, 2009). Simple discontinuation of heparin without alternative anticoagulation is associated with severe complications (Hassell, 2008).

Trials in adults have reported an incidence of HIT that varies between 1% and 30%. The diagnosis can be challenging in severely ill patients, because heparin use is a ubiquitous part of intravenous and central line flushes in the pediatric ICU, and because most of these patients have a variety of potential reasons for thrombocytopenia. Venous clots around indwelling catheters may be more common in children because the diameter of central lines is larger than the size of the vessel (DeAngelis et al., 1996).

Critical Care Myopathy

Survivors of critical illness are at risk for polyneuropathy and myopathy syndromes causing weakness ranging in severity from brief and reversible skeletal muscle weakness to inability to wean from mechanical ventilation. There is an enormous deficit in knowledge about the incidence, causes, treatment, and prognosis of these syndromes, particularly in children (Williams et al., 2007). Pediatric patients with sepsis and SIRS are at particular risk, and in adult patients with sepsis and multiorgan failure the incidence of these syndromes approaches 100% (Berek et al., 1996; Latronico et al., 1996). Although data linking the combination of neuromuscular blockade and systemic steroids with ICU-acquired polyneuropathy and myopathy are limited, most clinicians agree that the combination should be avoided whenever possible. Hyperglycemia is a modifiable independent risk factor for critical care myopathy (Herridge et al., 2008). Tight glucose control may decrease its incidence in adults, but this preventive strategy not been investigated in children (van den Berghe et al., 2001).

A high index of suspicion is required for diagnosis. Identification of critical illness myopathy and polyneuropathy helps to predict respiratory failure after extubation and can help in planning rehabilitation. Neuropathy and myopathies are frequently lumped together because they are indistinguishable without relatively invasive tests, and because treatment for both syndromes is supportive. In both syndromes, weakness is usually symmetrical, and sensory symptoms are less common. Laboratory tests are usually normal and are of limited use. Nerve conduction studies and electromyography can help to differentiate between axonal neuropathy and muscle atrophy

or necrosis. Slow recovery over weeks to months is the norm, although many adults show diminished exercise capacity and quality of life years after critical illness (Herridge, 2009).

ICU-Acquired Infections

The National Nosocomial Infections Surveillance system found that nosocomial infections occur in ICUs at a rate of 13 per 1000 patient days. About 23% of nosocomial infections are urinary tract infections, and 97% of these are associated with urinary catheters. Central line-associated bloodstream infection (CLABSI) occurs in 1.0 to 5.6 per 1000 catheter days. Bloodstream infections associated with catheters are the most commonly reported nosocomial infection in pediatric intensive care. Duration of catheter use, TPN, and immunosuppression are correlated with CLABSI (Barsanti and Woeltje, 2009). The majority of pathogens causing CLABSI are found on the skin. A multidisciplinary strategy, involving, for example, maximum barrier precautions for catheter placement, antibiotic-coated catheters, handwashing campaigns, and use of chlorhexidine for dressing changes, significantly decreased rates of infection (Bhutta et al., 2007). The most important preventative for CLABSI is early removal of central venous catheters.

Clostridium difficile is increasingly recognized as a preventable cause of significant morbidity in the ICU. More virulent strains are emerging and have been implicated in ICU mortality. *C. difficile* spores can remain in the environment for a prolonged period of time and are spread by health care workers (Barsanti and Woeltje, 2009). Affected patients should be isolated, and general infection prevention measures should be in place for all patients. Use of broad-spectrum antibiotics increases the risk for *C. difficile* infection and should be carefully considered.

SUMMARY: THE ROLE OF THE INTENSIVIST

Pediatric critical care medicine is rapidly evolving. The initial resuscitation of the acutely ill patient is no longer a mystery. The difficulty lies in accomplishing what is needed during the first precious hours after their presentation. The most important area of growth in critical care is our understanding of the state of prolonged critical illness. We are only beginning to understand how ventilation practices, metabolic management, and hormone states affect the development of MODS and delayed mortality. In the next decade, we are likely to learn more about the impact of therapeutic strategies during the protracted phase of critical illness on long-term functional outcomes. Nowhere is this more important than in pediatric critical care, where most patients survive the acute illness but the disabilities in the survivors of ICU medicine may persist for many years. Incremental improvements are made in critical care. There are no miracle drugs; rather, attention to the small details improves the incidence of organ failure, the length of stay, and, we hope, the outcome.

As our support of individual organ systems becomes more complex, it is ever more tempting to refer to the organ-specific subspecialist to manage that aspect of care, but there is evidence that the continuous presence of a fellowship-trained intensivist improves outcomes and lowers cost (Pollack et al., 1988; Pronovost et al., 2002). Consultation with the specialist is invaluable, but each consultant focuses on the specialty's organ

system. It is the job of the intensivist to consider the specialist's recommendations, and then negotiate the barriers of ego, control, and reimbursement to do what best serves the patient's long-term interests.

In addition to coordinating interaction of therapeutic approaches to various organ systems, the intensivist must coordinate the approach to patients' families. Parents are integral to good pediatric critical care. Because they often remain continuously at the bedside, they see a parade of doctors, who all have an opinion about the appropriate treatment for their child. Particularly when patients have a prolonged course in the ICU or when the end of life is near, the intensivist must ensure that the family receives one unambiguous message from the health care team.

Finally, no one person can provide perfect critical care. The intensivist needs a variety of specialists, surgeons, anesthesiologists, and primary care physicians to generate an

ideal treatment plan. The intensivist relies on technicians to run the machines, and on respiratory therapists, perfusionists, and renal replacement staff. Nonphysician support staff, including nutritionists, pharmacists, social workers, psychologists, and physical and occupational therapists, are an important part of the patient's care and of the family's experience in the hospital. The care a patient receives ultimately depends on the nurses. The nurses, with their dedication, education, and support of critical care, are the intensivist's most important ally.

Anesthesiology has served as a model for patient safety and was the first medical specialty to recognize patient safety as an independent problem (Gaba, 2000). The safety of infants and children undergoing general anesthesia has improved considerably since the 1970s, as evidenced by significant decreases in anesthesia mortality despite the fact that more complicated surgical procedures have been performed on sicker children and more premature infants.

Since the 1980s, anesthesiologists' awareness of and interest in the subject of patient safety has reached a new peak, and a number of new steps have been taken to ensure perioperative patient safety (Keats and Siker, 1985; Smith and Norman, 1987; Runciman, 1988a; Runciman, 1988b). In addition to advanced technology for patient monitoring, standards for basic patient monitoring have been implemented (American Society of Anesthesiologists [ASA], 1986; Eichhorn et al., 1986). Documentation of the quality assurance (QA) process has been emphasized as an integral and essential component for hospital accreditation by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) in the United States. To further improve the quality of patient care, a number of national and international organizations have been created, including the International Committee on Prevention of Anesthesia Mortality and Morbidity, the Anesthesia Patient Safety Foundation, the Australian Patient Safety Foundation, and the ASA Committee on Patient Safety and Risk Management (Cooper and Pierce,

1986; Cooper, 1988; Pierce, 1984, 1988; Runciman, 1988b). The Institute of Medicine of the National Academies is an independent, nonprofit organization that seeks to ask and answer the nation's questions about health and health care. Their reports, such as the *Preventing Medication Errors* series, have analyzed complex problems in the modern health care industry and provided solutions that have been widely adopted. Sessions on patient safety topics have also been incorporated into the programs of the American Society of Anesthesiologists and Society for Pediatric Anesthesia annual meetings.

Nevertheless, anesthesia-related morbidity and mortality still do occur during the administration of anesthesia and can happen with any anesthesiologist under various situations. An analysis of anesthesia mishaps from closed anesthesia malpractice claims in the United States, before the new patient monitoring standards with pulse oximetry and capnography were instituted, indicated that at least 80% of the claims consisted of preventable hypoxic damage caused by human errors rather than mechanical failures (Davis, 1984).

Allnutt (1987), a member of the British Army Personnel Research Establishment, examined human factors in anesthesia-related mishaps in comparison with those in military aviation accidents. He stresses that "both pilots and doctors make many errors" (i.e., performance that deviates from the ideal). "Usually there is sufficient slack in the system for the error to be ... noticed and corrected, but some apparently innocuous errors

are not noticed and some systems are not so forgiving as others” (such as a high performance aircraft in flight). “Thus recovery from a control error when flying at high speed, low level may not be possible, whereas the same error in the cruise [at high altitude] might barely occasion comment.” A basic tenet of Allnutt’s theory is that “all human beings, without any exception whatsoever, make errors and that such errors are a completely normal and necessary part of human cognitive function.” He goes on to state that “to claim exemption on the grounds of being a senior professor [or a] test pilot ... or of having 30 years’ experience or 3000 accident-free hours, is the first step on the road to disaster.” The first step toward the prevention of catastrophe is for the pilot or the anesthetist to accept that he or she is as likely as anyone else to make an error (Pierce, 1988).

In this chapter, some of the important aspects of patient safety, the incidence and causes of mortality and morbidity, and measures for the prevention of anesthesia-related mishaps are discussed.

ANESTHESIA-RELATED MORTALITY

Overall Anesthesia-Related Mortality

The number of deaths associated with general anesthesia has declined steadily over the past several decades as the standard of anesthesia practice has improved and as advances have been made in instrumentation, anesthetic and adjuvant drugs, and safety monitors and standards. An extensive survey of 10 university hospitals by Beecher and Todd (1954) involving nearly 600,000 anesthetic cases between 1948 and 1952 suggested that mortality primarily attributable to anesthesia occurred in 1:2680 anesthesia cases (3.7:10,000), whereas the overall anesthesia-associated mortality was 1:1580 (6.3:10,000) anesthesia procedures (Graff et al., 1964). A survey by Dornette and Orth (1956) showed similar mortality rates. Data from the Baltimore Anesthesia Study Committee (1953 to 1963) showed an anesthesia-related death rate of 2.7:10,000 cases. During the 1970s and 1980s, statistics on anesthesia-related mortality in the United States were scarce, apparently because of medicolegal concerns. Anesthesia-related mortality from Canadian, British, and European sources during this time ranged from 0.7 to 2.2:10,000 anesthetic procedures (Bodlander, 1975; Harrison, 1978; Hovi-Viander, 1980; Turnbull et al., 1980; Lunn and Mushin, 1982; Hatton et al., 1983; Vickers and Lunn, 1983).

In the 1980s, European and Australian studies showed much lower rates of operative mortality directly attributed to anesthesia. A report from the British Confidential Enquiry into Perioperative Deaths (CEPOD), a survey that was jointly organized by the Associations of Anaesthetists and Surgeons of Great Britain and Ireland during 1985 and 1986 and included more than 480,000 general anesthetic procedures, indicated that mortality attributable to anesthesia alone was 1:185,000 (0.054:10,000) procedures (Buck et al., 1987). However, anesthesia, along with other causes, was thought to be a contributory factor in the death of between 1.4 (surgeons’ estimate) and 9.8 (anesthetists’ estimate) per 10,000 cases. A prospective survey of anesthesia outcome by the French Health Ministry during the time from 1978 to 1982, in which nearly 200,000 general anesthetic cases were documented, revealed an intraoperative and early postoperative death rate solely attributable

to anesthesia to be 0.76:10,000 procedures, and an intraoperative death rate of 0.44:10,000 cases (Table 40-1) (Tiret et al., 1986, 1988).

Clearly, it is difficult to compare the incidence of anesthesia-related death among reports from different parts of the world, because the definition and inclusion criteria (e.g., all inclusive vs. ASA physical status [PS] 1 and 2), perioperative duration (48 hours vs. 30 days), and the definition of anesthesia contributions (anesthesia contributory vs. primary cause) to mortality may differ markedly.

A longitudinal comprehensive anesthesia-related mortality study from New South Wales, Australia, which was continued by the same author using the same criteria since 1960 (interrupted between 1980 and 1983 because of the temporary loss of legal confidentiality), has indeed shown a steady decline in anesthetic mortality from 1.8:10,000 cases in 1960 to 0.38:10,000 cases by 1984 (Holland, 1984, 1987). Similarly, a longitudinal study from South Africa has also shown a decreasing trend in anesthesia-related mortality from 3.3:10,000 between 1956 and 1965 to 0.7:10,000 between 1983 and 1987 (Table 40-2) (Harrison, 1978, 1990).

In the United States, Eichhorn (1989) analyzed data from nine Harvard University-affiliated hospitals between 1976 and 1988. He reported 11 major anesthesia-related intraoperative accidents, including five deaths based on more than 1 million anesthetic procedures in relatively healthy patients (ASA PS 1 and 2); the anesthetic mortality was 0.05:10,000 cases;

postoperative mortality, including two deaths from halothane hepatitis, was excluded from these statistics. After implementation of patient monitoring standards in 1985, there was only one serious accident (no mortality) in 319,000 general anesthesia procedures (Eichhorn et al., 1986). Of the 11 major accidents, eight cases were considered preventable with proper monitoring, especially with capnography. Unrecognized hypoventilation (seven cases) was the most common cause of major mishaps. Inadequate supervision of residents and nurse anesthetists was also contributory. Although Eichhorn's statistics were based on a malpractice insurance database and are likely different and considerably lower than the data based on a peer-review process, anesthesia-related safety appears to have improved significantly.

Irita and others (2004) analyzed morbidity and mortality statistics in Japan from 1999 to 2002 from the Japanese Society of Anesthesiologists annual survey. They reviewed 3,855,384 cases completed during that time. The incidence of cardiac arrest and mortality totally attributable to anesthesia management was 0.47 and 0.1 per 10,000 anesthesia procedures. Half of the anesthesia-related deaths were caused by airway or ventilatory problems; the other causes were medication-related and infusion/transfusion accidents.

Practitioners of anesthesiology have institutionalized patient safety in their scientific and governing bodies (such as the ASA Anesthesia Patient Safety Foundation and similar organizations in other countries) (Cooper and Gaba, 2002). In 1999, the Committee on Quality of Health Care in America for the Institute of Medicine published a report entitled *To Err Is Human: Building a Safer Health Care System* (Kohn et al., 1999). The report stated, "Anesthesia is an area in which very impressive improvements in safety have been made." This statement was based on the statistics that anesthesia-related mortality rates had decreased from two deaths per 10,000 anesthetic procedures in the 1980s to about 1 death per 200,000 to 300,000 anesthetic procedures administered at the time the report was published (probably quoting the report by Eichhorn [1989]). Such dramatic decreases in anesthetic mortality can be attributed to a variety of mechanisms, including wide acceptance of new monitoring guidelines, improvement in monitoring techniques, safer anesthetic drugs, and adoption of QA mechanisms and other systematic approaches for reducing human and systemic errors (Gaba, 2000; Stoelting, 2000; Lagasse, 2002).

Mortality in Infants and Children

Among the pediatric age group, the anesthesia-related mortality has been reported to be disproportionately high in the literature. In the 1950s, Beecher and Todd (1954) and Stevenson and others (1953) found that accidental deaths resulting from anesthesia were disproportionately high during the first decade of life. Between 1947 and 1956 at the Babies Hospital/Columbia-Presbyterian Medical Center, Rackow et al. (1961) found that the rate of cardiac arrest associated with anesthesia in infants younger than 1 year of age (1 in 617 cases, or 16.2:10,000) was higher than in children aged 1 to 12 years (1 in 1678, or 6.0:10,000) and in adults (1 in 2580, or 3.9:10,000) (Beecher and Todd, 1954). Hypoventilation and hypoxia from ether overdose were among the common causes of death. Smith (1956) emphasized the importance of certain factors contributing to the high anesthetic mortality in pediatric anesthesia. These factors included: lack of proper equipment, improper preoperative rehydration and stabilization, inadequate intraoperative monitoring, error in fluid replacement, and aspiration of vomitus. Today, half a century later, some of these factors are still applicable.

In a report by the Baltimore Anesthesia Study Committee, anesthesia-related mortality for children younger than 15 years of age was found to be 3.3:10,000 cases (vs. 0.6:10,000 for those aged 15 to 24 years) (Phillips and Frazier, 1957; Graff et al., 1964). These authors also found that the ratio of anesthesia deaths to total surgical deaths was higher in the neonatal period than in any other age group. Furthermore, 57% of the deaths related to anesthesia occurred in healthy children (ASA PS 1 and 2). Respiratory problems were implicated in 83% of the anesthesia-related deaths (Graff et al., 1964) (Table 40-3).

In contrast, in a review of 73 anesthesia-related cardiac arrests in children between 1960 and 1972 (33% resulted in death), Salem and others (1975) found that both respiratory (airway obstruction) and cardiovascular causes (blood loss,

[†]Estimated.

POCA, Perioperative cardiac arrest.

preoperative anemia, inappropriate injection of succinylcholine and potassium) were equally responsible. In retrospect, most of these accidents were preventable.

In an attempt to improve patient safety during anesthesia in infants and children, a number of important innovations and improvements in perioperative management and monitoring were made by the pioneering pediatric anesthesiologists in the 1950s and 1960s. These innovations include homemade pediatric blood pressure cuffs and precordial stethoscopes (by Robert Smith in Boston) and endotracheal intubation (by Margo Demming in Philadelphia). Fellowship training in pediatric anesthesia also began in several cities in North America and in the United Kingdom in the 1950s and spread across the continent by the early 1970s (see Chapter 41, History of Pediatric Anesthesia).

By the mid-1970s, anesthesia-related morbidity and mortality decreased considerably. Management of known hazards, such as the full stomach, preoperative fever, and hypovolemia, was greatly improved by increased experience and knowledge (Smith, 1975). Smith (1980) reported the anesthesia-related mortality rate of 2:10,000 general anesthesia cases in children (0 to 10 years old) during the decade ending in 1966 at the Children's Hospital in Boston; the mortality rate decreased to 0.6:10,000 anesthesia cases in the decade ending in 1978. Furthermore, there was a series of 35,710 consecutive tonsillectomies and adenoidectomies, mostly in children, without a single death at the Eye and Ear Hospital of Pittsburgh (Petruscak et al., 1974). There were 7500 consecutive anesthesia procedures for cleft lip and cleft palate repairs without a death at the Children's Hospital in Boston (Smith, 1975). Elwyn, in his 5-year study between 1970 and 1975 at the Primary Children's Hospital in Salt Lake City, reported one anesthetic death in 29,101 anesthetic procedures (0.34:10,000) in children under 11 years of age (Smith, 1980). Downes and Raphaely (1979) reported an anesthetic mortality of 0.2:10,000 cases (from a total of 50,000 patients) at Children's Hospital of Philadelphia. Most fatalities occur during the first year of life, beyond which the risk of mortality is no higher than that in teenagers and young adults (Table 40-3) (Smith, 1975).

Despite advances in pediatric anesthesia, statistics from the 1980s still showed anesthesia-related mortality rates in children that were three to four times higher than in the general patient population, although the mortality rates in children had decreased considerably and appeared to have reached a plateau (Keenan and Boyan, 1985; Gibbs, 1986; Olsson and Hallen, 1988).

As part of a study of closed malpractice claims by the Committee on Professional Liability of the ASA, Morray and others (1993) compared pediatric and adult closed claims and found a different distribution of serious outcomes in children compared with those in adults. Of 2400 closed malpractice claims, 238 (10%) were in the pediatric age group (15 years old or younger). A majority of cases involved children younger than 3 years of age, and 28% of all pediatric cases involved infants younger than 1 year of age. Respiratory events (mostly inadequate ventilation) were more common than among adult claims (43% vs. 30%), and mortality was higher (50% vs. 35%), mostly attributable to inadequate ventilation. Anesthesia care was judged inadequate more often. The authors concluded that 89% of the pediatric claims that were related to inadequate ventilation could have been prevented with proper monitoring through the use of pulse oximetry and capnography (Morray

et al., 1993). Jimenez and others (2007) reviewed 532 pediatric claims from 1973 to 2000. They concluded that claims for death (41%) and brain damage (21%) remained the dominant injuries in pediatric anesthesia claims in the 1990s. Half of the claims in 1990 to 2000 involved patients 3 years old or younger, and one fifth of the patients had ASA PS scores of 3 to 5. Cardiovascular (26%) and respiratory (23%) events were the most common damaging events. The proportion of claims reported as preventable by better monitoring decreased to 16% in the 1990s.

Analysis of anesthesia-related incidents reported to the Australian Incident Monitoring Study (AIMS) showed almost identical characteristics among pediatric age groups (van der Walt et al., 1993). Of the first 2000 cases reported, 10% involved infants and children. Incidents involving respiratory and breathing circuit systems accounted for nearly half of the adverse incidents. As with the ASA Closed Claims Project, the Australian reviewers estimated that 89% of all applicable problems in AIMS could have been detected and potentially prevented by the combination of pulse oximetry and capnography (van der Walt et al., 1993).

A study from Singapore, based on a QA database, reports no fatalities among 10,000 consecutive general pediatric anesthetic procedures from 1997 to 1999 (Tay et al., 2001). A 2004 QA database study from Hôpital d'Enfants Armand Trousseau in Paris also reports zero mortality among 24,165 general anesthesia procedures in children between 2000 and 2002 (Murat et al., 2004). On the other hand, from the Pediatric Perioperative Cardiac Arrest (POCA) Registry in the United States between 1994 and 1997, the anesthesia-related mortality rate was estimated to be 0.36:10,000 (Morray et al., 2000) (see related section). Obviously, a large-scale prospective and longitudinal study is needed to determine the overall pediatric anesthesia-related mortality in the early 21st century.

ANESTHESIA-RELATED MORBIDITY IN INFANTS AND CHILDREN

Perioperative Cardiac Arrests

Incidences of POCA have been reported from North America, Europe, and Australia. Estimated incidence of cardiac arrests ranged 17 to 24:10,000, and as with the mortality rates, the rates are three to 10 times higher in infants than in older children (Olsson and Hallen, 1988; Turet et al., 1988; Cohen et al., 1990). Studies by Keenan and Boyan (1985) and by Morgan and others (1993) also showed higher incidences of cardiac arrest in younger children (younger than 10 to 12 years) than in older children. Most common causes leading to cardiac arrest involved respiratory and cardiovascular systems and included relative drug overdose, vagal stimulation, hypoventilation, and succinylcholine-induced asystole.

Keenan and others (1991) reported the effect of specialty training in pediatric anesthesia on the safety of children, especially in infants. In a single university hospital setting, the incidence of POCA in infants younger than 1 year of age was 19:10,000 with mortality when residents were supervised by nonpediatric attending anesthesiologists, whereas no cardiac arrest occurred when pediatric anesthesiologists were in charge.

Braz and others (2006) looked at the causes of POCA in children at a teaching hospital in Brazil. They reviewed 15,253 anesthesia procedures that took place between 1996 and 2004. There were 35 cardiac arrests (22.9:10,000) and 15 deaths (9.8:10,000). They identified seven anesthesia-related cardiac arrests but no deaths. The main causes of anesthesia-related cardiac arrest were respiratory events (71.5%) and medication-related events (28.5%). Major risk factors for cardiac arrest were neonates and children under 1 year of age with an ASA PS of 3 or poorer, emergency surgery, and general anesthesia.

Flick and others (2007) reviewed pediatric cardiac arrest data from 1998 to 2005 at the Mayo Clinic. A total of 92,881 anesthetics were administered to children under the age of 18 for noncardiac and cardiac procedures during the study period. The incidence of POCA and mortality during noncardiac procedures was 2.9:10,000 and 1.6:10,000, and the incidence of cardiac arrest during cardiac procedures was 127:10,000. The incidence of POCA attributable to anesthesia was 0.65:10,000, representing 7.5% of the 80 POCA. Both cardiac arrests and mortality were highest among neonates undergoing cardiac procedures. Regardless of procedure type, most patients who experienced POCA (88%) had congenital heart disease. Factors found to be associated with mortality included higher ASA PS, age, the need for mechanical ventilation before surgery, and the cause of the POCA.

Pediatric Perioperative Cardiac Arrest Registry

In order to accurately estimate the incidence of cardiac arrests and adverse outcomes, the Pediatric POCA Registry was formed in 1994 under the combined auspices of the ASA Committee on Professional Liability, the Quality Assurance Committee of the Section on Anesthesiology of the American Academy of Pediatrics (AAP) (Murray, 2004). The registry included 63 institutions, of which 75% were university hospitals and 40% were children's hospitals. All cardiac arrests requiring cardiopulmonary resuscitation during the immediate perioperative period are eligible for inclusion. During the first 4 years of the registry (1994 to 1997), participating institutions administered an estimated total of 1,089,200 anesthetics to children younger than 18 years old (Murray et al., 2000). A total of 289 cardiac arrests were registered, of which 150 cases were considered as anesthesia-related. The mean overall incidence of anesthesia-related cardiac arrest was 1.4:10,000 with a mortality rate of 26% (0.36:10,000). Of the total anesthesia-related cardiac arrests, 55% occurred in infants younger than 11 months of age (Murray et al., 2000).

Of the major causes of anesthesia-related cardiac arrests, medication-related (37%) and cardiovascular causes (32%) were most common, together accounting for 69% (Table 40-4). In contrast, the respiratory causes represented only 20%, a marked reduction from the incidence of 43% reported by the ASA Closed Claim Project (Murray et al., 2000). Equipment-related causes comprised 7% of the total (Murray et al., 2000). With regard to the patients' physical status, 33% were those with ASA PS 1 and 2, a significant decrease from earlier studies of pediatric mortality (57% of deaths), a significant improvement and a move in the right direction, although the percentage is still too high (Graff et al., 1964). Of medication-related cardiac arrests, cardiovascular depression with halothane alone or in combination with other drugs (mostly opioids) accounted for 66% of all medication-related arrests. In healthy children

TABLE 40-4. Mechanisms of Cardiac Arrest

Mechanism	Number of Cardiac Arrests
Medication-related inhalation agents	55 (37%)
Halothane alone	26 (46%)
Halothane plus an intravenous medication	11 (20%)
Sevoflurane alone	2 (4%)
Intravenous medications	
Single	5 (9%)
Combination	5 (9%)
Intravenous injection of local anesthetic	5 (9%)
Succinylcholine-induced hyperkalemia	1 (2%)
Cardiovascular	48 (32%)
Presumed cardiovascular, unclear etiology	18 (38%)
Hemorrhage, transfusion related	8 (17%)
Inadequate/inappropriate fluid therapy	6 (13%)
Arrhythmia	5 (10%)
Hyperkalemia	4 (8%)
Air embolism	2 (4%)
Pacemaker related	2 (4%)
Vagal response	1 (2%)
Pulmonary hypertension	1 (2%)
Tetralogy hypercyanotic spell	1 (2%)
Respiratory	30 (20%)
Laryngospasm	9 (30%)
Airway obstruction	8 (27%)
Difficult intubation	4 (13%)
Inadequate oxygenation	3 (10%)
Inadvertent extubation	2 (7%)
Presumed respiratory, unclear etiology	2 (7%)
Inadequate ventilation	1 (3%)
Bronchospasm	1 (3%)
Equipment related	10 (7%)
Central line	4 (40%)
Breathing circuit	2 (20%)
Peripheral intravenous catheter	1 (10%)
Other	3 (30%)
Multiple events	5 (3%)
Hypothermia	1 (<1%)
Unclear etiology	1 (<1%)

Modified from Murray JP et al.: Anesthesia-related cardiac arrest in children: initial findings of the Pediatric Perioperative Cardiac Arrest (POCA) Registry. *Anesthesiology* 93:614, 2000.

with ASA PS 1 and 2, 64% of cardiac arrests were medication-related in comparison with 23% in those with ASA PS 3 to 5 (Fig. 40-1) (Murray et al., 2000; Mason, 2004). Among the patients who sustained anesthesia-related cardiac arrest in the POCA Registry, death was associated most strongly with an ASA

FIGURE 40-1. Primary cause of anesthesia-related cardiac arrest in patients of ASA PS 1 to 2 compared with patients of ASA PS 3 to 5; *p < 0.01. (From Morray JP et al.: Anesthesia-related cardiac arrest in children: initial findings of the Pediatric Perioperative Cardiac Arrest [POCA] Registry, *Anesthesiology* 93:6, 2000.)

PS 3 to 4 and emergency surgery (Morray et al., 2000). Similar correlations between cardiac arrest or death and ASA PS 3 to 4 were found in the earlier study by Keenan and Boyan (1985).

Since the last publication of the POCA Registry that was based on data between 1994 and 1997, more than 200 POCA cases have been added to the registry (from 2000 to 2003), and about one half of these cardiac arrests were found to be anesthesia-related (Morray, 2004). In a preliminary report on this new series of cardiac arrests, the cause profile has changed considerably from that of 1994 through 1997 (Fig. 40-2) (Morray, 2004). Medication-related cardiac arrests decreased markedly, from 37% to 12% of the total causes, primarily because of the near disappearance of cardiovascular depression by inhaled anesthetics causing cardiac arrest (Morray, 2004). These welcome changes appear to coincide with the replacement of halothane with sevoflurane (with its lower incidence

FIGURE 40-2. Causes of anesthesia-related cardiac arrest in children between 1994 and 1996 vs. between 2000 and 2003. (From Morray JP: Unexpected cardiac arrest in the anesthetized child. Presented at the Society of Pediatric Anesthesia Spring Meeting, March 4-7, 2004.)

of causing myocardial depression and bradycardia) as an anesthetic of choice for induction. As the consequence of reductions in cardiac arrests with medication (primarily from halothane), cardiovascular causes of cardiac arrest increased relatively, from 32% to 52%. Hypovolemia from hemorrhage and a metabolic consequence of massive transfusion and resultant hyperkalemia were the common causes of cardiac arrest under this category (Morray, 2004). Also, with a reduction in medication-related cardiac arrest in healthy infants, the incidence of cardiac arrest in patients with ASA PS 1 to 2 declined considerably from 33% to 19%, one of the most remarkable differences between the first and second databases (Table 40-5).

Bhananker and others (2007) subsequently published a study related to cases submitted to the POCA registry between 1998 and 2004. During that time, the registry received 397 reports of POCA in children. Of these cardiac arrests, 193 were judged as anesthesia related. Three quarters of the anesthesia-related arrests occurred in patients of ASA PS 3 to 5. Between 1998 and 2004, cardiovascular causes of cardiac arrest accounted for the highest proportion of anesthesia-related cardiac arrests (41%), in part because of a dramatic decrease in medication-related cardiac arrest. Among these, the most common identifiable cause was hypovolemia related to blood loss. The majority of these cardiac arrests resulted from blood loss that occurred during either spinal fusion or craniotomy and craniectomy. The most common anesthesia-related factors were underestimation of blood loss (48%) and inadequate venous access (22%). As reported in the preliminary communication by Morray (2004) on cases from the POCA Registry between 2000 and 2003, medication-related cardiac arrests decreased dramatically to 18% of all cardiac arrests (12% for 2000 to 2004, see above) from the 37% reported from

1994 to 1997, apparently because of the decrease in the use of halothane for induction of anesthesia. However, it is important to remember that sevoflurane is also a cardiac depressant, and cardiac arrests related to its effects have been identified in the registry. Most cardiac arrests occurred during anesthesia maintenance (58%). Nearly one quarter (24%) occurred in the induction or preinduction phase, and 19% occurred during emergence, transport, or recovery (Fig. 40-3). Eight of 10 cardiac arrests caused by electrolyte imbalance were caused by hyperkalemia from the transfusion of stored blood. The use of fresh blood cells and saline washing of irradiated blood may help in reducing the incidence of transfusion-associated hyperkalemia. Equipment-related cardiac arrests accounted for 5% of the anesthesia-related incidents, and half of these were secondary to central venous catheter complications. Six percent of the causes of cardiac arrest were unknown. Mortality after anesthesia-related cardiac arrest was 28%. The only factors predictive of mortality after cardiac arrest were ASA PS and emergency surgery.

Information about POCA in children (younger than 18 years) between 1988 and 2005 was reported from the Mayo Clinic (Flick et al., 2007). Out of a total of 92,881 anesthesia procedures, of which about 5% were for the repair of congenital heart disease, the incidence of POCA for noncardiac procedures were 2.9:10,000 and the incidence during the cardiac surgery was 127:10,000. The incidence of cardiac arrest attributable to anesthesia, however, was 0.65:10,000 procedures, representing 7.5% of all POCA, much lower than in some of the published reports. Both the incidence of arrest as well as mortality rates were highest among neonates (younger than 30 days' postnatal life) undergoing cardiac procedures (POCA: 435:10,000; mortality: 389:10,000) (Flick et al., 2007).

Other Perioperative Adverse Events

Computerized data acquisition on nonfatal adverse outcome has become commonplace in most hospitals for QA or quality improvement (QI); such information in pediatric anesthesia has started to appear in the literature. Excellent reviews on this subject have been published (Holzman, 1994; Duncan, 1995).

Cohen and others (1990) reviewed perioperative adverse events in over 29,000 children between 1982 and 1987 at Winnipeg Children’s Hospital. Unlike the adult surgical population, a majority of children (70%) were healthy and had no preoperative medical problems. Infants younger than 1 year of age, particularly those younger than 1 month of age (61% of whom underwent intraabdominal, intrathoracic, or major cardiovascular surgery), had a significantly higher intraoperative incidence of airway obstruction and other adverse respiratory events (9.4%) and hypotension (3.9%) than did older children. Among children 1 to 10 years of age, the most common problem was arrhythmias (3.9% to 9.3%). In the recovery room, infants younger than 1 month of age had hypotension (13.9%), respiratory events (11.6%), and abnormal temperature (4.7%). In older children, the most common adverse event in the recovery period was vomiting (5.9%), followed by airway obstruction (3.2%). This study was performed during the pre-sevoflurane era, when essentially all inhalation inductions were performed with halothane, with potent myocardial depression and bradycardia (Table 40-6).

A report from Hôpital d’Enfants Armand Trousseau in Paris was based on a QA database involving over 24,000 pediatric anesthesia cases for a 30 months between 2000 and 2002, when halothane had been completely eliminated from clinical use (Murat et al., 2004). Although this database did not include open-heart and neurosurgical cases, the nature of adverse events and their incidence have changed considerably. As a whole, respiratory events were most common, representing 53% of all intraoperative events (Table 40-7). As with other reports, respiratory events were more common among infants (3.6:10,000 vs. fewer than 1.5:10,000 in older children); in ear, nose, and throat (ENT) surgery than in other surgery; in children who were intubated vs. those who were not intubated, and in those with ASA PS 3 to 5 vs. PS 1 or 2 (Murat et al., 2004). Cardiac events represented 12.5% of all intraoperative events and were mostly observed in sick children (ASA PS 3 to 5).

In contrast to earlier reports, the incidence of bradycardia was greatly decreased (13:10,000) and arrhythmias essentially disappeared. There were eight cardiac arrests (3.3:10,000), of which five children were in the ASA PS 3 to 5 category and four were infants 6 months old or younger (Table 40-7). There were no anesthesia-related deaths (Murat et al., 2004). Vomiting was the most common adverse event postoperatively, with an overall incidence of 6%. As with previous studies, vomiting was more common in older children than in infants and occurred more often after ENT surgery compared with other surgery and in children who were intubated vs. those who were not (Murat et al., 2004). Similarly, based on QA data of 10,000 surgical cases, Tay and others (2001) in Singapore found critical perioperative incidents four times higher in infants younger than 1 year of age than in older children (8.6% vs. 2.1%). Respiratory events were most common (77.4%) with laryngospasm accounting for 35.7%. There were no anesthesia-related deaths (Tay et al., 2001).

Down syndrome is the most common autosomal chromosomal disorder in humans. Children with Down syndrome have a number of characteristics that place them at high risk for anesthesia complications, including craniofacial and cardiac anomalies. A study of 488 patients undergoing 930 procedures revealed several anesthesia-related complications. The most common complications were severe bradycardia (3.7%), natural airway obstruction (1.8%), difficult intubation (0.5%), postintubation croup (1.8%), and bronchospasm (0.4%) (Borland et al., 2004). The rates of bradycardia, obstruction, and postintubation croup were statistically significant and more than twice the rate of patients without Down syndrome, suggesting the need for increased vigilance in these patients.

Bradycardia

An outcome study from the Medical College of Virginia examined the incidence of bradycardia in nearly 8000 children younger than 4 years of age (Keenan et al., 1994). Bradycardia (fewer than 100 beats per minute) was more common in infants (1.27%) and decreased with age. The incidence in the group of

children who were 4 years old was only 0.16%. Causes of bradycardia included disease or surgery (35%), inhalation anesthesia (35%), and hypoxemia (22%). Of these children, hypotension occurred in 30%, asystole or ventricular fibrillation in 10%, and death in 8%. Significant associated factors predisposing children to bradycardic events, based on multiple logistic regression analysis, were ASA PS, emergency surgery, duration of surgery (longer than 4 hours), and the absence of a trained pediatric anesthesiologist supervising the anesthetic management (Keenan et al., 1994).

Laryngospasm and Bronchospasm

The incidences of laryngospasm and bronchospasm have been studied in a series of large population studies in Stockholm by Olsson and Hallen (1984, 1988). The incidence of laryngospasm in children younger than 9 years of age was 1.7%. The presence of respiratory infection raises the incidence to 9.6%. The incidence of laryngospasm was also increased in patients with obstructive lung disease (6.4%) and in those with a history of previous anesthetic complications (5.5%). The incidence of

Modified from Murat I et al.: Perioperative anaesthetic morbidity in children: a database of 24,165 anaesthetics over a 30-month period, *Pediatr Anesth* 14:161, 2004.

bronchospasm in the same age group increased from 0.4% to 4.1% in those with respiratory infection. The incidence of bronchospasm was also elevated (2.4%) in patients at high risk (ASA PS 3 or higher) (Olsson, 1987).

Up to 40% of children preparing for anesthesia have an upper respiratory tract infection (URI). Possible effects of recent or current URIs and the incidence of respiratory events have been studied by a number of investigators using parental interviews or written questionnaires. Of more than 1500 children, Schreiner and others (1996) found that patients who developed laryngospasm were more than twice as likely to have an active URI than were patients in the control group without URIs. A survey of more than 2000 children by Parnis and others (2001) did not find statistically significant differences in the long-term outcome of children with a recent history of URI. They did,

however, find that orotracheal intubation was associated with an increased probability of respiratory complications compared with the use of a face mask or laryngeal mask airway (LMA). Similarly, in more than 1000 children, Tait and others (2001) found no difference between children with active or recent URIs vs. asymptomatic children, with respect to the incidence of laryngospasm, bronchospasm, or long-term respiratory sequelae. However, children with current or recent URIs had significantly more overall adverse respiratory events, including breath-holding and major desaturation (arterial oxygen saturation [SpO₂] of less than 90%). Independent risk factors for adverse respiratory outcome in children with active URIs included tracheal intubation (younger than 5 years of age), history of prematurity, reactive airways disease, parental smoking, surgery involving the airway, and the presence of copious secretions and

nasal congestion (Tait et al., 2001). A logistic regression analysis was created to look at the relationship between preoperative URI symptoms and adverse events during emergence from anesthesia. No association was found between particular URI symptoms and the rate of adverse events, but adverse events were increased if peak URI symptoms had occurred within the preceding 4 weeks (Homer et al., 2007).

The LMA has been advocated as an alternative to tracheal intubation for airway management in children with URIs. Von Ungern-Sternberg and others (2007) studied over 800 children having elective surgery with an LMA. A medical history of recent URI within the 2 weeks before anesthesia approximately doubled the risk of laryngospasm, oxygen desaturation, and coughing both intraoperatively and in the recovery room. This risk was further increased in younger children and in children undergoing ENT surgery (Tait et al., 2001). Flick and others (2008) reviewed 130 cases of laryngospasm in children at the Mayo Clinic and found that the use of an LMA was associated with laryngospasm even when adjusted for the presence of upper respiratory tract infections and airway anomaly.

Passive smoke exposure was studied in 405 children undergoing mask anesthesia procedures. The incidence of airway complications during anesthesia or postanesthesia recovery was significantly higher in children with passive smoke exposure. Intraoperative laryngospasm and airway obstruction were 4.9 and 2.8 times, respectively, more likely in children with passive smoke exposure (Jones and Bhattacharyya, 2006). Perioperative assessment of children undergoing surgery should include screening for passive smoke exposure to alert anesthesia providers to potential complications.

Aspiration

Studies before the 1970s reported high morbidity and mortality from pulmonary aspiration of gastric contents (Mendelson, 1946). The Baltimore Anesthesia Study Committee reported a mortality rate of 39% in children associated with pulmonary aspiration (Graff et al., 1964) (see Chapter 13, Induction, Maintenance, and Recovery). Studies reported since the 1980s, however, indicate marked improvements in outcome.

From a computer database covering the years between 1967 and 1985, Olsson and others (1986) reviewed more than 185,000 anesthesia cases in all ages and identified 83 cases of pulmonary aspiration of gastric contents (4.7:10,000 cases). The rate of gastric aspiration in children younger than 9 years of age (8.6:10,000) was nearly three times higher than that in young adults (20 to 49 years old). In 47% of patients with aspiration, pneumonia or atelectasis developed, as confirmed by chest radiograph. The mortality rate in children was relatively low (0.2:10,000) (Olsson et al., 1986). Risk factors associated with aspiration included the skill and experience of anesthesiologists, a number of coexisting diseases, ASA PS 3 to 5, emergency surgery, nighttime operation, history indicating an increased risk of regurgitation (e.g., esophageal disease, pregnancy), and difficult intubation. Other high-risk categories included children with intestinal obstruction, increased intracranial pressure, increased abdominal pressure, and obesity. Incidence of gastric aspiration was even lower in studies from the French-speaking countries (1.0:10,000) and from Norway (2.9:10,000) in the 1980s (Tiret et al., 1988; Mellin-Olsen et al., 1996). No fatalities were reported.

Borland and others (1998) studied the incidence and outcome of perioperative aspiration during the 5 years between 1988 and 1993 involving over 50,000 general anesthetic cases at Children's Hospital of Pittsburgh. They identified 52 cases of aspiration (10.2:10,000 cases), of which 25 patients aspirated gastric contents (4.9:10,000) (the rest were blood or pharyngeal secretions). Approximately 80% of aspirations occurred during induction. Most patients were treated aggressively with fiberoptic bronchoscopy through the endotracheal tube (ETT), removal of solid particles, and continuous positive pressure ventilation. Most patients had radiographic evidence of aspiration (e.g. infiltration, pneumonia, atelectasis, or pulmonary edema), but fulminant chemical pneumonitis secondary to aspiration, as reported in early publications, was absent (Mendelson, 1946). No death was attributable to aspiration. Among the different pediatric age groups, the incidence of aspiration was highest among children 6 to 11 years of age (0.22%). Several risk factors for intraoperative aspiration were identified: ASA PS 3 or higher, a history of previous esophageal surgery, and patients with previous chemotherapy undergoing central venous catheter (Broviac catheter) placement. Twenty-nine percent of these children were kept intubated in the postanesthesia care unit (PACU) for several hours or longer, but only 23% of these patients stayed overnight. None of these children developed clinically significant pneumonia, and there were no deaths (Borland et al., 1998).

Similarly, a study from the Mayo Clinic reported a low incidence of aspiration (3.8:10,000). In this report, however, the incidence of aspiration was similar to that of adults (3.1:10,000). There was no serious respiratory morbidity and no associated deaths (Warner et al., 1999). These epidemiologic studies suggest that the incidence of gastric aspiration and associated morbidity and mortality, especially in children, has declined considerably. The risk of aspiration in general, with the exception of the Mayo Clinic report, remained higher in infants and children than in adults (Olsson et al., 1986; Tiret et al., 1988; Warner et al., 1999; Flick et al., 2002).

Postoperative Complications

Postoperative Hypoxemia

During general anesthesia, static tension of the thoracic inspiratory muscle is abolished and the balance between the outward recoil of the thorax and the inward recoil of the lungs is altered. This change in balance results in the reduction of resting lung volume (functional residual capacity [FRC]), airway closure, collapse of alveoli (microatelectasis), and increased venous admixture, particularly in infants and young children (see Chapter 3, Respiratory Physiology in Infants and Children). By means of pulse oximetry, Motoyama and Glazener (1986) were the first to demonstrate that a large proportion of healthy infants and children undergoing simple elective surgical procedures (42%) become hypoxemic in the PACU. Patients sleeping in the PACU tend to be more hypoxemic and for a longer duration than those who are awake and sitting up, but the presence of hypoxemia is not clinically obvious and does not correlate with the recovery score (Motoyama and Glazener, 1986; Soliman et al., 1988). In a study involving a 1152 healthy infants, children, and adults (ASA PS 1) undergoing plastic surgical procedures, postoperative SpO₂ was monitored regularly for 2 hours. The incidences

FIGURE 40-4. The recovery tendencies of arterial oxygen saturation (SpO₂) within the first hour after operation in four age groups. Group 1: infants younger than 1 year old; group 2: toddlers aged 1 to 3 years; group 3: children aged 3 to 14 years; group 4: teenagers and adults aged 14 to 58 years. (From Xue FS et al.: *A comparative study of early postoperative hypoxemia in infants, children, and adults undergoing elective plastic surgery*, *Anesth Analg* 83:709, 1996.)

of both moderate (SpO₂, 86% to 90%) and severe (SpO₂, less than 86%) hypoxemia were the highest among infants (36.6% and 16.7%, respectively), followed by toddlers (20% and 10% in children 1 to 3 years old), children (14% and 3.3%), and adults (8% and 0.6%). The duration of hypoxemia was also significantly longer in infants than in older age groups (Fig. 40-4) (Xue et al., 1996).

Patients also become hypoxemic as often during the short transport from the operating room to the PACU, because the benefit of oxygen breathing to maintain oxygenation lasts only a few minutes (Pullerits et al., 1987). Children with upper respiratory infection and infants younger than 6 months of age are at increasing risk of developing hypoxemia (DeSoto et al., 1988; Kataria et al., 1988; Xue et al., 1996). Most pediatric anesthesiologists, therefore, recommend routine oxygen administration during the transport of children to and in the PACU (Duncan, 1995).

Postoperative Apnea

Postoperative apnea in prematurely born infants has become a major clinical concern since the early 1980s, when the number of premature infants surviving neonatal intensive care started

to increase. Apnea is usually defined as the cessation of breathing lasting longer than 15 to 20 seconds or lasting for a shorter duration when associated with bradycardia, cyanosis, or pallor (Thach, 1985). Apneic spells in these infants after simple surgical procedures are mostly central in origin (cessation of respiratory effort), although some infants have mixed (central and obstructive) apneas (Kurth and LeBard, 1991). Postoperative apnea occurs more commonly in infants with a previous history of apnea and those younger than 42 to 44 weeks' postconception (Liu et al., 1983). Apnea is uncommon after 44 weeks' postconception, although apnea in older ex-premature infants (up to 55 weeks' postconception) has been reported after more extensive surgical procedures (Kurth et al., 1987; Malviya et al., 1993). Malviya and others (1993) recommend that all former premature infants younger than 44 weeks' postconception be monitored for at least 12 hours postoperatively. Another important risk factor for postoperative apnea appears to be the presence of anemia (Welborn et al., 1991).

In 1995, Coté and others published the results of a meta-analysis of data from eight published reports of postoperative apnea between 1987 and 1993 involving 384 ex-premature infants after inguinal hernia repair. They concluded that apnea was strongly and inversely correlated both with gestational age and postconceptional age; an associated risk factor was continuing episodes of apnea at home; small-for-gestational-age infants seemed to be somewhat protected from apnea compared with those with normal or large-for-gestational-age infants; anemia (hematocrit less than 30) was a significant risk factor even beyond 43 weeks' postconceptional age; and relationships of postoperative apnea with history of necrotizing enterocolitis, neonatal apnea, respiratory distress syndrome, bronchopulmonary dysplasia, or operative use of opioids and muscle relaxants could not be determined (Coté et al., 1995). The probability of apnea in infants without anemia who are free of apnea in the recovery room decreases with postconceptional and postnatal ages but is not less than 5% (with 95% confidence limits) until the postconceptional age of 48 weeks (35 weeks' gestational age) and no less than 1% until postconceptional age of 56 weeks (with a gestational age of 32 weeks) or postconceptional age of 54 weeks (with a gestational age of 35 weeks) (Fig. 40-5) (Coté et al., 1995). In 2008, Murphy and others looked at the incidence of apneas in premature infants after inguinal hernia repair in 126 infants

FIGURE 40-5. Probability of postoperative apnea vs. postconceptional and gestational ages of former preterm infants. (From Coté CJ et al.: *Postoperative apnea in former preterm infants after inguinal herniorrhaphy: a combined analysis*, *Anesthesiology* 82:809, 1995.)

over a 5 years. Their data confirmed both the incidence and the risk factors for postoperative apnea of Coté's meta-analysis (Murphy et al., 2008).

Based on these findings, it is generally recommended in the United States that expreterm infants younger than 44 to 46 weeks' postconception be admitted overnight for monitoring after general anesthesia. Whether the infant with postconceptual age between 46 and 48 weeks or even 52 weeks is admitted overnight depends on the decision made case by case between the anesthesiologist and the surgeon, based on a number of factors. These factors include the general health of the infant and his or her home environment (e.g., parents, passive smoking, and distance from the hospital). However, the decision often depends on the general policies of the hospital administration and insurance providers, and these policies do not necessarily represent the best interest of the patient or the health care providers. In countries like France and Japan, where economic pressure on health care resources is less stringent than in the United States, most infants younger than 60 weeks' postconception are admitted overnight for monitoring (Murat, 2002).

The incidence of postoperative apnea was reported to be lower after spinal anesthesia alone than after general (halothane or sevoflurane) anesthesia, but spinal anesthesia combined with ketamine increases the incidence of apnea more than that with general anesthesia (Welborn et al., 1990). Caffeine or methylxanthine may be helpful in preventing postoperative apnea and bradycardia in preterm infants (Welborn et al., 1988). Caffeine is usually preferred, because it has been proposed to have fewer hemodynamic consequences, a greater therapeutic index, and a longer half-life. A dose of 10 mg/kg of caffeine appears to be a safe and effective dose for prophylaxis of postoperative apnea. The infants treated with caffeine had a relative risk of 0.09 for postoperative apnea and bradycardia (McNamara et al., 2004). A long-term study on the effects of caffeine for apnea of prematurity (called the *CAP Study*) has been conducted (Schmidt, 2005).

Upper airway obstruction is an increasingly common indication for adenotonsillectomy in children. Adenotonsillectomy has established effectiveness for the treatment of obstructive sleep apnea (OSA). However, more than 20% of children with OSA have respiratory compromise requiring medical intervention in the postoperative period (Rosen et al., 1994). Nixon and others (2005) studied the postoperative course of children with OSA undergoing adenotonsillectomy surgery. They found that obstructive events occurred postoperatively in all children, but were more common and profound in those with severe OSA preoperatively. They recommend continuous pulse oximetry and overnight admission for children with severe OSA in a unit skilled in pediatric airway management. Schwengel and others (2009) reviewed the current literature on OSA in children and determined several clinical features that predict respiratory compromise after adenotonsillectomy (Box 40-1).

Postintubation Croup

The major cause of postintubation croup is subglottic injury and edema associated with traumatic intubation, especially with an oversized ETT. Koka and others (1977) made an important observation that the incidence of postintubation croup increases markedly when there is no air leak around the ETT with the airway pressure exceeding 40 cm H₂O. Consequently, it has become a standard practice in pediatric anesthesia to choose

Box 40-1 Predictors of Respiratory Compromise and Persistent Obstructive Sleep Apnea after Adenotonsillectomy

Severe obstructive sleep apnea on polysomnography
History of prematurity, especially with respiratory disease
Age less than 3 years
Morbid obesity
Nasal problems (e.g., deviated septum or enlarged turbinates)
Mallampati score 3 or 4
Neuromuscular disorders or disordered pharyngeal tone
Genetic or chromosomal disorders
Craniofacial disorders
Enlarged lingual tonsils
Upper respiratory infection within 4 weeks of surgery
Cor pulmonale
Systemic hypertension
Marked obstruction on inhalational induction
Disordered breathing in the PACU
Difficulty breathing during sleep
Growth impairment resulting from chronic obstructed breathing

Modified from Blum RH, McGowan FX: Chronic upper airway obstruction and cardiac dysfunction: anatomy, pathology, and anesthetic implications, *Paediatr Anaesth* 14(1):75–83, 2004; Guillemainault C, Huang YS, Glamman C, et al: Adenotonsillectomy and obstructive sleep apnea in children: a prospective survey, *Otolaryngol Head Neck Surg* 136(2):169–175, 2007; Gerber ME, O'Connor DM, Adler E, Myer CM 3rd: Selected risk factors in pediatric adenotonsillectomy, *Arch Otolaryngol Head Neck Surg* 122(8):811–814, 1996; McGowan FX, Kenna MA, Flemming JA, O'Connor T: Adenotonsillectomy for upper airway obstruction carries increased risk in children with a history of prematurity, *Pediatr Pulmonol* 13(4):222–226, 1992; Fricke BL, Donnelly LF, Shott SR, et al: Comparison of lingual tonsil size as depicted on MR imaging between children with obstructive sleep apnea despite previous tonsillectomy and adenoidectomy and normal controls, *Pediatr Radiol* 36(6):518–523, 2006.

an ETT that produces air leak around the tube with a pressure lower than 30 cm H₂O. With this preventive measure in clinical practice, the incidence of postintubation croup has decreased dramatically from 1% to less than 0.1%, along with reductions in the severity of croup (Litman and Keon, 1991). With the presence of a URI, however, the incidence of airway complications and the tendency for oxygen desaturation increase (Cohen and Cameron, 1991; Rolf and Coté, 1992).

Until the late 1980s and early 1990s, the use of cuffed ETTs was not generally recommended in most pediatric anesthesia textbooks for children younger than 5 to 8 years of age, depending on the authors (Fisher, 1989; Uejima, 1989). The primary reason for it had been that the inner diameter (ID) of a cuffed ETT had to be 1 to 2 sizes (0.5 to 1.0 mm) smaller than the uncuffed tube to accommodate the passage through the larynx of a bulky cuff, and consequently flow resistance would be drastically increased in those children most commonly breathing spontaneously under general anesthesia (with ether) before mechanical ventilation became a common practice (Gronert and Motoyama, 1996). More recently, cuffed ETTs have been used increasingly in young children and even in infants, and such practice has shown to be associated with decreased, rather than increased, incidence of postintubation croup (Motoyama, 2009). This decrease is in part a consequence of choosing a cuffed ETT that is 1 to 2 sizes smaller than a "properly" fitting uncuffed tube, thereby markedly reducing the need for reintubation attempts. (Keine, 1997; James, 2001; Fine and Borland,

2004; Cohen and Motoyama, 2006). Indeed, Murat (2001) reported that after a complete elimination of uncuffed ETTs at the Children's Hospital in Paris, there was not a single incidence of postintubation croup over 3 years. A new microcuffed pediatric ETT has been developed that seals with a high-volume, low-pressure cuff (Dullenkopf et al., 2005). This tube uses an ultrathin, walled polyurethane cuff that is shorter and more distally placed. It can stay away from the cricoid mucosa while the airway is sealed at the upper to midtrachea, and away from the carina even in the neonate, where the posterior membranous wall can stretch and accommodate a complete seal with a low cuff pressure of less than 15 cm H₂O without increases in airway complications (Dullenkopf et al., 2005). In a study of 500 children, the microcuffed tube exchange rate was 1.6%, with only 0.4% having postintubation croup requiring therapy (Dullenkopf et al., 2005; Weiss and Gerber, 2006).

Postoperative Nausea and Vomiting

Although rarely life-threatening, postoperative nausea and vomiting (PONV) remains the single most common complication resulting in unscheduled overnight admissions in same-day surgery settings (Cohen et al., 1990; Patel and Rice, 1991). PONV occurs twice as often in children as in adults, increasing until puberty and then decreasing to adult incidence rates. The average incidence of PONV in children over 3 years of age is reported to be over 40%. The incidence of PONV has decreased considerably with newer anesthetics and techniques as well as with more effective medications (Murat et al., 2004). The incidence of PONV is higher after certain types of surgery, including adenotonsillectomy, eye-muscle surgery for strabismus, and orchiopexy. Other factors affecting the incidence of PONV include the gender and age of the child (uncommon in infants), PONV after previous surgery or history of motion sickness, anesthesia techniques (inhaled anesthetics and nitrous oxide vs. intravenous anesthesia with propofol), tracheal intubation, intraoperative opioids, inadequate pain control, gastric distention, and the skill of the anesthesiologist (Patel and Rice, 1991; Martin et al., 1993; Weir et al., 1993; Weinstein et al., 1994; Duncan, 1995; Villeret et al., 2002). A mandatory requirement for oral fluid intake and early ambulation before discharge from the short stay unit has also been associated with increased incidence of vomiting (Schreiner et al., 1992; Weinstein et al., 1994). Serotonin (5-HT₃) receptor antagonists (such as ondansetron and granisetron) have shown to be highly effective in preventing or treating PONV and are the preferred first-line agents for children, especially because ondansetron has become available as a less expensive generic drug (Fujii et al., 1996; Patel et al., 1996; Gan et al., 2007; Glass and White, 2007). Prophylactic use of dexamethasone and transdermal scopolamine were also found to be effective (Aouad et al., 2001) (see Chapter 11, Intraoperative and Postoperative Management). Gan and others (2003) developed consensus guidelines for the management of PONV. Strategies to reduce baseline PONV risk factors include the use of regional anesthesia, use of propofol for induction and maintenance of anesthesia, use of intraoperative supplemental oxygen, use of hydration, avoidance of nitrous oxide, avoidance of volatile anesthetics, minimization of intraoperative and postoperative opioids, and minimization of neostigmine (Gan et al., 2007). Droperidol has been effectively used for many years for PONV prophylaxis. However, because of the increased risk of extrapyramidal symptoms, high levels of sedation, and the

United States Food and Drug Administration's (FDA's) "black box" warning about QT prolongation, droperidol was recommended to be reserved for patients in whom all other therapies have failed and who are being admitted to the hospital (Gan et al., 2003). Children at moderate to high risk for PONV should be given antiemetic prophylaxis with combination therapy with 2 or 3 prophylactic antiemetics from different antiemetic drug classes.

In comparison with PONV, the studies on postdischarge nausea and vomiting (PDNV) have been lacking. Oral opioid analgesics for postoperative pain management are a major factor contributing to PDNV in the ambulatory surgery facilities or after discharge from a hospital (Glass and White, 2007). Long-acting antiemetics (e.g., transdermal scopolamine or palonosetron) may offer an advantage over the commonly used antiemetics (Glass and White, 2007).

Complications of Regional Anesthesia

The potential benefits of peripheral nerve blocks for surgical procedures, when compared with general anesthesia, include improved postoperative analgesia, with an associated decrease in postoperative pain medication use, decreased nausea and vomiting, and quicker recovery and discharge times from the hospital (Hadzic et al., 2004). Regional anesthesia techniques in children have become more popular in the past decade. A survey by the ASA Closed Claims Project on the complication of regional anesthesia revealed that of 2400 closed anesthesia malpractice claims cases, 29 adult patients and 1 pediatric patient who developed cardiac arrest during regional anesthesia, resulting in death or severe brain damage, were identified (Murray et al., 1993). From the analysis of these data, mostly from the time before the ASA monitoring guidelines, including the mandatory use of pulse oximetry and capnography, had been adopted, it can be concluded that cardiac arrest resulting in death or other major outcomes can occur during apparently well-managed spinal or epidural anesthesia in young, healthy patients undergoing relatively minor procedures because respiratory insufficiency from sedation was not recognized; and that pulse oximetry would have given an early warning of respiratory insufficiency (Caplan et al., 1988; Cheney, 1988; Keats, 1988). An examination of the closed claims database from 1980 to 2000 by Lee and others showed that the most common complication associated with peripheral nerve block claims was nerve damage (31%) followed by pneumothorax (25%) and eye damage (18%). Block-needle trauma was the cause of 38% of these nerve injury claims. (Lee et al., 2008). The increasing use of ultrasound for the placement of peripheral nerve blocks has the promise of decreasing the incidence of nerve damage caused by block needle trauma (Marhoffer et al., 2005). Unintentional intravascular injection or signs of local anesthetic toxicity were associated with one third of the 19 claims with death or brain damage. Outcomes from this potentially lethal complication may be improved with the recent introduction of 20% intralipid as a rescue agent for local anesthetic toxicity (Lee et al., 2008).

The Japanese Society of Anesthesiology has conducted annual surveys concerning critical incidents in the operating room since 1994. Irita and others (2005) investigated critical incidents associated with regional anesthesia between 1999 and 2002. In patients receiving regional anesthesia, 628 critical incidents, including 108 cardiac arrests and 45

subsequent deaths were reported. The incidences of cardiac arrest and mortality resulting from anesthetic management were 0.54 and 0.02:10,000 with spinal anesthesia, 0.55 and 0.10:10,000 with combined spinal-epidural anesthesia, and 0.72 and 0.14:10,000 with epidural anesthesia, respectively (Irita et al., 2005).

Valley and Bailey (1991), in a retrospective survey involving 138 pediatric patients who received caudal morphine, reported 11 patients (8%) with postoperative respiratory depression. All but one incident occurred in infants younger than 12 months of age and within 12 hours of caudal morphine administration (70 mcg/kg). Krane (1988) reported a life-threatening delayed respiratory depression in a 2.5-year-old boy that occurred 3.5 hours after the administration of caudal morphine (100 mcg/kg, a much higher dose than today's standards of 30 to 50 mcg/kg) for postoperative analgesia. Intravenous naloxone was continued until 16.5 hours after caudal morphine to maintain adequate breathing. Jones and others (1984) used intrathecal morphine in 56 children undergoing open-heart surgery. Respiratory depression occurred (most commonly, 3.5 to 4.5 hours after morphine administration) in six of 27 patients (22%) who received 30 mcg/kg of morphine and in three of 29 children (10%) who received 20 mcg/kg. Patients receiving epidural or intrathecal morphine should therefore be admitted overnight and their respiration continuously monitored.

Giaufre et al. (1996) reported on a 1-year prospective study (1993 to 1994) of morbidity and mortality associated with regional anesthesia by the French Language Society of Pediatric Anesthesia. The study involved over 24,000 regional-block procedures out of about 85,000 pediatric anesthesia cases of which central blocks (approximately 15,000 cases [62%]) were the most common, followed by peripheral nerve blocks (17%) and others (22%). Of the central blocks, caudal block was most common (12,000, or 80% of central block or 50% of the total), followed by lumbar epidural (1700) and spinal anesthesia (500). A total of only 23 incidents was reported, with a morbidity rate of zero for peripheral blocks, 11 (0.7:1000) for caudal blocks, nine (3.7:1000) for lumbar epidural blocks, two (6.8:1000) for sacral epidural blocks, and one (2:1000) for spinal anesthesia (Giaufre et al., 1996). Complications included eight dural punctures (resulting in total spinal block in four cases), six intravascular injections (resulting in seizures or arrhythmias), two overdoses with arrhythmias, and one case of opioid-related apnea. No fatalities were reported. Thus, this study appears to establish the safety of regional anesthesia in children, although there had been some concerns and controversies about the safety of performing regional blocks in children under general anesthesia, because this is widely accepted as an unsafe practice in adults (Giaufre et al., 1996).

More recently, an analysis of a prospective audit of children receiving epidural infusion analgesia (EIA) in the United Kingdom and Ireland has been published; the audit included 10,633 EIA cases over 5 years (2001 to 2005) (Llewellyn and Moriarty, 2007). Of 96 incidents reported, 56 (1:198) were associated with the insertion and maintenance of EIA (mostly of low severity); five incidents were graded as 1 (serious) (1:2000); nine incidents were graded as 2 (moderate) (1:1100). Only one child had residual effects after 12 months after surgery (1:10,000). There were no reported deaths with EIA. There were four cases of compartment syndrome (1:1400), but none of them appeared to be masked by the presence of working epidural analgesia (Llewellyn and Moriarty, 2007).

Complications Arising from Sedation

According to the data compiled by the United States Department of Health and Human Services, more than 80 deaths attributable to midazolam occurred within 3 years after its introduction for clinical use in 1986. Midazolam was used, often in combination with fentanyl, for the sedation of patients undergoing various procedures without the supervision of anesthesiologists (Bailey et al., 1990). Of these deaths associated with midazolam, 78% were respiratory events, with opioids being used in 57% of these cases (Bailey et al., 1990).

A collaborative study by the American Society of Gastrointestinal Endoscopy and the United States Food and Drug Administration, involving over 21,000 endoscopic procedures with sedation, revealed the incidence of serious cardiorespiratory outcome to be 54:10,000 cases with a mortality rate of 3:10,000; that is 10 to 50 times higher than the reported deaths associated with general anesthesia (Tiret et al., 1986, 1988; Buck et al., 1987; Holland, 1987; Eichhorn, 1989; Arrowsmith et al., 1991). These extremely high morbidity and mortality rates of conscious and deep sedations (apparently including inadvertent general anesthesia and deaths) performed by clinicians who were not anesthesiologists and without adequate skills, proper monitoring, or supervision have led the way to the establishment and modifications of the new sedation guidelines by the AAP Section of Anesthesiology (Committee on Drugs, Section on Anesthesiology, American Academy of Pediatrics, 1985, 1992). Although the terms adopted (*conscious sedation* in particular) were misnomers (if not oxymorons), in hindsight the guidelines included the approach similar to that commonly practiced by anesthesiologists; that is, proper fasting, preprocedural history and physical examinations with a special attention to the airways, informed consent, monitoring including pulse oximetry, documentation of drugs used and vital signs during and after the procedure, and discharge criteria (Coté, 2004).

The JCAHO (1992) in the United States modified its regulations and published rules to develop new guidelines in each health care institution it accredits (available at www.jcaho.org). To further improve patient safety for sedation in accordance with the new JCAHO regulations, a task force by the ASA developed new guidelines for sedation by nonanesthesiologists (Gross et al., 2002). The sedation guidelines were again updated in 2002 (American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists, 2002) with the new terminology (available at www.asahq.org/standards) and were later incorporated by JCAHO and by the AAP (Committee on Drugs, Section on Anesthesiology, American Academy of Pediatrics, 2002). The term *conscious sedation* has been eliminated, and instead, three stages of procedural sedation are described: minimal, moderate, and deep stages (plus general anesthesia) (Coté, 2004).

Under the new JCAHO regulations, the director of anesthesia service in each institution has a responsibility for developing new "within-institution" sedation guidelines by nonanesthesiology services to further improve patient safety. General guidelines include onsite availability of oxygen and positive pressure oxygen delivery system (that can provide the minimum of 90% oxygen for 60 minutes), a resuscitation kit (including drugs, laryngoscope, and ETTs), a suction apparatus, and monitors (pulse oximeter, electrocardiography, and blood pressure apparatus). Documentation for sedation should include evaluation of health status before sedation, informed consent, record of

drugs given (the time and doses), and vital signs (oxygen saturation, heart and respiratory rates). For deep sedation, there must be a dedicated person (e.g., registered nurse or respiratory therapist) in addition to the practitioner, whose only responsibility is monitoring and who is trained to perform resuscitation.

Using a QA database created specifically for procedural sedation, Malviya and others (1997) identified 239 adverse outcomes (20% of 1140 children), mostly after receiving recommended doses of chloral hydrate. Oxygen desaturation (5.5%) was the most common adverse outcome, and laryngospasm and apnea occurred in five children. Inadequate sedation occurred in 150 (13.2%) children. These findings appear to indicate that the establishment and enforcement of safety guidelines for procedural sedation have considerably reduced the incidence of adverse outcomes.

Analysis of adverse sedation events reported to the United States Food and Drug Administration (FDA) between 1969 and 1996 by Coté and others (2000) revealed that of 95 incidents reported, 60 ended in death (51) or permanent neurologic injury (9). Although the incidence of respiratory events (about 80% of all events; mostly hypoxia, laryngospasm, and apnea) was similar between hospital and nonhospital settings, inadequate resuscitation (57.1% vs. 2.3%) and death or permanent neurologic injury (92.8% vs. 37.2%) occurred more often in nonhospital vs. in hospital environments. Death or severe adverse outcome occurred disproportionately more often (32 of 95 cases) involving sedation for dental procedures (mostly at nonhospital settings). Ten children sustained death or permanent neurologic injury in the car or at home after being discharged from medical supervision despite deep levels of residual sedation. Unsupervised sedative medication by a parent at home (or by a technician at a facility) caused an additional two cardiac arrests in the car on the way to the hospital or clinic (Coté et al., 2000). The results of this report imply the inadequacy of existing (or the nonexistence of) discharge criteria and their practice. Two reports have further addressed these issues.

Motas and others (2004) studied the efficacy and safety of procedural (light or deep grade) sedation in 86 children under 12 years of age undergoing sedation by nonanesthesia services (for computed tomography scans, cardiac catheterizations, gastrointestinal endoscopy, and dental procedures). A variety of medications were used by different services, including intravenous pentobarbital, intravenous midazolam with fentanyl or meperidine, oral chloral hydrate with meperidine and hydroxyzine, and intramuscular or intravenous ketamine (Motas et al., 2004). An independent observer applied the Bispectral Index (BIS) monitor (40 to 60, general anesthesia; 61 to 70, deep sedation; 71 to 90, minimum, and over 90, awake) and the University of Michigan Sedation Scale (UMSS) (0 to 4 observational scale: 0, awake; 1, minimal sedation [tired, sleepy]; 2, moderately sedated [easily arousable]; 3, deeply sedated [deep sleep, arousable only with strong stimulus]; and 4, unarousable or general anesthesia) at 10-minute intervals for 1 hour. The goal of either light or deep sedation was attained in 53% (BIS) and 72% (UMSS) of cases. Depth consistent with general anesthesia was observed in 35% (BIS) and 0% (UMSS) of patients, and depth consistent with awake state (failure) was observed in 12% (BIS) and 28% (UMSS) of cases. About 8% of patients experienced desaturation and airway events. The patients were often sedated either too deeply or not enough, and the goal of either light or deep procedural sedation was not achieved in large numbers of children.

Malviya and others (2004) assessed the readiness for discharge in 29 children after procedural sedation for echocardiographic examinations with either chloral hydrate (93%) or midazolam with diphenhydramine (7%). A trained observer used a BIS monitor, UMSS scores every 10 to 15 minutes, a Modified Maintenance of Wakefulness Test (MMWT), and the visual observation of the time until the child was able to stay awake for 20 minutes, until revised discharge criteria were met (BIS greater than 90, UMSS of 0 or 1, MMWT greater than 20 minutes). There were moderate correlations among BIS, UMSS, and MMWT ($p < 0.01$). Revised criteria correctly identified wakefulness (BIS value greater than 90) in 88% of patients. However, when discharged by the nurse, only 55% of patients returned to the baseline BIS value (greater than 90); it took longer to meet the revised criteria (more appropriate and safer) compared with standard criteria (nursing judgment) (75 minutes vs. 13 minutes, $p = 0.001$).

Thus, Malviya and others (2004) clearly demonstrated that sedation with chloral hydrate can result in prolonged sedation even after the children reached currently used (but unsatisfactory) discharge criteria by nurses, with a potential for airway obstruction and adverse outcome (Coté et al., 2000). The results of this study have several important implications. First, the currently practiced guidelines are inadequate and need changes that make use of more reliable criteria, such as UMSS, MMWT, BIS monitor, or their combinations, to further improve patient safety associated with procedural sedations. Second, the duration of postsedation monitoring should be increased beyond what is currently practiced, and the hospital must respond to increase staffing needs for nurses in the recovery area and to provide additional space for adequate patient observation (quiet space for MMWT) and recovery, changes that have associated cost increases. Third, the anesthesia service should provide additional guidelines to nonanesthesiologists for the proper selection of sedative and hypnotic drugs, with shorter elimination half-life to shorten the recovery time (Coté, 2004). In addition, office-based procedures that are performed with the patient under sedation should either be performed under the care of anesthesiologists within the office setting or moved to hospital-based facilities to further decrease untoward events (see Chapter 35, Anesthesia for Office-Based Pediatric Anesthesia).

Cravero and others (2006) looked at data collected by the Pediatric Sedation Research Consortium (PSRC), a collaborative group of 35 institutions. A total of 26 institutions submitted data on 30,037 sedation and anesthesia procedures outside of the operating room from 2004 to 2005. Serious adverse events were rare in the institutions involved in the study; there were no deaths. Cardiopulmonary resuscitation (CPR) was required once. Less serious events were more common with oxygen desaturations below 90% for more than 30 seconds, occurring 157 times per 10,000 sedations. Unexpected apnea, excessive secretions, and vomiting had rates of 24, 41.6, and 47 per 10,000 encounters, respectively (Cravero et al., 2006). They concluded that pediatric sedation and analgesia for procedures outside of the operating room are unlikely to yield serious adverse outcomes in a collection of institutions with highly motivated and organized sedation services. However, the safety of this practice depends on the system's ability to manage less serious events (Cravero et al., 2006).

In 2008, Cravero and others looked at the safety of pediatric sedation and anesthesia with propofol for procedures outside of the operating room. Thirty-seven members of the PSRC submitted data on 49,836 propofol sedation and anesthesia

cases from 2004 to 2007. There were no deaths, CPR was required twice, and aspiration during sedation or anesthesia occurred four times. Less serious events were more common with O₂ desaturation below 90% for more than 30 seconds, occurring 154 times per 10,000 sedation and anesthesia administrations. Central apnea or airway obstruction occurred 575 times per 10,000 sedations. Stridor, laryngospasm, excessive secretions, and vomiting had rates of 50, 96, 341, and 49 per 10,000 encounters, respectively. They concluded that, in the hospital setting of those institutions participating in the PSRC, the reported incidence of serious events in pediatric propofol sedation and anesthesia is low. However, the reported incidence of events that have the potential to harm and that require timely rescue interventions is significant, occurring once per 89 propofol administrations (Cravero et al., 2009).

Bhananker and others (2006) reviewed closed malpractice claims from the ASA database since 1990 to assess the patterns of injury and liability associated with monitored anesthesia care (MAC) compared with general and regional anesthesia. More than 40% of claims associated with MAC involved death or permanent brain damage, similar to general anesthesia claims. Respiratory depression (25%) was the most common damaging mechanism in MAC claims. Nearly half of these claims were judged as preventable by better monitoring.

COMMON CAUSES OF ANESTHESIA-RELATED MISHAPS

Judgment Errors

If one accepts the theory that “to err is human” and recognizes that “all human beings, without any exception whatsoever, make errors and [errors] are a completely normal and necessary part

of human cognitive function,” then it is not surprising to realize that most anesthetic mishaps involve human errors and are preventable (Salem et al., 1975; Cooper et al., 1978; Allnutt, 1987; Holland, 1987; Kohn et al., 1999). Cooper and others (1978), with the use of a carefully structured interview technique with a group of anesthesiologists, collected accounts of incidents in which human error or equipment failure occurred. These investigators found that 82% of incidents were caused by preventable human error; the remaining incidents were mostly caused by equipment failure. Analysis of 238 closed anesthesia malpractice claims involving pediatric patients revealed that 43% of these claims were related to inadequate ventilation and resulted in death or severe permanent neurologic damage (Murray et al., 1993). Murray and others concluded that 89% of these cases could have been prevented if they were monitored with pulse oximetry or capnography.

Holland (1987) compared incidences of various categories of mishaps during his three decades of investigation involving anesthesia-related mortality in patients of all ages (Table 40-8). In the 1960s, anesthetic overdose, wrong choice of anesthetics, inadequate preoperative preparation, and inadequate crisis management dominated as common causes of adverse outcomes, indicating inadequacy (according to today's standard) of equipment and the physicians' experience with administering anesthesia. The total incidence of management errors involving fatality was 2.7:10,000 anesthesia procedures. There has been a dramatic decrease in the incidence of management errors with time, as well as changes in the dominant categories of error in management over the decades. In the 1980s, inadequate preparation and inadequate postoperative management ranked high among the categories of errors causing anesthesia-related fatalities. Incidence of management errors decreased to 0.55:10,000 anesthetics, about one fifth that in the 1960s. Factors commonly associated with preventable adverse outcomes (both fatal and nonfatal) include a failure to perform proper review

of patients and anesthesia apparatus, distraction (e.g., inattention, haste, fatigue, and boredom), lack of experience, and lack of a skilled assistant (Craig and Wilson, 1981; Derrington and Smith, 1987).

Emergency or Urgent Cases

Inadequate preanesthetic preparation occurs most often with emergency or urgent cases and most commonly represents failure to appreciate the patient's degree of dehydration and electrolyte imbalance (Holland, 1987). In the CEPOD study cited previously, more than 20% of anesthesia-related deaths occurred after surgery performed as emergencies, and an additional 40% occurred in operations classified as urgent (Buck et al., 1987). In the New South Wales study, the risk of anesthesia-attributable death in patients undergoing emergency anesthesia is 10 times that of the overall incidence (Holland, 1987). In the British CEPOD study, anesthesiologists were dissatisfied with preoperative preparations in 14% of cases that ended with anesthesia-related deaths, but they presumably were pressured or persuaded by surgeons into administering anesthesia. On the basis of these findings, Lunn and Devlin (1987) emphasize the importance of proper preanesthetic preparation as an important deterrent of tragic outcome. In children, the incidence of bradycardic episodes, both fatal and nonfatal, during anesthesia was reported to be significantly higher among emergency surgical procedures (2.7%) than in elective procedures (1.1%) (Keenan et al., 1994).

Timing of Occurrence

Keenan and Boyan (1985) in a 15-year study of cardiac arrest resulting from anesthesia in a university hospital setting, found 18 of 27 cases that occurred during the induction of anesthesia, whereas the remaining nine occurred intraoperatively. However, in five of six patients in the pediatric age group who sustained cardiac arrest (aged 1 day to 6 years), the cardiac arrest occurred during the maintenance of anesthesia. In most other reports, critical incidents or mishaps, including the cardiac arrests reported from the POCA Registry as discussed earlier in this chapter, have occurred most often during the maintenance period of anesthesia (Cooper et al., 1978; Craig and Wilson, 1981; Gibbs, 1986; Bhananker et al., 2007). The maintenance period is not the quiet interlude between often stormy induction and emergence that many anesthesiologists had for a long time supposed (Epstein, 1978). In a survey involving 112,000 general anesthetic cases in a teaching hospital between 1975 and 1983, the incidence of intraoperative adverse events among adults was lower than events in the PACU (Cohen et al., 1988). In contrast, the incidence of adverse events in children tended to be higher during surgery than in the PACU (Tiret et al., 1988). Machine-patient disconnection was a common occurrence in the 1970s before the disconnect alarm became a standard feature of anesthesia machines, as mandated by the American National Standard Institute Z79 Committee on Anesthesia Equipment (Cooper et al., 1978).

Anesthetic Overdose

Drug overdose as the cause of anesthetic death occurs, although the incidence has decreased since the 1980s and it accounted for only 5.4% of anesthetic deaths reported to

the Medical Defense Union of the United Kingdom between 1970 and 1979 (Utting et al., 1979; Holland, 1984, 1987). In a 15-year study between 1969 and 1983 by Keenan and Boyan (1985) an "absolute overdose" (a dose well in excess of the usual clinical range) caused one third of all cardiac arrests resulting from anesthesia. Of six incidents of cardiac arrest in children in this series, absolute overdose with halothane was responsible in five cases; the other resulted from airway obstruction during nitrous oxide-curare anesthesia.

As described earlier, the POCA Registry database revealed that from 1994 to 1997, cardiovascular depression with halothane accounted for 66% of all medication-related cardiac arrests. In healthy children with ASA PS 1 or 2, 64% of all cardiac arrests were medication-related, in comparison with 23% in those with ASA PS 3 to 5 (Murray et al., 2000). The database from 2000 to 2003, when halothane had been replaced by sevoflurane as the primary inhalation induction agent, showed a dramatic decrease in medication-related cardiac arrest, from 37% to 12% of the total arrests, indicating the importance of safer anesthetic drugs for reducing medication-related complications (Fig. 40-2) (Murray, 2004).

Risk Factors in Pediatric Anesthesia

A number of perioperative risk factors specific to infants and children have been identified.

Age

Infants younger than 1 year of age are at higher risk of developing complications (Tiret et al., 1988; Cohen et al., 1990). A prospective survey in France between 1978 and 1982 involving 440 institutions and a total of 40,240 anesthetic procedures found 27 major complications, of which nine occurred in infants (0.43:10,000 cases), an incidence significantly higher than that in children (0.05:10,000) (Tiret et al., 1988). Infants younger than 1 year of age also showed a significantly higher incidence of airway obstruction and other respiratory problems than did older children (Cohen et al., 1990). Cohen and others (1990) reported that the intraoperative incidence of complications in children was about the same as that in adults, but postoperative complications (35%) were twice as common as in adults (17%). The POCA Registry database from 1994 to 1997 revealed that 83 of 150 cases, or 55%, of anesthesia-related cardiac arrests occurred in infants younger than 12 months of age (Table 40-5) (Murray et al., 2000).

Physical Status

Correlation between POCA and ASA PS has been reported in adults (Keenan and Boyan, 1985). In a large-scale prospective survey in France involving infants and children, Tiret and others (1988) showed a highly significant correlation between the ASA PS classification and the incidence of major perianesthetic complications in children (Table 40-9). They also found a highly significant correlation between the perioperative adverse outcomes and the number of coexisting diseases. The POCA Registry database between 1994 and 1997 showed 100 of 150 (66.7%) of all anesthesia-related cardiac arrests occurred among children with ASA PS 3 to 5 (Murray et al., 2000) (Table 40-5).

Emergency Surgery

The French study by Tiret et al. (1988) showed a threefold increase in perioperative complications in pediatric emergency cases compared with the scheduled cases (Table 40-9). Similarly, Keenan and others (1994) found a highly significant increase of bradycardic episodes in children during emergency surgery compared with those with elective procedures (2.7% vs. 1.1%).

Training

Proper training or experience is particularly important for minimizing the incidence of adverse outcome in the field of pediatric anesthesia. In a retrospective study in a large university hospital over a span of 7 years, Keenan and others (1991) reviewed the incidence of cardiac arrests occurring in infants younger than 1 year of age. No anesthesia-related cardiac arrests occurred when trained pediatric anesthesiologists were in charge of pediatric cases. In contrast, when nonpediatric anesthesiologists were supervising, cardiac arrests (including deaths) occurred at a rate of 19.7:10,000 pediatric anesthesia procedures. In a subsequent prospective study from the same institution for the period of 9 years ending in 1992, the incidence of bradycardic episodes was significantly higher when

pediatric anesthesiologists were not supervising the trainees administering anesthetics to infants (2.1%) compared with when pediatric anesthesiologists supervised the trainees (0.8%) (Keenan et al., 1994).

PREVENTION OF ANESTHESIA-RELATED MISHAPS

The first important step toward patient safety is prevention of critical events. As is clear from the foregoing discussion, a number of steps should be taken to achieve this goal.

Preanesthetic Preparation

Preoperatively, the patient's past medical history, especially the anesthetic history if there is any, should be reviewed thoroughly, and the patient should be examined carefully. The anesthesia machine, accessories, and drugs should also be checked carefully, because failure to perform these steps properly has been identified as a major cause of anesthesia-related mishaps, including death (Holland, 1984, 1987; Derrington and Smith, 1987). In an emergency or urgent situation (perhaps with the exception of exsanguination, cardiac tamponade, or acute upper airway obstruction), clinicians should try to take at least minimal necessary steps (e.g., fluid resuscitation, transfusion, correction of electrolytes, acid-base imbalance, and fever) to stabilize the patient for anesthesia and surgery in a coordinated effort with the surgeon. The anesthesiologist should not yield to unreasonable pressures to start the case before the patient is best prepared under these circumstances. Indeed, hypovolemia and anemia are reported to be the major causes of anesthesia-related cardiac arrest in infants and children (Salem et al., 1975).

If the anesthesiologist is unfamiliar or uncomfortable with uncommon pathophysiology (e.g., an infant with a cyanotic heart disease coming for noncardiac surgery or a child with craniopharyngioma and diabetes insipidus), the anesthesiologist should not hesitate to ask for consultation with a senior anesthesiologist or other specialists. In addition, especially in an emergency situation (such as posttonsillectomy bleeding or acute epiglottitis), an experienced assistant, preferably an attending pediatric anesthesiologist, should be standing by for the induction. Keenan and others (1994) found a significantly lower incidence of bradycardic events with the presence of a pediatric anesthesiologist during induction. In teaching institutions, resident trainees should always be supervised by a pediatric attending anesthesiologist for a pediatric patient. Lack of an experienced assistant has been associated with anesthesia-related mortality and a high rate of morbidity (Craig and Wilson, 1981; Derrington and Smith, 1987; Eichhorn, 1989; Keenan et al., 1994). A reluctance to ask for help, whether out of insecurity, pride, or ill-conceived heroism (or machismo), has no place in a pediatric anesthesia emergency and is the first step toward disaster.

Vigilance

A timely recovery from impending failure is the key to patient safety. It is therefore extremely important to recognize without delay that something is going wrong. Sustained attention or

Modified from Tiret L et al: Complications related to anaesthesia in infants and children: a prospective survey of 40,240 anaesthetics, *Br J Anaesth* 61:263, 1988. ASA PS, American Society of Anesthesiologists physical status.

vigilance is essential for patient safety during the maintenance of anesthesia, because critical events most commonly occur at the time of presumably reduced mental and physical workload (Cooper et al., 1978; Craig and Wilson, 1981; Gibbs, 1986; Gaba et al., 1987). One should develop the habit of scanning all of the monitors regularly in an orderly fashion, as a pilot in flight scans the instrument panel at regular intervals, to keep up with minute deviations in the patient's cardiorespiratory stability. A survey by Cooper and others (1984), however, suggested that at least 33% of critical incidents occurring during the maintenance of anesthesia resulted from errors in judgment rather than from inattentiveness. Vigilance is an important deterrent but by itself is not sufficient for prevention of critical incidents. However, the notion that all human beings, including all anesthesiologists, make mistakes should not be used as an excuse to discount the importance of vigilance, especially in pediatric anesthesia (Allnutt, 1987). The anesthesiologist should aim for near perfection by minimizing factors that adversely affect vigilance, such as fatigue, distraction, and boredom. An audible tone for the pulse and oxygen saturation, as well as an audible tone for capnographic alarm limits and loss of pressure is advocated by the Anesthesia Patient Safety Foundation (APSF) as a method to enhance patient safety and improve vigilance. A better understanding and application of ergonomic principles may improve vigilance and help reduce anesthesia-related mishaps in the future (Gravenstein and Weinger, 1986).

Monitors and Monitoring Standards

The fact that most anesthesia-related fatalities involve human error clearly supports the concept that monitoring devices are essential for patient safety even for the experienced, conscientious, and vigilant anesthesiologist. The ASA Closed Claims Project indicated that in 28% of these cases, proper monitoring already available commercially could have averted the mishaps (Cheney, 1988). Of particular interest to anesthesiologists is that the median cost of legal settlement in cases in which improved monitoring would probably have prevented the complication or death was more than 10 times higher than in cases in which better monitoring would have had no effect on occurrence or outcome (Cheney, 1988). In a similar review involving 238 (10% of 2400 total claims) closed anesthesia malpractice claims concerning children, a vast majority (approximately 89%) of pediatric claims that were related to inadequate ventilation (43% of total) could have been prevented with pulse oximetry, capnography, or both (Murray et al., 1993). The proportion of claims assessed as preventable by better monitoring decreased from an average of 63% in the 1970s to 16% in the 1990s (Jimenez et al., 2007).

In 1985, minimum standards for patient monitoring during anesthesia at Harvard University teaching hospitals were adopted and later published (Eichhorn et al., 1986). Similar but slightly more specific standards for basic intraoperative monitoring, proposed by the ASA, were approved by the House of Delegates in 1986. Both sets of standards specifically mandate that oxygenation, ventilation, circulation, and body temperature be evaluated continually (at regular intervals) or continuously (without interruption). For each of the components, the clear objective to ensure adequacy, followed by specific methods, is stated (see Chapter 10, Equipment; Chapter 11, Monitoring; and Chapter 13, Induction, Maintenance, and Recovery). There

is a strong emphasis on combining clinical evaluation and technological methods. Although no specific methodology or instrumentation is mandated for monitoring cardiopulmonary and other indices, the ASA standards strongly encourage quantitative methods, such as pulse oximetry and capnography, over qualitative clinical assessment, with inspection and auscultation for cardiopulmonary monitoring. In addition, the New York State Hospital Code (1988) dictates that pulse oximetry and capnography be used to monitor all patients undergoing general anesthesia to reduce anesthesia-related morbidity and mortality. Eventually, most other states followed with similar laws mandating intraoperative monitoring with pulse oximetry and capnography. Accordingly, most malpractice liability insurers in the United States have required that anesthesiologists follow these standards whenever possible (Orkin, 1989). The APSF endorses the use of audible alarms on physiologic monitors.

Similar standards for basic patient monitoring have also been proposed in the United Kingdom, Australia, and other industrialized countries (Sykes, 1987; Cass et al., 1988; Runciman, 1988b). They are similar to the ASA standards in terms of machine monitoring (i.e., oxygen analyzer, low-flow alarm, and ventilator disconnect alarm). The standards for minimum patient monitoring, however, differ considerably, depending in part on the patient's physical status and the degree of surgical involvement (i.e., minor, standard, or major operation) (Sykes, 1987).

With the advent of pulse oximetry in the late 1980s, the anesthesiologist's ability to detect hypoxemia has improved markedly (see Chapters 10, Equipment, and 11, Monitoring). Coté and others (1988, 1991) have demonstrated that major hypoxemic events (arterial saturation of oxygen [SA_{O_2}] equal to 80% lasting more than 30 seconds) can occur without visible cyanosis or obvious changes in the cardiorespiratory patterns in children and that pulse oximetry detects such events more quickly than other means of monitoring. Cooper and others (1987), as part of peri-anesthetic QA activity, found a significant reduction in undesirable anesthesia-related incidents that require intervention after the introduction of pulse oximetry in the operating room.

Technological Improvements

Another technological patient safety strategy is the use of engineered safety devices that physically prevent errors from occurring (Gaba, 2000). An example of this human factor design is the pin index safety system in pneumatic connections, which uses geometric features on the yoke to prevent a gas hose or cylinder from being connected to the wrong gas yoke. This system is not infallible, however, and misconnections can still occur without proper vigilance (Ellett et al., 2009). New technologies have also been developed to improve management of the patient's airway, including the video laryngoscope, improved fiberoptic laryngoscopes, and LMAs. These devices improve the management of the pediatric (upper) airway in both routine and emergency situations.

According to the APSF, the use of automated information management systems could improve the future ability to link intraoperative events to both short-term and long-term outcomes (Gravenstein, 2001). Collection of real-time data obtained from the millions of anesthetics administered annually worldwide could lead to a better understanding of best anesthesia practices and improved patient safety. Such data collection studies are increasingly common. In pediatric critical care, a

collaborative project of over 70 pediatric intensive care units and Virtual Pediatric Systems has accumulated data on over 250,000 critically ill children and is providing benchmarking and quality data to guide critical care practice (Wetzel, 2009). The Society for Pediatric Anesthesia is sponsoring a similar prospective data collection methodology to collect detailed incident data across the field of pediatric anesthesia to provide benchmarking data.

Selection of Safer Anesthetics and Adjuvant Drugs

The POCA Registry data analyses have clearly demonstrated the safety of sevoflurane over halothane as the agent of choice for inhalation induction of anesthesia (Murray, 2004). Between 1994 and 1997, cardiac arrest associated with medication accounted for 37% of all cardiac arrests, from which halothane with or without other drugs accounted for 66% (Murray et al., 2000). From 2000 to 2003, when sevoflurane had replaced halothane as the inhalation induction agent of choice, medication-related causes of cardiac arrests decreased drastically, from 37% to 12%. Concomitantly, the incidence of cardiac arrests among healthy children (ASA PS 1 or 2) decreased from 33% to 19% of all cardiac arrests (Murray, 2004).

The developing nervous system is highly susceptible to neurotoxic insults during rapid synaptogenesis, during the brain growth spurts, and before neurons have migrated to their final destination and fully differentiated (Rabinowicz et al., 1996). In 2003, data were released that clearly showed that modern anesthetics cause widespread neurodegeneration in the developing rat brain (Jevtovic-Todorovic et al., 2003). Since that time, several more studies have confirmed that data by showing anesthesia-related increases in brain cell death and reductions in functional performance in rats. Although the exact mechanism of anesthesia-induced neurodegeneration in animals remains unclear, the evidence points toward the involvement of γ -aminobutyric acid (GABA) and N-methyl-D-aspartic acid (NMDA) receptors. All commonly used anesthetics are thought to exploit their effects on GABA or NMDA receptors to produce unconsciousness and immobility during painful stimulation. Moreover, all commonly used anesthetics that were investigated for their neurodegenerative properties, such as benzodiazepines, ketamine, propofol, nitrous oxide and isoflurane, have been shown to exacerbate neuronal cell death (Loepke et al., 2008). Although the documented neurotoxic effects of anesthetics in the developing animal model are noteworthy and alarming, the implications of these findings for clinical practice remains uncertain. The complexity of the mammalian nervous-system development complicates the extrapolation of data derived from animal models to humans. The FDA convened an Advisory Committee Meeting in April of 2007 to review all of the available evidence regarding the potential neurodegenerative effects of anesthetics in infant and juvenile animals. The panel determined that, based on the current knowledge and lack of appropriate alternatives, there was no scientific basis to recommend changes in clinical practice. Future research in this area with animals and nonhuman primates is needed to further understand the exact mechanisms behind anesthesia-related neurodegeneration and the long-term effects of modern anesthetic agents on the development of the human brain. Increased research on the mechanisms of anesthetic action are needed to discover drugs with greater specificity or mechanisms of action

that do not involve the GABA and NMDA receptors, as well as adjuvant drugs and techniques that may limit their deleterious effects. Until the risk of neurocognitive injury is understood, pediatric surgical specialists, in conjunction with anesthesiologists and pediatricians, should identify surgical procedures that can be delayed until older ages without incurring additional risk (McGowan and Davis, 2008).

Improved Education and Training

The steady decline in anesthesia-related mortality and morbidity over the past several decades has been attributed to increases in better-trained and better-qualified physicians administering anesthesia (Holland, 1987). In a survey of potentially harmful anesthesia-related events, Cooper and others (1978) found that 25% of these events were associated with inadequate training or unfamiliarity with equipment or devices; further training of these anesthetists (presumably trainees) would have prevented some of these events. In addition, an anesthesia-related mortality study from Harvard University has shown that in 8 of 11 cases of fatalities attributed primarily to anesthesia, inadequate supervision of residents, medical students, and nurse anesthetists was considered contributory (Eichhorn, 1989).

As mentioned previously, Keenan and others (1991) reported the importance of specialty training in pediatric anesthesia for the reduction of cardiac arrests in infants. No anesthesia-related cardiac arrests occurred when trained pediatric anesthesiologists were in charge of pediatric cases, whereas cardiac arrests occurred at a rate of 19.7:10,000 when non-pediatric anesthesiologists were supervising trainees. The same investigators also reported in a subsequent prospective study that the incidence of bradycardic episodes was significantly higher when pediatric anesthesiologists were not supervising the trainees anesthetizing infants (2.1%) than when trained pediatric anesthesiologists were in charge (0.8%) (Keenan et al., 1994). These results emphasize the importance of training and experience for a better anesthetic outcome.

There has been an explosion of interest in patient safety over the last four decades, and sessions on patient safety are now common in the scientific programs of the ASA and SPA annual meetings. There is also an increasing amount of patient-safety research being done each year, with the APSF awarding grants for research funds since its inception in 1985. The results of this research are reported in anesthesiology journals, scientific and educational meetings, and textbooks. The availability of these data have raised physician awareness of patient safety. Realistic patient and infant simulators were introduced in the 1980s. Since that time there have been great advances in simulator technology and science, and these simulators are available at many anesthesia training programs and as a component of many scientific meetings. Anesthesia has become the leader in the application and adoption of simulators that provide strong patient safety implications through education, training, and research (Stoelting and Khuri, 2006).

Quality Assurance

Documentation of the QA or QI process, especially that of fatal and morbid events, has been mandated in an effort to reduce the risk to and improve the outcome of patients undergoing

anesthesia. In a pilot prospective study, Currie and others (1988) found the QA survey helpful in identifying nonfatal, non-morbid, often transient events for peer review soon after such events took place. The survey demonstrated disproportionately high incidences of nonfatal events occurring with pediatric and emergency or out-of-hours cases. Induction and maintenance periods seem to be equally hazardous, up to four times more so than the emergence and recovery periods. As noted in other studies, airway events were most common (53%) (Cooper et al., 1978, 1984; Craig and Wilson, 1981). The authors concluded that the advantage of their method lies for the most part in its inherent lack of inertia: rapid evaluation, response, and feedback in a confidential and nonjudgmental atmosphere, resulting in the improvement of patient care in a unique manner (Cooper et al., 1978; Currie et al., 1988). QA or QI programs should be continued to prevent adverse events caused by human factors or errors (active failure) by learning from events and “near misses” as a group. Equally important, the QA program is the process of continually evaluating the environment in which anesthesia is practiced, and identifying systemic problems (environmental factors or latent failures) responsible for or potentially causing adverse events, which have not been obvious, so as to implement strategies or new guidelines to improve the structure or environment and prevent future occurrence of adverse events.

Environmental factors (latent failures) may play a major role and may be responsible for adverse outcomes impeding the safety and quality of patient care. These factors may include inadequate safety mechanisms (e.g., poor organization, unclear drug labeling), inadequate or nonfunctional monitoring systems, and poor communication among the surgeons, anesthesiologists, and operating room personnel. Indeed, in an analysis of 110 adverse events from more than 13,000 anesthetic procedures, Lagasse and others (1995) identified only 8% caused by human errors, whereas 92% of adverse events were attributable to system errors.

The impact of anesthetic management characteristics on severe morbidity and mortality in patients (between 62 and 65 years of age) was analyzed by the Dutch Association of Anesthesiology (Arbous et al., 2005). In a case-controlled study in the cohort of nearly 870,000 cases between 1995 and 1997, 807 patients who remained comatose or died within 24 hours of undergoing general anesthesia were identified and compared with 883 control cases without severe outcome. The incidence of postoperative death was 8.8:10,000 in this age group. Anesthetic management factors that were statistically significantly associated with a decreased risk included: equipment check with a protocol and checklist (odds ratio: 0.64), documentation of the equipment check (odds ratio: 0.61), a directly available anesthesiologist (odds ratio: 0.46), no change of anesthesia provider during the case (odds ratio: 0.44), two rather than one person present at emergence (odds ratio: 0.69), reversal of muscle relaxant or of the combination of relaxant and opioid (odds ratio: 0.1 and 0.29, respectively), and postoperative pain medication vs. no pain medication (Arbous et al., 2005).

Critical events related to anesthesia occur commonly during the practice of anesthesia. A well-trained, motivated, vigilant anesthesiologist normally detects these events in time and takes proper measures to prevent disaster. Anesthesia-related accidents causing catastrophic injury or death, therefore, are rare, especially in relation to the rate of such potentially harmful events. Because humans are imperfect and make mistakes as part of normal human cognitive behavior, catastrophic accidents

can occur almost at random to any anesthesiologist (Allnutt, 1987). The availability of both machine and patient monitors and adherence to monitoring standards are indispensable.

From the preceding presentation, it is apparent that young children, especially infants, are more vulnerable to anesthesia-related mishaps, whereas such a risk in older, healthy children is relatively low. Because of the small size and physiologic differences in the cardiopulmonary and other organ systems in young infants, as outlined earlier in this book, safety in pediatric anesthesia demands additional clinical training and vigilance. Anesthetic complications in infants and children and their management, when applicable, have been discussed in appropriate chapters elsewhere in this book.

For the safety of infants and young children, a high-risk group in terms of anesthesia-related morbidity and mortality, more clinical training, adequate preoperative preparation, vigilance, and adherence to monitoring standards (especially the use of a pulse oximeter and precordial stethoscope continuously) are all important and indispensable. When in doubt, the clinician should not hesitate to transfer the young and unstable patient to a specialized center for pediatric anesthesia and surgery to provide them with a better opportunity for survival.

SUMMARY

Anesthesia-related mortality has declined steadily over the past several decades as the percentage of general anesthetics administered by trained anesthesiologists has increased and as newer and safer anesthetics and adjuvant drugs, anesthetic equipment, and monitoring and safety standards in the industrialized nations have improved. Yet, anesthesia-related adverse events remain relatively higher in infants younger than 1 year of age than in older children and adults. As in adults, anesthesia-related catastrophe is still caused predominantly by judgment errors and environmental factors that are potentially preventable (Lagasse, 2002). Critical incidents occur more often during the induction and maintenance of anesthesia than during emergence and recovery. Emergency and urgent surgeries are associated with a disproportionately high incidence of anesthesia-related adverse events, in part because of inadequate pre-anesthesia patient preparation.

Analyses of closed malpractice insurance claims as well as the POCA Registry sponsored by the ASA have been informative in developing a future strategy for preventing anesthesia-related mishaps. Emphasis on strict monitoring standards and QA surveillance, developed and sustained since the late 1980s, seem valuable both in preventing near misses and in heightening anesthesiologists' awareness of such events. For patient safety in pediatric anesthesia, better clinical training, adequate preanesthetic preparations, vigilance, and adherence to monitoring standards are essential. Anesthesiologists must remain motivated and continue to pursue harmless anesthesia, yet at the same time be proud leaders of patient safety (Cooper and Gaba, 2002).

Summary **1308**

The pediatric anesthesiologist does not generally diagnose or cure patients but rather guides and supports each young patient through the operative experience with the least possible mental and physical stress. The history of pediatric anesthesia is best told by tracing the steps others have taken; steps toward increased precision in regulation and control of neurologic, respiratory, cardiovascular, and other body systems to serve both the surgeon and child (Smith, 1991).

The goals of pediatric anesthesiology as a specialty include the reduction of perioperative morbidity and mortality and the promotion of ancillary resuscitative and supportive fields through teaching, research, and organizational activity throughout the world.

PHASE I: PEDIATRIC ANESTHESIA BEFORE 1940

Primitive Period

Before the introduction of ether in 1846, circumcisions, amputations, tumor excisions, and correction of gross deformities were performed on infants and children without any relief of pain. Struggling was controlled by use of force, but pain was accepted as an unavoidable part of life. Crude attempts were occasionally made with alcoholic “spirits,” nerve compression, or even brief strangling, coupled with headlong surgical

speed; however, these attempts resulted in predictably poor outcomes for both operation and patient. Harelip repair had been attempted without pain relief measures in many parts of the world for hundreds of years. In Japan, general anesthesia with the herb mixture *tsu san sen* was used successfully for breast cancer operations in 1804 by Seishu Hanaoka. In 1837, Gancho Homma reported a series of general anesthesia procedures with the use of the same herb mixture for children over 5 years of age for harelip repair, but it was withheld from use in younger patients because of its toxicity (Iwai and Satoyoshi, 1992). The conviction that small infants did not need anesthesia was not effectively suppressed until recently (Anand and Hickey, 1987). For many years, the “whiskey nipple” had been used widely as a sedative supplement to local anesthesia in infants undergoing abdominal procedures, and wine has been given for ritual circumcisions for millennia.

Early Control of Pain: Ether and Chloroform

The introduction of ether was the first giant step in the history of anesthesia. Although Crawford Long used ether in his rural practice in Georgia beginning in 1842, and his third ether-anesthesia procedure was for a toe amputation in a 7-year-old boy (Long, 1849), it was not until the famous public demonstration of ether anesthesia at the Massachusetts General Hospital in Boston in 1846 that ether was widely accepted for use during

surgery (Morton, 1847). The discovery that sensation, or pain, and along with it consciousness and motion, could be abolished temporarily by ether was widely acclaimed; however, little was known about ether's actions, how to use it, or what its dangers might be. Ether was accepted only gradually over several years, with many surgeons retaining the belief that ordinary men (the wealthy excluded) should be able to tolerate surgery without anesthesia! However, for children and ladies, who were considered to be "more sensitive," anesthesia was considered appropriate, although Morton himself was reluctant to administer it to young subjects because of the high incidence of nausea and vomiting in this population (Bigelow, 1846; Warren, 1847; Pernick, 1975).

It was soon found that pouring ether onto a handkerchief or small cloth was a practical method of administration with small children. One simply pressed the cloth to the patient's face until the child was quiet and limp. The cloth was then withdrawn, and the surgeon was granted 3 or 4 minutes to operate as the child regained consciousness. The use of continuous administration of ether caught on slowly with gradual familiarization with the new agent. The early impression that ether was easy to administer, effective, and safe led to the belief that it was a trivial service that any inexperienced person, often an orderly or a parent, could perform. The unfortunate result was that throughout the rest of the century, the administration of anesthesia continued to be held in poor repute as a medical activity, rarely attracting physicians with special interest or ability in the field. Nurses eventually began to assume increasing responsibilities for providing anesthesia care. As late as 1940, a physician, in the lead article published in the first edition of the new journal *Anesthesiology*, noted, "During my internship I was trained by a nurse. I was given a cone, a can of ether, and a few empirical tricks" (Haggard, 1940).

In England, chloroform was accepted more readily because of its smoother and more rapid action. Soon, however, the incidence of deaths became so alarming that the British established a dictum that only physicians should be allowed to administer anesthesia (Eckenhoff, 1966). The fortunate result was that throughout the British Empire, anesthesia flourished as a medical specialty and its workers gained equal status with other physicians and became early leaders in the field.

Another great advantage for the British in the early development of anesthesia was the presence of the astounding John Snow (1813 to 1858), who made epidemiologic advances of national importance, ran an active medical practice, and kept notes on hundreds of anesthesia experiences and research experiments, mostly in the last 10 years of his life (1846 to 1856) (Griffith, 1934). Snow first described signs by which a practitioner could monitor and control the depth of anesthesia in patients of all ages (Snow, 1847). His five stages of anesthesia (excitement, loss of consciousness, relaxation, eye movement, and depth of respiration) served as a guideline throughout the remainder of the century and formed the basis of Guedel's important guide, *Inhalation Anesthesia*, published in 1937. Snow explored both ether and chloroform, preferring the latter, which he found well suited to infants and children. However, he warned of chloroform's danger with excessive depth (Snow, 1858). His record of successfully anesthetizing 147 infants for harelip repair is hardly conceivable in view of the mortality that this operation continued to bear well into the next century.

After the remarkable advances made by Snow, anesthesia in England progressed at a slower pace. For nearly 20 years,

chloroform and ether remained the only anesthetic agents available, and progress consisted mainly of developing methods of administration, comparing advantages and dangers, and simply studying how to keep children asleep and still for longer periods of time. Despite its recognized danger, chloroform remained the principal agent in England and throughout Europe. Efforts to reduce the complications associated with chloroform included many warnings, as well as attempts to increase its safety, such as diluting it with ether (CE) and with alcohol and ether (ACE). The introduction of nitrous oxide into general use by 1870 and ethyl chloride shortly after 1900 were important advances because they reduced or replaced the use of chloroform in many operations. Both of these agents were non-irritating and relatively acceptable, making them particularly adaptable for induction. Because induction had been seen as a troublesome stage of anesthesia, the use of these agents generated much interest.

British physician anesthetists began to publish articles and texts in increasing numbers. Buxton alone produced five editions of his *Anaesthetics: Their Uses and Administration* between 1888 and 1912. Many texts related to adult care contained advice on pediatric problems, of which harelip continued to attract the most attention. Numerous references to pediatric anesthesia could be found in *The Lancet*, Britain's premier medical journal, and in 1923, C. Langton Hewer wrote *Anaesthesia for Children*, the first text on pediatric anesthesia to be written in English.

In the United States, the special needs of children were given slight consideration for many years. The child was treated as "a little adult"; surgeons operated with large instruments, and all equipment was adult sized. Ether remained the principal agent. Although criticism of chloroform became more vehement, its use was advocated in the United States as recently as 1957 (Kopetsky, 1903; Schwartz, 1957). Progress was made by trial and error, with little communication among those using anesthesia. Most literature in the United States concerning anesthesia for children was written by surgeons before 1900.

Interest grew slowly around the turn of the century, and nurses and surgeons began to develop skills sufficient to carry children through longer and more difficult procedures. Thousands of tonsillectomies were being practiced by 1900, and appendectomy was an accepted, although often dangerous, procedure. Orthopedic surgery was the most active type of pediatric surgery during this time, and most procedures were easily managed by simple ether techniques. One of the first signs of concern for the child's anxiety when undergoing anesthesia was voiced by James Gwathmey in 1907. He recommended that one should "add a few drops of the mother's cologne to the ether mask and induce the child in the mother's arms." Another step toward easing induction came in 1928 with the introduction of tribromoethanol, the German Avertin, which was used widely as a rectal agent. It provided almost certain sleep in 7 to 8 minutes and was of special value before ether induction, because unlike the barbiturates used later, it had a bronchodilating effect that facilitated rather than retarded induction. However, the drug required preparation immediately before use. That, in addition to the repeated occurrence of fecal incontinence, led to its abandonment.

Between 1925 and 1940, activity in both pediatric surgery and anesthesia began to accelerate. William Ladd, whose interest stemmed from his experience in caring for children injured in a massive explosion in Halifax, Nova Scotia in 1917, led the

■ **FIGURE 41-1.** Ms. Betty Lank served as chief nurse anesthetist at Children's Hospital Boston from 1935 to 1969.

development of pediatric surgery in North America (Goldbloom, 1917; Steward, 1983; Smith, 1959). His work at Children's Hospital Boston was devoted to the correction of neonatal defects, including harelip. Ladd performed harelip repair seated, with the infant held facing him in the lap of a nurse. The anesthetist stood behind the nurse, directing ether from a vaporizing bottle into the infant's mouth via a metal mouth hook.*

The introduction of cyclopropane in 1930 proved particularly helpful for pediatric anesthetists in the management of infants, although it required assembly of a closed-system apparatus. Lamont and Harmel developed a miniaturization of the to-and-fro canisters Waters described in Wisconsin, and they used this technique for Blalock's "blue baby" (tetralogy of Fallot) operations at Johns Hopkins Hospital. In Boston, Betty Lank,[†] an enterprising nurse anesthetist, further redesigned the miniature to-and-fro apparatus with less dead space and shrank adult celluloid masks to infant size, enabling her to provide anesthesia, relaxation, and controlled respiration for Ladd's infants as well as for Robert Gross' widely heralded division of a patent ductus arteriosus in 1938—without endotracheal intubation (Fig. 41-1).

By 1940, considerable progress had been made in the ability of minimally trained anesthetists to provide satisfactory operating conditions for the surgeons of that time (Smith, 1959). Ladd strenuously corrected the previous concept by establishing the dictum "The child is not a little man." Supportive warming, preoperative correction of electrolyte balance, and intraoperative charting became standardized. Clinical signs of anesthetic depth, described by Guedel in 1937, served well. This might be termed the height of the art of pediatric anesthesia in the United States, where simple expedients still prevailed.

In England, there had been more progress in airway control. After World War I, Magill and Rowbotham popularized tracheal

*An accurate description of the first anesthetic agents given by one of the writers (RMS) for Dr. Ladd at Children's Hospital Boston in 1946.

[†]Ms. Lank, who served as chief nurse anesthetist at Children's Hospital Boston from 1935 to 1969, was one of several remarkable nurses who provided much of the anesthesia care for children at major pediatric centers in the United States until physician anesthesiologists trained and experienced during World War II returned home and began developing interest and expertise in pediatric care.

intubation for adult procedures, and in 1937, Philip Ayre of Newcastle-Upon-Tyne reported his classic method of endotracheal intubation with a T-tube device for harelip repair in neonates (Ayre, 1937). Although Robson of Toronto had described intubation of children using digital guidance rather than a laryngoscope, it had received little attention (Robson, 1936).

PHASE II: EMERGENCE OF PEDIATRIC ANESTHESIA, 1940 TO 1960

Factors in the Rapid Development of Interest

Before and during this period, activity accelerated in related fields, and much information became available defining normal and abnormal infants in such texts as Clement Smith's *The Physiology of the Newborn Infant* (1945), Taussig's *Congenital Malformations of the Heart* (1947), and Nelson's *Textbook of Pediatrics* (1950). The practice of adult anesthesia had become established, providing fresh information on new agents and techniques easily adaptable to children. As yet, the only established pediatric anesthesiologist in North America was Charles Robson in Toronto; in England, it was Robert Cope at London's Hospital for Sick Children. Among those interested in pediatric anesthesia, M. Digby Leigh made himself well known (Fig. 41-2). Trained by Waters in Wisconsin, Leigh was appointed head of anesthesia at Montreal Children's Hospital, where he taught and (with his invaluable associate Kathleen Belton) authored *Paediatric Anaesthesia* (1948) the first North American text on this subject. Leigh and Belton described the use of spinal anesthesia for intrathoracic procedures, an original pediatric circle absorption apparatus, and a nonbreathing valve. Leigh moved to Vancouver, British Columbia in 1947 and then to Los Angeles in 1954, where he started the first annual pediatric anesthesia teaching conference in America. He was a brilliant technician and a stern teacher, and he delighted his audiences with his

■ **FIGURE 41-2.** Dr. M. Digby Leigh.

■ **FIGURE 41-3.** Dr. G. Jackson Rees.

stinging repartee. His foresighted attempts to monitor exhaled carbon dioxide in 1952, however, were rebuffed by incredulous scoffers (Conn, 1992).

In the meantime, in Liverpool, G. Jackson Rees (Fig. 41-3) had been named anesthetist at the Alder Hey Children's Hospital by his mentor and teacher, Cecil Grey. Together they conceived the idea that practically all surgery could be performed under the simple and nonexplosive combination of nitrous oxide and curare. Rees, adapting the Ayre T-tube system by adding an expiratory limb and breathing bag (the well-known Jackson-Rees system), proceeded to carry out this concept with astounding success. With minor alterations this technique was to survive through years of short-lived, complicated types of apparatus. Rees' conviction that respiration should be controlled in infants with reduced tidal volumes and rates of 60 to 80 breaths per minute also met with criticism, but it proved to be rational when increased tidal volumes were found to cause barotrauma (volutrauma) and surfactant inactivation.

The new field of pediatric surgery, spearheaded by Gross, was calling for more skilled anesthetists, and at the end of World War II, large numbers of young physicians were released from military service, many of whom chose the uncharted field of pediatric anesthesia. McQuiston and Smith found posts at children's hospitals in Chicago and Boston, respectively, and Rackow worked at Columbia Presbyterian Hospital in New York, each to participate in early advances. In 1946, C. Everett Koop recruited Margo Deming to head the Department of Anesthesia at the Children's Hospital of Philadelphia as a teacher and investigator. Dr. Koop is currently a Professor at Dartmouth Medical School.

Little had happened in the field of anesthesia on the home front during World War II. After the war, numerous problems, many not even envisioned at the outset, were resolved by the exceptionally harmonious cooperation between pediatric surgeons and anesthesiologists. Whereas the success of individual operations is the natural goal of the surgeon, and improved

supportive measures are the steps noted by anesthesiologists, all are interdependent and are considered together.

Foundations of Clinical Control and Support

Neonatal Surgery and Anesthesia

Among the surgical challenges in the beginning of the 1940s, three congenital defects were dominant: tracheoesophageal fistula (TEF), omphalocele, and congenital diaphragmatic hernia (CDH). Both Leven and Ladd performed secondary multiprocedure repair of TEF in 1939 (Smith, 1959). Primary repair, first accomplished by Haight in 1941, then became the most important challenge in pediatric surgery, each case demanding all-day and all-night efforts of all participants. In Boston, the operation was carried out with the patient under the influence of cyclopropane via mask with a to-and-fro apparatus and the endotracheal intubation being reserved for emergency use during operation. Control of the exposed pleura during esophageal anastomosis required complete immobility, and the operation, in the words of Ladd, was "like stitching the wing of a butterfly" (Smith, 1959). Supportive management played a large part in the survival of these infants, both during and after the operation. Warmth was maintained by heating and humidifying the operating room, wrapping limbs in sheet-wadding, and using a semiclosed to-and-fro absorption technique. Blood pressure was measured by a locally introduced cuff with a latex bladder encircling the arm (Fig. 41-4). Fluids and blood were administered via an open-top burette with rubber tubing and "cut down" metal cannula in the saphenous vein. Postoperative survival depended largely on the remarkably able services of one or two very special nurses.

Repair of omphalocele posed different problems. Here the forceful closure of the abdomen over the extruded viscera often caused severe compression of the lungs and abdominal blood vessels. The challenge to the anesthetist was that of providing

■ **FIGURE 41-4.** Smith's latex blood pressure cuffs: newborn and infant sizes.

adequate relaxation while preserving ventilation and circulation. Skin closure was possible only rarely, leaving the alternative of delayed closure, which often failed. The use of muscle relaxants facilitated closure but increased the risk of postoperative hypoventilation. Mortality was appreciable.

Of the three defects, CDH at first appeared to be the easiest to correct, and anesthesia often was managed with open-drop ether without mortality. By 1950, however, postoperative deaths became an obvious and unsolved problem. It later became evident that the CDH-related deaths occurred in the sickest of infants, who in an earlier time would have died before repair could be attempted. The management of CDH subsequently became, and still is, one of the most engrossing problems of neonatal surgery.

Herniorrhaphy and Pyloromyotomy

During this time period, herniorrhaphy and pyloromyotomy could be performed with a patient under local anesthesia by the average surgeon, but open-drop divinyl ether (Vinethene) was definitely preferable. The problem most often encountered in infants with inguinal hernia was whether to cancel the operation when the infant's hemoglobin was 9.8 g/dL instead of the "required" 10 g/dL, or to transfuse. Transfusion commonly was chosen. Before 1912, attempts to correct pyloric stenosis by gastroenterostomy had resulted in a 50% mortality rate. The Ramstedt pyloromyotomy effected one of the great achievements of pediatric surgery in creating a simple procedure for this common lesion, thereby saving the life of an otherwise normal child. Anesthetic management after early diagnosis was centered on the prevention of aspiration of the accumulated stomach contents and was best accomplished by drainage via a large-bore urethral catheter immediately before operation. In Boston, trachea intubation was not considered necessary unless contrast medium had been used for diagnosis, whereas intubation was routinely used in other centers. In cases of delayed diagnosis, the operation was postponed for rehydration and correction of electrolyte disorders or anemia.

Early Attempts to Control Fear

It soon became evident that for the small child, the fear of needles and the horrors of anesthetic induction were deeply upsetting and of long duration. Concern about this most unfortunate anesthetic by-product was voiced by psychologists, pediatricians, anesthesiologists, and others, as well as numerous mothers reporting prolonged night terrors, bed-wetting, and dependence (Levy, 1945; Jackson, 1951; Eckenhoff, 1953).

Some attention had been paid to premedication shortly before this time. French Armand-Delille (1932) recommended morphine, and Waters (1938) promoted the combination of morphine and scopolamine, but the response to the outburst of concern came in a flood of reports on a variety of ineffective agents. The basic error in most studies was, and still is, the use of age or weight for estimation of drug dosage, when neither reflects the child's state of mind. General use of intramuscular barbiturates plus morphine mixed with either atropine or scopolamine resulted in severe horror of needles, an uncomfortably dry mouth, and an unpredictable degree of sedation, seldom better than 65% successful. Attempts to improve this record continued to play a large part in the activities and literature of pediatric anesthesiologists with only slight improvement

with regard to the effectiveness of sedative drugs. However, the concentration of attention of numerous investigators on this problem did result in the development of close personal interest in each child studied, possibly responsible for much of the benefit credited to the drug being promoted.

Methods of induction showed somewhat more success than those of sedation. Thiopental replaced rectal tribromoethanol, providing greater ease of administration via either the intravenous or the rectal route, whereas induction with nitrous oxide, cyclopropane, or divinyl ether eliminated much use of the dreaded ether (Weinstein, 1939). With the repeated failure of sedative agents, greater skills were developed by caring anesthesiologists to gain the confidence of children in preoperative visits and then to divert their attention at induction by telling them stories or by simply lulling them to sleep. Hypnosis was used for induction by Betcher (1958), Marmer (1959), and a few others for the total operation in short procedures. It was particularly valuable for the repair of facial lacerations in small children who had recently eaten. Unfortunately, this potentially useful and harmless method gained only limited acceptance.

Control of the Airway

The importance of airway management became evident with the first anesthesia procedures, and after years of progress it still presents formidable difficulties. For patients of all ages, hypoxia resulting from laryngospasm, oral secretions or blood, abscesses or tumors, aspiration of vomitus, or simply blockage by the tongue has been an ever-present danger. Many deaths from early harelip procedures resulted primarily from hemorrhage, as did later deaths from tonsillectomy.

By 1940, two simple but extremely fundamental aids had been introduced. To prevent obstruction by the tongue, metal and rubber oral airways had been used successfully for a decade and were often fitted with a metal nipple for insufflation of vaporized ether. Suction apparatus was first available in the form of bulb syringes used alone or fitted with rubber catheters and then later as portable motorized pumps situated at the head of the operating table (ether and cyclopropane notwithstanding) or by means of a centrally operated pipeline.

Endotracheal Intubation

The greatest advance in pediatric anesthesia between 1940 and 1960 was in control of the airway by tracheal intubation. Early use in England and Canada met with little resistance. In the United States, however, opposition by surgeons raised the first major obstacle to progress in the new specialty. (It must be admitted that reasonable concern had been aroused in those who had witnessed the traumatic attempts of inexperienced individuals to perform unnecessary intubations.) It was the efforts of Rees in England; Leigh, then in Canada; the British-American Gillespie (1939); Americans Deming (1952), Pender (1954), and others; and their supportive younger surgeons that brought forth grudging acceptance of tracheal intubation of infants and children in the United States in the 1940s and 1950s.

The ongoing development of this technique led to an increased understanding of laryngeal anatomy; replacement of the "classic" hyperextension of the head by use of the "sniffing" position for intubation; a succession of different types of tracheal tubes, including the tapered tube of Cole (1945) that

enjoyed more than a decade of popularity; a variety of tube materials progressing from coarse rubber to nonreactive plastic; and laryngoscopes of several types and sizes (Eckenhoff, 1951).

As with ether and other major advances, the advent of tracheal intubation brought a host of disadvantages and a few real dangers that in turn led to a glut of literature concerning complications, including subglottic stenosis, laryngeal irritation from large tubes, and tracheitis caused by contamination (Baron and Kohlmoos, 1951; Flagg, 1951; Smith, 1953a; Colgan and Keats, 1957). This proved to be just the beginning.

“Total Control” of Respiration: The Muscle Relaxants

After the first clinical use of d-tubocurarine by Griffith and Mitchell in Canada in 1942, Canadians and British accepted it readily and began extensive use in both children and adults, to be followed by much investigation in later years (Anderson, 1951; Stead, 1955; Leigh et al., 1957; Rees, 1958). Again, in the United States there was much opposition, this time by anesthesiologists as well as surgeons, to whom the concept of total “takeover” of an essential body function, termed *controlled respiration*, appeared to be a dangerous and unacceptable “physiologic trespass” (Gross, 1953; Beecher and Todd, 1954). Beecher threatened one of the authors of this chapter that “heads would roll” if he and others persisted in support of its use. In the meantime, Cullen (1943) had found it quite safe for adults and children, using it as a sole agent for infant surgery. This practice was abandoned after Scott Smith of Utah was tested under total curarization and suffered acutely on painful stimulation (Smith, 1947; Smith et al., 1947). As with tracheal intubation, the total acceptance of neuromuscular blocking agents in the United States required many years. By 1960, however, the terms *controlled respiration* and *assisted respiration* had gained widespread use.

Pediatric Breathing Systems: Assisted and Controlled Respiration

With the stimulating effect of ether on respiration in light surgical planes, assisted respiration was seldom needed. Open chest surgery, cyclopropane, and particularly muscle relaxants definitely changed this picture and led to a succession of considerably diverse devices (Dorsch and Dorsch, 1975). The to-and-fro absorption method, using soda-lime canisters of graduated sizes, was particularly adaptable to infants but caused heat retention and the aspiration of lime dust. For larger children, the canisters were bulky and heat retention was even more troublesome.

Special interest was taken in infant circle absorption systems. The Leigh, Ohio, and Bloomquist models were not only difficult to handle but also introduced the problems of valve resistance and dead space (Leigh and Belton, 1948).

To eliminate problems of carbon dioxide accumulation, several nonbreathing valves were designed by Leigh and Belton (1948), Stephen and Slater (1948), and others. Although compact in design, they were not easy to manage and were definitely ill-suited for use with explosive agents.

The saga of apparatus variously called *rebreathing* (British), *nonbreathing* (United States), and *partial rebreathing* (general) is complicated and involved numerous studies and modifications of the basic Ayre T system over 30 years (Fig. 41-5) (Ayre, 1937). After the Rees elongation of the expiratory limb

■ FIGURE 41-5. Original Ayre T-tube nonbreathing system.

with an attached breathing bag, the addition of exhaust valves placed either proximal (Mapleson A) or distal (Mapleson D) to the face brought intensive examination, as did the estimation of proper flow rates of incoming gases. Evaluation by Mapleson (1954) and Inkster (1956) did much to clarify these issues at the time, but more problems lay ahead.

Cardiovascular and Thermal Control

Between 1940 and 1960, revolutionary advances were made in several areas involving the combined efforts of anesthesiologists and surgeons. The intentional reduction of arterial blood pressure, extensively explored by Enderby (1950) and others in England, was cautiously extended to pediatric use by Anderson (1955) with trimethaphan camphorsulfonate (Arfonad). This served as a reasonably safe agent. It was the initial step in induced hypotension to reduce surgical blood loss in major pediatric surgery and to prevent excessive blood pressure elevation during correction of coarctation of the aorta. However, the agent was unpredictable and soon was replaced by more controllable agents and techniques.

Controlled Reduction of Body Temperature and Cardiopulmonary Arrest

After Gross' ligation of a patent ductus arteriosus in 1938, correction of coarctation of the aorta, repair of vascular rings, and shunt procedures for tetralogy of Fallot were successfully performed under closed or semiclosed inhalation anesthesia, usually with cyclopropane (Harmel and Lamont, 1948; Harris, 1950; Smith, 1952). McQuiston, endeavoring to reduce the oxygen requirements of Dr. Potts' cyanotic infants, cooled them 3° to 4° C on a simple ice-water mattress, thereby introducing

the practice of hypothermic control of body metabolism into pediatric anesthesia (McQuiston, 1949). Efforts to reduce oxygen demand by further lowering temperatures to 30° C with immersion in ice water provided surgeons time for simple intracardiac aortic or pulmonary valvotomy (Lewis and Taufic, 1953; Virtue, 1955).

The drive to bypass both the heart and lungs initiated by Gibbon in 1937 became exciting in the early 1950s, with competing surgeons Lillihei, Kirklin, and Kay and their respective anesthesiologists Matthews et al. (1957), Patrick et al. (1957), and Mendelsohn et al. (1957) all contributing toward the first practical use of the pump oxygenator in 1955, 2 years before publication of the articles cited.

The supplementation to bypass perfusion by moderate hypothermia (30° C) and different methods of induced cardiac arrest produced the greatest “takeover” of body function to date and the means of performing intracardiac surgery on all but small infants.

Mild and moderate hypothermia techniques were also used in this period for neurosurgery, orthopedic surgery, and harelip repair (Kilduff et al., 1956).

Control During Maintenance of Anesthesia

As more extensive procedures were developed and surgeons began to prefer accuracy to speed, 4-hour operations became more common and the methods of maintenance and support grew more demanding. Experience, skill, and constant observation were still primary factors that were assisted by a few simple devices (Fig. 41-6). During this time the precordial stethoscope became essential for use with every infant or child throughout the field of anesthesia (Smith, 1953b).

■ **FIGURE 41-6.** Smith’s teaching precordial stethoscope with a single chest piece and two headpieces.

A precordial or esophageal stethoscope served first to keep the anesthetist in direct contact with the child at all times, providing unaltered information as to the clarity and strength of breath sounds and the rate, rhythm, and strength of heart sounds (Smith, 1991). Strength of heart sounds was an important guide to the degree of blood loss at that time. Arterial blood pressure could be obtainable with standard apparatus for larger children and with a specially constructed latex cuff with an inflatable bladder for infants (the Smith cuff). During this phase, the electrocardiograph was occasionally brought into operating rooms, encased in antiexplosive shielding (shaped like a torpedo) and serving relatively little purpose. Body temperature was measured intermittently at oral, nasal, or rectal sites, the standard glass thermometer giving way to the safer but less accurate thermostat devices. The anesthesia chart was considered a necessary item, gaining in importance as procedures grew increasingly complex and legal suits more common.

Control of Blood Loss

Methods of estimating blood loss at the time consisted of assessing blanching of conjunctivae, evaluating the strength of heart sounds, measuring arterial blood pressure, and weighing bloodied sponges, purposely used without moistening. Whereas speed was still considered essential in pediatric surgery during the excision of Wilms’ and other large tumors, massive hemorrhage might exsanguinate small infants before replacement was possible. Attempts to restore the loss with cold, acidified blood brought failing hearts to irreversible cardiac arrest. A major advance to controlling these situations occurred when surgeons were persuaded to time their work by the advice of the anesthesiologist rather than by the clock. Although the cautery soon reduced blood loss drastically when used, it was not adopted immediately by all.

Progress in Local Anesthesia

Ladd had used local infiltration for abdominal procedures in premature infants in the late 1930s, and Leigh wrote of spinal anesthesia for open chest work in the 1940s, but improved inhalation methods outmoded both. Except for brachial plexus block, little attention was paid to these methods in the United States (Small, 1951; Eather, 1958; Smith, 1959). In many other countries, however, where inhalation anesthesia was less advanced, there was considerable dependence on regional and spinal anesthesia for both infants and children.

Halothane Opens a New Era

Although anesthesia with relaxants and nitrous oxide permitted the use of electrical instruments in the operating room, explosive gases were still popular until the introduction of halothane. After its first use in England by Johnstone in 1956 (in 10% concentration), this nonflammable, nonirritating, and potent agent was promptly introduced in Canada by Junkin et al. (1957) and in the United States by Stephen and colleagues (1958). Subsequently, flammable anesthetic agents were totally abolished in the United States, thus opening the way to revolutionary changes, first in the control of blood loss by cautery and then in the development of electronic devices for monitoring and physiologic control.

Supportive Care and Oxygen Therapy

Related fields brought important aid to pediatric anesthesiologists during this period. The time-honored rule developed by Holliday and Segar (1957) for pediatric fluid administration based on metabolic requirements serves to this day. Also of great importance, particularly in reducing the morbidity and mortality of small infants undergoing surgery, was the control of infection by the use of antibiotic agents.

The interest of pediatricians caring for neonates led to the development of enclosed incubators with regulated oxygen, warmth, and humidification for infants with respiratory distress syndrome. Improved oxygen tents were developed for older children, including those with cystic fibrosis. The poliomyelitis epidemics of the 1950s in Europe and North America initiated a succession of ventilating devices to replace the enclosed “iron lung” in use since 1929. Pediatric anesthesiologists and pediatricians shared responsibility for this work, which opened a new field for anesthesiologists.

In related areas, Virginia Apgar introduced her scoring system for neonatal assessment, Peter Safar launched his crusade for mouth-to-mouth ventilation and further work in cardiopulmonary resuscitation, and the first multidisciplinary adult intensive care unit in North America was developed (Apgar, 1953; Safar, 1958).

The first pediatric intensive care unit was established in Goteburg, Sweden, in 1955.* Similar units were established in Stockholm (Feychtung), Liverpool (Rees), and Melbourne (MacDonald and Stocks) between 1960 and 1964. In North America, the first pediatric intensive care unit was established by Downes at the Children’s Hospital of Philadelphia in 1967, followed by Children’s Hospital of Pittsburgh (Kampschulte), Yale-New Haven Hospital (Gilman), Massachusetts General Hospital (Todres and Shannon), and the Hospital for Sick Children in Toronto (Conn) within the next 4 years (Downes, 1992).

Teaching and Research

Throughout Europe and North America, communication among anesthesiologists began to accelerate. The Great Ormond Street Hospital for Sick Children in London and the Alder Hey Hospital in Liverpool became teaching centers in England; the Hospital for Sick Children in Toronto in Canada and the Children’s Hospitals of Boston and Los Angeles in the United States became centers to which various novice and experienced anesthetists came from all parts of the world for clinical training. Residents on affiliation from teaching hospitals were rotated through brief training periods for instruction in basic, safe, and practical methods of anesthetic control of children undergoing standard operations and in special methods for those at higher risk.

On the heels of Leigh and Belton’s *Pediatric Anesthesia* (1948), Stephen’s *Elements of Pediatric Anesthesia* (1954) and Smith’s *Anesthesia for Infants and Children* (1959) were published, with details of advances to date. Articles on new agents and techniques steadily increased in the anesthesia-related

literature. Whereas some reported personal early experiences based on limited numbers, many were of lasting value, including those involving tracheal abnormalities by Eckenhoff (1951) and Colgan and Keats (1957), tracheoesophageal repair by Zindler and Deming (1953), and the important warning of Leigh et al. (1957) concerning bradycardia after the intravenous administration of succinylcholine.

Research, on the other hand, was still in its infancy, there being little space, time, or funds for sophisticated investigation. As previously mentioned, many clinical studies offered practical current value concerning new agents and techniques. Whereas those concerning preoperative sedation outnumbered others, many reports covered airway resistance, valves, and dead space (Macon and Bruner, 1950; Mapleson, 1954; Orkin et al., 1954; Hunt, 1955; Inkster, 1956). The introduction of muscle relaxants initiated other studies, including those of Hodges (1955), Stead (1955), Telford and Keats (1957), and Bush and Stead (1962). The addition of halothane led to a more critical analysis of this agent than had been done for previous anesthetics.

This period established such fundamental techniques and basic concepts that Rees subsequently (1991) stated, “Paediatric anaesthesia in Great Britain and Ireland shows that by 1950 it had reached a point at which current practice is recognizable.... Future pediatric anaesthetists are therefore unlikely to experience the great excitement their predecessors enjoyed between 1930 and 1950, but will derive satisfaction from changes less dramatic as the curve of improvement approaches perfection.”

PHASE III: ERA OF NONFLAMMABLE ANESTHETICS, 1960 TO 1980

With sound fundamental approaches defined and restrictions resulting from flammable agents eliminated, the way was cleared for rapid and extensive advances in all areas of pediatric anesthesia. Clinical control would drive ahead and research would become more productive, but this phase saw the greatest progress in the development of organized teaching and communication.

Unfortunately, progress was not marked in the control of fear. Despite continued efforts to address this problem by many skilled workers, sedatives were still unpredictable and intramuscular needles were still in general use (Poe and Karp, 1946; Rackow and Salanitro, 1962; Root, 1962). The introduction of ketamine (Ketalar) by Domino et al. (1965) created mixed feelings based on its early postoperative psychological reactions, but the agent found a place in pediatric use for uncontrollable patients and to accomplish minor but painful procedures.

A major change in the methods for controlling fear was in giving permission to parents to be at the child’s bedside at all times, including “sleep-in” privileges, and later, to preinduction and induction areas. Whereas many parents were assuaged by these moves, statistics failed to show great help for the children (Schulman et al., 1967).

Increasing Clinical Precision

Modification of the partial rebreathing systems by Bain and Spoerel (1972), by which the exhalation tube passes inside the inhalation arm, provided a means of scavenging expired gases,

*The excellent first-hand report of Downes (1992) on the development of pediatric critical care is recommended.

thereby greatly enhancing the use of this popular pediatric method. This marked a major evolution of airway systems for pediatric anesthesia.

Steps toward greater precision in monitoring were taken in the measurement of infant blood pressure by Doppler sonography and by oscillotometry (Dinamap) (Marcy and Cook, 1988). In the determination of arterial oxygen saturation, the transcutaneous electrode (ear oximetry) was used with limited success (Saunders et al., 1976). It was during this period that “control by the numbers” gained predominance over the unreliable art of anesthesia. Led by Downes of Philadelphia and others, arterial blood gas determinations, blood sugar, hemoglobin, electrolytes, and other measurements were serially evaluated intraoperatively in adjacent laboratories (Smith, 1990). Insertion of arterial and central venous catheters became commonplace, and urinary catheterization became an important guide to fluid and electrolyte replacement.

Progress in controlling fluid balance included the recognition of the importance of electrolytes in all intravenous solutions (Bennett et al., 1970; Herbert et al., 1971). New concepts concerning blood replacement included Davenport’s practical recommendation to give blood when loss reached 10% of blood volume, followed later by Furman’s more precise suggestion to maintain the hematocrit level above 28% to 30% in children and 40% in the newborn (Davenport and Barr, 1963; Furman et al., 1975). At this time, the concept of replacement of preoperative fluid deficit was widely adopted.

Airway problems presented ongoing challenges, and their management continued to register improved methods of control. Great emphasis was placed on the prevention of food aspiration and the damaging effects of hypoxia. The Sellick maneuver (1961) and many warnings from Salem (1970) about “the full stomach” were forever fixed in the mind of each new resident.

The treatment of acute epiglottitis by nasotracheal intubation instead of the former mandatory use of tracheostomy was a major change and clear advance, speeding recovery and significantly reducing serious complications (Oh and Motoyama, 1977).

Management of “the difficult airway” began to assume a larger role in both adult and pediatric anesthesia as more complicated procedures were undertaken on more deformed patients. By this time, some 120 different types of laryngoscope blades had been invented, each with some minor modifications to suit the designer, usually with no major advantage. It was the introduction of the fiberoptic laryngoscope that enabled anesthesiologists to intubate infants and children for whom this had been virtually impossible (Taylor and Towley, 1972; Stiles, 1974).

The startling appearance of what became known as malignant hyperthermia caused great concern, but widespread warnings about “triggering agents” and the discovery of a specific counteragent, dantrolene, usually brought it under reasonable control, at least when it was recognized early (Denborough et al., 1960; Britt, 1979; Gronert, 1980).

Surgical Progress

Interesting progress occurred in the evolution of infant surgery. TEF repair became a standardized procedure, and mortality was generally limited to infants with serious cardiac defects. Problems related to omphalocele repair were largely overcome by the introduction of Schuster’s staged mesh sac closure (1967). CDH, however, brought about increasing difficulties as smaller

and more premature infants were encountered. Acidosis, shunting, and pulmonary hypertension posed problems yet to be solved (Raphaely and Downes, 1973; Dibbins, 1976). Attempts to use extracorporeal membrane oxygenation (ECMO) predicted later value for this procedure (Bartlett et al., 1979).

After the breakthrough in cardiac surgery accomplished by the establishment of extracorporeal circulation in larger children, the next step was to find a means of operating within the hearts of neonates without obstruction by intracardiac catheters. In 1965, the use of hyperbaric oxygenation served as a temporary answer, providing surgeons 3 to 5 minutes of inflow occlusion for the performance of aortic valvotomy and other brief procedures (Bernhard et al., 1966). The use of oxygen at 3 to 4 atmospheres of pressure substantially increased plasma oxygen-carrying capacity, while presenting increased potency of nitrous oxide and increased flammability (Smith et al., 1964).

The final hurdle in the approach to infant cardiac surgery was passed by the successful combination of deep hypothermia and extracorporeal circulation, providing time for the most complicated reconstruction of neonatal cardiac defects (Horiuchi et al., 1963; Hikasa et al., 1967). Rendering an infant virtually dead by complete cessation of respiration and circulation at a body temperature of 15° C appeared to be the ultimate in physiologic control. Agents and techniques have undergone several changes in subsequent years but remain fundamentally similar.

Somewhat less dramatic, but also of great importance, was the initiation of renal transplantation in 1954, which subsequently saved the lives of thousands of children and adults with end-stage renal disease.

Among many well-known tenets established, two of particular interest to anesthesiologists were the danger of succinylcholine in patients with elevated serum potassium levels and the evident tolerance to anesthesia in patients with hemoglobin levels as low as 6 g/dL (Powell and Miller, 1975).

The craniofacial repair devised by Tessier and others (1967) for correction of the disfiguring deformities of Apert syndrome and Crouzon disease was a bold undertaking. It was equally challenging for the anesthesiologists involved with difficult airway management, prolonged maintenance, marked fluid and blood loss, and a particularly precarious period of recovery while the child’s head was so completely swathed in tight bandages that only the endotracheal tube was visible.

Anesthetic management to separate conjoined twins at birth was of such unique interest that any report of a single case was welcomed for publication. A separate team of surgeons and anesthesiologists was assigned to each twin, and multiple problems of shared organ systems, hemorrhage, and airway obstruction were noted (Furman et al., 1971; Winston et al., 1987).

Postoperative Patient Management: Ventilation, Resuscitation, and Intensive Care

For many years, much attention had been directed toward controlling the responses of children during the introductory phases of anesthesia. Postoperative care, however, often consisted of little more than a prompt return to the child’s room with orders for checks every 4 hours, and nothing by mouth. The advent of various new and extensive operations made it evident that the survival of patients depended to a large extent on their supportive control during recovery—a third dimension of anesthesia.

One of the first needs to be met was the ability to provide prolonged tracheal intubation, fostered by Brandstater (1962), MacDonald and Stocks (1965), and Hatch (1968). The continuation of earlier efforts to devise ventilation machines for infants and children with cardiopulmonary pathology brought a succession of models, some as adaptations of those made for adults and others designed specifically for younger patients.

Recovery rooms or postanesthesia care units (PACUs) for routine postoperative care had been established in many hospitals over previous decades, but areas staffed by highly trained personnel and fully equipped for high-risk patient care became mandatory. The earliest units of this type, termed *critical care* or *intensive care units*, appeared in Goteburg, Sweden, in 1955; others were established in France in 1962, England in 1964, and Australia in 1963. In America they appeared in Philadelphia in 1967, Pittsburgh and Boston in 1969, and Toronto in 1971, where Conn established a prototype of the modern multidisciplinary unit for infants and children, including near-drowning survivors (Downes and Raphaely, 1975; Conn et al., 1980; Downes, 1992).

Important new approaches to resuscitation replaced such outmoded maneuvers as anal dilation, drugs promoted as respiratory stimulants, and the prone pressure method. During the trial-and-error development of pediatric cardiac surgery and the poliomyelitis epidemics, apparent death became an indication for immediate slashing into the chest and manual cardiac compression. When it became evident that the patients occasionally survived both the original insult and the therapeutic assault, the term “cardiac arrest” was coined (Singer, 1977). Because the exact cause of these mishaps commonly was uncertain, each was considered “an act of God,” and successful resuscitation was considered a feather in the cap of any anesthesiologist who had been associated with one. Intelligent procedures of ventilation and closed-chest cardiac compression, combined with electric and pharmacologic stimulation, brought far greater reason, order, and success.

Organized Teaching

This period marked the definite establishment of teaching facilities for the specialized training of pediatric anesthesiologists. With markedly enlarged departmental staffs, didactic and clinical instruction became available in numerous institutions. Residents became capable of managing most types of cases and also received instruction in ancillary services. Accreditation for residency training in pediatric centers was established in Boston in 1970, to be followed by several others by 1980.

Teaching clinics were established for residents and others throughout the United States, Canada, and England. Edward Eger stood out as teacher par excellence over 3 decades. Annual symposia on pediatric anesthesia initiated by Leigh in 1962 were followed by those organized by Conn in Toronto, Downes in Philadelphia, Salem in Chicago, Ryan in Boston, and others. Literature became increasingly available in periodicals, including both new editions of previously published texts and added texts such as those by Davenport (1967) of Canada and an excellent Australian text by Brown and Fisk (1979). Early exponents of the specialty became popular at local and national meetings, and an international exchange of speakers grew rapidly, stimulating interest and exchanging information on the rapidly developing scene.

International Progress

At this time, it became evident that considerable progress was being made in many parts of the world. In France, Deleuge pioneered the modern stage, her text *Memento a l'Usage de l'Anesthesiologiste-Reanimateur Pediatrique* passing through several editions. Rapid advances were taking place in France in many aspects of pediatric anesthesia. A marked difference in their approach appeared with the use of combinations of intravenous phenothiazines, antihistamines, and barbiturates in place of inhalation agents and had remarkable success (G. Durand-Gurry, personal communication, 1993). Their work in regional anesthesia and pharmacology was also outstanding (Saint Maurice et al., 1986; Murat et al., 1988). Early leaders in Europe included Suuterinen of Finland; Swensson, Feyting, and Ekstrom-Jodal of Sweden; and Rondio and Wezyk of Poland. South African and Australian workers, adopting British methods, also kept abreast or ahead of other areas. Douglas Wilson has been called the real pioneer of pediatric anesthesia in Western Australia, and Margaret McLellan, John Stocks, Ian McDonald, M.A. Denborough, and others contributed on local and international levels. Japanese interest in pediatric anesthesia began later, but proceeded vigorously beginning in 1958; the publication of *Pediatric Anesthesia* in 1958 by Onchi and Fujita served as a valuable guide (Iwai and Satoyoshi, 1992). Throughout Latin America, Brazilian physicians and others followed North American methods to some extent, but in these countries, especially in Mexico, local and regional anesthetic techniques were depended on and consequently more highly developed than inhalation anesthesia (Fortuna, 1967; Melman et al., 1975). The great number of students who studied in North America and Europe from India, the Philippine Islands, and other Asiatic areas resulted in the growth of this organized activity and clinical excellence in their respective nations.

Research Stimulated by Clinical Advances

The introduction of various breathing devices, new muscle relaxants, and halogenated agents provided material for extensive investigation. The demonstration of the more rapid uptake of anesthetic gases by infants than by adults became a classic study, as did Motoyama's measurements of pulmonary mechanics, with some of his contributions illuminating the pulmonary physiology of infants and children (Salanitre and Rackow, 1969; Motoyama, 1977; Motoyama and Cook, 1980). Bush and Stead (1962), Cook (1974), Goudsouzian et al. (1975), and other researchers did much to establish the comparable actions of successive neuromuscular blocking agents in the search for safer, shorter-acting, and reversible types (hence, greater control). The advent of new halogenated agents aroused the pharmacologic investigation of metabolism, toxicity, cardiovascular depression, and seizures, and the increased potency demanded vaporizers of greater accuracy (Brennan, 1957; Fabian et al., 1958; Lomaz, 1965). Other notable achievements included the establishment of minimum effective doses (ED_{50}) of halothane by Nicodemus and others (1969) and the minimum alveolar concentration (MAC) as a standard measure of potency, followed by the application of MAC to demonstrate the higher halothane requirement for infants than for adults (Eger et al., 1965; Gregory et al., 1969).

PHASE IV: PROGRESS AND SOPHISTICATION, 1980 TO PRESENT

This latest phase consists of many events now in progress that are described in this book. The entire scenario in the operating room has evolved enormously, with anesthesiologists setting multicomputerized monitors and infusion pumps, with numerous syringes loaded and coded, and with a large cabinet within reach that holds drugs and other equipment for all possible occasions. Children often receive an oral sedative, and anesthesia is induced with minimal resistance, often with a parent present. Variable time is then consumed while surgeons await the fixation of additional monitors, endotracheal tubes, and numerous catheters. Multiple medications are delivered by the intravenous route, generally measured by micrograms per kilogram. The ventilator is set at a prescribed rate and tidal volume or inspiratory pressure, and surgeons are allowed to approach and drape the patient, erecting a high sterile shield between themselves and the anesthesiologist. Charting is often automated. Communication occurs with other anesthesiologists and the surgeons and nurses. In long but simple cases, boredom can be a hazard, as is a tendency to watch the many monitors rather than the patient.

Fortunately, this is only one part of the picture. In the next room, a premature infant may be receiving spinal anesthesia for herniorrhaphy, and in another, a liver transplantation may have been in progress for the past 8 hours. In the many additional operating rooms, various procedures go on, more than half of which are outpatient cases.

Recognition of Risk

During this phase, there has been a widespread appreciation that infants and small children are at increased risk for complications from anesthesia and surgery. Previous reports had shown that these were often related to cardiovascular factors (including hypovolemia and anemia), respiratory difficulties (e.g., airway obstruction, hypoxia, and inadequate ventilation), or electrolyte imbalance (e.g., hyperkalemia, hyponatremia, and hypoglycemia) (Salem et al., 1975). Additional reports from the United States described some of the problems in greater detail, as did others from France, Scandinavia, Canada, and England (Olsson and Hallen, 1988; Turet et al., 1988; Cohen et al., 1990; Lunn, 1992; Moryay et al., 1993; Keenan et al., 1994; Holzman, 1994). In particular, postoperative apnea, especially in very premature infants, was noted by several investigators, and overnight hospitalization in these situations was widely adopted (Steward, 1982; Gregory and Steward, 1983; Liu et al., 1983). In addition, other groups of patients were noted to be at increased risk of postoperative respiratory complications, such as children with obstructive sleep apnea who appear more sensitive to the respiratory depressant effects of narcotics (Brown et al., 2004, 2006; Sanders et al., 2006). Furthermore, there were indications that risk in small children could be decreased if individuals specially trained and experienced in pediatric anesthesia provided the anesthesia care (Keenan et al., 1991; Moryay, 1994; Berry, 1995; Downes, 1995). Although this concept remains controversial, surgeons, pediatricians, and parents increasingly have begun to appreciate the important role of pediatric anesthesiologists.

Growth in Pediatric Facilities

In part because the post-World War II “baby boomers” were now having their own children, pediatric facilities exhibited enormous growth during this period. Freestanding children’s hospitals, which had existed for more than a century, expanded, and new pediatric hospitals were established. Some of these evolved as pediatric “hospitals within a hospital,” whereby large general hospitals developed specific buildings, wings, or floors to provide specialized care for children. Currently, several large children’s hospitals in the United States are performing more than 20,000 surgical procedures per year. Some children’s hospitals perform more operations and have more operating rooms and staff than major hospitals caring for adult patients. Reports have been published indicating that the outcome (at least for some conditions in small children) is better when surgery is performed by pediatric specialists in large pediatric centers (Bratton et al., 2001; Kososka et al., 2001). The American Academy of Pediatrics (2002, 2003) has disseminated several policy statements emphasizing the need to have proper personnel and facilities available whenever children require surgery or anesthesia.

Changing Patterns of Care

There has also been a great impetus to perform surgical procedures in younger and younger patients. Whereas this was not possible or was fraught with danger in earlier eras, better equipment and surgeons well trained in pediatric subspecialties have made this not only feasible but also desirable for children. Outcome studies in several areas have shown that corrective procedures performed in infancy, rather than palliative procedures done initially and followed by full repair later in life, lead to improved long-term results. For example, in 1975 the American Academy of Pediatrics advocated surgical repair of elective urologic defects in children after the age of 4 years but by 1996 was recommending these repairs occur in infancy. Likewise, repair of congenital cardiac anomalies shifted from early palliative procedures (largely shunts) to corrective repairs in the neonatal period (Jenkins et al., 1995). This tendency to perform more complex surgical procedures in younger patients undoubtedly contributed to the growth of major pediatric centers.

At the opposite end of the age spectrum, pediatric institutions were also seeing an increasing population of older patients who had survived diseases generally considered pediatric in nature. For example, patients treated for cystic fibrosis, meningomyelocele and hydrocephalus, congenital heart disease, leukemias, and many “syndromes” were now routinely surviving into adulthood and arriving well past childhood for surgical procedures. Hospitals and their physicians catering to adults often exhibited a reluctance to manage these patients. This led to the interesting paradox of pediatric subspecialists and pediatric hospitals being involved in the ongoing management of patients who clearly are no longer children. Compounding this issue has been the growth of surgical specialties in which the care of children and adults is often undertaken simultaneously, such as fetal surgery or transplantation from living related donors. Thus, pediatric hospitals are now caring for patients well into their 20s, 30s, and beyond.

It is not simply the age of patients requiring surgery that has changed but also the setting of much of the surgery itself.

The vast majority of pediatric surgical procedures currently occurs in ambulatory patients who never remain overnight in the hospital. Patients often arrive for their procedure in the morning and go home later the same day. This creates additional challenges to anesthesiologists who must rely on surgeons to screen patients for significant coexisting medical problems, because patients are often not seen in advance of the procedure by their anesthesiologist. Even when postsurgical hospitalization is required, patients undergoing elective surgery are rarely admitted before the day of the procedure. This is the case even when the surgical procedure is quite complex, such as scoliosis repair, craniofacial reconstruction, or repair of congenital cardiac lesions. For these situations, patients can be evaluated in preoperative clinics by an anesthesiologist along with any necessary consultants. Laboratory and radiologic studies can also be obtained and blood cross-matched when necessary. This preoperative assessment also provides an opportunity to answer questions about anesthesia and the perioperative experience and to attempt to manage patient and parental anxiety.

Finally, pediatric anesthesiologists have become increasingly involved in caring for children outside the operating rooms when immobility or analgesia is required for nonsurgical procedures. This has largely occurred in the radiology departments, where increasingly sophisticated equipment and techniques have led to major advances in diagnosis (e.g., computed tomography, magnetic resonance imaging, and positron emission tomography) and new, less-invasive treatment options (e.g., in the catheterization laboratory or radiation therapy suite). Anesthesiologists are being requested to provide care for patients in several other areas of the hospital as well, including the gastrointestinal suite for endoscopy, the oncology unit for lumbar punctures and bone marrow aspirations, and so on. Whereas children clearly benefit from relief of pain and anxiety in these situations, this has greatly increased the demands for anesthesia services.

When anesthesiologists are unable or unwilling to assist in these areas, physicians from other specialties (including pediatricians, intensivists, and hospitalists) or nurses have stepped in (Malviya et al., 1997; Lowrie et al., 1998; Lightdale et al., 2008). Whether this affords a comparable degree of safety to administration of anesthesia by anesthesiologists in these situations remains to be seen. In any case, the large number of children requiring sedation or immobilization for nonoperative procedures has led to the development of sedation guidelines by several organizations representing anesthesiologists, pediatricians, emergency physicians, dentists, and others, with some variability among them (American Academy of Pediatrics, 1992; American Society of Anesthesiologists, 1996; American College of Emergency Physicians, 1997; American Academy of Pediatric Dentistry, 1997). A group of pediatric anesthesiologists at Dartmouth Hitchcock Medical Center convened in 2000 to develop a consensus among physicians from varied disciplines in this regard, and they continue to disseminate a bulletin via email to individuals interested in this ongoing issue (Dartmouth Sedation Project, 2000).

New Developments in Anesthesia

Although the scope of new developments in anesthesia is the subject of much of the remainder of this book, there are several major changes worth noting. The age-old, commonly

used, restriction of preoperative intake ultimately underwent scrutiny, which resulted in changes in concept and reduction of fasting time (Coté, 1990; Ferrari et al., 1999). New, potent, inhalational anesthetic agents have been developed, virtually replacing halothane as the “standard” for the previous generation. To induce anesthesia via mask, sevoflurane is used almost exclusively, because it acts faster and results in less bradycardia and hypotension (Sarner et al., 1995; Holzman et al., 1996). This has been especially important in infants. Isoflurane is often used for maintenance of anesthesia, in part because it is currently cost effective. Desflurane may be used when particularly rapid awakening is desired, although the need for special, temperature-regulated vaporizers has limited its popularity. None of these newer agents, however, has the smooth induction properties of sevoflurane. Concerns have been raised about breakdown products that may develop when sevoflurane interacts with some carbon dioxide absorbents, especially when desiccated, leading to overheating of the absorbent system, carbon monoxide production, or both (Holak et al., 2003). The clinical significance of this remains unclear.

A new, major feature in airway management has been the promotion of the laryngeal mask airway to eliminate tracheal intubation for many simple procedures, as well as provide airway access in emergency situations when intubation is difficult (Brain, 1983; Mason and Bingham, 1990; Pennant and White, 1993). Endoscopes have also been developed that permit fiberoptic intubation even in small children.

Several “descendants” of fentanyl have been developed, with remifentanyl capable of providing potent and transient analgesia when administered via constant intravenous infusion (Davis et al., 2001; Galinkin et al., 2001; Ross et al., 2001). Fentanyl transcutaneous “patches” have also been developed, largely to provide analgesia for chronic pain, and fentanyl is sometimes administered transnasally or transorally (Friesen et al., 1995; Viscusi et al., 2004). Potent opioids have been particularly useful for cardiac procedures when inhaled anesthetic agents are not well tolerated (Hickey and Hansen, 1984). Perhaps more significant, the prolonged debate over the need for anesthesia at all during surgery on small infants was finally terminated when Anand and Hickey (1987) produced evidence of physiologic stress in infants under light anesthesia. This brought general agreement that all infants should receive anesthesia during surgery, although the best method for doing this, especially when the patient is a fetus, remains to be fully elucidated.

However, concern has been expressed in recent years about potential adverse effects of many anesthetic agents on brain development. Studies in young animals receiving ketamine, midazolam, nitrous oxide, isoflurane, and other commonly used anesthetic agents have indicated increased apoptosis and cell death, at least in some experimental models, raising fears that similar findings could possibly occur when these drugs are administered to young children (Jevtovic-Todorovic and Olney, 2008). In view of the apparent increase in the incidence of autism and related disorders, much investigation is ongoing in this regard (Sun et al., 2008; Davidson et al., 2008). However, current consensus is that the benefits of a well-conducted anesthesia of the relatively brief duration necessary to perform most surgical procedures far outweigh the theoretical risk of anesthetic neurotoxicity (Soriano et al., 2005; Mellon et al., 2007; Loepeke et al., 2008).

Propofol has become the most common intravenous induction agent for adults, but has not completely replaced thiopental in children because propofol causes some discomfort when

injected into small peripheral veins. Midazolam has replaced diazepam as the intravenous benzodiazepine of choice for sedation in children; it is also the most popular oral sedative in the preoperative setting (Kain et al., 2000). Midazolam can be administered via several other routes (including intranasal) and is sometimes used rectally because production of methohexital, which is often used for this purpose, has ceased for economic reasons. The use of topical agents including lidocaine-prilocaine (EMLA; Freeman et al., 1993) or lidocaine-tetracaine (Synera; Sethna et al., 2005) for skin desensitization eases the discomfort of venipuncture for intravenous induction but requires adequate time to become effective. Intramuscular injections are now rarely necessary in pediatric anesthesia practice.

Several new, nondepolarizing muscle relaxants have replaced curare. Although pancuronium is commonly used for lengthy procedures, several shorter-acting agents (especially cisatracurium and vecuronium) are often administered for brief procedures and have fewer side effects. Rocuronium is often used to facilitate emergency endotracheal intubation, and succinylcholine is no longer administered without good cause because masseter spasm, malignant hyperthermia, or both occasionally develop after its administration, especially in the presence of potent inhaled anesthetic agents (Schwartz et al., 1984). In addition, the Food and Drug Administration (1997) issued a “black box” warning because of serious complications (including cardiac arrest resulting from acute hyperkalemia) associated with its use, particularly in young boys with unrecognized muscular dystrophy.

Although there was some use of local and regional anesthesia for children before 1940, the development of improved inhalation methods soon largely displaced other forms of anesthesia. Regional anesthesia became more commonplace in children, beginning in Europe with “single-shot” techniques (e.g., spinal, caudal, or peripheral nerve block) reducing the requirements for general anesthesia and providing postoperative analgesia (Abajian et al., 1984; Yaster and Maxwell, 1989; Dalens, 1989; Bosenberg and Ivani, 1998; Williams et al., 2006). Small, portable ultrasound machines have been introduced, which add great precision to the ability to deliver local anesthetic solutions to the desired location (Willschke et al., 2005, 2006; Marhofer et al., 2005; Marhofer and Chan, 2007; Tran et al., 2008). In addition, continuous infusions of local anesthetics with or without fentanyl are often delivered intraoperatively and postoperatively via catheters placed during surgery, especially via the epidural route. This reflects the much greater emphasis on the needs of the pediatric patient in the postoperative period. Pain control after surgery has been a major focus of pediatric anesthesiologists with patient-, parent-, or nurse-controlled analgesia available via computer-controlled infusion pumps for delivery of medications by the intravenous, epidural, or perineural route (Ganesh et al., 2007). Pain treatment services have become more important aspects of the mission of most departments of pediatric anesthesia to provide care for children with medical and surgical pain (Zeltzer et al., 1989; Berde and Sethna, 2002; Schecter et al., 2002).

In addition, outpatient pain treatment clinics evaluate and treat many chronic pain conditions in childhood; although largely directed by anesthesiologists, these are multidisciplinary (using nerve blocks, oral medications, acupuncture, hypnosis, and behavioral modification) and involve the participation of neurologists, neurosurgeons, psychiatrists, physical therapists, psychologists, and many other ancillary medical and nursing

personnel. Greater attention has been directed toward assessing and allaying preoperative fears and anxiety of patients and their families. Preoperative clinics are used to evaluate many patients in advance of their procedures, and significant attention has been devoted to methods of easing induction of anesthesia, especially the use of oral premedicants and parental presence during mask induction (Kain et al., 1998a, 1998b, 2000, 2003). In all instances, kindness remains the essential feature in preoperative management.

Progress in Monitoring

Technical advances have also greatly enhanced patient monitoring. Smaller equipment is now readily available so that young patients can be monitored as carefully as critically ill adults. Percutaneous catheters can be inserted directly into virtually any peripheral vein or artery; the Seldinger technique (if necessary with ultrasound guidance) can be used to insert central catheters (Ganesh and Jobes, 2008). Echocardiography can be performed transthoracically or transesophageally in small children as well as in adults. Its use has greatly facilitated the ability of cardiac surgeons to assess the repair of congenital heart lesions intraoperatively (Ungerleider et al., 1990). “Standard” monitoring is now quite extensive and sophisticated as promulgated by the American Society of Anesthesiologists (1986) and includes continuous pulse oximetry and capnography. It appears that the average anesthesiologist is often able to manage a procedure with little or no direct observation of the patient, although a precordial or an esophageal stethoscope is still considered valuable by many pediatric anesthesiologists.

Advances in the intensive care unit also have been significant during this time and extend into the operating rooms. Patients with severe lung injury are now managed with several new forms of respiratory support, including advanced mechanical ventilators, inhaled nitric oxide, and extracorporeal membrane oxygenation or ECMO (Neonatal Inhaled Nitric Oxide Study Group, 1997; Bartlett et al., 2000; Aharon et al., 2001; Campbell et al., 2003). This latter technique can be used for weeks at a time and as an emergency method of resuscitation from cardiac arrest when a reversible condition is suspected (Laussen, 2002).

Advances in Surgery

Numerous developments have occurred in surgical techniques that have greatly influenced anesthesia practice and are discussed elsewhere in this text. However, it is worthwhile noting that laparoscopic techniques, robotics, and intraoperative imaging have progressed so extensively and rapidly into pediatric practice that anesthesiologists have had to accommodate the special problems and challenges presented by these situations. Perhaps nowhere is this more apparent than the field of fetal surgery where surgeons, obstetricians, anesthesiologists, and neonatologists must collaborate to care for two patients simultaneously, as techniques for surgical repair of prenatal anomalies are developed and assessed (Harrison et al., 1982, 1993; Rosen, 1992; Cauldwell, 2002). Controversy remains, however, about the best way to provide analgesia during fetal procedures (Benatar and Benatar, 2001; Myers et al., 2002; Schwartz and Galinken, 2003; Lee et al., 2005).

Organ transplantation has extended beyond kidneys, and transplantation of the liver has become a major challenge for pediatric surgeons and anesthesiologists (Starzl et al., 1963). To support a young patient with hepatic failure through a repeat liver transplant potentially requiring replacement of multiple blood volumes while monitoring and maintaining cardiac function, temperature, and many components of blood chemistry during an 8- to 12-hour operation is one of the most demanding anesthesia-related tasks known. The record of 1000 liver transplantations performed at the Children's Hospital of Pittsburgh between 1980 and 1990 with a nearly 70% survival rate stands as a remarkable accomplishment of both surgeons and anesthesiologists (Robertson and Borland, 1990). Transplantation of the heart, lungs, or both appears similarly impressive, although it is not associated with the same degree of blood loss (Jamieson et al., 1984). Intestinal transplants more recently have emerged as a potential method for treating children with short bowel syndrome (Mazariegos et al., 2008). In any case, a shortage of available organs, especially those of a small size, greatly limits pediatric transplantation, and attempts to grow organs in cell culture has evolved into the new and fascinating field of tissue engineering (Langer and Vacanti, 1993; Lanza et al., 2000; Dunn, 2008).

Research Efforts

Activity in research is reaching a new level of excellence and productivity, whereas demands for clinical service and limitations of funding make this an ongoing challenge, and old problems persist. As noted by Berry (1993), failure in the endless search for better preoperative sedation lies in controversies regarding basic ground rules for investigation, especially in children. In many fields, understanding of the problems has been gradually extended, with resultant improvement in the practical management of patients. Physiologic studies of cerebral circulation in the neonate by Rogers and colleagues (1980), gas exchange in cardiac patients, pharmacologic biotransformation of sedatives, the infant and the myoneural junction, and hypoxia in children who have undergone anesthesia are but a few of the important initial studies (Goudsouzian and Standaert, 1986; Motoyama and Glazener, 1986; Saint-Maurice et al., 1986; Lindahl, 1989; Fletcher, 1993). The report by Lerman and others (1986) concerning postanesthetic vomiting after strabismus surgery is another illustration of one of the problems of the conscious child that remains particularly difficult to control. Advances in molecular biology, mapping the human genome, and genomic pharmacology offer great hope that it will be possible to “customize” care for individual patients in a continuing attempt to drive the curve of improvement mentioned by Rees (1991) “closer to perfection” (Holtzman and Marteau, 2000).

Development of the Subspecialty

Pediatric anesthesia organizations have advanced greatly over the recent generation. Although a small group of anesthesiologists from the United States and Canada have had a section within the American Academy of Pediatrics since 1966 (now called the Section on Anesthesiology and Pain Medicine), it was not until 1973 that pediatric activities formally became a part of the American Society of Anesthesiologists. At this same time, a separate organization devoted to pediatric anesthesiology was

established in the United Kingdom, but it was not until 1986 that the Society for Pediatric Anesthesia (SPA) was created in the United States. This is now the largest organization in the world devoted to pediatric anesthesiology with more than 4000 members largely from the United States. The SPA has held annual meetings since 1987 in association with the annual meeting of the American Society of Anesthesiologists. For several years, it has also organized an additional winter educational meeting. The goals of the SPA are listed in [Box 41-1](#); the SPA's presidents are listed in [Table 41-1](#).

The SPA collaborated with other pediatric anesthesiology groups in developing a proposal to have fellowship training formally accredited by the Accreditation Council for Graduate Medical Education (Rockoff and Hall, 1997). This was successful in 1997, and there are currently 45 programs in the United States that offer 1 year of training in pediatric anesthesiology to individuals who have completed a basic residency in anesthesiology (Accreditation Council for Graduate Medical Education, 2008). Furthermore, subspecialization within pediatric anesthesiology continues to advance informally with individuals developing additional experience in areas such as pediatric pain medicine, pediatric intensive care, pediatric cardiac anesthesiology, and others.

Box 41-1 Goals of the Society for Pediatric Anesthesia

1. To advance the practice of pediatric anesthesia through new knowledge
2. To provide educational programs on clinical, scientific, and political issues that are important to pediatric anesthesia practice
3. To promote scientific research in pediatric anesthesia and related disciplines
4. To provide a forum for exchange of ideas and knowledge among practitioners of pediatric anesthesia
5. To support the goals of the American Society of Anesthesiologists and the American Academy of Pediatrics

TABLE 41-1. Presidents of the Society for Pediatric Anesthesia

Year	President	Location
1986 to 1988	Myron Yaster, MD	Baltimore, Md.
1988 to 1990	Robert Crone, MD	Seattle, Wash.
1990 to 1992	Aubrey Maze, MD	Phoenix, Ariz.
1992 to 1994	Charles Lockhart, MD	Denver, Colo.
1994 to 1996	William Greeley, MD	Durham, N.C.
1996 to 1998	Mark Rockoff, MD	Boston, Mass.
1998 to 2000	Steven Hall, MD	Chicago, Ill.
2000 to 2002	Peter Davis, MD	Pittsburgh, Pa.
2002 to 2004	Anne Lynn, MD	Seattle, Wash.
2004 to 2006	Francis McGowan, MD	Boston, Mass.
2006 to 2008	Jayant Deshpande, MD	Nashville, Tenn.
2008 to 2010	Joseph Tobin, MD	Winston-Salem, N.C.

Finally, many additional textbooks directed to pediatric anesthesia have been published, and several have been updated into multiple editions; these include texts by Gregory (2002), Coté et al. (2009), Motoyama and Davis (2006), Berry (1990), Brown and Fisk (1992), Sumner and Hatch (1999), Steward and Lerman (2001), Bisonnette and Dalens (2002), and others. The further development of pediatric anesthesiology into subspecialties became evident in texts on topics such as uncommon diseases, neonatal anesthesia, pediatric pain regional anesthesia, cardiac anesthesia, and intensive care (Dalens et al., 1990; Saint-Maurice and Steinberg, 1990; Bush and Harkins, 1991; Katz and Steward, 1993; Hatch et al., 1995; Rogers, 1996; Tobias and Deshpande, 1996; Todres and Fugate, 1996; Schechter et al., 2002; Lake and Booker, 2004). The journal *Paediatric Anaesthesia*, originally edited by Bush in Liverpool and Saint-Maurice in Paris, became the first independent monthly publication devoted to this field. With its international editorial board members, it has led to enhanced worldwide relationships among pediatric anesthesiologists. *Anesthesia & Analgesia*, one of the largest anesthesia journals in the world, has also developed a separate section devoted to pediatric anesthesia. Furthermore, pediatric anesthesiologists are members of the editorial boards of *Anesthesiology* and several other well-respected international anesthesia journals.

SUMMARY

Pediatric anesthesia has advanced enormously from the days when anesthesiologists and surgeons adapted adult techniques and equipment to small children. It is clear that pediatric anesthesiology is a well-established and well-recognized subspecialty in its own right. It is one of the most popular fields to pursue for further training after the basic anesthesia residency, and its practitioners are desired by surgeons, pediatricians, and parents alike.

Challenges are ongoing as more complex surgical and diagnostic techniques are performed on younger and younger patients. Society will always have limited resources, and ensuring adequate allocation of funding, personnel, and research priorities is an increasing problem as the baby-boomer population ages, adults live longer with more complicated medical conditions, and geriatric problems demand society's greater attention.

Nevertheless, history has shown that talented and dedicated individuals can and will meet the challenges ahead, and there are few who doubt that things are better now for pediatric anesthesiologists—and their patients—than ever before.

Physicians are confronted with a variety of unique legal issues on a daily basis. It would be nearly impossible to cover all of them—even in broad strokes—in a single chapter. Accordingly, this chapter focuses on two issues that may be of specific importance to pediatric physicians: informed consent and related medical malpractice actions. It is important to note at the outset that this chapter is intended to provide only a broad overview of these issues; in most cases, the nuances of these issues are dictated by state laws. As such, the relevant state's laws should be consulted for more specific legal authority on these issues. This chapter attempts, however, to lay out the variety of considerations at play when determining whether both an adult and a minor patient have provided their informed consent to accept or decline the relevant medical treatment. It also provides an outline of two specific types of medical malpractice actions: one based on informed consent and one based on a negligence theory, which comprises the majority of malpractice actions in this country.

INFORMED CONSENT

Patient consent is one of the most prominent issues facing medical providers today. Consent becomes even more complicated when a patient is a minor. Recall the recent case of 12-year-old Parker Jensen, who was diagnosed with an extremely rare and aggressive cancer, Ewing's sarcoma, after physicians removed a tumor from the soft tissue of his mouth (Foy, 2003b; Watts, 2005). Parker's parents were undecided about the right course of treatment for their son and wanted to seek a second opinion (Foy, 2003a). Parker's physicians, however, sought a court order to remove Parker from his home in order for him to begin 49 weeks of chemotherapy that they—not necessarily Parker—believed was the appropriate course of treatment (Foy, 2003a). A battle ensued between Parker's parents and the state of Utah; the end result was that kidnapping and child neglect charges were filed against Parker's parents (Foy, 2003a). Parker's opinion was not nearly—if at all—as highly publicized.

The specific issues facing physicians are whose consent actually is required when the patient is a minor and what informed consent means for the practitioner.

Background

The notion of consent itself can be traced back to the laws of battery and trespass. In 1914 Judge Benjamin Cardozo likened assault to trespass of the body. He wrote, "Every human being of adult years and sound mind has a right to determine what shall be done with his own body; and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable in damages" (*Schloendorff v. Society of NY Hosp*, 1914). Thus, began the legal analysis of the notion of consent.

The issue of consent—and the circumstances under which a patient may be said to have consented to certain medical treatment—is an important one for physicians. Without patient consent to treatment, physicians may be sued for battery—the violation of a person's right to be free from unwanted touching (*McNeil v. Brewer*, 1999*; Syoboda et al., 2000). Subject to certain exceptions, such as emergencies that pose threats to a patient's life, any willful touching of another is unlawful without valid consent from the individual or another authorized to consent on that person's behalf (Syoboda et al., 2000). The requirement of consent primarily protects the patient's bodily integrity (Syoboda et al., 2000).

Informed Consent

Consent, however, gives the physician a privilege that protects him or her against liability for this tort as long as the patient is informed of the nature and consequences of treatment and

*For example, finding that an inmate's inclusion in a medical study did not constitute offensive conduct, an element of battery, when no blood was drawn without the inmate's consent.

gives knowing and intelligent consent to the proposed treatment the physician intends to provide (Schlam and Wood, 2000). “Informed consent” is designed to protect the individual’s autonomy in medical decision making; in other words, it is a real-world application of the adage that “every person has the right to determine what is done to his own body” (Schlam and Wood, 2000).

In turn, physicians are obligated to provide the patient with a “reasonable amount of information” for the patient to be able to make an informed decision (Schlam and Wood, 2000). It is worth noting here that some jurisdictions reject this approach for one that shifts the focus to what a “reasonable patient would need to know,” a standard that does not require expert testimony and thereby eases a patient’s burden of proof (Altman et al., 1992; Schlam and Wood, 2000). In other words, the patient must know for what he or she is giving consent (Syoboda et al., 2000). Informed consent is the “autonomous authorization of medical intervention ... by individual patients” (Beauchamp and Faden, 1995; Syoboda et al., 2000). It can really only follow after a discussion regarding the “nature of the proposed treatment procedures, possible alternative treatments, and the nature and the degree of the risk and benefits involved in accepting or rejecting treatment.” Consent is then considered “informed” when it is given “knowingly, competently, and voluntarily” (Schlam and Wood, 2000). It is worth noting, however, that if a physician doesn’t provide enough information to make an informed treatment and the patient consents, the physician may still be liable for negligence (Schlam and Wood, 2000).

Knowingly means that the physician has a duty of disclosure to provide adequate information to the patient in a manner that the patient can comprehend (Syoboda et al., 2000). “Adequate” means “the amount and kind of information that the average person in the patient’s position would want to have in reaching an informed decision” (Syoboda et al., 2000). This usually means that the clinician must fully explain the proposed procedure, the expected short-term risks and long-term consequences, the available alternatives and their risks and benefits, and the consequences of declining or delaying treatment (Syoboda et al., 2000). In short, physicians must disclose all material information; i.e., all “information which the physician knows or should know would be regarded as significant by a reasonable person in the patient’s position when deciding to accept or reject a recommended medical procedure” (*Arato v. Avedon*, 1993; Syoboda et al., 2000).

Competently means that the patient has the capacity, or ability, to understand “information relating to treatment decisions and to appreciate the consequences of a decision” (Syoboda et al., 2000). That a decision be made competently requires physicians to assess whether a patient can both understand the relevant medical information and make a rational decision based on that information (Syoboda et al., 2000).

The voluntariness requirement simply protects the patient’s right to make health care decisions free from manipulation or undue influence (Syoboda et al., 2000). Because of the power imbalance between a physician and the patient and the sometimes vulnerable state of the patient, there is a great danger of undue influence; as such, the manner in which physicians present information can significantly influence the relative importance the patient may attach to certain information and could persuade the patient to favor the option emphasized by the physician. Accordingly, physicians have a duty to distance themselves from their personal preferences and allow their pre-

sentation of information to reflect an objective assessment of the various interests at stake for the patient (Syoboda et al., 2000).

Background: Consent by Minor

As outlined above, competent adults are entitled to make decisions regarding their medical care themselves. But the framework of consent changes if the patient is a minor (Syoboda et al., 2000). The legal framework of consent highlights the courts’ recognition that the family must be protected by a broad right of privacy, limiting government interference in the intimate family workings (Watts, 2005). That right of privacy, however, is balanced by the fact that the state is permitted, in certain circumstances, to make determinations about the best interests of the child (Watts, 2005). When such a conflict arises—perhaps relating to the type, length, and necessity of medical treatments for a child, the question is about who possesses the ultimate right to make a child’s medical decisions (Watts, 2005). When does a minor have the right to have a voice in medical decisions regarding his or her own well being? Even if the minor has a voice, when is that voice determinative?

An analysis of a minor’s right to participate in his or her health care decisions reflects a huge variation from state to state over the amount, if any, of deference given to a minor to consent or refuse medical treatment (Watts, 2005). Traditionally, the view was that parents had total autonomy over a child’s medical care. That idea can be traced back to a time when children were considered the property of their parents (Schlam and Wood, 2000). Before that time, children had no rights, and parents reared their children without government restraint (Schlam and Wood, 2000). The Supreme Court has articulated several justifications for total parental autonomy (*Parham v. JR*, 1979; Watts, 2005). Primarily, they rest in the presumptions that children lack the maturity, experience, and capacity to make appropriate decisions and that the “natural bonds of affection” between parents and children will lead parents to act in the best interest of their children (*Parham v. JR*, 1979; Watts, 2005). Since that time, however, the Supreme Court has modified the notion of absolute parental autonomy in order to account for the interest of minors, particularly in the arena of health care decisions (Watts, 2005). The idea is that there are better means for protecting parental autonomy than disregarding the desires of the children (Hawkins, 1996; Schlam and Wood, 2000). Jurisdictions vary in the deference given to parental autonomy over a child’s health care (Watts, 2005).

Typically, the current view is that for most treatment provided to children, informed consent is provided by parents or guardians (*Health L Prac Guide*, 2008). Stated another way, parental permission for medical procedures on children, when appropriate and properly secured, constitutes an exception to the general requirement of personal consent to medical treatment (*Secretary, Dept Health and Comm Ser v. JWB and SMB*, 1992; Syoboda et al., 2000). In turn, parents are required to make decisions that are in the best interest of their children; they may not make decisions for their children that are likely to cause them physical harm or otherwise impair their healthy development (Syoboda et al., 2000). Parents, therefore, should be viewed as agents for their children, required to make decisions regarding medical interventions for their children in a manner consistent with the child’s best interest. Medical professionals,

in turn, owe a duty to their minor patients to assist parents in making decisions that conform to that standard (Syoboda et al., 2000). To assist “parents in making decisions that comport with their child’s best interest, medical professionals must satisfy the same requirements of informed consent that apply to decision-making by adults as outlined above (Syoboda et al., 2000). In short, a minor has the right to consent to medical treatment without third-party involvement in two key situations. First, an unemancipated minor may consent to treatment of specific types of conditions for which either the state legislature or the courts have granted such authority (Vukadinovich, 2004). Such authority applies to any minor who is capable of giving meaningful informed consent and who has one of the specified medical conditions; in other words, if the minor can be said to be a “mature minor” (Vukadinovich, 2004). Secondly, a minor who qualifies as emancipated, either by court order or on other grounds, may consent to medical treatment as if he or she were an adult (Vukadinovich, 2004).

The Mature Minor

Most state laws provide that when minors reach a specified age, they are empowered to provide informed consent for the diagnosis and treatment for specific conditions (usually involving mental health, substance abuse, pregnancy, and sexually transmitted diseases) without the knowledge or consent of their parents (*Health L Prac Guide*, 2008). Then when they reach yet another, older age, they are given sole decision-making power over their own health care; at this point, they are no longer considered minors.

The law does recognize the “mature minor doctrine,” which was developed to ensure treatment of minors when parental consent may cause intrafamily conflict or be difficult to obtain and to protect physicians who treat “mature minors” (Schlam and Wood, 2000). As a result of the mature minor doctrine, physicians may treat children even in the absence of parental consent or a court order, because it has become reasonable to assume that mature children are capable of providing informed consent pertaining to their own medical treatment in certain situations (Kreichman, 1989*; Schlam and Wood, 2000). Even if parents ultimately disagree with the treatment given, the physician should still be protected against liability by the doctrine, subject to any specific state law limitations that may apply.

Still, it is essential that physicians have a clear understanding of how to adequately determine and record indications of the maturity and decision-making competence of minor patients, as well as how to be assured that they have properly communicated with and obtained knowing and intelligent medical decisions from competent minor patients (Kreichman, 1989; Schlam and Wood, 2000). The Supreme Court has not been particularly helpful in offering guidance to physicians attempting to determine the maturity of a minor (Schlam and Wood, 2000). It did, however, hold in *Planned Parenthood of Central Missouri v. Danforth*, 428 US at 52-53, that a minor does not need parental consent if he or she “is sufficiently mature to understand the procedure and to make an intelligent assessment of” his or her circumstances. Jurisprudence has generally concluded that minors may be recognized as competent based on a vari-

ety of factors, including age (although it does not appear that any court has granted a patient younger than 14 years of age the right to consent), maturity, intelligence, and the nature and risks of the proposed treatment (Schlam and Wood, 2000). Accordingly, legal privileges are extended to these minors by allowing minors “who can understand the nature and consequences of the medical treatment offered” the right to consent to or refuse treatment (Schlam and Wood, 2000; O’Connor, 1994). That said, courts generally find children competent to consent or refuse treatment when the treatment has little risk, such as vaccinations, back pain, and cosmetic surgery (*Bishop v. Shurly*, 1926; *Gulf and SIR Co v. Sullivan*, 1928; *Younts v. St. Francis Hosp and Sch of Nursing*, 1970; *Cardwell v. Bechtol*, 1987; Schlam and Wood, 2000). However, ethicists agree that the ordinary indicia of competence should be balanced against the risks of treatment (Schlam and Wood, 2000). The mature minor doctrine has been consistently applied in cases in which the minor is nearing the age of majority, usually 15 years or older, the minor displays the capacity to understand the nature and risks of the treatment, and the nature of the treatment is not serious (Schlam and Wood, 2000). Courts will, however, generally protect physicians in their “non-negligent treatment of ... mature minor(s) who consent ... to a procedure after discussion with the physician” (Schlam and Wood, 2000). In addition, all states have statutes that give physicians the authority to treat minors, regardless of parental consent, in a variety of situations to “prevent certain negative consequences resulting from lack of medical care,” including but not necessarily limited to the provision of care for emergency medical situations, to an emancipated minor, and if the minor seeks treatment for certain specific medical conditions, such as mental illness and sexually transmitted diseases (Schlam and Wood, 2000).

Notwithstanding any of the above, children’s hospitals recognize an ethical obligation to involve children in the informed consent process to the maximum extent appropriate to their level of maturity (*Health L Prac Guide*, 2008). Where a minor expresses a reasonable desire to refuse offered care, an attempt is often made by the treatment team to reconcile the views of the child and the parents and to avoid invocations of any legal authority the parents may technically possess (*Health L Prac Guide*, 2008).

The Emancipated Minor

Notwithstanding the application of the mature minor doctrine, all states have statutes that give physicians the authority to treat minors, regardless of parental consent, to “prevent negative consequences resulting from lack of medical care,” such as in emergency situations or if the patient suffers from certain medical conditions (Schlam and Wood, 2000). One such situation arises if the minor is considered an “emancipated minor.” Emancipation for purposes of consenting to medical treatment may take various forms. It may be accomplished by court order when a child reaches a certain age. In such a case, often the State Department or Division of Motor Vehicles issues the minor an identification card reflecting the emancipated status, which the health care provider may request to see. It may also be accomplished by marriage. When a minor marries, that minor is deemed emancipated for purposes of consenting to or refusing medical treatment. Finally, a minor who is on active military duty has the authority to consent to medical treatment (Vukadinovich, 2004). The emancipated minor doctrine broadly

*Discussing mature minor doctrine and the capacity to understand the treatment as the primary concern with minor’s consent to the proposed treatment.

conveys to the minor the right to consent to or refuse medical treatment without the involvement of the minor's parent, guardian, or other third party, obviously without regard to whether the minor has reached the age of majority (Vukadinovich, 2004). The contours of each state's emancipated minor doctrine varies, but generally it is intended to protect minors who are no longer dependent on their parents—those parents who have “relinquished control over their child's behavior and personal affairs” (Schlam and Wood, 2000).

Generally, an emancipated minor may consent to any type of medical treatment and is afforded the same confidentiality rights as an adult, regardless of the manner in which the minor is emancipated (Vukadinovich, 2004). Accordingly, with few exceptions, when treating an emancipated minor, the health care provider must deal with the minor as if that patient were an adult (Vukadinovich, 2004).

Informed Consent and HIPAA

The ability to authorize disclosure of health information usually goes hand in hand with the right to give informed consent, as discussed above (*Health L Prac Guide*, 2008). Accordingly, where the law recognizes the parent as the appropriate individual to give informed consent on behalf of a child, the parent may also exercise the child's rights to disclose health care related information (*Health L Prac Guide*, 2008). Likewise, where the minor is authorized to consent to medical care independently, only the minor has the authority to consent to the disclosure of such information (*Health L Prac Guide*, 2008).

The Health Insurance Portability and Accountability Act (HIPAA) of 1996 and its implementing regulations, as a general statement, defer to state laws addressing the ability of a parent or guardian to obtain or otherwise disclose protected health information concerning a minor (*Health L Prac Guide*, 2008). HIPAA does, however, specify the following three situations in which a parent does not function as the personal representative of the minor for the purpose of disclosing protected health information:

1. When state or other law does not require the consent of the parent or other person before a minor can obtain a particular health care service, and the minor consents to such service,
2. When a court determines or other law authorizes someone other than the parent to make treatment decisions for the minor, and
3. When a parent agrees to a confidential relationship between the minor and physician (Code of Federal Regulations, 2008; *Health L Prac Guide*, 2008).

MEDICAL MALPRACTICE LITIGATION

A health care professional is not liable to a patient merely because the care rendered produced a bad result, because a bad result was brought about by an error in judgment, when there is a reasonable doubt or difference of opinion as to the patient's condition or proper course of treatment, and when the physician acts with reasonable care in exercising judgment (*Roach v. Hockey*, 1981; McClellan, 2005). There are four theories of medical malpractice under which a plaintiff may be able to

recover: breach of contract, negligence, lack of informed consent, and respondeat superior (McClellan, 2005). Negligence cases compose most of the medical malpractice actions against individual health care providers (Mastroianni, 2006). Informed consent cases are particularly relevant to pediatric physicians and pose a set of unique issues, as discussed previously. Accordingly, this chapter focuses on those types of actions. As stated, however, it is important to note that this chapter is intended to provide only an overview of malpractice actions; in reality, such litigation is incredibly complex, and the burdens of proof and type of evidence required to meet that burden are governed more specifically by each individual state's law.

Negligence

Most medical malpractice actions are based on a negligence theory. In negligence-based malpractice actions, the plaintiff is essentially taking the position that the conduct in question “falls below the standard established by law for the protection of others against unreasonable risk of harm” (Mastroianni, 2006). Stated another way, the plaintiff is arguing that the professional did not possess or employ the degree of skill or knowledge required of a professional rendering such care under the circumstances (*Incollingo v. Ewing*, 1971; *Shilkret v. Annapolis Emergency Hosp Assoc*, 1975; McClellan, 2005). In such cases, the plaintiff, who is typically either the patient or the patient's family (in the event the patient is incompetent or has died) must prove four elements of malpractice: duty, breach of standard of care, injury, and causation.

Duty

First, the plaintiff must establish that the defendant—typically the physician or the institution with which the physician is affiliated—had a legal duty to the plaintiff (Mastroianni, 2006). In the context of medical malpractice actions, the “duty” can include any number of obligations that health care professionals incur on entering into a physician–patient relationship, including duties mandated by state or federal statute, either implicitly or explicitly (Mastroianni, 2006). Generally during the physician–patient relationship, the physician has a duty to exercise the degree of care, diligence, and skill that physicians of reasonable and ordinary prudence would exercise under the same or similar circumstances (Shandell et al., 1981).

Courts have held that this duty may include any of the following actions:

- Fully informing the patient of the condition
- Giving the patient the care and attention required by the known exigencies of the patient's case
- Continuing to provide medical care and giving proper instructions to a patient as to the patient's future conduct
- Obtaining the patient's informed consent to the treatment proposed
- Exercising reasonable care in prescribing treatment
- Referring the patient to a specialist or procuring another physician if necessary
- Exercising reasonable care in supervising resident physicians who are actually treating the patient
- Keeping the patient's condition confidential

- Keeping reasonably abreast of current advances in the field
- Otherwise exercising the utmost good faith in dealing with the patient (Shandell et al., 1981).

Breach of Standard of Care

The very existence of the physician's duty imposes on certain responsibilities to exercise due care, and the plaintiff must establish that the defendant breached that standard of care (Mastroianni, 2006). Stated differently, the plaintiff must establish that the physician undertook a form of treatment that a reasonable, prudent member of the medical profession would not have taken under the same or similar circumstances (Shandell et al., 1981). The standard of care, then, is what is reasonable under the circumstances (Shandell et al., 1981).

The first step for any plaintiff, after proving the existence of a duty, is to establish the appropriate medical standard of care (Shandell et al., 1981). Generally, a plaintiff must show that the defendant deviated from a standard of care and skill possessed by reasonably prudent physicians practicing in the same field of medicine. If the physician who renders the medical care to a patient in question specializes in a particular branch of medicine, that physician is required to use the care and judgment of a reasonably prudent person engaged in that specialty (McClellan, 2005). To be clear, a health care provider is not required to provide the highest degree of care possible—only the ordinary degree of skill and care exercised by his or her peers (Shandell et al., 1981). In order to establish the standard of care, the plaintiff must identify the person with whom the professional is being compared. There are jurisdictional differences as to the requirements of a geographic similarity and specialty training (McClellan, 2005). It appears that the current trend is to apply a national, rather than a local, standard to determine the standard of care required of a physician (*Naccarato v. Grob*, 1970; *Shildret v. Annapolis Emergency Hosp Assoc*, 1975; *Bruni v. Tatsumi*, 1976; *Zeller v. Greater Baltimore Med Cntr*, 1986; McClellan, 2005).

Injury

The plaintiff must also establish that he or she suffered a “compensable” injury—or one for which it is possible to be compensated for the actual harm suffered, including pain and suffering, with a monetary award. In most negligence cases, only compensatory damages are awarded. However, in cases where the defendant's actions is deemed to have been “reckless” or an “extreme departure from the standard of care” (gross negligence), some states do allow a plaintiff to recover punitive damages as well (Mastroianni, 2006). A bad result alone, however, cannot be equated with malpractice and typically does not create a presumption of negligence (Shandell et al., 1981).

Causation

Finally, the plaintiff must establish that the defendant's actions were the cause of the injury (Mastroianni, 2006). The fact that a physician erred does not necessarily warrant the conclusion that the error was the cause of the plaintiff's injury. In other words, the physician may have erred, and the patient may have suffered, but unless the error caused the injury, the physician may not be liable (PLI, *Med Malpractice*). The plaintiff is required to establish that the physician's departure from the

standard of care was more likely than not to have been the proximate cause of the plaintiff's injury (PLI, *Med Malpractice*). It need not, however, be the sole cause—only a substantial factor in bringing about the injury (PLI, *Med Malpractice*). Typically, the plaintiff will establish the causation element through expert testimony, primarily because a jury must struggle to understand scientific processes that are unfamiliar and involve inherent uncertainty (Practicing Law Institute, 2009; Shandell et al., 1981).

Malpractice Resulting from Lack of Informed Consent

If certain requirements are met, a plaintiff may bring a cause of action against a physician for lack of informed consent. As previously stated, an action for lack of informed consent is an action for medical malpractice in which the practitioner failed to inform the patient of the alternatives to the proposed treatment or diagnosis and the reasonably foreseeable risks and benefits involved, such that the patient can make a knowledgeable evaluation (Practicing Law Institute, 2009). Generally, even when the physician adheres to the requisite standard of care in performing a procedure or conducting an examination, the patient may recover for injuries suffered as a result of the procedure or examination if the physician failed to obtain informed consent (*Armstrong v. Brookdale Univ Hosp and Med Cntr*, 2005).

An action for informed consent has the same four elements as any other action for medical malpractice: duty, breach, injury, and causation. The difference in an informed consent action is in the nature of the breach; that is, the physician was negligent in explaining the procedure rather than performing it. More specifically, in order to establish medical malpractice based on lack of informed consent, a plaintiff typically must establish that the medical procedure carried a specific risk that was not disclosed, the physician violated the applicable standard of disclosure, the undisclosed risk materialized, and the failure to disclose the information caused the patient's injury (Mastroianni, 2006).

Beyond those basic elements, each state has its own specific requirements for making a claim for informed consent, and more specifically, for how the plaintiff must go about establishing each of the requisite elements. By way of example, New York Public Health Law §2805-d(1) defines lack of informed consent as the “failure of the person providing the professional treatment or diagnosis to disclosure to the patient such alternatives thereto and the reasonably foreseeable risks and benefits involved as a reasonable medical ... practitioner under similar circumstances would have disclosed, in a manner permitting the patient to make a knowledgeable evaluation.” Under New York's statute, one may only recover for lack of informed consent in cases involving either nonemergency treatment or a diagnostic procedure that involved invasion or disruption of bodily integrity (NY Pub Health Law §2805-d[2]). In order to recover, a plaintiff in New York must establish that “a reasonably prudent person in the patient's position would not have undergone the treatment or diagnosis if he had been fully informed and that the lack of informed consent is a proximate cause of the injury or condition for which recovery is sought” (NY Pub Health Law §2805-d[3]).

It is important to note that the court distinguishes a lack of informed consent case from a case of battery, which lies against one who “intentionally touches another person,

without that person's consent, and causes an offensive bodily contact.... The intent required for battery is intent to cause a bodily contact that a reasonable person would find offensive" (*Jeffreys v. Griffin*, 2003; *Armstrong v. Brookdale Univ Hosp and Med Cntr*, 2005). In other words, in New York, a completely unpermitted touching by a medical practitioner is a battery, as distinct from a Section 2805-d claim (*Jeffreys v. Griffin*, 2003; *Armstrong v. Brookdale Univ Hosp and Med Cntr*, 2005). New Jersey also distinguishes a lack of informed consent case from a battery cause of action, reasoning that because physicians ordinarily lacked the intent to harm normally associated with the tort of battery, courts examining the nuances of the physician-patient relationship realized that conceptually a cause of action based on lack of patient consent fits better into the framework of a negligence cause of action. Accordingly, the framework for New Jersey's lack of informed consent cause of action can be characterized as a negligence type of action rather than an intentional tort (*Robinson v. Cutchin*, 2001; *Howard v. Univ of Medicine and Dentistry of New Jersey*, 2002).

New York has also provided, by statute, that five other classes of people may consent to medical care:

1. Anyone who is either 18 years old, married, or a parent, may give consent for his or her own care (because any such person is deemed to be emancipated).
2. Anyone who has been married or has given birth may consent to the child's care.
3. Anyone who is pregnant may consent to prenatal care.

4. A physician may consent to medical care for a minor in an emergency situation when delay would increase the risk for the patient's life or health.
5. A person with a parental relationship to a child may consent to the child's immunization (Practicing Law Institute, 2009; NY Pub Health Law §2804).

In New Jersey, a patient seeking to recover for lack of informed consent must prove that the physician withheld pertinent medical information concerning the risks of the procedure or treatment, the alternatives, or the potential results if the procedure or treatment were not undertaken (*Perna v. Pirozzi*, 1983; *Howard v. Univ of Medicine and Dentistry of New Jersey*, 2002). The information a physician must disclose depends on what a reasonably prudent patient would deem significant in determining whether to proceed with the proposed procedure (*Largey v. Rothman*, 1988; *Howard v. Univ of Medicine and Dentistry of New Jersey*, 2002). The plaintiff must also prove that a reasonably prudent patient in the plaintiff's position would have declined to undergo the treatment if informed of the risk that defendant failed to disclose (*Largey v. Rothman*, 1988; *Howard v. Univ of Medicine and Dentistry of New Jersey*, 2002).

during craniofacial surgery, 828, 828*f*
historical background in control of, 1299
mechanisms of, 163–165, 163*b*, 164*f*
during neonatal surgery, 559, 559*b*
prevention of, 176–178, 176*f*
- Height
relation to body surface area, 7*t*
typical patterns of physical growth and, 8*b*
- Heliox, 1254
- Helium-oxygen mixtures, 1254
- Hemangioma, 836–837, 1047
- Hematocrit
cardiopulmonary bypass and, 642
during liver transplantation, 921–922
before outpatient surgery, 1062
- Hematologic system
burn-related abnormalities of, 1011*t*, 1012–1013
congenital heart disease and, 1128*t*
graft-versus-host disease and, 1142*t*, 1143
liver failure and, 909, 909*t*
neonatal, 543–545, 545*t*
postoperative management in, 1137
preoperative review of, 279*t*, 284
renal insufficiency and, 779*t*
sickle cell disease and, 1130–1137
acute complications of, 1132–1134, 1133*f*
anesthetic management in, 1136–1137
chronic complications of, 1134
clinical severity and diagnostic testing in, 1131*f*
genetics and pathophysiology of, 1130–1132, 1131*f*, 1132*f*
hemoglobin structure, development, and function and, 1130
ocular manifestations in, 873*t*
orthopedic aspects of, 843*t*
outpatient procedures and, 1062, 1066
pain management in, 447–449
preoperative evaluation of, 284
preoperative preparation in, 1134–1135
red blood cell transfusion for, 410
routine preoperative blood transfusion in, 1135–1136, 1136*t*
thalassemia and, 1137
- Hematopoietic stem-cell transplantation, 943–946, 943*f*, 944*b*, 944*t*, 946*f*, 1142–1144
- Hematopoietic stem-cell transplantation
graft-versus-host disease and, 1142, 1142*t*
non-graft-versus-host disease complications in, 1143
- Hemifacial microsomia, 830–831
- Hemi-Fontan procedure, 633
- Hemodilution
in cardiopulmonary bypass, 641–642
coagulopathy and, 1157
during scoliosis surgery, 854
- Hemodynamic assessment in cardiac catheterization, 104
cardiac output in, 105–106
intracardiac pressures in, 104–105, 104*f*, 105*t*
oxygen consumption in, 105, 106*t*
oxygen content and saturation in, 105
shunts and, 106–107
vascular resistance in, 107
- Hemodynamic catheterization, 703, 703*t*
- Hemodynamic values in children, 703*t*
- Hemoglobin
fetal, 84, 598
oxygen affinity of, 61–64, 61*f*, 62*f*, 62*t*, 63*t*
of premature infant, 545
recommended concentration during anesthesia, 385
structure, development, and function of, 395–398, 396*f*, 397*f*, 398*f*, 399*f*, 1130
- Hemoglobin A, 396
- Hemoglobin F, 396
- Hemoglobin-based oxygen carriers, 416
- Hemoglobinopathies, 1130–1137, 1131*f*
- Hemolytic crisis in sickle cell disease, 1132
- Hemophilia, 1150–1151
acquired, 1156, 1156*f*
- Hemoptysis
congenital heart disease and, 1128*t*
cystic fibrosis and, 1125
- Hemorrhagic disease of newborn, 1154
- Hemostasis, 1144–1145, 1144*f*, 1145*f*
burn injuries and, 1020–1021
developmental, 1148–1149, 1149*f*, 1149*t*
during liver transplantation, 921–923
- Hemostatic drugs, 1163–1164, 1163*b*, 1163*t*
for blood conservation, 401–403, 402*f*, 403*f*
safety of, 1160
- Hemothorax, 998
- Heparin
in cardiopulmonary bypass, 642–643
protamine reversal of, 1154, 1154*t*
Heparin-induced thrombocytopenia, 1270–1271
- Hepatic artery thrombosis after liver transplantation, 927
- Hepatic blood flow, burn-related dysfunction of, 1012
- Hepatic clearance, 183, 183*f*, 185*f*
- Hepatic dysfunction-related coagulopathies, 1154
- Hepatic encephalopathy, 909–910, 913*t*
- Hepatic tumor, 758–760, 758*b*, 758*t*, 759*f*, 759*t*
- Hepatic venoocclusive disease, 1143
- Hepatitis B
post-transplant, 947
transfusion-transmitted, 411*t*
- Hepatitis C
contraindication to heart transplantation, 657
post-transplant, 947
transfusion-transmitted, 411*t*
- Hepatoblastoma, 758, 758*t*
- Hepatocellular carcinoma, 758, 758*t*
- Hepatocyte transplantation, 946
- Hepatolenticular degeneration, 912
- Hepatopulmonary syndrome, 908, 914–915
- Hepatorenal syndrome, 908*b*, 909
- Hepatotoxicity of inhaled anesthetic agents, 232
- Herbal remedies, perioperative complications of, 277–278, 278*t*
- Herbst appliance, 1029*f*
- Hering-Breuer deflation reflex, 30
- Hering-Breuer inflation reflex, 26, 30
- Herniorrhaphy, 1298
inguinal and umbilical, 749–750, 749*f*
- Heteropagus conjunction, 953
- Hexadrol. *See* Dexamethasone
- High-clearance continuous renal replacement therapy, 1265
- High-frequency ventilation, 523
- High-impulse cardiopulmonary resuscitation, 1214
- High-intensity magnetic field issues, 1055–1057
- High-voltage burn, 1021
- Hip, developmental dysplasia of, 867
- HIPPA. *See* Health Insurance Portability and Accountability Act
- Hirschsprung's disease, 760–761, 760*f*

Pediatric Drug Dosages

APPENDIX

Franklyn P. Cladis

A

Generic Name (Trade Name)	Route	Dose	Indication	Side Effects
Acetaminophen (Tylenol)	PO PR	10 to 15 mg/kg q 4 to 6 hr 20 to 40 mg/kg initial dose, then 20 mg/kg q 6 hr	Pain/fever	
Adenosine	IV	0.1 mg/kg bolus; if not effective, 0.2 mg/kg (12 mg maximum single dose)	SVT	Flushing, chest pain, bronchospasm
Albuterol	Nebulized	0.15 mg/kg in 2 mL normal saline solution	Bronchospasm	Tachycardia
Alfentanil	IV	10 to 150 mcg/kg bolus 0.5 to 3 mcg/kg per min	Anesthesia Adjunct for anesthesia maintenance	Apnea, bradycardia
Alprostadil	IV	0.05 to 0.1 mcg/kg per min	Patency of ductus arteriosus	Fever, apnea, arrhythmias
Aminocaproic acid (Amicar)	IV	100 mg/kg bolus, infusion 30 mg/kg per hr	Excessive bleeding from fibrinolysis	Hypotension, bradycardia, arrhythmias
Aminophylline	PO, IV	100 mg/kg load: 100 mg/kg dose every 6 hr 5 mg/kg load, infusion 1 mg/kg per hr	Bronchospasm	Arrhythmias
Amiodarone	IV	5 mg/kg bolus slowly, infusion 5 to 10 mcg/kg per min	Ventricular arrhythmias	Hypotension, arrhythmias (torsades de pointes)
Ampicillin	IV	50 mg/kg	Endocarditis prophylaxis	
Atracurium (Tracrium)	IV	0.5 mg/kg intubation 5 to 15 mcg/kg per min infusion	Neuromuscular blocker	Histamine release
Atropine	IV	0.01 to 0.02 mg/kg	Bradycardia	
Bupivacaine (Marcaine)	Neuraxial, peripheral	2.5 mg/kg	Epidural, caudal, peripheral nerve blockade	Seizures, arrhythmias
Butorphanol	IV	10 mcg/kg	Pain/fever	CNS depression, respiratory depression
Caffeine	PO, IV	5 to 10 mg/kg as caffeine base (10 to 20 mg/kg as caffeine citrate)	Apnea of prematurity	Tachyarrhythmias
Caffeine and Sodium benzate	IV	500 mg (per dose)	Relief of post dural puncture headache	Tachycardia, palpitations, nausea
Calcium chloride	IV	10 to 20 mg/kg (via central venous line)	Hypocalcemia, hypotension	Tissue necrosis
Calcium gluconate	IV	30 to 45 mg/kg	Hypocalcemia, hypotension	Tissue necrosis
Cefazolin (Ancef)	IV	25 mg/kg	Wound prophylaxis	
Chloral hydrate	PO/PR	50 to 75 mg/kg	Sedation	Arrhythmias
Cimetidine (Tagamet)	IV/PO	5 to 15 mg/kg q 6 to 12 hr	Gastric pH control	Confusion, headache
Cisatracurium (Nimbex)	IV	0.1 to 0.2 mg/kg bolus, infusion 1 to 5 mcg/kg per min	Neuromuscular blockade	
Clindamycin (Cleocin)	IV	5 to 10 mg/kg (slowly) q 6 to 8 hr 20 mg/kg (slowly) for SBE prophylaxis	Wound prophylaxis (penicillin [PCN] allergic)	Thrombophlebitis, hypotension
Clonidine	Neuraxial PO	1 to 3 mcg/kg 4 mcg/kg	Enhance neuraxial blockade Preoperative sedation	Hypotension, sedation Intraoperative hypotension

Continued

Generic Name (Trade Name)	Route	Dose	Indication	Side Effects
Codeine	PO	0.5 to 1 mg/kg	Pain	Sedation, nausea, vomiting, respiratory depression
Dantrolene	IV	2.5 mg/kg to maximum 10 mg/kg	Malignant hyperthermia	Slow to solubilize, drowsiness, muscle weakness
Desmopressin (DDAVP)	IV IV	0.3 mcg/kg (over 15 min) 2 to 4 mcg/day in 2 doses (≥12 years old)	Platelet dysfunction, von Willebrand disease Diabetes insipidus	Hyponatremia, hypertension, flushing Hyponatremia, hypertension, flushing
Dexamethasone (Decadron)	IV	0.5 to 1 mg/kg (maximum 16 to 20 mg)	Croup, airway edema, cerebral edema	Hypertension, headache, hyperglycemia
Dexmedetomidine	IV	Load 0.5 to 2 mcg/kg over 15 min infuse 0.3 to 2 mcg/kg/hr	Sedation and analgesia	Hypotension, bradycardia, transient hypertension with rapid administration
Diazepam (Valium)	PO IV	0.2 to 0.3 mg/kg 45 to 60 minutes preprocedure 0.05 to 0.3 mg/kg	Preoperative sedation	Hypotension, bradycardia
Digoxin	IV IV maintenance	0.03 mg/kg <2 years old 0.01 to 0.04 mg/kg >2 years old (digitalizing dose; 1/2 dose initially, then 1/4 q 6 hr × 2) 2 to 10 mcg/kg per day (IV dose = 75% oral dose)	SVT, CHF	Arrhythmias, atrioventricular block
Diphenylhydantoin (Dilantin)	IV	12 to 20 mg/kg (over 30 min to avoid hypotension; limit infusion rate to 50 mg/min)	Seizure, digoxin toxicity	Hypotension, skin necrosis at IV site, ataxia, gingival hyperplasia
Diphenhydramine (Benadryl)	IV	0.5 to 2 mg/kg (maximum single dose 50 mg) (maximum 150 mg/day if <12 years old, 300 mg if >12 years old)	Sedation, pruritus, acute dystonic reactions	Paradoxical excitement
Dobutamine	IV	2 to 15 mcg/kg per min (maximum dose 40 mcg/kg/min)	Heart failure	Increased heart rate, ectopy, hypotension
Dopamine	IV dose	2.5 to 20 mcg/kg per min	Heart failure, increased renal blood flow—low	Increased heart rate, ectopy
Doxacurium	IV	0.05 to 0.1 mg/kg intubation	Neuromuscular blocker	
Droperidol	IV	10 to 75 mcg/kg (maximum dose 1.25 mg)	Antiemetic	Hypotension, arrhythmias (FDA warning)
Edrophonium (Enlon, Tensilon)	IV	0.5 to 1.0 mg/kg	Neuromuscular blocking reversal agent	Bradycardia
EMLA cream	Topical	0 to 3 mo maximum 1 g (10 cm ²), 3 to 12 mo maximum 2 g (20 cm ²), 1 to 6 years old maximum 10 g (100 cm ²), 7 to 12 years old maximum 20 g (200 cm ²)	Dermal anesthesia for venipuncture	Methemoglobinemia, blanching of skin
Ephedrine	IV	0.02 to 0.2 mg/kg	Hypotension	Bradycardia, hypotension, confusion
Epinephrine (Adrenalin)	IV Endotracheal	10 mcg/kg q 3 to 5 min, infusion 0.01 to 1 mcg/kg per min 100 mcg/kg	Cardiac arrest, hypotension, heart failure	Tachycardia
Epinephrine, racemic	Nebulized	<2 years old 0.25 mL, >2 years old 0.5 mL of 2.25% solution in 3 mL normal saline solution	Upper airway edema	Tachycardia
Esmolol	IV	500 mcg/kg loading dose 50 to 300 mcg/kg per min infusion	Hypertension, tachycardia	Bradycardia
Etomidate	IV	0.3 mg/kg (0.2 to 0.6 mg/kg)	Anesthetic induction	Myoclonus, pain on injection, adrenal suppression

Generic Name (Trade Name)	Route	Dose	Indication	Side Effects
Fentanyl	IV	0.5 to 3 mcg/kg (may repeat q 30 min) 2 to 10 mcg/kg bolus, infusion 1 to 4 mcg/kg per hr	Analgesia and sedation Adjunct for induction and maintenance of anesthesia	Apnea, cough, laryngospasm, chest wall rigidity, bradycardia
Fentanyl (Oralet, Actiq)	PO	5 to 15 mcg/kg (200 mcg is smallest dose)	Sedation preoperatively	Sedation, pruritis, oxygen desaturation
Flumazenil	IV	0.01 mg/kg (maximum dose 0.2 mg) q 1 min up to 1 mg (maximum cumulative dose)	Benzodiazepine antagonist	Altered blood pressure, arrhythmias
Furosemide (Lasix)	IV	1 to 2 mg/kg q 6 hr (6 mg/kg per day maximum dose)	Diuretic	Hypokalemia, hyponatremia, potential ototoxicity
Gentamicin	IV	1.5 to 2.5 mg/kg	Antibiotic	Nephrotoxicity, ototoxicity, potentiate neuromuscular blockade
Glucagon	IM, IV	<20 kg 0.5 mg, >20 kg 1 mg	Antihypoglycemic, relaxant for gastrointestinal tract	Tachycardia
Glucose	IV	200 mg/kg, 4 mg/kg per min	Hypoglycemia	
Glycopyrrolate (Robinul)	IV	0.005 to 0.01 mg/kg	Antisialagogue, bradycardia	Tachycardia, flushing
Hydralazine	IV	0.05 to 0.3 mg/kg (15 min onset)	Hypertension	Tachycardia, flushing
Hydrocortisone (Solu-Cortef)	IV	1 to 2 mg/kg q 6 hr	Adrenal suppression, asthma	Hypertension, hyperglycemia
Hydromorphone (Dilaudid)	IV	0.01 to 0.015 mg/kg	Analgesia	Sedation, nausea, vomiting, respiratory depression
Hydroxyzine (Atarax, Vistaril)	IM PO	0.5 to 1 mg/kg q 4 to 6 hr 2 to 4 mg/kg q 6 to 8 hr	Sedation	Drowsiness
Ibuprofen	PO	10 mg/kg q 6 hr	Analgesic/antiinflammatory	Inhibition of platelet aggregation, renal failure
Inamrinone	IV	Load 3 to 4.5 mg/kg over 30 min, then 3 to 10 mcg/kg per min infusion	Heart failure	Arrhythmias, thrombocytopenia
Insulin, regular	IV	Load 0.01 to 0.1 unit/kg, infuse 0.1 unit/kg per hr	Hyperglycemia, DKA	Hypoglycemia
Intralipid 20%	IV	1.5 ml/kg bolus, then infuse 0.25 ml/kg/min over 30 to 60 min	Cardiac arrest secondary to local anesthetic toxicity	
Isoproterenol (Isuprel)	IV	0.05 to 1 mcg/kg per min	Bradycardia	Tachycardia, ventricular arrhythmias, hypotension
Ketamine	IV	0.5 to 1 mg/kg	Sedation	Hallucinations, tachycardia, may increase intracranial and intraocular hypersalivation, pressure, apnea, vomiting
	IV	1 to 2 mg/kg	Anesthesia	
	IV	2-5	Anti-hyperalgesia dose	
	IM	3 to 5 mg/kg	Sedation	
	IM PO	5 to 10 mg/kg 5 to 10 mg/kg	Anesthesia Sedation	
Ketorolac (Toradol)	IV	0.5 mg/kg	Analgesia	Inhibition of platelet aggregation, renal failure
Labetalol	IV	0.2 to 0.5 mg/kg (q 5 min)	Tachycardia, hypertension	Hypotension, bradycardia
Lidocaine	IV	1 mg/kg	Ventricular arrhythmias	Seizures
	IV	20 to 50 mcg/kg per min infusion		
Lidocaine	Intratracheal	3 to 4 mg/kg	Topical anesthesia	Arrhythmias, seizures

Continued

Generic Name (Trade Name)	Route	Dose	Indication	Side Effects
Lorazepam	IV	0.05 to 0.1 mg/kg (maximum 4 mg)	Sedation, anxiolysis	Neurotoxicity in neonates (preservative)
Mannitol	IV	0.25 to 1 g/kg (over 20 min)	Increased intracranial pressure, diuresis	
Meperidine (Demerol)	IV IV IM	1 to 2 mg/kg 0.5 mg/kg max dose (12.5 mg) 1 to 2 mg/kg	Analgesia, preoperative sedation Postoperative shivering	Accumulation of normeperidine in renal dysfunction
Methadone	IV	0.1 mg/kg	Analgesia	Sedation, nausea, vomiting, respiratory depression
Methohexital (Brevital)	IV PR	1 to 2 mg/kg 25 to 35 mg/kg (10% solution)	Anesthesia Sedation/anesthesia	Apnea
Methylene blue	IV	1 to 2 mg/kg may repeat in 1 hr	Antidote for drug-induced methemoglobinemia	Stains skin
Methylprednisolone (Solu-Medrol)	IV IV	2 mg/kg load, 0.5 to 1 mg/kg q 6 hr 30 mg/kg over 15 min, infusion 5.4 mg/kg per hr for 23 hr	Asthma exacerbation Acute spinal cord injury	Hypertension, psychosis, glucose intolerance
Metoclopramide (Reglan)	IV	0.1 to 0.5 mg/kg	Antiemetic	Extrapyramidal reactions
Midazolam (Versed)	IV IN PO	0.05 to 0.1 mg/kg 0.2 to 0.3 mg/kg (5 to 10 min onset) 0.5 to 1 mg/kg (20 to 30 min onset)	Sedation Sedation Sedation	Hypotension in neonates, hiccups Nasal irritation Bad taste
Milrinone	IV	50 mcg/kg load, infusion 0.25 to 0.75 mcg/kg per min	Heart failure	Hypotension
Morphine	IV/IM	0.05 to 0.1 mg/kg	Analgesia	Histamine release, apnea, sedation, nausea, vomiting
Nalbuphine	IV	0.01 to 0.02 mg/kg q 4 hr	Opioid-induced pruritis	
Naloxone (Narcan)	IV/IM	1 to 10 mcg/kg titrated	Apnea/sedation after opioids	Hypertension
Naproxen (Naprosyn)	PO	5 to 10 mg/kg q 12 hr	Analgesia, antiinflammatory	Inhibition of platelet aggregation, renal failure
Neostigmine	IV	0.05 to 0.07 mg/kg	Neuromuscular blockade reversal	Bradycardia, secretions
Nicardipine	IV	0.5 to 5 mcg/kg per min	Induced hypotension, hypertension	Hypotension
Nitroglycerin	IV	0.5 to 3 mcg/kg per min	Venodilation, myocardial ischemia	Hypotension
Nitroprusside	IV	0.5 to 10 mcg/kg per min	Induced hypotension, hypertension	Cyanide toxicity
Norepinephrine (Levophed)	IV	0.1 to 1 mcg/kg per min	Hypotension	Arrhythmias
Ondansetron (Zofran)	IV	0.05 to 0.1 mg/kg (maximum 4 mg)	Antiemetic	Headache
Oxycodone	PO	0.05 to 0.15 mg/kg q 4 to 6 hr	Analgesia	Sedation, nausea, vomiting, respiratory depression
Pancuronium (Pavulon)	IV	0.08 to 0.15 mg/kg	Neuromuscular blocker	Tachycardia
Pentobarbital (Nembutal)	IV	1 to 3 mg/kg (maximum 100 mg)	Sedation	Respiratory depression, apnea
Phenylephrine (Neo-Synephrine)	IV IV	1 to 10 mcg/kg 0.1 to 0.5 mcg/kg/min infusion	Hypotension	Hypertension

Generic Name (Trade Name)	Route	Dose	Indication	Side Effects
Potassium chloride	IV	0.5 mEq/kg (via CVP over 30 to 45 min)	Hypokalemia	Arrhythmias with rapid infusion
Procainamide	IV	3 to 6 mg/kg per dose over 5 min q 5 to 10 min (maximum 15 mg/kg), infusion 20 mcg/kg per min	Ventricular and atrial arrhythmias	Hypotension, QT prolongation
Prochlorperazine (Compazine)	IV/IM PO/PR	0.1 to 0.15 mg/kg q 6 hr (IV not recommended) 0.4 mg/kg per day divided q 6 to 8 hr	Antiemetic	High incidence of extrapyramidal reactions, sedation, hypotension
Promethazine (Phenergan)	IV/IM	0.25 to 0.5 mg/kg q 4 to 6 hr	Antiemetic	Sedation, contraindicated in children <2 years old
Propofol	IV	2 to 3 mg/kg; 100 to 200 mcg/kg per min infusion	Anesthesia	Apnea, hypotension
Propranolol (Inderal)	IV	0.01 to 0.1 mg/kg (over 10 min)	Tachycardia, hypertension	Hypotension, bradycardia
Prostaglandin E ₁	IV	0.05 to 0.1 mcg/kg per min	Maintain patent ductus arteriosus	Fever, apnea
Protamine	IV	1 mg for every 100 units of heparin to be neutralized	Heparin neutralization	Hypotension, bradycardia, pulmonary hypertension
Ranitidine (Zantac)	IV PO	1 to 1.5 mg/kg per day divided q 8 hr 2 to 3 mg/kg per day divided q 12 hr	Gastric pH control	
Remifentanyl	IV	1 to 4 mcg/kg bolus, infusion 0.1 to 0.5 mcg/kg per min	Analgesia, adjunct to anesthesia	Apnea, bradycardia
Rocuronium (Zemuron)	IV	0.6 to 1.2 mg/kg	Neuromuscular blocker	
Scopolamine	IV/IM	6 to 10 mcg/kg (maximum 0.3 mg/dose)	Antisialagogue, amnestic	Tachycardia, confusion
Sodium bicarbonate	IV	0.5 to 1 mEq/kg	Metabolic acidosis	
Succinylcholine	IV IM	1.5 to 2 mg/kg (fast onset) 5 mg/kg	Neuromuscular blocker (depolarizing) Neuromuscular blocker	Hyperkalemia, malignant hyperthermia trigger
Sufentanil	IV IV	0.25 to 1 mcg/kg bolus 0.1 to 1 mcg/kg per hr infusion	Anesthesia Adjunct for maintenance of anesthesia	Apnea, chest wall rigidity
Thiopental	IV	3 to 7 mg/kg	Anesthesia	Apnea
Tramadol	PO	1 to 2 mg/kg	Analgesia; structurally related to codeine; also inhibits reuptake of serotonin and norepinephrine	Nausea, vomiting, and dizziness
Vancomycin	IV	10 mg/kg (over 30 min)	Wound prophylaxis	Hypotension, histamine release, red man syndrome
Vasopressin	IV	0.0005 to 0.005 unit/kg per min	Vasopressor, diabetes insipidus	Hypertension
Vecuronium (Norcuron)	IV	0.07 to 0.2 mg/kg 0.8 to 1 mcg/kg per min infusion	Neuromuscular blocker	
Verapamil	IV	0.1 to 0.3 mg/kg (1 to 15 years old)	SVT, CHF	Bradycardia, hypotension

M, Intramuscular; *IN*, intranasal; *IV*, intravenous; *CHF*, congestive heart failure; *PR*, per rectum; *SVT*, supraventricular tachycardia; *DKA*, diabetic ketoacidosis; *PO*, orally; *ACT*, activated clotting time.

176	617	409	931
178	630	418	951
180	643	426	971

Formula: $\log y = a + b \cdot \log x$; $y = V_T$ (mL); $x =$ Body height (cm); $\log V_T$ (mL) = $-1.3956 + 1.8643 \cdot \log$ height (cm);SD $\log y \cdot x = \pm 0.0903$; $n = 170$; $r = +0.65$.

TABLE C-14. Tidal volume (V_T) in relation to age in boys and girls

Age (yr)	V _T (mL)		
	Mean	Lower Limits	Upper Limits
6	278	178	432
7	313	201	486
8	347	223	539
9	380	244	590
10	412	265	640
11	443	285	689
12	474	305	737
13	504	324	784
14	534	343	830
15	563	362	875
16	592	381	920
17	620	399	964

Formula: $\log y = a + b \cdot \log x$;
 $y = V_T$ (mL); $x = \text{Age}$ (yr);
 $\log V_T$ (mL) = 1.8438 + 0.7713 · log age (yr);
 SD log $y \cdot x = \pm 0.0969$; $n = 170$; $r = +0.57$.

TABLE C-15. Minute ventilation (MV) in relation to body height in boys and girls—cont'd

Height (cm)	MV (mL/min)		
	Mean	Lower Limits	Upper Limits
156	9,806	7,439	12,928
158	10,019	7,600	13,208
160	10,233	7,762	13,490
162	10,449	7,926	13,775
164	10,667	8,091	14,062
166	10,886	8,258	14,352
168	11,108	8,426	14,643
170	11,331	8,595	14,938
172	11,556	8,766	15,235
174	11,783	8,938	15,534
176	12,012	9,112	15,835
178	12,242	9,286	16,139
180	12,474	9,463	16,445

Formula: $\log y = a + b \cdot \log x$;
 $y = MV$ (mL/min); $x = \text{Body height}$ (cm);
 $\log MV$ (mL/min) = -0.3035 + 1.6815 · log height (cm);
 SD log $y \cdot x = \pm 0.0607$; $n = 170$; $r = +0.75$.

TABLE C-15. Minute ventilation (MV) in relation to body height in boys and girls

Height (cm)	MV (mL/min)		
	Mean	Lower Limits	Upper Limits
115	5,872	4,454	7,741
116	5,958	4,520	7,855
118	6,132	4,652	8,084
120	6,308	4,785	8,316
122	6,486	4,920	8,550
124	6,666	5,056	8,787

Index of Syndromes and Their Pediatric Anesthetic Implications

Franklyn P. Cladis

See also Video, Section 6, slide presentation

Name	Description	Anesthetic Implications	References
A			
Aarskog syndrome	Mutation in faciodigitogenital gene, growth retardation, rare congenital heart disease, mental retardation, hypermobility of cervical spine with possible hypoplasia, cryptorchidism	Care with neck manipulation	Baum and O'Flaherty, 1999; Butler et al., 2000
Aase syndrome	May be variant of Diamond Blackfan syndrome, anemia, radial hypoplasia	Check preoperative hematocrit; radial anomalies make arterial catheter insertion more difficult	Baum and O'Flaherty, 1999
Abetalipoproteinemia	Absence of apolipoprotein B, neuropathy with sensory and motor loss, malabsorption of lipids	May be deficient in fat-soluble vitamins with elevation in prothrombin time; succinylcholine is contraindicated with demyelination	Baum and O'Flaherty, 1999
Achondrogenesis	Types 1 and 2 result in severe defect in the development of bone and cartilage, micrognathia, very short stature, large cranium, micromelia; usually lethal	May be difficult airway; difficult intravenous access; care with positioning	Baum and O'Flaherty, 1999; Butler et al., 2000
Achondroplasia	Premature fusion of the bones, macrocephaly, sleep apnea, chest wall deformities— scoliosis and small rib cage, brainstem compression, spine stenosis and fusion, small stature, obesity, normal intelligence	May be difficult airway; may have cervical spine compression with positioning; altered lung mechanics secondary to chest wall deformity; regional anesthesia has been performed	Kalla et al., 1986; Berkowitz et al., 1990; Baum and O'Flaherty, 1999
Adrenoleukodystrophy	Adrenal cortical deficiency and CNS demyelination, secondary to accumulation of very long chain fatty acids, visual changes, retinopathy, hypotonia, ataxia, apraxia, neuropathy, spastic paraparesis, seizures, GERD	Concern regarding succinylcholine with demyelination and muscle atrophy; risk of aspiration; inhibitors of dopamine may exacerbate movement disorder; may require stress-dose steroids	Tobias, 1992; Nishina et al., 1993; Baum and O'Flaherty, 1999
Aicardia syndrome	Seen only in females, agenesis of corpus callosum, hypotonia, infantile spasm and seizures, kyphoscoliosis	Risk for aspiration; chronic antiseizure medication	Baum and O'Flaherty, 1999; Butler et al., 2000
Alagille syndrome	Congenital heart disease, biliary hypoplasia or atresia, HTN, vitamin K deficiency, renal dysplasia or stenosis	May have cirrhosis and portal HTN; increased prothrombin time; preoperative cardiac evaluation; check renal function	Choudry et al., 1998; Baum and O'Flaherty, 1999
Albright osteodystrophy	See Pseudohypoparathyroidism		
Alport syndrome	Sensorineural hearing loss, renal failure, can have myopathy or peripheral neuropathy	Check renal function preoperatively; possible hyperkalemia with myopathy or neuropathy and succinylcholine	Baum and O'Flaherty, 1999
Alström syndrome	Vision and hearing loss, cardiomyopathy uncommon, progressive renal dysfunction, obesity	Check renal function preoperatively; may need cardiac evaluation preoperatively	Baum and O'Flaherty, 1999

Name	Description	Anesthetic Implications	References
Angelman syndrome	Severe mental retardation, laughing, ataxia, seizures, "happy puppet syndrome"	Chronic antiseizure medications	Baum and O'Flaherty, 1999; Butler et al., 2000
Antley-Bixler syndrome	Craniosynostosis, frontal bossing, choanal stenosis or atresia with severe upper airway obstruction, proptosis	Choanal atresia may require early airway intervention (tracheostomy); may preclude the use of nasal tubes; eye protection for proptosis	LeBard and Thiemann, 1998; Baum and O'Flaherty, 1999
Apert syndrome	Craniosynostosis; midface hypoplasia; may have tracheal stenosis, congenital heart disease, mental retardation, increased ICP, cervical vertebrae	May be difficult intubation from midface hypoplasia, cervical fusion and tracheal stenosis; preoperative cardiac evaluation; caution with premedication if ICP elevated; IV access may be difficult	Baum and O'Flaherty, 1999; Butler et al., 2000
Argininosuccinic Acid Lyase and Argininosuccinic Acid Synthetase Deficiency	Urea cycle defect with hyperammonemia, mental retardation, seizures	Need high carbohydrate intake perioperatively with low protein intake; protein load (blood) may cause acute metabolic encephalopathy	Baum and O'Flaherty, 1999
Arthrogryposis Multiplex	Multiple congenital contractures, small mandible, short neck; may be associated myopathy or neuropathy	May be difficult intubation, difficult intravenous access; weak evidence for malignant hyperthermia	Baum and O'Flaherty, 1999
Asplenia	Duplication of right-sided structures, two right lungs, two right atria, usually a form of anomalous venous return, two sinoatrial nodes, absent spleen; may have malrotation	Preoperative cardiac evaluation, risk of infection from encapsulated organisms	Baum and O'Flaherty, 1999
Ataxia-Telangiectasia syndrome	Oculocutaneous telangiectases, cerebellar ataxia, peripheral nerve degeneration, immunodeficiency, recurrent lung infections, predisposition to malignancies	Aseptic technique with invasive procedures; potential hyperkalemia with succinylcholine in setting of neuropathy; may have glucose intolerance	Baum and O'Flaherty, 1999
B			
Baller-Gerold syndrome	Craniosynostosis, micrognathia, radial aplasia, congenital heart disease common, mental retardation, renal anomalies	Micrognathia may make intubation difficult; preoperative cardiac evaluation; check renal function; radial artery catheterization may be difficult	Baum and O'Flaherty, 1999; Butler et al., 2000
Bartter syndrome	Abnormalities in Na ⁺ , K ⁺ , and Cl ⁻ transport with hypokalemia, hypochloremia, metabolic alkalosis, mental retardation, muscle weakness	Check electrolytes (Na ⁺ , K ⁺ , and Cl ⁻) preoperatively; may have ileus secondary to hypokalemia; may have decreased muscle tone	Higa et al., 1993; Kannan et al., 1995; Baum and O'Flaherty, 1999
Becker Muscular Dystrophy	Abnormality in size or amount of dystrophin, later age of onset and milder course, respiratory muscle weakness, cardiomyopathy	Hyperkalemia with succinylcholine, low risk of malignant hyperthermia, risk of aspiration, preoperative cardiac evaluation	Baum and O'Flaherty, 1999; Russell and Hirsch, 1994
Beckwith-Wiedemann syndrome	Macroglossia, macrosomia, visceromegaly, increased risk of intraabdominal tumors, hypoglycemia, neonatal polycythemia, omphalocele; may have congenital heart disease	May have significant upper airway obstruction; preoperative cardiac evaluation; monitor blood glucose	Gurkowski and Rasch, 1989; Suan et al., 1996; Baum and O'Flaherty, 1999; Butler et al., 2000
Bernard-Soulier syndrome	Disorder of platelet function	May require platelet transfusion	Baum and O'Flaherty, 1999
Blackfan-Diamond syndrome	Congenital red cell hypoplasia, steroid therapy common	Check preoperative hemoglobin; may require transfusions; may need stress-dose steroids	Baum and O'Flaherty, 1999
Branchio-Oculofacial syndrome	Defects of the branchial arch involving the eye and face, pseudocleft lip, renal anomalies	No reports of difficult airway; check renal function preoperatively	Baum and O'Flaherty, 1999
C			
Campomelic Dysplasia	Short stature, micrognathia, short neck, kyphoscoliosis	May be difficult intubation; may have unstable cervical spine	Baum and O'Flaherty, 1999; Butler et al., 2000
Carpenter syndrome	Craniosynostosis, hypoplastic mandible, congenital heart disease common; may have increased ICP, mental retardation, obesity	May be difficult intubation; preoperative cardiac evaluation; may need to manage elevated ICP	Baum and O'Flaherty, 1999; Butler et al., 2000
Cat-Eye syndrome	Colobomas of iris; may have choanal atresia, congenital heart disease, anal atresia, renal abnormalities, radial anomalies	Check renal function; preoperative cardiac evaluation; radial artery catheter may be difficult	Baum and O'Flaherty, 1999; Butler et al., 2000
Catch-22 syndrome	See DiGeorge syndrome		

Continued

Name	Description	Anesthetic Implications	References
Catel-Manzke syndrome	Severe micrognathia, short neck, congenital heart disease common	May have significant upper airway obstruction; ventilation and intubation may be very difficult; preoperative cardiac evaluation	Baum and O'Flaherty, 1999; Butler et al., 2000
Central Core disease	Congenital myopathy with defect in ryanidine receptor	Increased risk of malignant hyperthermia, proximal muscle weakness	Baum and O'Flaherty, 1999; Frank et al., 1980
Cerebrocostomandibular syndrome	Severe micrognathia, gap in ribs with small thoracic cage, congenital heart disease	Intubation may be very difficult; severe restrictive lung disease; preoperative cardiac evaluation	Baum and O'Flaherty, 1999
Cerebrooculofacioskeletal syndrome	Degeneration of brain and spinal cord, hypotonia, hyporeflexia, micrognathia	May have hyperkalemia with succinylcholine	Baum and O'Flaherty, 1999; Butler et al., 2000
Charcot-Marie-Tooth syndrome	Hereditary peripheral neuropathy, respiratory insufficiency later in life, muscle atrophy	May have hyperkalemia with succinylcholine; may have perioperative respiratory complications	Anotgnini, 1992; Greenberg and Parker, 1992; Baraka, 1997; Baum and O'Flaherty, 1999
CHARGE association	Colobomas of the eye, heart disease (tetralogy of Fallot), atresia of choanae, retarded growth, genital anomalies (hypogonadism), ear anomalies (deafness)	May be difficult intubation secondary to micrognathia; preoperative cardiac evaluation; respiratory distress from choanal atresia	Stack and Wyse, 1991; Baum and O'Flaherty, 1999; Butler et al., 2000
Chédiak-Higashi syndrome	Defect in granular cells (neutrophils, monocytes, lymphocytes); immunodeficient; partial albinism; peripheral neuropathy; may have platelet abnormalities, steroid therapy	Risk for bacterial infections; use aseptic technique; may have hyperkalemia with succinylcholine; may require platelet transfusion; consider stress-dose steroids	Baum and O'Flaherty, 1999
CHILD syndrome	Congenital hemidysplasia, ichthyosiform erythroderma, limb defects, congenital heart disease, hypomelia, renal agenesis	Intravenous access may be difficult; preoperative cardiac evaluation; check renal function preoperatively	Baum and O'Flaherty, 1999
Chotzen syndrome	See Saethre-Chotzen syndrome		
Cockayne syndrome	UV light-induced DNA damage, small mandible, small trachea, precocious coronary artery disease and HTN, ataxia, muscle atrophy, vertebral abnormalities, kyphoscoliosis	Difficult intubation has been reported; may need smaller endotracheal tube; preoperative cardiac evaluation for ischemia; may need to treat HTN; check renal function preoperatively; succinylcholine may cause hyperkalemia with muscle atrophy	Cook, 1982; Woolridge et al., 1996; Sasaki et al., 1997; Baum and O'Flaherty, 1999
Coffin-Siris syndrome	Microcephaly, congenital heart disease, mental retardation, hypoplastic digits, renal anomalies, aggressive behavior	Preoperative cardiac evaluation; check renal function preoperatively	Baum and O'Flaherty, 1999; Butler et al., 2000
Cohen syndrome	Micrognathia, mitral valve prolapse, mental retardation, hypotonia, muscle weakness, obesity	May be difficult intubation; may be difficult ventilation secondary to obesity; perioperative complications secondary to obesity and muscle weakness	Baum and O'Flaherty, 1999; Butler et al., 2000
Congenital Adrenal Hyperplasia	Defect in the synthesis of cortisol with overproduction of an androgen cortisol precursor; virilization; clinical features depend on enzyme deficiency; may have salt wasting; may have hypoglycemia; may have hypokalemia and HTN; defect in aldosterone synthesis common	Check Na ⁺ , K ⁺ , and glucose preoperatively; stress-dose steroids; salt losing can be treated with salt-containing intravenous fluids and mineralocorticoid	White et al., 1987; Baum and O'Flaherty, 1999
Cornelia de Lange syndrome	Micrognathia and short neck, occasional congenital heart disease, severe mental retardation, seizures, apnea, GERD, micromelia	May be difficult intubation; risk of perioperative respiratory complications from GERD and apnea; may be difficult intravenous access	Munoz Corsini et al., 1998; Baum and O'Flaherty, 1999
Costello syndrome	Short neck, oral and nasal papillomas, hypertrophic cardiomyopathy, arrhythmias, congenital heart disease, mental retardation, swallowing difficulty and GERD	Airway papillomas may make intubation difficult; preoperative cardiac evaluation; perioperative respiratory complications secondary to swallowing difficulty and GERD	Dearlove and Harper, 1997; Baum and O'Flaherty, 1999; Butler et al., 2000
Cri du chat syndrome	Partial deletion of chromosome 5p; high-pitched cry; may have micrognathia and short neck, long epiglottis, laryngeal deformity, severe mental retardation, recurrent aspiration; congenital heart disease common	Difficult intubation described, preoperative cardiac evaluation, risk of aspiration at baseline, airway obstruction secondary to hypotonia	Yamashita et al., 1985; Brislin et al., 1995; Baum and O'Flaherty, 1999; Butler et al., 2000

Name	Description	Anesthetic Implications	References
Crouzon's syndrome	Craniosynostosis, proptosis, hypoplastic maxilla, rarely elevated ICP	Possible difficult intubation; eye care with proptosis	Payne and Cranston, 1995; Baum and O'Flaherty, 1999
Cutis Laxa	Disorder of elastin synthesis, emphysema, aortic dilation, coronary artery disease, pulmonary HTN, pendulous skin	Preoperative cardiac evaluation; intravenous access may be difficult	Baum and O'Flaherty, 1999
Cystic Fibrosis	See Chapter 36		
D			
Dejerine-Sottas syndrome	Motor and sensory neuropathy; distal muscle atrophy and weakness; may have autonomic abnormalities	May develop hyperkalemia with succinylcholine; autonomic dysfunction may cause thermal lability; no known association with malignant hyperthermia	Baum and O'Flaherty, 1999
Diastrophic Dysplasia	Short stature; can have subluxation of C2-3, micrognathia, laryngotracheal stenosis, limited joint mobility	May be difficult intubation; may require smaller-than-expected endotracheal tube; cervical subluxation possible; care with positioning	Baum and O'Flaherty, 1999; Butler et al., 2000
DiGeorge syndrome (CATCH-22 syndrome)	Microdeletion on chromosome 22; abnormalities of thymus, parathyroids, and great vessels; choanal atresia; may have micrognathia and short trachea, congenital heart disease, hypocalcemia and seizures in neonates, cellular immunodeficiency	May be difficult intubation; endobronchial intubation more likely with short trachea; preoperative cardiac evaluation; avoid nasal tubes with choanal atresia; monitor calcium, irradiate blood products	Flashburg et al., 1983; Wells et al., 1989; Baum and O'Flaherty, 1999; Butler et al., 2000
Down syndrome (Trisomy 21 syndrome)	Trisomy 21, macroglossia, pharyngeal hypotonia, smaller trachea, obstructive sleep apnea, recurrent lung infections, congenital heart disease common, atlantoaxial instability, duodenal atresia, congenital hypothyroidism	Airway obstruction may occur intraoperatively and postoperatively; reports of subluxation after intubation; may require neck films if symptomatic; may need smaller endotracheal tube; preoperative cardiac evaluation; bradycardia common after inhalation induction	Williams et al., 1987; Baum and O'Flaherty, 1999; Butler et al., 2000; Williams et al., 1987
Dubowitz syndrome	Small facies, mental deficiency, growth deficiency, rare congenital heart disease, micrognathia	May be difficult airway; preoperative cardiac evaluation; may have behavioral disturbance	Baum and O'Flaherty, 1999; Butler et al., 2000
Duchenne Muscular Dystrophy	X-linked muscular dystrophy, lack of dystrophin in muscle, respiratory muscle weakness, restrictive lung disease, cardiomyopathy, heart block or arrhythmias, scoliosis, delayed gastric emptying, obesity in second decade	Preoperative cardiac evaluation; postoperative mechanical ventilation possible; hyperkalemia with succinylcholine; no increased risk of malignant hyperthermia; increased risk of anesthesia induced thabdomyolysis; possible increased risk of aspiration secondary to respiratory muscle weakness and delayed gastric emptying	Baum and O'Flaherty, 1999; Butler et al., 2000
Dutch-Kentucky syndrome (Hecht Beals syndrome)	Limited mouth opening, mitral valve prolapse, flexion deformities	Difficult intubation reported requiring fiberoptic technique; preoperative cardiac evaluation	Browder et al., 1986; Geva et al., 1997; Baum and O'Flaherty, 1999
E			
Eagle-Barrett syndrome	See prune belly syndrome		
Edwards syndrome	See Trisomy 18		
Ehlers-Danlos syndrome	Defect in gene encoding collagen, 10 types; possible tracheal dilation, lung cysts, mitral valve prolapse, aortic root dilation, congenital heart disease, coronary disease, joint laxity; poor wound healing; vascular abnormalities (aneurysm) with poor integrity; platelet abnormalities	May bleed significantly from vascular aneurysm and bleeding diathesis; preoperative cardiac evaluation for congenital defects; premature ischemic heart disease and conduction abnormalities; risk for pneumothorax; may be difficult intravenous access	Baum and O'Flaherty, 1999; Butler et al., 2000
Ellis-van Creveld syndrome	Dwarfism; micrognathia; may have short trachea, congenital heart disease, restrictive lung disease	May be difficult intubation; endobronchial intubation more likely with short trachea; preoperative cardiac evaluation	Wells et al., 1989; Baum and O'Flaherty, 1999
Epidermolysis Bullosa	Abnormality of dermis and mucous membranes; degree of skin separation; bullae formation and scarring depends on type; may limit mouth opening; airway bleeding and obstruction possible	Any adhesive may cause skin sloughing and bullae formation; use nonadhesive technique to secure endotracheal tube, monitors, and intravenous catheters; protect skin from blood pressure cuff; pad pressure points; cover facemask with Xeroform or lubricate; may be difficult intubation; eye protection with lubricant; may be at risk for aspiration from esophageal disease	Baum and O'Flaherty, 1999
Escobar syndrome	See multiple pterygium syndrome		

Name	Description	Anesthetic Implications	References
F			
Fabry disease	Deficiency in lysosomal alphasgalactosidase A; may have temporomandibular joint involvement; may have ischemic heart disease, HTN, valvular disease, cerebrovascular disease, extremity pain, lymphedema, renal failure, hypohidrosis, angiokeratomas	May be difficult intubation from limited mouth opening; preoperative cardiac evaluation for ischemic heart disease and HTN; check renal function preoperatively; consider avoiding anticholinergics with hyperhidrosis	Baum and O'Flaherty, 1999
Facioauriculovertebral syndrome	See Goldenhar syndrome		
Fascioscapulohumeral Muscular Dystrophy	Weakness of facial and ocular muscles; no cardiac involvement; neck and shoulder muscle weakness	Hyperkalemia with succinylcholine; no reports of malignant hyperthermia	Dresner and Ali, 1989; Baum and O'Flaherty, 1999
Familial Dysautonomia	See Riley-Day syndrome		
Familial Periodic Paralysis	See Chapter 36		
Fanconi syndrome	Proximal renal tubular dysfunction (renal tubular acidosis); renal loss of amino acids, phosphate, glucose, bicarbonate, and potassium; may have muscle weakness from hypokalemia; may develop chronic renal failure	Check electrolytes preoperatively (potassium, phosphate, chloride, and bicarbonate); check acid-base status preoperatively; check renal function preoperatively	Joel and Rosales, 1981; Baum and O'Flaherty, 1999
Farber Disease	Deficiency of lysosomal enzyme ceramidase; ceramide deposition and granuloma formation may be disseminated; oral and laryngeal granulomas; pulmonary and cardiac granulomas; mental retardation; peripheral neuropathy with muscle atrophy	May be difficult airway secondary to oral granulomas; preoperative cardiac evaluation for valvular granulomas; succinylcholine can cause hyperkalemia	Baum and O'Flaherty, 1999
Femoral Hypoplasia–Unusual Facies syndrome	Craniosynostosis; cleft palate; micrognathia; may have congenital heart disease, femoral hypoplasia; may have renal anomalies	May be difficult intubation from micrognathia; preoperative cardiac evaluation; check renal function preoperatively	Baum and O'Flaherty, 1999; Butler et al., 2000
Fetal Alcohol syndrome	Secondary to in-utero exposure to alcohol, micrognathia, short neck, congenital heart disease, mental retardation, growth deficiency	May be difficult intubation; preoperative cardiac evaluation	Baum and O'Flaherty, 1999
Fetal hydantoin (Dilantin) syndrome	Secondary to in-utero exposure to Dilantin; microcephaly; midface hypoplasia; webbed neck; congenital heart disease; may have mental retardation, growth delay, hirsutism	May be a difficult intubation; preoperative cardiac evaluation	Baum and O'Flaherty, 1999; Butler et al., 2000
Fetal Rubella syndrome	Secondary to maternal rubella infection during first trimester, microcephaly, hearing loss, congenital heart disease, mental retardation, anemia and thrombocytopenia in the neonate, cataracts and glaucoma	Preoperative cardiac evaluation; check preoperative hemoglobin and platelet count during neonatal period	Baum and O'Flaherty, 1999
Fetal Valproate syndrome	Secondary to in utero exposure to valproic acid, congenital heart disease, meningocele, radial anomalies	Preoperative cardiac evaluation	Baum and O'Flaherty, 1999; Butler et al., 2000
Fetal Warfarin syndrome	Secondary to in utero exposure to warfarin, microcephaly, congenital heart disease, severe mental retardation, seizures	May have upper airway obstruction; preoperative cardiac evaluation; chronic antiseizure medication	Baum and O'Flaherty, 1999
Fibrodysplasia Ossificans Progressiva syndrome	Progressive ossification of muscles, joints, and subcutaneous tissue; affects neck, spine, shoulders, and jaw; may develop restrictive lung disease; cardiac conduction abnormalities; steroid therapy	May be very difficult intubation due to limited cervical motion and mouth opening; preoperative cardiac evaluation for conduction defects and supraventricular tachycardia; may need stress-dose steroids	Lininger et al., 1989; Newton et al., 1990; Baum and O'Flaherty, 1999; Butler et al., 2000
Fragile X syndrome	Defect in X chromosome, acromegalic facies, large ears, prognathism, mitral valve prolapse, mental retardation, behavioral issues, seizures	Preoperative cardiac evaluation for mitral valve prolapse; may have behavioral difficulties, chronic antiseizure medication	Baum and O'Flaherty, 1999; Butler et al., 2000
Fraser syndrome	Absent palpebral fissures with skin overlying the eyes (cryptophthalmos), choanal atresia, tracheal stenosis, micrognathia, congenital cardiac defects, syndactyly, renal anomalies	May be difficult intubation from laryngeal or tracheal stenosis; avoid nasal tubes if choanal atresia; preoperative cardiac evaluation; check renal function preoperatively	Jagtap et al., 1995; Baum and O'Flaherty, 1999

Name	Description	Anesthetic Implications	References
Freeman-Sheldon syndrome (also Sheldon-Freeman syndrome and Whistling Face syndrome)	Slowly progressive myopathy, increased muscle tone of face with microstomia, micrognathia, upper airway obstruction from increased tone of pharynx, dysphagia, joint contractures	May be very difficult intubation from microstomia and micrognathia; fiberoptic intubation through an LMA has been described; aspiration risk with vomiting; hyperkalemia possible with myopathy; unclear association with malignant hyperthermia	Jones and Dolcourt, 1992; Vas and Naregal, 1998; Baum and O'Flaherty, 1999; Butler et al., 2000
Friedreich Ataxia	Degeneration of corticospinal, spinocerebellar, and pyramidal tracts; ataxia; cardiomyopathy is common	Preoperative cardiac evaluation; hyperkalemia reported with succinylcholine	Baum and O'Flaherty, 1999
Fryn's syndrome	Micrognathia; congenital diaphragmatic hernia; congenital heart disease; mental retardation; may have renal anomalies	Difficult intubation; may have significant respiratory distress or death from congenital diaphragmatic hernia; preoperative cardiac evaluation; check renal function preoperatively	Baum and O'Flaherty, 1999; Butler et al., 2000
G			
Gaucher disease	Lysosomal storage disease, trismus in infants, pulmonary HTN, seizures and apnea in infants, cranial nerve involvement, splenomegaly with thrombocytopenia and anemia	May be difficult intubation from trismus; may be at risk for aspiration; check hematocrit and platelet count preoperatively	Tobias et al., 1993; Baum and O'Flaherty, 1999
Goldenhar syndrome	A subset of hemifacial microsomia: hemifacial microsomia, epibulbar dermoid, and rib, vertebral, scapular anomalies; microtia with hearing loss, congenital heart disease, renal anomalies; may have hydrocephalus, radial anomalies	May be very difficult intubation and mask ventilation; may have increased ICP; preoperative cardiac evaluation; check renal function preoperatively	Scholtes et al., 1987; Madan et al., 1990; Baum and O'Flaherty, 1999; Butler et al., 2000
Gorlin syndrome	Pigmented and atrophic skin changes; may have oral papillomas, congenital heart disease, GERD, renal dysplasia	May be difficult ventilation and intubation from papillomas; care with positioning with joint hypermobility; preoperative cardiac evaluation	Baum and O'Flaherty, 1999; Butler et al., 2000
H			
Hajdu-Cheney syndrome	Abnormality in skeletal tissue development, failure of cranial suture ossification, hypoplastic mandible, dental loss, cervical instability, short stature, cystic renal disease	May be difficult intubation from hypoplastic mandible and cervical instability; check renal function preoperatively	Baum and O'Flaherty, 1999; Butler et al., 2000
Hallerman-Streiff syndrome	Birdlike facies, mandibular hypoplasia, tracheomalacia, chronic upper airway obstruction; may have cor pulmonale, joint hyperextensibility	May be difficult intubation; can have significant airway obstruction; care with positioning	Ravindran and Stoops, 1979; Baum and O'Flaherty, 1999; Butler et al., 2000
Hallervorden-Spatz disease	Iron deposition in CNS, oromandibular rigidity, dystonia, rigidity, dementia, spasticity	Succinylcholine is contraindicated secondary to bedridden condition; oromandibular rigidity resolves under anesthesia; neuroleptic malignant syndrome has been reported	Roy et al., 1983; Hayashi et al., 1993; Baum and O'Flaherty, 1999
Henoch-Schönlein purpura	Usually postinfectious small vessel vasculitis, edema, renal dysfunction, lower extremity, and abdominal pain	Check renal function preoperatively	Baum and O'Flaherty, 1999
Holt-Oram syndrome	Upper limb defects and congenital heart disease	Preoperative cardiac evaluation	Baum and O'Flaherty, 1999
Hunter syndrome	Mucopolysaccharidosis II from lack of iduronate sulfatase, coarse facial features, soft tissue stiffness of lips and mouth, joint stiffness, coronary artery narrowing, hydrocephalus	Can be extremely difficult intubation; fiberoptic scope LMA has been used; preoperative cardiac evaluation for ischemia; care with positioning	Baum and O'Flaherty, 1999; Butler et al., 2000
Hurler syndrome	Mucopolysaccharidosis IH from abnormality in α -L-iduronidase (clinically similar to Hunter syndrome but more severe and rapid clinical course), coarse facial features, soft tissue stiffness of lips and mouth, joint stiffness, coronary artery narrowing, hydrocephalus, mental retardation	Extremely difficult intubation; fiberoptic scope and LMA have been used; preoperative cardiac evaluation for ischemia; care with positioning	Baum and O'Flaherty, 1999; Butler et al., 2000

Name	Description	Anesthetic Implications	References
J			
Jarcho-Levin syndrome	Dwarfism, limited cervical motion, short thoracic cage, rib anomalies, congenital heart disease	May be difficult intubation; preoperative cardiac evaluation; may have restrictive lung disease	Baum and O'Flaherty, 1999; Butler et al., 2000
Jervell and Lange-Nielsen syndrome	See Prolonged QT syndrome		
Jeune syndrome	Asphyxiating thoracic dystrophy, thoracic cage deformity, lung hypoplasia, may have pulmonary HTN, chronic renal failure	Severe respiratory insufficiency; preoperative cardiac evaluation for pulmonary HTN and cor pulmonale, check renal function preoperatively	Borland, 1987; Baum and O'Flaherty, 1999; Butler et al., 2000
K			
Kabuki syndrome	Similarity in facial appearance with Japanese Kabuki actors, congenital heart disease, may have pectus excavatum, mental retardation, renal anomalies	Preoperative cardiac evaluation; check renal function preoperatively	Baum and O'Flaherty, 1999; Butler et al., 2000
Kartagener syndrome	Marked by situs inversus and immotile cilia, chronic sinusitis, chronic respiratory tract infection, bronchiectasis, dextrocardia; may be asplenic; immotile sperm	Thick secretions may complicate airway management; nasal intubation relatively contraindicated in chronic sinusitis; situs inversus reverses many procedures; mainstem intubation occurs on left; reverse placement of electrocardiographic and defibrillator pads	Baum and O'Flaherty, 1999; Ho and Friedland, 1992
Kasabach-Merritt syndrome	Hemangioma and thrombocytopenia, high output cardiac failure, microangiopathic hemolytic anemia, may develop disseminated intravascular coagulation	May need transfusion therapy with red cells, platelets, and fresh frozen plasma	Baum and O'Flaherty, 1999
Kearns-Sayre syndrome	Mitochondrial myopathy, external ophthalmoplegia, heart block, cardiomyopathy, proximal muscle weakness, ataxia, may have elevated lactate with exercise	May develop lactic acidosis; consider avoiding lactated Ringer's; preoperative cardiac evaluation for heart block and myopathy; possible hyperkalemia with succinylcholine and mitochondrial myopathy; may be sensitive to non-depolarizing muscle relaxants; no clear association between mitochondrial myopathy and malignant hyperthermia	Baum and O'Flaherty, 1999
King Den borough syndrome	Congenital myopathy, pectus excavatum, low set ears, micrognathia	Malignant hyperthermia susceptible	Davis and Brandom, 2009; Iwatsabo et al., 2001.
Klinefelter syndrome (XXY syndrome)	47, XXY karyotype; developmental delay; behavioral problems; hypogonadism; infertility	Behavioral problems may complicate the perioperative period	Baum and O'Flaherty, 1999
Klippel-Feil sequence	Short neck and limited cervical spine immobility, micrognathia, congenital heart disease, may have renal anomalies	Intubation may be extremely difficult; neurologic injury may occur with neck hyperextension; preoperative cardiac evaluation	Baum and O'Flaherty, 1999; Butler et al., 2000
Klippel-Trénaunay-Weber syndrome	Unilateral extremity hypertrophy with arteriovenous fistulas and hemangiomas; may have high output failure; may have facial, intracranial, and epidural hematomas	May have significant bleeding from arteriovenous fistulae; may have thrombocytopenia; preoperative cardiac evaluation for high output failure; neuraxial hemangiomas may complicate epidural and spinal anesthesia	Baum and O'Flaherty, 1999; Ezri et al., 1996
L			
Langer-Giedion syndrome	Micrognathia; may have congenital heart disease; may have seizures; may have anemia; vertebral and rib anomalies	May be difficult intubation; preoperative cardiac evaluation; check hematocrit preoperatively	Baum and O'Flaherty, 1999; Butler et al., 2000
Larsen syndrome	Flat face, subglottic stenosis, tracheomalacia, congenital heart disease, cervical spine instability, multiple joint dislocations	Care with intubation with neck extension, smaller endotracheal tube with sub-glottic stenosis, preoperative cardiac evaluation, care with positioning with joint dislocations	Stevenson et al., 1991; Baum and Tobias, 1996; Baum and O'Flaherty, 1999; Butler et al., 2000
LEOPARD syndrome	Lentigines, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonic stenosis, abnormal genitalia retarded growth, deafness	May be deaf; preoperative cardiac evaluation for conduction defects and pulmonic stenosis	Rodrigo et al., 1990; Baum and O'Flaherty, 1999

Name	Description	Anesthetic Implications	References
Leprechaunism	Mutation of insulin receptor gene, hyperglycemia and hypoglycemia, precocious puberty	Check perioperative; glucose	Baum and O'Flaherty, 1999
Lesch-Nyhan syndrome	Developmental delay, hypertonia, spasticity, self-mutilation, hyperuricemia and renal stones, megaloblastic anemia	Check hematocrit preoperatively; check renal function preoperatively	Williams et al., 1997; Baum and O'Flaherty, 1999
Liddle syndrome	Defect in sodium channel, HTN, hypokalemic metabolic alkalosis, may have renal failure	Check preoperative electrolytes (K ⁺ , HCO ₃ ⁻); check renal function; check blood pressure preoperatively	Baum and O'Flaherty, 1999
Limb-Girdle Muscular Dystrophy	Respiratory tract infections, conduction disorder, muscle weakness of pelvis and legs	Preoperative cardiac evaluation for conduction disorders; succinylcholine may cause hyperkalemia; no known association with malignant hyperthermia	Baum and O'Flaherty, 1999
Lowe syndrome	Cataracts, mental retardation, renal failure, rickets	Check renal function preoperatively; check electrolytes (Ca ⁺⁺) preoperatively	Baum and O'Flaherty, 1999
Lown-Ganong-Levine syndrome	Accessory pathway that bypasses atrioventricular node, atrial tachyarrhythmias	Reentrant tachycardia can be treated with adenosine or β-blockade	Baum and O'Flaherty, 1999
M			
Marfan syndrome	Connective tissue disorder, defect in fibrillin, lens dislocations, pectus excavatum, pulmonary blebs, pneumothorax, dilation of aorta and pulmonary artery, aortic insufficiency and mitral valve prolapse, recurrent joint dislocations	Preoperative cardiac evaluation for aortic and valvular pathology, aortic dissection possible, pneumothorax possible with positive pressure ventilation, care with positioning	Wells and Podolakin, 1987; Baum and O'Flaherty, 1999; Butler et al., 2000
Maroteaux-Lamy syndrome	Mucopolysaccharidosis, heart failure common in second and third decade, recurrent respiratory infections, obstructive sleep apnea, short stature, decreased joint mobility, anemia and thrombocytopenia	May be very difficult intubation; preoperative cardiac evaluation; care with positioning; check preoperative hematocrit and platelet count	Baum and O'Flaherty, 1999
McArdle syndrome	Glycogen storage disease (V) with subsequent myopathy, muscle pain, no cardiac involvement	May develop hyperkalemia with succinylcholine	Baum and O'Flaherty, 1999
McCune-Albright syndrome	Fibrous dysplasia of bones, café-au-lait spots, precocious puberty, may have thyrotoxicosis and hyperadrenalism	Care with positioning secondary to pathologic fractures; cushingoid patients may have difficult intravenous access	Baum and O'Flaherty, 1999
Meckel-Gruber syndrome (Meckel syndrome)	Microcephaly; short neck; micrognathia; congenital heart disease; may have occipital encephalocele, hydrocephalus, seizures, renal dysplasia	May be difficult intubation; preoperative cardiac evaluation; check preoperative renal function; anticonvulsant medications may affect neuromuscular blockade and opioid metabolism	Baum and O'Flaherty, 1999; Butler et al., 2000
MELAS syndrome	Mitochondrial myopathy, encephalopathy, lactic acidosis, stroke, blindness and hearing loss, cardiomyopathy, diffuse CNS degeneration with strokelike infarcts	Preoperative cardiac evaluation, possible hyperkalemia with succinylcholine, no clear association with malignant hyperthermia	Baum and O'Flaherty, 1999
Melnick-Needles syndrome	Small face; micrognathia; glaucoma; respiratory track infections; may have pulmonary HTN, hypotonia	May be difficult intubation	Baum and O'Flaherty, 1999; Butler et al., 2000
Menkes Kinky Hair syndrome (Menkes syndrome)	Abnormal copper transport, microcephaly, cerebral degeneration, seizures, characteristic kinky hair, gastroesophageal reflux	Difficult ventilation and intubation is described; anticonvulsant medications may affect neuromuscular blockade and opioid metabolism	Baum and O'Flaherty, 1999; Butler et al., 2000
MERRF syndrome	Myoclonus, Epilepsy, Ragged Red Fibers Defect in mitochondrial DNA, hearing loss, epilepsy, myopathy, central nervous system degeneration	May be acidemic; avoid lactated Ringer's in those with lactic acidosis; possible hyperkalemia with succinylcholine; no clear association with malignant hyperthermia	Baum and O'Flaherty, 1999
Miller syndrome (Postaxial Acrofacial Dysostosis syndrome)	Craniofacial syndrome, malar hypoplasia, eyelid colobomas, micrognathia, congenital heart disease, postaxial limb deficiency, renal anomalies	May be very difficult ventilation and intubation; preoperative cardiac evaluation; check preoperative renal function; may be difficult intravenous access; eye care essential	Baum and O'Flaherty, 1999; Butler et al., 2000

Continued

Name	Description	Anesthetic Implications	References
Möbius sequence	Congenital sixth and seventh cranial nerve palsy, micrognathia, feeding difficulties and aspiration, congenital cardiac defects possible, limb defects	May be difficult to intubate; decreased ability to manage secretions; eye care essential; preoperative cardiac evaluation; may develop perioperative apnea or hypoventilation	Baum and O'Flaherty, 1999; Butler et al., 2000
Morquio syndrome	Mucopolysaccharidosis (IV), short neck with decreased mobility, spine and thoracic deformities with respiratory insufficiency, aortic valve pathology, atlantoaxial instability, short stature	Preoperative cervical spine evaluation, may be difficult intubation, preoperative cardiac evaluation for aortic valve, care with positioning	Baum and O'Flaherty, 1999
Multiple Pterygium syndrome	Multiple pterygia, micrognathia, decreased range of motion of neck, rare congenital heart defects	Difficult intubation described; LMA has been used; care with positioning; weak evidence for malignant hyperthermia	Baum and O'Flaherty, 1999; Butler et al., 2000
Multiple Synostosis syndrome	Multiple synostosis of digits with decreased joint mobility, developmental delay	Care with positioning	Baum and O'Flaherty, 1999; Butler et al., 2000
Myotonia Congenita	See Chapter 36		
Myotonic Dystrophy	See Chapter 36		
N			
Nager syndrome (Mandibulofacial Dysostosis syndrome)	Absent zygomatic arches, downsloping palpebral fissures, colobomas, hearing loss, micrognathia, congenital heart disease, radioulnar synostosis, similar to Treacher Collins	Difficult or impossible intubation described; intravenous access may be difficult due to limb anomalies; preoperative cardiac evaluation	Baum and O'Flaherty, 1999; Butler et al., 2000
Neu-Laxova syndrome	Microcephaly, micrognathia, short neck, canine facies, congenital heart disease, renal anomalies, usually lethal	May be difficult intubation; preoperative cardiac evaluation; check preoperative renal function	Baum and O'Flaherty, 1999; Butler et al., 2000
Neurofibromatosis (von Recklinghausen disease)	Neurofibromas of central and peripheral nervous system, café-au-lait spots and bone lesions, association with pheochromocytoma	Neurofibromas may involve airway, increased sensitivity to succinylcholine and nondepolarizing muscle relaxants described, neurofibromas may involve neuraxial space	Yamashita et al., 1977; Baum and O'Flaherty, 1999; Butler et al., 2000
Noonan syndrome	Webbed neck; low-set ears; micrognathia; pectus excavatum; congenital heart disease, especially pulmonic stenosis; chylothorax; lymphedema; mental retardation; platelet and coagulation disorders; renal dysfunction	May be difficult intubation; may have bleeding diathesis; preoperative cardiac evaluation; check preoperative renal function; intravenous access may be difficult with lymphedema, weak evidence for malignant hyperthermia	Campbell and Bousfield, 1992; Schwartz and Eisenkraft, 1992; Baum and O'Flaherty, 1999; Butler et al., 2000
O			
Oculodentodigital syndrome (oculodentosseous dysplasia)	Microphthalmia, cleft lip or palate, micrognathia or mandibular overgrowth, small nose, syndactyly	May be difficult intubation	Baum and O'Flaherty, 1999; Butler et al., 2000
Oral-Facial-Digital syndrome (Type I)	Cleft lip and palate, micrognathia, choanal atresia, mental retardation, hydrocephalus, syndactyly, digital asymmetry, polycystic kidney disease, affects females, types II-IX clinically similar to type I	Upper airway obstruction possible; check renal function preoperatively	Baum and O'Flaherty, 1999; Butler et al., 2000
Oromandibular-Limb Hypogenesis	Small mouth, cleft palate, moebius, micrognathia, limb deficiency	May be difficult intubation	Baum and O'Flaherty, 1999; Butler et al., 2000
Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia)	Vasculopathy with multiple telangiectases, pulmonary arteriovenous fistula with right-to-left shunting, paradoxical emboli, and bleeding, CNS arteriovenous fistulas and aneurysms, gastrointestinal bleeding	Patients can have life-threatening bleeding from nose, lung, brain, and gastrointestinal tract; check hematocrit preoperatively; avoid nasal instrumentation; care with laryngoscopy to avoid bleeding; paradoxical emboli can occur; consider avoiding neuraxial blocks	Waring et al., 1990; Radu et al., 1992; Baum and O'Flaherty, 1999
Osteogenesis Imperfecta	Mutation in a gene for collagen, four types, blue sclera in type I, hearing loss, kyphoscoliosis, restrictive hearing loss, extremely fragile bones, multiple fractures, hyperextensibility, short stature	Fractures may occur with any manipulation; care with intubation, care with positioning; consider radiologic evaluation for fractures; type I may have platelet dysfunction; weak evidence for malignant hyperthermia	Barros, 1995; Porsborg et al., 1996; Baum and O'Flaherty, 1999; Butler et al., 2000

Name	Description	Anesthetic Implications	References
P			
Pallister Hall syndrome	Hypothalamic hamartoblastoma, panhypopituitarism, imperforate anus, cleft lip and/or palate, micrognathia, dysplastic tracheal cartilage, hypoplastic lung, congenital heart disease, thyroid hypoplasia	May be difficult intubation; abnormal tracheal cartilage may alter tracheal tube size; preoperative cardiac evaluation; preoperative evaluation of hypothalamic pituitary axis; may require stress-dose steroids	Baum and O'Flaherty, 1999; Butler et al., 2000
Pearson syndrome	Sideroblastic anemia, exocrine pancreatic dysfunction (may have Fanconi syndrome)	Preoperative hematocrit, preoperative electrolytes (K ⁺ , Cl ⁻ , HCO ₃ ⁻ , PO ₄ ⁻)	Baum and O'Flaherty, 1999; Butler et al., 2000
Pendred syndrome	Deafness, hypothyroid, goiter	Preoperative thyroid studies	Baum and O'Flaherty, 1999
Pentalogy of Cantrell	Defect in ventral midline development, cystic hygroma, cleft lip and/or palate, congenital diaphragmatic hernia, pulmonary hypoplasia, omphalocele, renal anomalies, congenital heart disease	Preoperative cardiac evaluation, may have significant pulmonary hypoplasia and pulmonary HTN	Laloyaux et al., 1998; Baum and O'Flaherty, 1999
Peter's Plus syndrome	Ophthalmologic anomalies (glaucoma, decreased vision), micrognathia, congenital heart disease, dwarfism, developmental delay, seizures	May be difficult intubation (rare); preoperative cardiac evaluation; anticonvulsant medication may affect neuromuscular blockade and opioid metabolism	Baum and O'Flaherty, 1999; Butler et al., 2000
Pfeiffer syndrome	Acrocephalosyndactyly, coronal and/or sagittal synostosis, midface hypoplasia, proptosis, obstructive sleep apnea, congenital heart defects, broad thumbs and broad great toes, may have fused elbows, usually normal intelligence	May be difficult intubation (rare); may have increased ICP; preoperative cardiac evaluation; may have airway obstruction	Tobias et al., 1998; Baum and O'Flaherty, 1999
Pierre Robin sequence	Micrognathia, glossoptosis, airway obstruction, may also have cleft palate (not necessary for diagnosis)	May be very difficult to intubate; successful intubation described with fiberoptic scopes, LMA, and Bullard, prone positioning, and tongue suture to displace tongue forward	Populaire et al., 1985; Schelle and Schulman, 1991; Baraka, 1996; Perkins et al., 1997; Baum and O'Flaherty, 1999; Butler et al., 2000
Poland syndrome	Hypoplasia of chest muscles and ribs on one side, rare dextrocardia, unilateral syndactyly	Respiratory complications	Sethuraman et al., 1998; Baum and O'Flaherty, 1999
Pompe disease	Glycogen storage disease, macroglossia, respiratory and swallowing muscle weakness, cardiomegaly, hypotonia	May be difficult to ventilate and intubate, increased risk for perioperative respiratory complications, preoperative cardiac evaluation	McFarlane and Soni, 1986; Rosen and Broadman, 1986; Baum and O'Flaherty, 1999
Porphyria	Defect in heme synthesis with overproduction of heme precursors; precipitating factors include infection, starvation, drugs, and pregnancy; acute attacks cause abdominal pain; autonomic instability with HTN; neuropathy, neuropsychiatric abnormalities; electrolyte abnormalities; may also have hemolytic anemia, hepatic failure, and cirrhosis	Preoperative fasting should be minimized; can administer glucose-containing solution; premedication may decrease stress; avoid barbiturates; etomidate pentazocine; Ketamine may be safe; safe anesthetics include opioids, propofol, nitrous oxide, isoflurane, sevoflurane, desflurane, and muscle relaxants; neuropathy may cause respiratory muscle weakness and aspiration	Jensen et al., 1995; Kanbak, 1997; Baum and O'Flaherty, 1999
Potter syndrome	Secondary to oligohydramnios, low-set ears, beaked nose, micrognathia, lung hypoplasia, renal agenesis	May be difficult intubation, respiratory failure secondary to pulmonary hypoplasia; check preoperative renal function	Baum and O'Flaherty, 1999
Prader-Willi syndrome	Secondary to partial deletion of chromosome 15; obesity; hypotonia; developmental delay; hypogonadism; obstructive sleep apnea; may have pulmonary HTN, hypotonia, developmental delay, hypogonadism, diabetes mellitus	Anesthetic concerns related to obesity; difficult mask ventilation; potential difficult airway; decreased functional residual capacity; perioperative respiratory complications; monitor perioperative glucose	McKenzie, 1991; Dearlove et al., 1998; Baum and O'Flaherty, 1999; Butler et al., 2000
Progeria	Premature aging, micrognathia, beaked nose, premature coronary artery disease, cerebrovascular disease, HTN, diabetes mellitus	Perioperative cardiac evaluation for ischemic heart disease; may be difficult intubation secondary to micrognathia and stiff joints	Chapin and Kahre, 1979; Baum and O'Flaherty, 1999; Butler et al., 2000

Continued

Name	Description	Anesthetic Implications	References
Prolonged QT Interval syndrome (Jervell-Lange-Nielson syndrome; Romano-Ward syndrome)	Prolonged QT interval on electrocardiogram, congenital deafness with Jervell-Lange Nielson syndrome	Tachyarrhythmias and sudden death; torsades de pointes; prevention by avoiding drugs that prolong QT interval; volatile anesthetics prolong QT interval; avoid epinephrine; treat torsades with defibrillation, magnesium, correcting electrolytes, β -blocker	Dunn et al., 1991; Richardson et al., 1992; Holland, 1993; Michaloudis et al., 1996
Proteus syndrome	Hemihypertrophy, hypertrophic cardiomyopathy, emphysematous lung disease, renal anomalies, cervical spine abnormalities	Perioperative cardiac evaluation; may have abnormal lung function; check preoperative renal function	Pennant and Harris, 1991; Baum and O'Flaherty, 1999
Prune-Belly syndrome (Eagle-Barrett syndrome)	Absence of abdominal wall musculature, urinary tract dilation; cryptorchidism; lung hypoplasia secondary to in-utero urinary tract obstruction with oligohydramnios; may have congenital heart disease	Increased risk of perioperative respiratory complications secondary to decreased ability to cough; check preoperative renal function; preoperative cardiac evaluation	Henderson et al., 1987; Baum and O'Flaherty, 1999
R			
Rett syndrome	Only in females, progressive encephalopathy beginning at 6 to 18 months, seizures, spasticity, behavioral problems	Anticonvulsant medication may affect neuromuscular blockade and opioid metabolism	Dearlove and Walker, 1996; Baum and O'Flaherty, 1999
Riley-Day syndrome (familial dysautonomia)	Deficiency of dopamine hydroxylase, blood pressure instability, abnormal sweating, hypersensitivity to catecholamine, emotional lability, decreased respiratory drive to hypercarbia and hypoxia, decreased or lack of tear formation, decreased peripheral pain sensation	Increased risk of aspiration; may have exaggerated response to inotropes; may have exaggerated depression of respiratory drive with narcotics; perioperative eye care; decreased postoperative pain requirements	Stenquist and Sigurdsson, 1982; Axelrod et al., 1988; Baum and O'Flaherty, 1999
Riley-Smith syndrome	Macrocephaly, mild developmental delay, lipid storage myopathy, seizures	Anticonvulsant medication may affect neuromuscular blockade and opioid metabolism; may develop hyperkalemia with succinylcholine	Baum and O'Flaherty, 1999
Robinow syndrome (Fetal Face syndrome)	Frontal bossing, micrognathia; may have congenital heart disease; genitourinary and renal anomalies	May be difficult intubation; check preoperative renal function; preoperative cardiac evaluation	Baum and O'Flaherty, 1999; Butler et al., 2000
Rubinstein-Taybi syndrome	Defect in cAMP-mediated induction of protein synthesis, microcephaly, micrognathia, obstructive sleep apnea, congenital heart disease in 30%, developmental delay, seizures, broad thumbs and toes	May be difficult to intubate; preoperative cardiac evaluation; anticonvulsant medication may affect neuromuscular blockade and opioid metabolism; may have delayed recovery from anesthesia	Stirt, 1981; Dunkley and Dearlove, 1996; Baum and O'Flaherty, 1999; Butler et al., 2000
Russell-Silver syndrome	Short stature, micrognathia, café-au-lait spots, normal intelligence, hypoglycemia with fasting	May be difficult to intubate; monitor perioperative glucose and use glucose-containing solutions	Diner et al., 1994; Baum and O'Flaherty, 1999; Butler et al., 2000
S			
Saethre-Chotzen syndrome	Acrocephalosyndactyly, craniosynostosis, maxillary hypoplasia, normal intelligence, syndactyly	No reports of difficult intubation; may have increased ICP	Baum and O'Flaherty, 1999
Sanfilippo syndrome	Mucopolysaccharidosis III, coarse facies, rare cardiac involvement, severe developmental delay, behavioral disturbances, seizures	May be difficult intubation; anticonvulsant medication may affect neuromuscular blockade and opioid metabolism; may have behavioral problems	Kemphorne and Brown, 1983; Myles and Westhorpe, 1989; Baum and O'Flaherty, 1999
Schinz-Giedion syndrome	Growth and mental deficiencies, congenital heart disease, seizures, renal anomalies, choanal atresia	Preoperative cardiac evaluation; anticonvulsant medication may affect neuromuscular blockade and opioid metabolism; check preoperative renal function	Baum and O'Flaherty, 1999; Butler et al., 2000
Schwartz-Jampel syndrome	Myotonia secondary to sodium channel defect, micrognathia, joint contractures	May be difficult intubation; myotonic contractures can occur during anesthetic or surgical manipulation; muscle relaxation does not relax contractions; hyperkalemia with succinylcholine; myotonic contractures can be precipitated by reversal of muscle relaxant; may be associated with malignant hyperthermia	Ray and Rubin, 1994; Theroux et al., 1995; Baum and O'Flaherty, 1999; Butler et al., 2000

Name	Description	Anesthetic Implications	References
Scimitar syndrome	Partial anomalous pulmonary venous return, hypoplastic right lower lobe, recurrent pulmonary infections, pulmonary HTN	Preoperative cardiac evaluation	Baum and O'Flaherty, 1999
Shprintzen syndrome	See Velocardiofacial syndrome		
Shwachman syndrome	Metaphyseal chondrodysplasia, recurrent pneumonia, hypotonia, short stature, exocrine pancreatic insufficiency, pancytopenia, immunologic abnormalities	Preoperative hematocrit and platelet count	Baum and O'Flaherty, 1999
Smith-Lemli-Opitz syndrome	Abnormality in cholesterol synthesis, microcephaly, micrognathia, lung hypoplasia, congenital heart disease, mental retardation, seizures, renal anomalies, thymic hypoplasia	May be difficult intubation; preoperative cardiac evaluation; anticonvulsant medication may affect neuromuscular blockade and opioid metabolism; blood should be irradiated if thymic hypoplasia; no clear association with malignant hyperthermia	Peterson and Crouch, 1995; Haji-Michael and Hatch, 1996; Baum and O'Flaherty, 1999; Butler et al., 2000
Sotos syndrome	Cerebral gigantism, excessive head growth, congenital heart disease, mental retardation, behavioral problems	No reports of difficult airway; preoperative cardiac evaluation	Jones et al., 1991; Baum and O'Flaherty, 1999
Stevens-Johnson syndrome	Secondary to hypersensitivity to exogenous agents (drugs), erythema multiforme, urticarial lesions	Placement of monitors may be difficult secondary to skin lesions; care with positioning	
Stickler syndrome	Flat facies, hearing loss, cleft palate, pectus excavatum, hyperextensible joints, may be associated with Pierre Robin sequence	May be difficult intubation, may have hearing loss	Baum and O'Flaherty, 1999
Sturge-Weber syndrome	Capillary hemangiomas in distribution of cranial nerve V, port wine stain, congenital glaucoma, may have mental retardation and seizures	Hemangiomas of the mouth and upper airway may make intubation difficult; may have increased intraocular pressure; anticonvulsant medication may affect neuromuscular blockade and opioid metabolism	Batra et al., 1994; Baum and O'Flaherty, 1999; Butler et al., 2000
T			
Tangier disease	Low high-density lipoprotein and serum cholesterol; orange tonsils; neuropathic abnormalities with cranial, sensory, or motor findings; muscle wasting; splenomegaly; hemolytic anemia	Succinylcholine may cause hyperkalemia; check preoperative hematocrit and platelet count; possible premature ischemic heart disease and platelet dysfunction	Mentis, 1996; Baum and O'Flaherty, 1999
Thrombocytopenia-Absent Radius syndrome (TAR syndrome)	Thrombocytopenia precipitated by stress; infection; surgery; congenital heart disease; bilateral absence of radii (thrombocytopenia worst during infancy)	Preoperative cardiac evaluation; check preoperative platelet count	Baum and O'Flaherty, 1999
Tourette syndrome	Involuntary motor and vocal tics, behavioral abnormalities	No specific anesthetic concerns	Morrison and Lockhart, 1986
Treacher Collins syndrome	Mandibulofacial dysostosis, malar hypoplasia, downsloping palpebral fissures, microphthalmia, low-set ears, small mouth, micrognathia, obstructive sleep apnea, congenital heart disease	May be extremely difficult airway; fiberoptic endoscopy, LMA, and Bullard laryngoscope have all been used; preoperative cardiac evaluation	Rasch et al., 1986; Brown et al., 1993; Inada et al., 1995; Baum and O'Flaherty, 1999; Butler et al., 2000
Trisomy 8 syndrome	Strabismus, micrognathia, webbed neck, congenital heart disease, mental retardation, seizures	May be difficult intubation; anticonvulsant medication may affect neuromuscular blockade and opioid metabolism; preoperative cardiac evaluation	Baum and O'Flaherty, 1999
Trisomy 9 syndrome	May have microcephaly, cleft lip and palate, micrognathia, congenital heart disease, profound mental retardation	May be difficult intubation; anticonvulsant medication may affect neuromuscular blockade and opioid metabolism; preoperative cardiac evaluation	Baum and O'Flaherty, 1999
Trisomy 13 syndrome (Patau syndrome)	Occipital scalp defect, low-set ears, cleft lip and palate, micrognathia, congenital heart disease common, severe mental retardation, seizures, renal anomalies, capillary hemangiomas, most die within 6 months, radial anomalies	May be difficult intubation; preoperative cardiac evaluation; check preoperative renal function; placement of radial catheter may be difficult; anticonvulsant medication may effect neuromuscular blockade and opioids	Pollard and Beasley, 1996; Baum and O'Flaherty, 1999; Butler et al., 2000
Trisomy 18 syndrome (Edwards syndrome)	Prominent occiput, microcephaly, micrognathia, short sternum, congenital heart disease, clenched hands, rocker bottom feet, renal anomalies	May be difficult intubation; preoperative cardiac evaluation; check preoperative renal function	Baum and O'Flaherty, 1999; Butler et al., 2000

Continued

Name	Description	Anesthetic Implications	References
Trisomy 21 syndrome	See Down syndrome		
Tuberous Sclerosis	Triad of mental retardation, seizures, and adenoma sebaceum on face; hamartomas of the lung; cardiac rhabdomyomas; may develop endocrinopathies	Oral adenomas may make intubation difficult; preoperative cardiac evaluation, spontaneous pneumothorax may occur; anticonvulsant medication may affect neuromuscular blockade and opioid metabolism	Lee et al., 1994; Schweiger et al., 1994; Baum and O'Flaherty, 1999; Butler et al., 2000
Turner syndrome	Caused by single X chromosome; micrognathia and short webbed neck; broad chest; congenital heart disease (coarctation); HTN; short stature; lymphedema of hands and feet; renal anomalies; may be hypothyroid	May be difficult intubation; preoperative cardiac evaluation; intravenous access may be difficult secondary to lymphedema; check preoperative renal function	Divekar et al., 1983; Baum and O'Flaherty, 1999; Butler et al., 2000
V			
VATER Association	Vertebral anomalies; anal atresia; tracheoesophageal fistula; esophageal atresia; radial and renal anomalies; increased incidence in tracheoesophageal fistula, diabetic mothers, and trisomy 18	Preoperative cardiac evaluation; check radiographs of vertebrae and radii; check preoperative renal function	Baum and O'Flaherty, 1999; Butler et al., 2000
Velocardiofacial syndrome (DiGeorge syndrome, Shprintzen syndrome)	Deletion of chromosome 22; microcephaly; micrognathia; congenital heart disease; developmental delay; may have T-cell immunodeficiency; neonatal hypocalcemia	May be difficult intubation; preoperative cardiac evaluation; blood should be irradiated if T-cell immunodeficiency; check preoperative calcium in neonates	Baum and O'Flaherty, 1999
von Hippel Lindau syndrome	Retinal, CNS, and visceral hemangioblastomas; may be associated with pheochromocytoma; may have renal, pancreatic, or hepatic cysts; may develop cerebellar tumors	Epidural analgesia has been described despite descriptions of spinal cord involvement; may have increased ICP; preoperative evaluation for pheochromocytoma	Matthews and Halshaw, 1986; Mugawar et al., 1998; Baum and O'Flaherty, 1999
W			
Walker-Warburg syndrome (HARD syndrome)	Retinal defects, microtia, cleft lip and palate, CNS anomalies, hydrocephalus, seizures, mental retardation, muscular dystrophy	May have increased intraocular pressure and ICP; anticonvulsant medication may affect neuromuscular blockade and opioid metabolism; succinylcholine may cause hyperkalemia	Baum and O'Flaherty, 1999
Watson syndrome	Valvular pulmonary stenosis, slightly decreased intelligence, may have neurofibromas and café-au-lait spots	Preoperative cardiac evaluation	Baum and O'Flaherty, 1999; Butler et al., 2000
Weaver syndrome	Macrocephaly, large tongue, short neck, developmental delay, seizures, behavioral problems	May be very difficult intubation; anticonvulsant medication may affect neuromuscular blockade and opioid metabolism	Turner and Downing, 1985; Baum and O'Flaherty, 1999
Weber-Christian disease	Fevers and panniculitis; necrosis of fat involving the retroperitoneal, pericardial, and meningeal areas; may have heart failure; involvement of retroperitoneal tissue may cause adrenal insufficiency; may develop restrictive pericarditis and seizures	Preoperative cardiac evaluation for cardiac failure; avoid trauma to fat; anticonvulsant medication may affect neuromuscular blockade and opioid metabolism	Baum and O'Flaherty, 1999
Weill-Marchesani syndrome	Glaucoma, blindness, subvalvular aortic stenosis	Preoperative cardiac evaluation	Baum and O'Flaherty, 1999
Werdnig-Hoffman disease	Spinal muscular atrophy; anterior horn cell degeneration; decreased ability to swallow; respiratory tract infections; may have respiratory failure spine deformities; normal intelligence	Increased risk of perioperative aspiration; may be chronically ventilated; succinylcholine may cause hyperkalemia	Baum and O'Flaherty, 1999; Butler et al., 2000
Whistling face syndrome	See Freeman-Sheldon syndrome		
Williams syndrome (Williams-Beuren syndrome)	Deletion of elastin gene on chromosome 7; elfin facies; severe congenital heart disease; high incidence of sudden death; mild developmental delay; may be very gifted musically; precocious social skills; "cocktail party personality;" rarely has behavioral problems; may be hypercalcemic	Preoperative cardiac evaluation	Baum and O'Flaherty, 1999; Butler et al., 2000; Kececioglu et al., 1993

Name	Description	Anesthetic Implications	References
Wiskott-Aldrich syndrome	Recurrent pulmonary infections; vasculitis may affect coronary and cerebral arteries, renal insufficiency; thrombocytopenia; eczema; immune deficiency	Check preoperative platelet count and hematocrit; irradiate blood products; consider preoperative cardiac evaluation of coronary arteries; check preoperative renal function; consider stress-dose steroids if taking steroids on a chronic basis	Baum and O'Flaherty, 1999
Wolff-Parkinson-White syndrome	Accessory pathway bypasses atrioventricular node; reentrant tachycardia; may have structural heart disease	Adenosine and β -blockade terminate the tachycardia	Lavoie et al., 1995
Z			
Zellweger syndrome	Dysfunction and absence of peroxisomes; micrognathia; congenital heart disease; hypotonia with respiratory insufficiency; adrenal atrophy; contractures	Preoperative cardiac evaluation; care with positioning; may require stress-dose steroids	Baum and O'Flaherty, 1999

CHAPTER QUESTIONS

Chapter 2: Behavioral Development

1. The developmental milestone that is appropriate for a 9-month-old infant include:
 - A. Crawls.
 - B. Walks alone.
 - C. Uses two words together.
 - D. Has no stranger anxiety.
2. The developmental milestone that is appropriate for a 3-month-old infant include:
 - A. Holds its head up steadily.
 - B. Rolls over.
 - C. Babbles, "ah-goo."
 - D. Recognizes that someone is a stranger.

Chapter 3: Respiratory Physiology in Infants and Children

1. Regarding developmental changes in oxygen affinity of hemoglobin (P_{50} , or P_{aO_2} at which hemoglobin is 50% saturated) in healthy neonates, infants, and children, which of the following statements are correct? (more than one may be correct)
 - A. At birth, P_{50} is low (18 to 20 mm Hg vs. the adult P_{50} of 27 mm Hg) and blood tissue O_2 unloading is low in spite of high total hemoglobin levels (approximately 18 g/dL).
 - B. Premature infants with hematocrit values less than 30 have a higher risk of postoperative apnea caused by inadequate oxygen supply to the brain.
 - C. By 9 months of age, P_{50} increases (to approximately 30 mm Hg) above the adult level of 27 mm Hg, and the tissue O_2 unloading increases in spite of "physiological anemia of infancy" (hemoglobin level of 10 to 11 g/dL).
 - D. Throughout childhood, P_{50} stays relatively higher than that of the adult (27 mm Hg); the oxygen unloading at the tissue level is equivalent with relatively low normal hemoglobin levels (11 to 12 g/dL vs. 15 g/dL in adults).
2. Which of the following statements are correct for neonates and young infants? (more than one may be correct)
 - A. The chest wall is extremely compliant in infants. The chest-wall vs. lung-compliance ratio of the neonate is 4:1 (vs. 1:1 in adults).
 - B. FRC is maintained with sustained thoracic inspiratory muscle tone, especially in young infants.
 - C. Anesthesia abolishes inspiratory muscle tone, which results in the collapse of FRC, airway closure, and atelectasis, especially when a patient is breathing 100% oxygen.
 - D. During the emergence from anesthesia, breathing with an air/oxygen mixture (but not preoxygenation with 100% O_2) and deep sighs followed by CPAP recruits atelectatic lung segments and maintains a better postoperative oxygenation.

3. Regarding anesthesia and the maintenance of upper airways in children, which of the following statements are correct? (more than one may be correct)
 - A. The pharynx is kept patent by the tonic and cyclic contractions of upper airway dilator muscles when a child is awake.
 - B. Negative pressure in the pharynx during inspiration, produced by the contraction of the diaphragm, triggers the feedback mechanism by which the upper airway muscle tone increases and simultaneously attenuates diaphragmatic contractions so as to keep the pharyngeal airway patent.
 - C. Relaxation of upper airway muscles during the anesthetic induction results in the collapse of the pharynx and upper airway obstruction.
 - D. The upper airway dilator muscles include the genioglossus, geniohyoid, and tensor veli palatini muscles.

Chapter 4: Cardiovascular Physiology

1. Cardiac function in neonates is best described by which of the following statements? (more than one may be correct)
 - A. The neonate's left ventricle is less compliant than the adult's left ventricle.
 - B. In experiments with animals, fetal myocardium is less sensitive to increases in afterload than the myocardium in adult hearts.
 - C. The slope of a series of end-systolic pressure-volume curves represents contractility.
 - D. Neonates have higher rates of myocardial oxygen consumption than adults.
2. Which of the following shunts does the fetal circulation contain? (more than one may be correct)
 - A. Placenta.
 - B. Foramen ovale.
 - C. Ductus arteriosus.
 - D. Foramen secundum.

Chapter 5: Regulation of Fluids and Electrolytes

1. Which of the following are correct statements? (more than one may be correct)
 - A. All of the nephrons of the kidney are formed by 36 weeks' gestation.
 - B. The GFR reaches adult levels by 6 months of age.
 - C. Preterm infants conserve sodium better than full-term infants.
 - D. At birth, neonates cannot effectively concentrate their urine.

- Which of the following statements are correct? (more than one may be correct)
 - High fractional excretion of sodium in premature infants leads to a negative sodium balance.
 - Premature infants require more sodium (mmol/kg/day) than full-term infants.
 - Adult urine concentrating abilities are reached by 1 year of age.
- Which statements are true? (more than one may be correct)
 - The earliest signs of hyperkalemia are prolonged PR interval and peaked T-wave.
 - U-waves are associated with hyperkalemia.
 - Spironolactone (Aldactone) is a competitive inhibitor of aldosterone.

Chapter 6: Thermoregulation: Physiology and Perioperative Disturbances

- With regard to thermoregulation, which of the following best describes an infant?
 - Homeotherm with small body surface area-to-mass ratio.
 - Poikilotherm with small body surface area-to-mass ratio.
 - Homeotherm with large body surface area-to-mass ratio.
 - Poikilotherm with large body surface area-to-mass ratio.
 - What is the correct order (from highest to lowest) of the mechanisms for heat loss in a neutral thermal environment?
 - Radiation, evaporation, convection, conduction.
 - Evaporation, radiation, convection, conduction.
 - Radiation, convection, evaporation, conduction.
 - Evaporation, convection, radiation, conduction.
 - Anesthetic agents affect thermoregulatory mechanisms by:
 - Lowering hypothermic threshold and increasing hyperthermic threshold.
 - Increasing hypothermic threshold and increasing hyperthermic threshold.
 - Lowering hypothermic threshold and lowering hyperthermic threshold.
 - Increasing hypothermic threshold and lowering hyperthermic threshold.
- Which statement is true regarding inhaled anesthetic agents in children?
 - Right-to-left shunting affects wash-in of insoluble anesthetic agents more than that of soluble agents.
 - Wash-in of anesthetic agents is slower in infants than in adults.
 - Increased cardiac output increases wash-in of anesthetic agent.
 - An increase in minute ventilation decreases wash-in of anesthetic agent.
 - What is the extent of metabolism of anesthetic agents from greatest to least?
 - Halothane > sevoflurane > isoflurane > desflurane.
 - Sevoflurane > halothane > isoflurane > desflurane.
 - Sevoflurane > halothane > isoflurane > desflurane.
 - Halothane > sevoflurane > desflurane > isoflurane.
 - Epinephrine in a 1:100:000 dilution has:
 - 1 microgram/mL.
 - 10 microgram/mL.
 - 100 microgram/mL.
 - 1000 microgram/mL.
 - Regarding the pharmacology of muscle relaxants, which statement is correct?
 - The ED₉₅ is the dose expected to produce a 95% block.
 - The ED₉₅ is the dose expected to produce complete block in 95% of people.
 - The onset time is the time from drug administration to the beginning of the neuromuscular block.
 - Duration of neuromuscular block is the time from administration until neuromuscular transmission returns to 90%.
 - With regard to neuromuscular blocking drugs (NMBD), which of the following statements is correct?
 - Neonates and infants are more sensitive to NMBDs than children and adults.
 - Lower doses (mg/kg) are needed to get a similar effect in infants than adults.
 - Clearance and volume of distribution of NMBDs is less in infants and children.
 - The elimination half-life of an NMBD is similar in infants and adults.

Chapter 7: Pharmacology of Pediatric Anesthesia

- Which statement is true regarding drug pharmacology?
 - Highly extracted drugs are affected by liver blood flow, and the volume of distribution is determined by protein binding.
 - Drugs with low hepatic extraction are affected by liver blood flow.
 - Drugs with high extraction and protein binding coefficients are affected by hepatic enzyme clearance and protein binding.
 - In general, neonates have:
 - Small volume of distribution and large clearance of drugs.
 - Small volume of distribution and low clearance of drugs.
 - Large volume of distribution and large clearance of drugs.
 - Large volume of distribution and small clearance of drugs.
- Which statement is true regarding parental presence in the operating room?
 - Parental presence is more effective than premedication.
 - Parental presence and premedication are more effective than premedication alone.
 - Parents perceive their presence at induction as less helpful than anesthesiologists perceive parental presence.
 - Anxious parents at induction increase the child's anxiety.

Chapter 9: Preoperative Preparation

2. Which children are more likely to be anxious?
 - A. Children between 6 and 10 years of age are more anxious than children between the ages of 1 and 5 years.
 - B. Gregarious children are more likely to be anxious.
 - C. Children in daycare are more likely to be anxious.
 - D. Children of divorced parents are more likely to be anxious.
3. Which statement is true regarding postoperative behavioral changes?
 - A. Behavioral changes occur in 20% of children at 2 weeks postoperatively.
 - B. Postoperative behavioral changes are seen in children between the ages of 6 and 10 years.
 - C. Increased preoperative anxiety is not associated with postoperative behavioral changes.
 - D. Premedication does not affect postoperative behavioral changes.
4. Which of these concepts applies to preschool-aged children?
 - A. Their world is sociocentric.
 - B. Their thinking is not very literal.
 - C. They remember sequences and causality well.
 - D. They cannot appreciate the feelings of others.

Chapter 12: Airway Management

1. Regarding the development of nasal and oral cavities in utero, which of the following statements are correct?
 - A. Cleft lip and palate are among the most rare congenital anomalies.
 - B. Cleft lip and palate typically occur alone and not as part of a syndrome.
 - C. Cleft palate is common in patients with Pierre Robin sequence.
 - D. The anterior two thirds of the tongue derives from the first brachial arch and is innervated by the branch of the ninth cranial (glossopharyngeal) nerve, whereas the posterior third derives from the third brachial arch and is innervated by the tenth cranial (vagus) nerve.
2. Which of the following statements are correct regarding airway-fluid (gas flow) physics? (more than one may be correct)
 - A. Laminar flow of a fluid (e.g., gas) through a cylindrical tube is proportional to the fourth power of the radius, proportional to the pressure gradient across the tube and inversely proportional to the fluid viscosity. When the radius is doubled, the flow increases to 16-fold of the control.
 - B. In turbulent flow conditions, the flow is proportional to the fifth power of the radius. This means that when the radius is halved, the flow decreases to 1/32 of the control.
 - C. In the upper and lower conducting airways, the flow pattern is turbulent, whereas in the small airways in the periphery of the normal lung, the flow pattern is laminar.
 - D. About two thirds of the total airway resistance ($R = P/\text{flow}$) is in the upper (extrathoracic) airways.
 - E. Of the lower airway resistance, small airways with laminar flow contribute only 3% to 4% of total resistance.
3. With regard to the shape of the developing larynx in infants and children, which of the following statements are correct? (more than one may be correct)
 - A. Eckenhoff's 1951 review, based on cadavers, stated that the shape of the larynx in children is funnel shaped, with the narrowest point being the cricoid ring, rather than cylindrical in shape as in adults.
 - B. Recent studies in anesthetized children demonstrate that the pediatric larynx is cylindrical with the narrowest level at the vocal cords, although it is expandable.
 - C. The shape of the cricoid ring (the narrowest solid structure) is oval rather than circular.
 - D. Recent advances in the understanding of pediatric airway anatomy is the basis for the recent trend of using cuffed endotracheal tubes, rather than uncuffed tubes, in infants and children regardless of a patient's age.

Chapter 13: Induction, Maintenance, and Recovery

1. Regarding the preparation for induction of general anesthesia in children, which of the following statements are correct? (more than one may be correct)
 - A. The international recommendation for preinduction fasting (NPO; 2-4-6 rule) in healthy children is as follows: 2 hours for clear liquids; 3 to 4 hours for breast milk; 4 hours for infant formulas in infants younger than 3 months of age; 6 hours for infant formulas and light meals in infants older than 6 months of age; and 8 hours for heavy meals, based on numerous clinical studies.
 - B. In children, the most common premedication in the United States is oral midazolam.
 - C. In an induction area, anesthetic and monitoring equipment, and airway equipment, and other essential supplies must be complete, readily available, and confirmed with a checklist.
 - D. For monitoring during induction, at a minimum pulse oximeter and capnography should be included. A precordial stethoscope is used for continuous monitoring of breath sounds and the quality of heart tones.
2. For fluid maintenance during general anesthesia, which of the following statements is correct? (more than one may be correct)
 - A. The classic recommendation for maintenance fluids is:
 - Body weight up to 10 kg; 4 mL/kg per hour.
 - Body weight 11 to 20 kg; 40 mL + 2 mL/kg per hour above 10 kg.
 - Body weight 21 kg and up; 60 + 1 mL/kg per hour above 20 kg of body weight.
 - B. For every 100 cal of energy expenditure (or 100 mL of water), which of the following meet a child's requirements for maintenance of fluid and electrolytes? (more than one may be correct)
 - 3 mmol of sodium.
 - 1 mmol of potassium.
 - 5 mmol of chloride.
 - 5 g of dextrose and.
 - 5% dextrose in 0.45% (half normal) saline.

- C. Glucose-containing maintenance fluid (usually 5% dextrose) could be problematic because of osmotic diuresis and electrolyte imbalance, as well as worsening outcome in cerebral ischemia.
- D. Perioperative hypoglycemia in healthy pediatric patients is rarely a problem, and the majority of healthy patients do not require perioperative glucose supplement.
3. Regarding intubation and the technique of extubation, which of the following statements are correct?
- A. Cuffed endotracheal tubes are increasingly and commonly used for infants and young children over the last decade without increases in upper airway complications.
- B. Ideally, lungs should be deeply and repeatedly inflated with air-oxygen mixture but with positive end-expiratory pressure to recruit atelectatic air spaces, which commonly develop during the course of general anesthesia.
- C. Extubation while the patient is waking up (stage 2) can increase the chance of upper airway obstruction (laryngospasm).
- D. After extubation and the reestablishment of breathing, the patient can be transported in the lateral position with an oxygen mask to avoid hypoxemia.

Chapter 14: Blood Conservation

1. Which of the following statements most accurately reflects hemoglobin physiology in the pediatric patient?
- A. Under normal circumstances, the P_{50} increases from 19 mm Hg at one day of life to the adult value by 6 months and then exceeds the adult value at 12 months.
- B. Under normal circumstances, the P_{50} increases from 19 mm Hg at one day of life to the adult value by 12 months but does not exceed the adult value.
- C. Under normal circumstances, the P_{50} increases from 19 mm Hg at one day of life to the infant value by 6 months and then increases to the adult value at 12 months.
2. The mechanism of action of the antifibrinolytics tranexamic acid and ϵ -aminocaproic acid includes which of the following?
- A. Reversible inhibition of serine proteases.
- B. Reversible inhibition of plasminogen.
- C. Irreversible inhibition of plasminogen.
- D. Restoration of platelet adhesiveness.
3. Which of the following is the estimated blood volume for a full-term newborn?
- A. 70 to 75 mL/kg.
- B. 75 to 80 mL/kg.
- C. 80 to 90 mL/kg.
- D. 90 to 100 mL/kg.

Chapter 15: Pain Management

1. The FLACC pain tool is composed of which of the following clinical features to assess pediatric pain?
- A. Facial expression, leg movement, respiratory rate, pulse oximetry, and consolability.
- B. Agitation, respiratory rate, blood pressure, muscle tone, and facial tension.
- C. Facial expression, leg movement, activity, crying, and consolability.
- D. Crying, requires oxygen, increased vital signs, expression, and sleepless.

2. Which of the following statements most accurately describes codeine metabolism?
- A. Codeine, like oxycodone and hydrocodone, has intrinsic analgesic properties and is metabolized by *CYP2D6* to morphine.
- B. Codeine, like oxycodone and hydrocodone, has intrinsic analgesic properties and is metabolized by *CYP2D6* to hydromorphone.
- C. Codeine, unlike oxycodone and hydrocodone, has no intrinsic analgesic properties and is metabolized by *CYP2D6* to morphine.
- D. Codeine, unlike oxycodone and hydrocodone, has no intrinsic analgesic properties and is metabolized by *CYP2D6* to hydromorphone.
3. Which of the following opioid-induced side effects has low-dose naloxone infusion (0.25 to 1 mcg/kg per hour) been shown to reduce?
- A. Constipation and urinary retention.
- B. Respiratory depression and sedation.
- C. Tolerance and withdrawal.
- D. Pruritus and vomiting.

Chapter 16: Regional Anesthesia

1. An 8-month-old, 8-kg infant is brought to the operating room for an exploratory laparotomy for a bowel obstruction secondary to a volvulus. The plan for postoperative analgesia includes an epidural catheter with ropivacaine. What is the most appropriate infusion rate if 0.1% ropivacaine is used?
- A. 1.5 mL/hr.
- B. 2.5 mL/hr.
- C. 3.5 mL/hr.
- D. 4.5 mL/hr.
2. During the placement of the epidural for the same patient, a test dose is performed. Which of the following is the most sensitive marker for an intravascular injection?
- A. Heart rate increase of more than or equal to 10 beats per minute.
- B. Systolic blood pressure increase of 15%.
- C. T-wave amplitude increase of 25%.
- D. Heart rate increase of greater than or equal to 20 bpm.
3. The same infant receives a bolus of 1 mL/kg of 0.2% ropivacaine via the epidural catheter. Five minutes after the bolus, the infant develops a wide-complex tachyarrhythmia without a pulse. CPR is started, the infant is intubated, and intravenous epinephrine is administered. Which of the following is the next most appropriate step to provide?
- A. High-dose epinephrine, (100 mcg/kg).
- B. Amiodarone, 5 mg/kg IV bolus.
- C. Procainamide, 15 mg/kg IV bolus.
- D. 20% Intralipid, 1.5 mL/kg IV bolus.

Chapter 17: Neonatology for Anesthesiologists

1. Which statements are true regarding premature infants? (more than one may be correct)
- A. Prematurity is defined as an infant born before 36 weeks' gestation.
- B. In the United States, premature births account for 5% of all births.
- C. Prematurity is the leading cause of infant mortality in the United States.

- Which statements are true regarding the neonate? (more than one may be correct)
 - Almost all alveoli develop after birth.
 - Type 2 pneumocytes are more prominent before 34 weeks' gestation.
 - Healthy neonates breathe 30 to 60 times per minute.
 - Surface active material starts to appear in the lungs as early as 20 weeks' gestation.
- Which of the following statements are true? (more than one may be correct)
 - Neonates cannot autoregulate cerebral blood flow.
 - Apgar scores are predictors of mortality.
 - Hypoglycemia is defined as a blood sugar less than 40 mg/dL.
 - Infants normally lose weight in the first few days of life.

Chapter 18: Anesthesia for General Surgery in the Neonate

- An 8-hour-old infant is brought to the nursery with excessive drooling, cyanotic spells, and coughing that is relieved by suctioning. On physical examination, the infant is noted to have an anorectal anomaly and a murmur, and on chest x-ray and abdominal plain films, vertebral body defects are noted. The diagnosis of tracheoesophageal fistula is suspected. Which would be the most common type of tracheoesophageal abnormality?

- A
 - B
 - C
 - D
 - E
 - F
- Which of the following is the most common location of a congenital diaphragmatic hernia?
 - Bochdalek.
 - Morgagni.
 - Paraesophageal.
 - A premature infant who was asphyxiated at birth and had a birth weight of 1800 g is noted to develop abdominal distension and bloody stools on day 5 of life. The neonate is intubated, ventilated, and given antibiotics for sepsis. Which of the following is an absolute indication for surgery?
 - Metabolic acidosis.
 - Abdominal wall erythema.
 - Persistently dilated loop of bowel.
 - Portal vein gas.
 - Pneumoperitoneum.

Chapter 19: Anesthesia for Fetal Surgery

- Concerning changes in maternal physiology during pregnancy, which of the statements below are correct? (more than one may be correct)

- The pregnant woman is at high risk of hypoxia caused by increased O_2 consumption, decreased FRC, and upper airway narrowing because of venous engorgement.
 - The risk of pulmonary edema is increased after open fetal surgery and uterine manipulation in part because of decreased plasma protein and release of factors increasing pulmonary vascular permeability.
 - Supine hypotension may occur because of compression of the inferior vena cava.
 - The pregnant woman is at increased risk of aspiration of gastric contents because of hormonal changes with a resultant decrease in the gastric sphincter tone and displacement of the stomach by the pregnant uterus.
- Concerning fetal and fetoplacental physiology, which of the following statements are correct? (more than one may be correct)
 - Fetal circulation through the left and right sides of the heart is in parallel rather than in series, as it is in the mature heart.
 - The major portion of the blood returning from the umbilical vein bypasses the liver through the ductus venosus, flows through the foramen ovale and the left ventricle, and perfuses the upper part of the body.
 - Normal Pao_2 (umbilical) is around 19 mm Hg, and umbilical venous PO_2 is about 29 mm Hg.
 - Maternal hyperventilation and hypocapnia cause fetoplacental vasoconstriction and fetal hypoxia, whereas hypercapnia with acidosis increases placental blood flow and fetal PO_2 .
 - Regarding fetal surgery, which of the following statements are correct? (more than one may be correct)
 - Minimally invasive interventions are most commonly performed fetal surgical procedures that include the treatment for twin-twin transfusion sequence (TTTS), twin reversed arterial perfusion sequence (TRAPS), and release of amniotic bands.
 - The ex utero intrapartum therapy (EXIT) procedure is performed for upper airway lesions including cystic hygroma, cervical teratoma, and congenital high airway obstruction syndrome (CHAOS), as well as sacrococcygeal teratomas.
 - The EXIT procedure requires adequate uterine relaxation. Deep-inhalation anesthesia with or without nitroglycerine infusion has been used successfully.
 - The EXIT procedure requires the readiness of a second operating room with separate anesthesia and surgical teams for neonatal resuscitation and surgery.

Chapters 20: Anesthesia for Congenital Heart Surgery, and 21: Congenital Cardiac Anesthesia: Non-Bypass Procedures

- Patients with a ventricular septal defect (VSD) and increased pulmonary blood flow are at risk for pulmonary hypertension. Which of the following is compatible with the diagnosis on physical examination?
 - Jugular venous distension, soft second heart sound, widely split second heart sound, and large liver.
 - Jugular venous distension, loud second heart sound, single second heart sound, and large liver.

- C. Jugular venous distension, soft second heart sound, single second heart sound, and large liver.
D. Jugular venous distension, loud second heart sound, widely split second heart sound, and large liver.
- In patients with Fontan physiology, blood flow to the pulmonary circulation is affected by which of the following?
 - RV function.
 - Pulmonary vascular resistance.
 - Ventricular mixing.
 - Atrial mixing.
 - The components to the diagnosis of Tetralogy of Fallot include which of the following?
 - RVH, overriding aorta, pulmonary outflow obstruction, and VSD.
 - RVH, overriding aorta, pulmonary outflow obstruction, and ASD.
 - RVH, aortic stenosis, overriding pulmonary artery, and VSD.
 - RVH, aortic stenosis, overriding pulmonary artery, and ASD.
 - Treatment of TET spells includes which of the following?
 - 100% oxygen, morphine, slowing heart rate, and fluid administration.
 - 100% oxygen, morphine, increasing heart rate, and fluid administration.
 - 100% oxygen, morphine, increasing heart rate, and fluid restriction.
 - 100% oxygen, morphine, decreasing heart rate, and fluid restriction.
 - In patients with an ASD, the murmur is caused by which of the following?
 - Turbulence through the ASD.
 - Increased blood flow through the pulmonary valve.
 - Increased blood flow through the mitral valve.
 - Increased blood flow through the aortic valve.
 - Complete the statement about blood gas and temperature. As temperature decreases,
 - Solubility of oxygen and carbon dioxide decrease.
 - Solubility of oxygen increases and carbon dioxide decreases.
 - Solubility of oxygen and carbon dioxide increase.
 - Solubility of oxygen decreases and carbon dioxide increases.
 - Using alpha stat methods, cooled blood from an otherwise healthy patient will demonstrate which of the following when the sample is warmed to 37°C?
 - pH of 7.4 and a CO₂ of 40.
 - pH of 7.5 and a CO₂ of 30.
 - pH of 7.2 and a CO₂ of 60.
 - Using pH stat methods, cooled blood from an otherwise healthy patient will demonstrate which of the following when the sample is warmed to 37°C?
 - pH 7.4 and a CO₂ of 40.
 - pH 7.5 and a CO₂ of 30.
 - pH 7.2 and a CO₂ of 60.
 - Which of the following describes fetal circulation?
 - Low SVR, high PVR, and high PBF.
 - Low SVR, high PVR, and low PBF.
 - High SVR, low PVR, and high PBF.
 - High SVR, high PVR, and low PBF.
 - Complete this statement. In the fetus,
 - Fetal hemoglobin is shifted to the right.
 - Fetal hemoglobin levels are greater than adult high levels.
 - 2,3-DPG levels are greater than in adults.
 - The neonatal myocardium is characterized by which of the following?
 - More myofibrils, higher sarcomere volume, and well-developed SR.
 - Fewer myofibrils, lower sarcomere volume, and poorly developed SR.
 - Fewer myofibrils, lower sarcomere volume, and well-developed SR.
 - More myofibrils, higher sarcomere volume, and poorly developed SR.
 - Patients with William syndrome typically have which of the following?
 - Supravalvular aortic stenosis, elfin facies, and increased risk of sudden death.
 - Supravalvular aortic stenosis, normal facies, and no increased risk of sudden death.
 - Supravalvular aortic stenosis, elfin facies, and no increased risk of sudden death.
 - Supravalvular aortic stenosis, normal facies, and increased risk of sudden death.
 - Which of the following characteristics is true of truncus arteriosus?
 - Associated 22q11 deletion, DiGeorge syndrome, and left-to-right shunt.
 - Associated 22q11 deletion, DiGeorge syndrome, and right-to-left shunt.
 - In the neonatal period, critical coarctation of the aorta and ductal closure are associated with which of the following?
 - Bounding pulses in upper extremities and poor pulses in lower extremities.
 - Acidosis oliguria, myocardial dysfunction, and poor pulses in all extremities.
 - Complete this statement. In patients undergoing ablation procedures,
 - There is a high incidence of PONV.
 - The choice of general anesthetic agent greatly impacts the electrophysiologic procedure.
 - Dexmedetomidine has no effect on AV and SA node function.

Chapter 22: Anesthesia for Neurosurgery

- Which of the following statements most accurately reflects pediatric neurophysiology?
 - CSF production is higher in children than adults; the cerebral metabolic rate is higher in children than adults; and intracranial compliance is lower in children than adults.
 - CSF production is higher in children than adults, the cerebral metabolic rate is higher in children than adults; and intracranial compliance is higher in children than adults.
 - CSF production is lower in children than adults; the cerebral metabolic rate is higher in children than adults; and intracranial compliance is lower in children than adults.
 - CSF production is higher in children than adults; the cerebral metabolic rate is lower in children than adults; and intracranial compliance is lower in children than adults.

2. Cerebral salt wasting is best characterized by which of the following?
 - A. Hyponatremia, hypervolemia, and increased urinary secretion of sodium.
 - B. Hyponatremia, hypovolemia, and increased urinary secretion of sodium.
 - C. Hyponatremia, hypovolemia, and decreased urinary secretion of sodium.
 - D. Hypernatremia, hypovolemia, and decreased urinary secretion of sodium.
3. A 3-year-old child with a traumatic brain injury from a motor vehicle accident is in the pediatric intensive care unit. The head CT scan shows no bleeding, and the ICP monitor indicates a mildly elevated intracranial pressure but no evidence of brain-stem herniation. The child is intubated with muscle relaxant and is mechanically ventilated. Which of the following is the most appropriate strategy for managing ventilation?
 - A. Ventilation to maintain $Paco_2$ of less than 25 mm Hg.
 - B. Ventilation to maintain $Paco_2$ of 25 to 35 mm Hg.
 - C. Ventilation to maintain $Paco_2$ of 35 to 45 mm Hg.
 - D. Ventilation to maintain $Paco_2$ of greater than 45 mm Hg.
2. Which of the following statements are true? (more than one may be correct)
 - A. Airway fires may occur in the presence of nitrous oxide.
 - B. The 4 E's for an airway fire are extract, eliminate, extinguish, and evaluate.
3. Supraglottitis symptoms include which of the following? (more than one may be correct)
 - A. Dysphagia.
 - B. Dyphonia.
 - C. Dyspnea.
 - D. Drooling.
 - E. Crouplike cough.

Chapter 23: Anesthesia for General Abdominal, Thoracic, Urologic, and Bariatric Surgery

1. A 2-month-old infant is brought to the emergency room with a history of projectile vomiting. The infant is thought to have pyloric stenosis and the diagnosis is confirmed by ultrasound. Which of the following electrolyte disorders would be present at the time of admission?
 - A. Metabolic acidosis, hypernatremia, and hypokalemia.
 - B. Metabolic acidosis, hyponatremia, and hypokalemia.
 - C. Metabolic alkalosis, hypokalemia, and hyperchloremia.
 - D. Metabolic alkalosis, hypokalemia, and hypochloremia.
2. Complete this statement. In patients with mediastinal masses, the risk of anesthesia is increased in patients with
 - A. Tracheal cross-sectional area less than 50% of predicted.
 - B. Peak expiratory flow rate greater than 60% of predicted.
 - C. Children older than 12 years of age.
 - D. Spontaneous ventilation.
3. A 16-year-old patient who is morbidly obese is scheduled for bariatric surgery. Which of the following physiologic features apply to patients with morbid obesity?
 - A. Cardiac reserve is decreased, LV work is raised, and gastric volume is raised.
 - B. Cardiac reserve is decreased, LV work is raised, and gastric volume is normal.
 - C. Gastric volume is normal, gastric pH is more acidic, and the incidence of gallstones is increased.

Chapter 24: Anesthesia for Pediatric Otorhinolaryngologic Surgery

1. Regarding obstructive sleep apnea in children, which of the following statements are true? (more than one may be correct)
 - A. The most common course is upper airway narrowing and adenotonsillar hypertrophy.
 - B. Peak prevalence is between 2 and 8 years of age.
 - C. Polysomnograph is the gold standard.
 - D. Children with nadir saturations of 85 during sleep are more sensitive to opioids.

Chapter 25: Anesthesia for Plastic Surgery

1. An 8-month-old infant with Treacher Collins syndrome comes to the preoperative clinic for evaluation. The infant is scheduled for microtia repair. Which of the following craniofacial anomalies best describes this disorder?
 - A. Craniosynostosis.
 - B. Craniofacial clefting.
 - C. Craniofacial hypoplasia.
 - D. Vascular malformation.
2. Which of the following is the most significant anesthetic concern for this infant?
 - A. Decreased hearing and difficulty communicating.
 - B. Difficult endotracheal intubation.
 - C. Difficult intravenous access.
 - D. Cervical fusion, which occurs in 10% of these patients.
3. Clinical requirements for the diagnosis of Pierre Robin sequence include which of the following?
 - A. Retrognathia, glossoptosis, and airway obstruction.
 - B. Retrognathia, cleft lip, and cleft palate.
 - C. Retrognathia, cleft palate, and large tongue.
 - D. Retrognathia, cleft palate, and airway obstruction.

Chapter 26: Anesthesia for Orthopedic Surgery

1. Complete this statement. Respiratory impairment from scoliosis typically occurs at a Cobb's angle of
 - A. 40 degrees.
 - B. 60 degrees.
 - C. 80 degrees.
 - D. 100 degrees.
2. Which of the following statements regarding somatosensory-evoked potentials is most accurate?
 - A. Propofol increases latency and decreases amplitude but less than sevoflurane.
 - B. Ketamine augments SSEP amplitude.
 - C. Sevoflurane and desflurane produce dose-dependent increases in latency and decreases in amplitude but have minimal effect up to 0.5 MAC.
 - D. Opioids increase latency and decrease amplitude in a dose-dependent manner.
3. A 9-year-old child is under general anesthesia for the placement of an intramedullary rod for a femur fracture. Shortly after induction of general anesthesia, the child becomes acutely hypoxic with increased peak inspiratory pressures. What clinical feature would most likely suggest the diagnosis of fat embolus?
 - A. Sudden decrease in oxygen saturation.
 - B. Sudden increase in end-tidal CO_2 .
 - C. Sudden increase in airway pressures.
 - D. Sudden increase in heart rate.

- A. Increased tryptase level.
- B. Fat droplet cells in a bronchoalveolar lavage.
- C. Right middle-lobe infiltrate on portable chest x-ray.
- D. Generalized erythematous rash on trunk.

Chapter 27: Anesthesia for Ophthalmic Surgery

1. A mother brings her 3-year-old child into the preoperative clinic in preparation for eye muscle surgery. She would like to know what the perioperative concerns for this surgery include. The most likely concern would be which of the following?
 - A. Eye pain.
 - B. Malignant hyperthermia.
 - C. Diplopia.
 - D. Postoperative nausea and vomiting.
2. During the strabismus surgery for this child, manipulation of the extraocular muscle decreases the heart rate to 40 bpm. This reflex is propagated by which cranial nerves?
 - A. III and X.
 - B. IV and X.
 - C. V and X.
 - D. VI and X.
3. Which of the following is the most appropriate initial management for the bradycardia in the previous question?
 - A. Notify the surgeon to release traction on the muscle.
 - B. Administer atropine, 20 mcg/kg.
 - C. Give chest compressions, starting with 100 bpm.
 - D. Administer epinephrine, 10 mcg/kg.

Chapter 28: Anesthesia for Organ Transplantation

1. The postreperfusion syndrome that occurs after liver transplantation includes which of the following?
 - A. Increased cardiac output.
 - B. Increased blood pressure.
 - C. Increased pulmonary artery pressure.
 - D. Decreased central venous pressure.
2. Which of the following are correct statements about kidney transplantation? (more than one may be correct)
 - A. Infants receiving adult kidneys commonly become hypothermic.
 - B. Fluid restriction is essential after graft reperfusion.
 - C. Kidneys that are transplanted from living, related donors produce better survival rates in recipients than do organs that are transplanted from cadavers.
 - D. Infants and children with delayed graft function after transplantation have an increased incidence of graft loss over the next 5 years.
3. Which of the following are correct statements about liver transplantation? (more than one may be correct)
 - A. Hepatic artery and portal vein thrombosis are common vascular complications.
 - B. Growth retardation is common.
 - C. Chronic renal disease is uncommon in 10-year survivors of liver transplantation.
 - D. Retransplantation is more common in recipients of living donor grafts compared with those who have received whole cadaver grafts.

Chapter 30: Anesthesia for the Pediatric Trauma Patient

1. A 5-year-old child has fallen off an ATV and sustained head and abdominal wounds. On arrival the child is noted to be cool with poor perfusion. The child is unresponsive and was receiving bag/mask ventilation in the field. The child's blood pressure is 60/40 with a heart rate of 155 and a pulse oximeter reading of 100%. The pupils are midsize and reactive to light. Attempts at peripheral venous cannulation are unsuccessful. Which of the following is the next step?
 - A. Intubate.
 - B. Attempt central line placement.
 - C. Place intraosseous device.
 - D. Warm the patient.
2. An 8-month-old infant arrives in the ER as an unrestrained passenger in a motor vehicle accident. The infant has been placed in a C-collar and is somewhat somnolent with stable vital signs. Which of the following statements concerning neck films is true for children?
 - A. Children 10 years of age and younger have a higher incidence of C5 to C7 injuries compared with adults.
 - B. Infants and small children with normal neck films are cleared with respect to their C-spines.
 - C. Pseudosubluxation anterior displacement of C2 on C3 less than 3 mm is a normal variant.
 - D. Subluxation of cervical vertebrae and odontoid fractures are more common in adults.
3. In patients requiring massive blood volume replacement (more than 1 blood volume), the ratio of FFP to packed red blood cells (PRBC) should be which of the following?
 - A. 1:1.5.
 - B. 1:2.
 - C. 1:3.
 - D. 1:4.

Chapter 31: Anesthesia for Burn Injuries

1. A 4-year-old child arrives in the trauma bay after being caught in a house fire. The child is awake but fearful and crying with a hoarse voice. On examination, it is noted that the child has soot on his face and is tachypneic, but the lungs sound clear on bilateral auscultation. There are no other obvious injuries. The child is receiving oxygen via a face mask, and the oxygen saturation is 94%. The most appropriate initial management for this child includes:
 - A. Obtaining a chest x-ray.
 - B. Changing the face mask to a nonrebreathing face mask.
 - C. Ventilating the child with a mask and preparing him for intubation.
 - D. Obtaining an arterial blood gas sample for Pao₂ and carboxyhemoglobin.

Chapter 32: Anesthesia for Pediatric Dentistry

1. Which of the following statements is most accurate?
 - A. During adolescence, dental caries is more common than asthma.
 - B. Dental caries is the most common chronic condition of children between the ages of 2 and 6 years old.
 - C. Maternal nutrition and behavior are not significant factors in the development of pediatric dental caries.
 - D. Patient nutrition is the most important factor determining the development of dental caries.

2. The permanent dentition begins its eruption pattern with the permanent first molar. This usually occurs at approximately what age?
 - A. 3 years.
 - B. 6 years.
 - C. 9 years.
 - D. 12 years.
3. Which of the following patients requires subacute bacterial endocarditis prophylaxis?
 - A. A 2-year-old child with unrepaired VSD.
 - B. A 2-year-old child with a history of a VSD repair with a synthetic patch placement that took place one year ago.
 - C. A 2-year-old child with a history of a heart transplant that took place one year ago. The transplanted heart is unremarkable.
 - D. A 2-year-old child with a history of previous infective endocarditis.

Chapter 36: Systemic Disorders

1. Regarding children with HIV infection and AIDS, which of the following statements are correct? (more than one may be correct)
 - A. In the United States, nearly all HIV infections in children are caused by vertical transmission from HIV-infected mothers via the exposure to infected blood or secretions.
 - B. The chance of HIV transmission is increased with preterm birth, low birth weight, and low maternal CD4 lymphocyte counts.
 - C. Dramatic decreases in vertical transmissions of HIV over the past 15 to 20 years in the U.S. are attributed to caesarian section, as well as prenatal, intrapartum, and neonatal antiretroviral treatments.
 - D. In the U.S., postpartum HIV transmission via breast feeding is the least common mode of transmission, whereas it is quite common in the developing countries.
2. Regarding surgical and anesthetic management of children with HIV or AIDS, which of the following statements is incorrect?
 - A. A majority of children with AIDS develop lung disease caused by bacterial and viral infections; in addition, 20% to 30% of them develop lipid interstitial pneumonia with tachycardia, wheezing, coughs, hypoxemia, and even clubbing.
 - B. The most common opportunistic infection responsible for pneumonia in children with AIDS is caused by *Pneumocystis carinii*.
 - C. These patients often require anesthetic care for bronchoscopy and bronchoalveolar lavage. The risk of HIV transmission from saliva is rare.
 - D. The estimate of the average risk of HIV transmission with a contaminated needle stick is estimated to be 3% to 4%.
3. Concerning latex allergy, which of the following statements are correct? (more than one may be correct)
 - A. Reactions to latex exposure are divided into three types: irritant contact dermatitis, type IV hypersensitivity (urticaria), and type I (or IgE-mediated) hypersensitivity.
 - B. Children with spina bifida or urinary tract anomalies have increased risk of latex allergy.
 - C. The type I hypersensitivity often occurs immediately at the beginning of surgical procedure.
 - D. Intraoperative manifestation of type I hypersensitivity may include bronchospasm, hypoxemia, and hypotension, which are difficult to treat.

Chapter 37: Malignant Hyperthermia

1. Which of the following may be initial signs of an MH episode? (more than one may be correct)
 - A. Tachycardia.
 - B. Sweating.
 - C. Muscle stiffness.
 - D. Increased temperature.
2. Which of the following conditions are associated with an acute MH episode? (more than one may be correct)
 - A. There is no increased carbon dioxide production.
 - B. It occurs more often in males.
 - C. There may not be a significant increase in creatine kinase.
 - D. MH may occur without a metabolic acidosis.
3. Which of the following statements is true about preparation of the anesthesia machine for the patient who is susceptible to MH?
 - A. It is the same for all types of anesthesia workstations.
 - B. It is the same whether or not the ventilator, carbon dioxide absorber, and gas delivery tubing is changed.
 - C. 10 L/min of fresh gas flow are required for 10 minutes.
 - D. The aim is to produce less than 5 ppm of anesthetic vapor in the gas delivery system.
4. What is the usefulness of genetic testing for MH susceptibility?
 - A. It is very likely to confirm the diagnosis of MH susceptibility in a patient who had postoperative fever and muscle pain.
 - B. Postmortem testing can help the family after death from MH.
 - C. If there is no sequence variant on the examination of *RYR1* hot spots, individuals can be treated as if they are negative to MH-susceptibility.
 - D. It requires that a patient travel to the location where the test will be performed.

Chapter 38: Cardiopulmonary Resuscitation

1. A 2-year-old child develops laryngospasm on induction of anesthesia. The child becomes hypoxic and develops bradycardia with a capillary refill rate greater than 5 seconds. At what heart rate should chest compressions be started?
 - A. 40 bpm.
 - B. 60 bpm.
 - C. 80 bpm.
 - D. 100 bpm.
2. A child with known prolonged QT syndrome develops a pulseless polymorphic arrhythmia. The child is intubated, chest compressions are started, and the child receives one dose of epinephrine. What is the next most appropriate drug?
 - A. Amiodarone.
 - B. Procainamide.
 - C. Lidocaine.
 - D. Magnesium sulphate.

3. The cornerstone of effective pediatric cardiopulmonary resuscitation is high-quality CPR. Which of the following features most accurately describe high quality CPR?

A. Rate 100 bpm, depth $\frac{1}{2}$ to $\frac{3}{4}$ diameter of chest, and change of compressors every 2 minutes.

B. Rate 100 bpm, depth $\frac{1}{3}$ to $\frac{1}{2}$ diameter of chest, and change of compressors every 2 minutes.

C. Rate 100 bpm, depth $\frac{1}{3}$ to $\frac{1}{2}$ diameter of chest, and change of compressors every 4 minutes.

D. Rate 120 bpm, depth $\frac{1}{3}$ to $\frac{1}{2}$ diameter of chest, and change of compressors every 2 minutes.

ICT	islet cell transplantation	NIH	National Institutes of Health
ICU	intensive care unit	NIRS	near-infrared spectroscopy
ID	internal diameter	NMB	neuromuscular block(er)
IHAST	Intraoperative Hypothermia in Aneurysm Surgery Trial	NMDR	nondepolarizing muscle relaxant
IHCA	in-hospital cardiac arrest	NO	nitric oxide
ILCOR	International Liaison Committee on Resuscitation	NOS	nitric oxide synthase
ILIH	ilioinguinal/iliohypogastric	NPH	neutral protamine Hagedorn
IM	intramuscular/intramuscularly	NPO	nothing by mouth
INR	International Normalized Ratio	NRCPR	National Registry of CPR
IO	intraosseous	NRGA	normally related great arteries
IRDS	idiopathic (infantile) respiratory distress syndrome (HMD)	NS	nerve stimulation
IRV	inspiratory reserve volume	NSAIDs	nonsteroidal antiinflammatory drugs
ISC	irreversibly sickled cell	O₂	oxygen
ITD	impedance threshold device	OAC-CPR	only abdominal compression CPR
ITP	idiopathic thrombocytopenic purpura	OD	outer diameter
ITPR	intrathoracic pressure regulator	OHCA	out-of-hospital cardiac arrest
IV	intravenous/intravenously	OI	osteogenesis imperfecta
IVC	inferior vena cava	OLT, OLTx	orthotopic liver transplantation
IVIG	IV gamma globulin	OMIM	Online Mendelian Inheritance in Man
IVRA	intravenous regional anesthesia	OPO	Organ Procurement Organization
IVS	intact ventricular septum	OPTN	Organ Procurement and Transplantation Network
JET	junctional ectopic tachycardia	OR	operating room
JIA	juvenile idiopathic arthritis	OSHA	Occupational Safety and Health Administration
kg	kilogram	OTCD	ornithine transcarbamylase deficiency
L	liter	P₅₀	Arterial oxygen tension (PaO ₂) at 50% hemoglobin saturation
L	levo-	Pa	Pulmonary arterial pressure
LA	left atrium	Pa	Alveolar pressure
LABA	long-acting β ₂ -agonist		

Paco₂	partial pressure of arterial carbon dioxide	SAR	slowly-adapting (pulmonary stretch) receptors
PACU	postanesthesia care unit	SBP	systolic blood pressure
PAD	preoperative autologous donation	SBT	small bowel transplantation
PAH	pulmonary artery hypertension	SCD	sickle cell disease
PAI	plasminogen activator inhibitor	SCFE	slipped capital femoral epiphysis
PAK	pancreas after kidney (transplantation)	SCI	spinal cord injury
PALS	pediatric advanced life support	SCID	severe combined immunodeficiency (syndrome)
Palv	alveolar pressure	SCV-CPR	simultaneous compression-ventilation CPR
Pao	airway opening pressure	SDR	selective dorsal rhizotomy
Pao₂	partial pressure of oxygen in arterial blood	sec	second
PAP	pulmonary artery pressure	SGA	small for gestational age, <5th percentile for gestational age
PAPVR	partially anomalous pulmonary venous return	SIADH	syndrome of inappropriate ADH secretion
P_a	Atmospheric pressure	SIDS	sudden infant death syndrome
PBF	pulmonary blood flow	Sjvo₂	jugular venous oxygen saturation
PC	phosphatidylcholine	SLE	systemic lupus erythematosus
PCA	patient-controlled analgesia	So₂	oxygen saturation of hemoglobin
Pco₂	partial pressure of carbon dioxide	SOS	Shikani Optical Stylet
PCRA	patient-controlled regional analgesia	SP-A (B, C, D)	Surfactant protein A (B, C, D)
PCV	pressure-controlled ventilation	SPK	simultaneous kidney-pancreas (transplantation)
PDA	patent ductus arteriosus	Spo₂	Sao ₂ as measured with a pulse oximeter
PDPH	postdural puncture headache	SSEP	somatosensory evoked potentials
PE	phosphatidylethanolamine	SVAS	supravalvular aortic stenosis
PEA	pulseless electrical activity	SVC	superior vena cava
PEEP	positive end-expiratory pressure	SVC-RA	superior vena cava-right atrium
PEFR	peak expiratory flow rate	Svo₂	systemic venous oxygen saturation
PELD	pediatric end-stage liver disease (in patients younger than 12 years)	SVR	systemic vascular resistance
PETco₂	end-tidal carbon dioxide tension	SVT	supraventricular tachycardia
PFO	patent foramen ovale	T₃	triiodothyronine
PG	phosphatidylglycerol	T₄	thyroxine
PGE₁	prostaglandin E ₁	TA	tricuspid atresia
pGz	periodic acceleration	TAFI	thrombin-activatable fibrinolysis inhibitor
PICC	peripherally inserted central catheter	TA-GVHD	Transfusion-associated graft-versus-host disease
PICU	pediatric intensive care unit	TAP	transverses abdominis plane
PIVKA	proteins induced in vitamin K's absence	TAPVR	total anomalous pulmonary venous return
PIZZ	protease inhibitor phenotype ZZ (homozygous)	TBI	traumatic brain injury
PLA	perilaryngeal airway	TCD	transcranial Doppler
PNB	peripheral nerve block	TcMEP	transcranial MEP
PO	oral	TCPC	total cavopulmonary connection
PO₂	partial pressure of oxygen	TE	expiratory time
POCA	perioperative cardiac arrests	TEF	tracheoesophageal fistula
PONV	postoperative nausea and vomiting	TEG	thromboelastogram/thromboelastograph/thromboelastography
PPH	portopulmonary hypertension	TF	tissue factor
PPHN	persistent pulmonary hypertension of the neonate	TFPI	tissue factor pathway inhibitor
Ppl	pleural pressure	TGA	transposition of the great arteries
PRG	pontine respiratory group of neurons	TGFβ	transforming growth factor-β
PRS	postreperfusion syndrome	THAM	tris-hydroxymethyl aminomethane
PS	phosphatidylserine	Ti	inspiratory time
PS	pulmonary stenosis	Ti/Trot	respiratory duty cycle
Pstil	static recoil pressure of the lungs	TIVA	total intravenous anesthesia
PT	prothrombin time	TLC	total lung capacity
PTA	pancreas transplantation alone	TMJ	temporomandibular joint
PTLD	posttransplantation lymphoproliferative disease	TNFα	tumor necrosis factor-α
PTT	partial thromboplastin time	TOF	tetralogy of Fallot
PV	pulmonary valve	TPA	tissue plasminogen activator
Pv	pulmonary venous pressure	TPG	transpulmonary gradient
PVC	polyvinylchloride	TRALI	transfusion-related acute lung injury
Pvo₂	venous oxygen tension	TRH	thyrotropin-releasing hormone
PVOD	pulmonary vascular occlusive disease	TSH	thyroid-stimulating hormone
PVR	pulmonary vascular resistance	TT	tracheal tube
Q_p	total pulmonary blood flow	TTI	transthoracic impedance
Q_p / Q_s	pulmonary-to-systemic blood flow ratio	Trot	total respiratory time (Ti + Te)
Q_s	total systemic blood flow	TV	tricuspid valve
ΔR (Rvis)	viscoelastic component of Rrs	TXA₂	thromboxane A ₂
R	resistance	UNOS	United Network of Organ Sharing
RA	right atrium	URI	upper respiratory tract infection
RAD	reactive airways disease	VAE	venous air embolus
RAP	right atrial pressure	V_A / Q_p	ventilation/pulmonary perfusion ratio, also V/Q
RAR	rapidly adapting (irritant) receptor	VATS	video-assisted thoracoscopic surgery
RAST	radioallergosorbent test	Vbas	basilar artery flow velocity
Raw	airway resistance	Vd	volume of distribution
RBC	red blood cell	VC	vital capacity
REM	rapid eye movement (sleep)	VCAM-1	vascular cell adhesion molecule-1
rFVIIa	recombinant factor VIIa	VCV	volume-controlled ventilation
rFVIII	recombinant factor VIII	V_E	minute volume (= V _T × f = V _T /Ti × Ti/Trot)
Rint	resistive component of Rrs	VF	ventricular fibrillation
RIS	Rapid Infusion System	VFCA	ventricular fibrillation cardiac arrest
ROP	retinopathy of prematurity	Visov	volume of isoflow
ROSC	return of spontaneous circulation	VLBW	very low birth weight, <1500 g
Rrs	total resistance of the respiratory system	V max₂₅	maximum expiratory flow at 25% FVC (FEF ₇₅ or MEF ₂₅)
RSI	rapid sequence induction	Vmca	middle cerebral artery flow velocity
RSV	respiratory syncytial virus	VOC	vasoocclusive crisis
RTO	retransplantation operation	VRG	ventral respiratory groups of neurons
Rus	airway resistance of upstream segment	VSD	ventricular septal defect
RV	right ventricle	Vt	tidal volume
Rv	residual volume	VT	ventricular tachycardia
Rv/TLC	residual volume to total lung capacity (ratio)	V_T/Ti	Mean inspiratory flow (neural drive)
RVDC	right ventricular-dependent coronary circulation	VVB	venovenous bypass
Rvis	see ΔR	vWD	von Willebrand disease
RVOTO	right ventricular outflow tract obstruction	vWF	von Willebrand factor
SABA	short-acting β ₂ -agonist	WASP	Wiskott-Aldrich syndrome protein
Sao₂	systemic arterial oxygen saturation	WHO	World Health Organization
