Specific drugs used for the maintenance of anesthesia have not been shown to affect the outcome of neurosurgical procedures when properly administered (Todd et al., 1993). The most frequently used technique during neurosurgery consists of an opioid (i.e., fentanyl, sufentanil, or remifentanil) along with inhaled nitrous oxide (70%) and low-dosage (0.2% to 0.5%) isoflurane. Routine administration of a preoperative benzodiazepine such as midazolam (0.5 mg/kg orally, or 0.1 mg/kg intravenously) should provide some degree of amnesia of perioperative events as well as minimize anxiety.

Chronic administration of anticonvulsant drugs, such as phenytoin and carbamazepine, induces rapid metabolism and clearance of neuromuscular blockers and opioids because of the enhanced activity of the hepatic P450 enzymes (Soriano and

Martyn, 2004). Patients receiving chronic anticonvulsant therapy require larger dosages of muscle relaxants and narcotics because of the induced enzymatic metabolism of these agents (see Fig. 22-6) (Soriano et al., 2001). Muscle relaxants should be withheld or permitted to wear off when assessment of motor function during neurosurgery is planned.

Fluid and Electrolyte Management

Meticulous fluid management is critical in the care of neurosurgical patients who are children. Diminutive size and immature renal function make fluid and electrolyte imbalances common. Water freely diffuses through the BBB and disruptions in tight junctions, and inequality of pressure gradients in osmolality, hydrostatic pressure, and colloid oncotic pressure facilitate the net movement of fluid across the BBB into the brain, resulting in increased ICP. Osmolar gradients are maintained only when the BBB is intact; when it is disrupted, large molecules that are typically excluded, such as albumin, enter the brain and can worsen edema.

There is no absolute formula for volume replacement in pediatric neuroanesthesia. Hemodynamic stability during intracranial surgery requires careful maintenance of intravascular volume, but preoperative fluid restriction or diuretic therapy may lead to blood pressure instability and even cardiovascular collapse if sudden blood loss occurs during surgery. Therefore, normovolemia should be maintained throughout the procedure. Estimation of the patient's blood volume is essential in determining the amount of allowable blood loss and when to transfuse blood. Blood volume depends on the age and size of the patient.

Normal saline is commonly used as the maintenance fluid during neurosurgery because it is mildly hyperosmolar (308 mOsm/kg) and should minimize cerebral edema. Isotonic crystalloid solutions are commonly used during anesthesia and for cerebral resuscitation. However, rapid infusion of large quantities of normal saline (>60 mL/kg) can be associated with hyperchloremic acidosis (Scheingraber et al., 1999). The calculated maintenance rate of fluid administration depends on the weight of the patient (Holliday and Segar, 1957). These rates are based on normal physiologic conditions. Increases in insensible losses, blood loss, or other conditions such as diabetes insipidus or the syndrome of inappropriate antidiuretic hormone excretion, as noted later, should be considered when determining the proper amount of fluid administration. Depending on the extent and length of the surgical procedure and the exposure of vascular beds, additional fluid administration (3 to 10 mL/kg per hour) may be necessary. Unlike adults, children can become hypovolemic from scalp injuries and isolated traumatic brain injury. Hypotonic crystalloids should be avoided, and the role of colloids is controversial. In 2007, the SAFE study reported that patients with TBI who received fluid resuscitation with albumin had higher mortality rates than those who received fluids with crystalloids (Myburgh et al., 2007). The use of hydroxyethyl starch is discouraged because of its role in exacerbating coagulopathy. Hypertonic saline (0.1 to 1.0 mL/kg) may be used to increase CPP, but, in this setting, well-conducted studies show that there is no advantage to hypertonic saline compared with conventional prehospital fluid protocols (Cooper et al., 2004), and the very large, randomized SAFE trial found that there was no difference in 28-day survival between albumin and

saline resuscitation for intensive care patients. However, in a subgroup of patients with TBI, fluid resuscitation with albumin was noted to have higher mortality rates than resuscitation with crystalloid (Myburgh et al., 2007).

Because the potential for significant blood loss is likely in most craniotomies in infants and children, the maximum allowable blood loss should be determined in advance to know when blood should be transfused to the patient. However, there are no guidelines regarding an appropriate threshold for transfusing blood, as it is unclear what hematocrit is needed for optimal oxygen delivery for the pediatric brain and in different disease states. Thus, the decision to transfuse should be dictated by the type of surgery, underlying medical condition of the patient, and potential for additional blood loss both intraoperatively and postoperatively. Hematocrits of 17% to 25% may warrant blood transfusion. Packed red blood cells (10 mL/kg) raise the hematocrit by 10%. Blood losses may be replaced with 3 mL of normal saline per 1 mL of loss blood, or a colloid solution such as 5% albumin equal to the volume of blood loss. It can be difficult to accurately estimate blood loss during intracranial procedures, as the anesthesiologist may have a compromised view of the surgical field, and blood loss may be hidden in the drapes or elsewhere.

Infants are at particular risk for perioperative hypoglycemia. Small premature neonates, with limited reserves of glycogen and limited gluconeogenesis, require continuous infusions of glucose at 5 to 6 mg/kg per minute to maintain serum levels. At the same time, the stress of critical illness and resulting insulin resistance can produce hyperglycemia that, in turn, is associated with neurologic injury (Jeremitsky et al., 2005; Van den Berghe et al., 2005) and poor outcomes in adults (Van den Berghe et al., 2001). However, it is unclear if tight glycemic control offers significant benefits to children (Branco and Tasker, 2007; Klein et al., 2007). Limited evidence now suggests that tight control may carry undue risk of hypoglycemia, and newer data are less supportive of very tight glycemic control (Van den Berghe et al., 2006). Retrospective studies from children suggest that both hyperglycemia (glucose level at 200 to 250 mg/100 mL) and hypoglycemia occur after TBI (Sharma et al., 2009), and that hyperglycemia is associated with poor outcome. Continuous intraoperative monitoring is not yet the standard of care. Hourly glucose checks are recommended.

Brain swelling can occur during neurosurgical procedures, with devastating consequences. Aggressive hyperventilation should be reserved for when herniation is impending and immediate life-saving maneuvers are required. However, a study in adults demonstrated that moderate hyperventilation may improve surgical conditions (Gelb et al., 2008). There is considerable evidence in patients with TBI that even mild hyperventilation leads to hypoperfusion (Coles et al., 2002). Although there are no data suggesting such a phenomenon in other neurosurgical patient populations, other methods of reducing intracranial pressure can be used. Elevation of the head above the heart and the use of hyperosmolar therapy (e.g., mannitol or hypertonic saline) are generally used initially.

Mannitol (0.25 to 0.5 g/kg) transiently alters cerebral hemodynamics and raises serum osmolality by 10 to 20 mOsm/kg (Soriano et al., 1996). However, repeated dosing can lead to extreme hyperosmolality, renal failure, and further brain edema. Hypertonic saline increases serum sodium, decreases ICP, and increases CPP titrated to a serum sodium rate change and brain edema (Khanna et al., 2000). Administration is typically 3 mL/kg

of 3% (hypertonic) saline targeted to a serum sodium rate change of 0.05 mEq/hr and serum sodium levels of 155 to 160 mEq/L. However, the endpoints depend on the initial serum sodium and the degree of brain edema (typically 155 to 160 mEq/L). Three percent normal saline is generally administered centrally to avoid phlebitis and tissue necrosis, but hypertonic saline concentrations of 2% may be administered peripherally. Theoretical risks include central pontine myelinolysis and renal failure. Furosemide is a useful adjunct to mannitol for decreasing acute cerebral edema and has been shown in vitro to prevent rebound swelling caused by mannitol (McManus and Soriano, 1998; Thenuwara et al., 2002).

Nonosmotic secretion of antidiuretic hormone (ADH) makes hyponatremia common after neurosurgery. Elevated ADH levels can result from a variety of stimuli, ranging from pain and nausea to fluid shifts and intravascular hypovolemia. Acute hyponatremia can provoke seizures and can be treated with hypertonic saline, fluid restriction, and diuretics (Porzio et al., 2000). The syndrome of cerebral salt wasting is also common in children and can be seen after head trauma and all manner of neurosurgical procedures. The syndrome has been diagnosed with increasing frequency and reported in association with meningitis (Celik et al., 2005), calvarial remodeling (Levine et al., 2001; Byeon and Yoo, 2005), tumor resection (Jimenez et al., 2006), and even hydrocephalus (Table 22-7). Although it is easily confused with other entities (Singh et al., 2002), a recent retrospective review put its incidence at 11.3 per 1000 procedures (Jimenez et al., 2006). In these patients, the mean duration of symptoms was 6 days, with a range of 1 to 5. Cerebral salt wasting, the result of excessively high atrial or brain natriuretic peptide levels (Berger et al., 2002), is marked by hyponatremia, hypovolemia, and excessive urinary excretion of sodium. Although the classic treatment involves saline administration, more rapid resolution has been achieved with fludrocortisone (Papadimitriou et al., 2007).

Diabetes insipidus is a well-known complication of surgical procedures involving or adjacent to the pituitary and hypothalamus. It is most frequently seen in association with craniopharyngioma, where it can be a manifesting symptom in 40% of cases (Ghirardello et al., 2006). Diabetes insipidus is recognized by a rising serum sodium (>145 mg/dL) accompanied by copious (>4 mL/kg per hour) output of dilute urine. Severe

TABLE 22-7. Comparison of Syndrome of Inappropriate Antidiuretic Hormone (SIADH), Cerebral Salt Wasting (CSW), and Diabetes Insipidus

	SIADH	CSW	Diabetes Insipidus
CVP	High (>5)	Low (<5)	Low
UOP	Decreased	Increased	Increased
Urine sodium	High (>20 mmol/L)	High (>20 mmol/L)	< 20 mmol/L
Urine osmolality	High	Low or normal	Low
Serum osmolality	Low	Low or normal	High
ADH	High	Normal	—

ADH, Antidiuretic hormone; CVP, central venous pressure; UOP, urinary osmotic pressure.

dehydration and hypovolemia may develop. One effective protocol employs maximal antidiuresis with IV vasopressin and strict limitation of IV fluids (Wise-Faberowski et al., 2004). This strategy avoids the pitfalls of titrating drug to urine output and recognizes that renal blood flow remains normal in the normovolemic, but maximally antidiuresed, child. Because urine output can be minimal (0.5 mL/kg per minute), other clinical markers of volume status must be used.

MONITORING

Patients undergoing major craniotomies are at risk of sudden hemodynamic instability resulting from hemorrhage, venous air emboli, herniation syndromes, or manipulation of cranial nerves. The potential massive blood loss warrants placement of an arterial cannula for continuous invasive blood pressure monitoring as well as for sampling serial blood gases, electrolytes, glucose levels, and hematocrit. The usefulness of central venous catheterization remains controversial. Cannulation of the jugular or subclavian veins with multiorificed catheters in adults is often preferred, particularly when VAE is anticipated. However, these catheters are too large for infants and most small children. In infants, even when VAE occurred, a central venous catheter was frequently not successful for aspirating air, presumably because of the high resistance of the small-gauge catheters used in these patients (Cucchiara and Bowers, 1982). Therefore, the risks of a central venous catheter may outweigh its benefits.

Venous Air Embolus

Venous air embolus can occur during craniotomies in infants and children, primarily because the head of a small child is large in relation to the rest of the body, and it rests above the heart in either the prone or the supine position. Venous sinuses have dural attachments that impede their ability to collapse. Other conduits for VAE include bone, bridging veins, and spinal epidural veins. When air enters the central circulation, right ventricular output is impeded, leading to pulmonary edema and bronchoconstriction and cor pulmonale, cardiovascular collapse, and death in the most severe cases. Air may gain access to the systemic circulation through right-to-left intracardiac shunts. Potential cardiac shunts exist in many healthy infants and children and may become clinically significant if pulmonary hypertension develops acutely after a large air embolism. Paradoxical air emboli may cause cerebral or coronary artery obstruction, with subsequent cerebral infarction or ventricular fibrillation. Although the incidence of VAE is greatest in the sitting position, it has been reported in the lateral, supine, and prone positions. The incidence of VAE in children undergoing suboccipital craniotomy in the sitting position is not significantly different from that in adults, but children appear to have a higher incidence of hypotension and a lower likelihood of successful aspiration of central (intravascular) air (Cucchiara and Bowers, 1982).

Venous air emboli pose a risk during craniotomies in infants and children, primarily because the head of a small child is large in relation to the rest of body and rests above the heart in both the prone and supine positions (Harris et al., 1987; Faberowski et al., 2000). Standard neurosurgical techniques may elevate

the patient's head even further by elevating the head of the table to improve cerebral venous drainage, which can increase the risk for air entrainment into the venous system through open venous channels in bone and sinuses (Grady et al., 1986). Patients with cardiac defects with potential for right-to-left shunting, such as patent foramen ovale or a patent ductus arteriosus, are at high risk for paradoxical air emboli leading to cerebral or myocardial infarction.

Prompt recognition of VAE is crucial to successful management (Fig. 22-10). Precordial Doppler ultrasonography has been demonstrated to be the earliest and most sensitive indicator of intracranial air. It enables diagnosis before the pathologic consequences occur. The Doppler probe is best positioned on the anterior chest, usually just over or to the right of the sternum at the fourth intercostal space (i.e., the nipple line). An alternative site between the scapulae on the posterior thorax can be used in infants in the prone position weighing approximately 6 kg or less (Soriano et al., 1994). Doppler positioning can be confirmed by listening for the characteristic change in sounds after rapid administration of a few milliliters of saline into a central or peripheral venous catheter. When VAE occurs, there is reflex pulmonary vasoconstriction and ventilation/perfusion mismatch caused by the air blocking passage of blood. This reflex results in increased dead-space ventilation and causes a sudden decrease in end-tidal CO_2 concentration. Monitoring the end-tidal CO_2 concentration is very useful in making the diagnosis and can be used to monitor the severity and duration of air emboli. An increase in end-tidal nitrogen concentration during continuous monitoring is a specific sign of air emboli, but it is usually of such small magnitude that it is difficult to detect with devices currently available in clinical practice. Increases in right atrial and pulmonary artery pressures correlate with the size of emboli, but these delayed findings alone should not be relied on for monitoring and diagnosis. Echocardiography (trans-thoracic or transesophageal) may be the most specific method for detecting small air emboli but is not easily used intraoperatively, especially in small infants and children. In addition to the

FIGURE 22-10. The relative sensitivities of various monitoring techniques to the occurrence of venous air embolism (VAE). BP, Blood pressure; CO, cardiac output; CVP, central venous pressure; ECG, electrocardiogram; ET-CO₂, end-tidal CO₂; PAP, pulmonary arterial pressure; physiologic, physiologic; T-echo, transesophageal echo. characteristic changes in Doppler sounds, sudden decreases in end-tidal CO₂, dysrhythmias, and ischemic changes in the electrocardiogram can occur with VAE.

Aspiration of air from a central venous catheter is rarely successful unless massive amounts have been entrained. If small venous air emboli are detected by other devices (e.g., Doppler, end-tidal CO₂), the value of central venous catheter aspiration for air is quite limited. As soon as a change in Doppler sounds is noted during surgery (and not believed to be caused by administration of IV medications), the surgeon should be informed and nitrous oxide and inhalation agents discontinued. Attempts should immediately be made to identify and occlude the site of air entry, either by flooding the operative field with saline when appropriate (such as during a posterior fossa craniotomy) or by applying bone wax to bone edges. The head of the table can be lowered if necessary, which will have the effect of increasing cerebral venous pressure and stopping entrainment of air as well as augmenting the patient's peripheral venous return and increasing systemic blood pressure. Jugular veins can be compressed manually, although great care must be taken to avoid simultaneous compression of the carotid arteries. Attempts can be made to aspirate air through a central venous catheter if one is in place. The application of positive end-expiratory pressure increases central venous pressure but also decreases cardiac filling pressure, cardiac output, and blood pressure; extreme increases in positive end-expiratory pressure are usually unwarranted. One must be prepared to provide vasopressor support and fluid resuscitation.

Once the patient has been stabilized, the procedure is resumed and a revised anesthesia plan is instituted. The decision to administer nitrous oxide after successful treatment of VAE is controversial. If reinstitution of nitrous oxide is associated with another decrease in end-tidal CO₂ concentration or clinical deterioration, then residual air bubbles are probably present and nitrous oxide should be discontinued. If no changes occur, many clinicians reinstitute nitrous oxide unless repeated episodes of VAE occur. Hemodynamic support may be necessary to avoid hypotension, maintain adequate cerebral perfusion pressure, and minimize ischemic injury. Therefore, dopamine and epinephrine are effective in supporting systemic pressure and restoring cerebral blood flow, even in very low birth weight infants (Munro et al., 2004).

Neurophysiologic Monitoring

Recent advances in neurophysiologic monitoring have enhanced the ability to safely perform neurosurgical procedures in functional areas of the brain and spinal cord. However, the neurodepressant effects of many commonly used anesthetic agents limit the usefulness of these monitors. In general, electrocorticography (ECoG) and EEG can be used with low levels of volatile anesthetics. Somatosensory evoked potentials used during spinal and brainstem surgery can also be depressed by high levels of volatile agents and, to a lesser extent, nitrous oxide. An anesthetic technique using high-dosage opioids and minimal inhaled agents (<1 MAC) is the most appropriate type of monitoring. Alternatively, total IV anesthesia (TIVA) techniques can be used. Spinal cord and peripheral nerve surgery may require electromyography (EMG) and detection of muscle movement as an endpoint.

TABLE 22-8. Effect of Surgical Brainstem Manipulation

Brainstem Area	Signs	Changes in Monitor
CN V	Hypertension, bradycardia	Arterial pressure, ECG
CN VII	Facial muscle movement	EMG
CN X	Hypotension, bradycardia	Arterial pressure, ECG
Pons, medulla	Arrhythmias, hypotension or hypertension, tachycardia or bradycardia, irregular breathing pattern	ECG, arterial pressure, end-tidal CO ₂ monitor

CN, Cranial nerve; ECG, electrocardiogram; EMG, electromyogram.

Therefore, muscle relaxation should be avoided or discontinued after tracheal intubation to facilitate monitoring. Table 22-2 lists common anesthetics and their effects on various neurophysiologic monitors. Motor evoked potential (MEP) can be used to monitor the integrity of the motor tracts of the spinal cord by stimulating the motor cortex and detecting the action potentials in the corresponding muscle groups (Table 22-8). Volatile anesthetic agents, including nitrous oxide, have a dosage-dependent depressant effect on the MEP. IV anesthetics (propofol, opioids, ketamine, and dexmedetomidine) preserve the MEP.

Monitors of Cerebral Oxygenation

The primary cause of cerebral ischemia in infants and children is cerebral hypoperfusion secondary to systemic arterial hypotension or sustained intracranial hypertension. The four major intraoperative modalities for monitoring cerebral ischemia are EEG, TCD, cerebral oximetry, and jugular bulb catheters.

Electroencephalography

The EEG is the most commonly used monitor for cerebral ischemia and has been intensively investigated during anesthesia. Electroencephalographic waveforms are the summation of excitatory and inhibitory postsynaptic potentials from the superficial layers of the cerebral cortex. Both regional and global ischemias result in profound depression of EEG activity, characterized by an attenuation of high-frequency activity and the appearance of slow waves in the corresponding area (Fig. 22-11). This feature makes the EEG the most reliable intraoperative monitor for focal cerebral ischemia. Direct analysis of the raw EEG by an electrophysiologist is the gold standard for monitoring cerebral ischemia. Conditions in which cerebral perfusion may be compromised can be monitored with scalp EEG electrodes or direct ECoG with subdural strip electrodes. Cerebrovascular disease is rare in infants and children, but two conditions in which EEG monitoring may be beneficial are temporary clipping of cerebral aneurysms and moyamoya disease. Cerebral aneurysm clipping can result in ischemia in the cerebral regions supplied by adjacent arteries. Direct ECoG in the region at risk can detect cerebral ischemic during test occlusion of the aneurysm and can serve as a guide for proper positioning of the aneurysm clip and institution of pharmacologic interventions to improve cerebral perfusion.

■ **FIGURE 22-11.** Slowing on the electroencephalogram (EEG). An intraoperative EEG of a child with impaired perfusion of the left hemisphere reveals characteristic waves with slow frequencies and high amplitudes (arrows) in the left-side leads.

Jugular Bulb Catheters

Jugular bulb catheters may also be inserted retrograde into the internal jugular using angiocatheters for intermittent sampling, or fiberoptic catheters for continuous readings, and are a useful tool for determining cerebral oxygenation via jugular venous oxygen saturation ($SjvO_2$). Normal $SjvO_2$ ranges from 50% to 75%; values at either extreme reflect global ischemia or hyperemia. $SjvO_2$ monitoring can provide early diagnosis of global ischemia and is useful to guide decisions for optimizing hyperventilation therapy, perfusion pressure, fluid management, and oxygenation in head injury patients (Chan et al., 1992; Skippen et al., 1997). Matta and coworkers (1994) have demonstrated in adults that $SjvO_2$ monitoring detects critical intraoperative cerebral desaturation that would otherwise have been untreated, and Moss and coworkers (1995) have used $SjvO_2$ monitoring to determine the minimum blood pressure that should be maintained to avoid hypoperfusion during aneurysm surgery.

Transcranial Doppler

Transcranial Doppler ultrasonography measures cerebral blood flow velocity primarily from the first segment of the middle cerebral artery, and it uses fast Fourier and waveform analysis to provide relative values to flow and resistance. It has been used to detect decreases in CBFV during internal carotid occlusion and carotid endarterectomy, and to monitor for cerebral

emboli during cardiopulmonary bypass and neurosurgery. Changes in cerebral hemodynamics caused by pharmacologic interventions can also be measured with the TCD. The major limitation of TCD is stabilization of the Doppler probe over the temporal bone and its inability to provide absolute values of CBF. Nevertheless, changes in systolic and diastolic velocities measured by TCD provide valuable indices and trends in cerebral perfusion and cerebral vascular resistance. Cycles of flow velocities measured in the brain correspond to the phases of the cardiac cycle (systole and diastole) and reflect changes in heart rate. For example, the number of pulses measured reflects the heart rate, and a decrease in diastolic CBFV may indicate altered cerebral vasoreactivity and excessive runoff or steal of CBF. Attention to cerebral venous drainage, pH, and arterial partial pressure of CO_2 , mechanical ventilation, and hematocrit levels may be necessary in this circumstance. TCD ultrasonography estimates CBF assuming that changes in CBF changes are proportional to changes in CBFV, and mean flow velocities are used to represent mean CBF. Systolic and diastolic flow velocity parameters are often used to examine resistance of the cerebral vessels and also brain death.

Cerebral Oximetry

Near-infrared spectroscopy (NIRS) provides a noninvasive assessment of cerebral intravascular oxyhemoglobin and deoxyhemoglobin (oxyhemoglobin and deoxyhemoglobin) and mitochondrial cytochrome oxygenation by measuring the

abilities of these two chromophores to absorb near-infrared light. Quantitative measurement of changes in cerebral chromophore oxygen (O_2) concentration is related to the overall optical attenuation of near-infrared light, and it has been used to assess O_2 delivery and extraction, cerebral blood volume, CBF (by an indicator dye technique), and the redox state of the brain. NIRS correlated with mean arterial pressure and is effective in identifying premature infants with impaired cerebrovascular autoregulation (Tsuji et al., 2000). The equipment used in these studies is primarily a research prototype and is not commercially produced. Therefore, this technique has yet to find a niche in routine intraoperative monitoring. Regional cerebral oximetry (rSo_2) (INVOS, Somanetics Corporation, Troy, MI) is a simpler NIRS modality that measures relative changes in oxygen extraction in the total blood volume of a small brain area. This technique uses two wavelengths to determine oxyhemoglobin and total cerebral hemoglobin concentrations. Because approximately 75% of the blood volume in the brain is venous, the cerebral oximeter measurement reflects venous oxyhemoglobin saturation and has been reported to correlate with jugular bulb saturation.

Nerve Root Monitoring

Neurosurgical procedures for tethered spinal cord syndrome and spasticity often use EMG monitoring to aid in identification and dissection of the nerve roots. The tethered spinal cord syndrome from spinal dysraphism is associated with conditions such as myelomeningocele, lipoma of the filum terminalis, spina bifida occulta, and adhesions from prior spinal surgery. Identification of functional nerve roots may be difficult and can result in an inadvertent injury during the surgical dissection. EMG monitoring can be helpful for identifying functional nerve roots. Placement of the EMG electrodes in the external anal and urethral (in females) sphincter allows continuous monitoring of the nerve roots supplying the pudendal nerves (S2 to S4). Movement and evoked action potentials of the anterior tibialis and sural muscles can also be detected both visually and by EMG, respectively. Muscle contractions can be readily observed by using clear sterile plastic drapes. Inserting a balloon manometer into the bladder and recording changes in pressure during stimulation can assess detrusor muscle function. Muscle relaxation must be discontinued before stimulation to accurately detect motor activity. The patient should be deeply anesthetized, because direct nerve root stimulation often elicits a significant sympathetic response and pain.

A specific modality for monitoring spinal cord reflexes is the Hoffman reflex (HR), which is a measure of motor neuron excitability and is significantly increased in children with spastic diplegia. This response can be evoked by directly stimulating the nerve root and recording the direct efferent muscle response and the HR (Fig. 22-12). The HR represents the reflex potential emanating from the motor neurons of the spinal cord (Logigian et al., 1994). An abnormal reflex would have an exaggerated HR amplitude. Inhalational agents, nitrous oxide, barbiturates, and benzodiazepines all depress the HR (Soriano et al., 1995). An opioid-based anesthetic with intermittent doses of ketamine or propofol does not appear to suppress the HR. Because the EMG is the observed endpoint of HR, muscle relaxation should be avoided.

■ **FIGURE 22-12.** The Hoffman reflex (HR). The initial biphasic wave represents the muscle response (MR) and is followed by the HR.

SPECIFIC PEDIATRIC NEUROSURGICAL CONDITIONS

Congenital anomalies of the CNS generally occur as midline defects. This dysraphism may occur anywhere along the neural axis involving the head (encephalocele) or spine (meningomyelocele). The defect may be relatively minor and affect only superficial bony and membranous structures, or it may include a large segment of malformed neural tissue.

Encephaloceles

Encephaloceles are neural tube defects that are protrusions of brain and CSF arising from the occiput to the frontal area (Fig. 22-13). They can even look like nasal polyps if they protrude through the cribriform plate. Large defects may present challenges to endotracheal intubation. Much blood loss can occur,

■ **FIGURE 22-13.** A newborn infant with an occipital encephalocele. Neurologic function was intact. The anesthesiologist's primary challenge is to control and intubate the airway in the lateral position to avoid traumatizing the lesion.

especially if venous sinuses are entered. Adequate IV access should be ensured, and blood products should be available.

Myelodysplasia

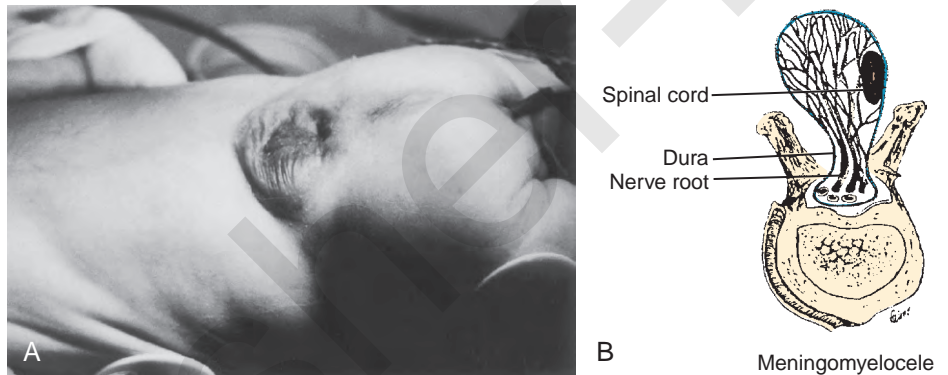

Defects in the spine are known as spina bifida. If a bulge containing CSF without spinal tissue exists, it is called a meningocele. When neural tissue is also present in the lesion, the defect is called a meningomyelocele. Open neural tissue is known as rachischisis. Hydrocephalus is usually present when paralysis occurs below the lesion and is usually associated with an Arnold-Chiari malformation (see later) (Figs. 22-14 and 22-15).

Most patients with a meningocele present for primary closure within the first day or two of life to minimize the risk of infection. Many are now scheduled electively before birth for repair, because the defect is usually apparent on prenatal ultrasonography. Many neurosurgeons prefer to insert a ventriculoperitoneal shunt at the time of initial surgery. Alternatively, a shunt may be inserted a few days later or even occasionally deferred if there is no evidence of hydrocephalus at birth. A major anesthetic consideration is positioning the neonate for induction at surgery. In most cases, tracheal intubation can be performed with the infant in the supine position and the

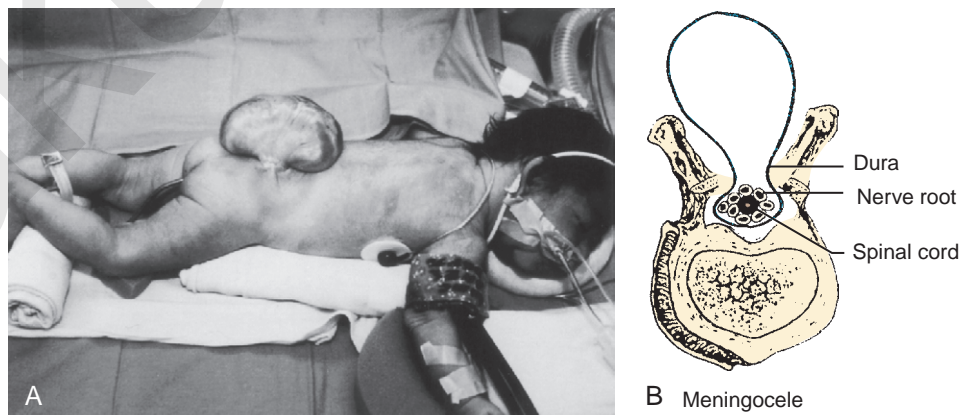

uninvolved portion of the patient's back supported with towels (or a "donut" ring), so that there is no direct pressure on the meningocele. For very large defects, it is occasionally necessary to place the infant in the lateral position for induction and intubation. Succinylcholine is rarely necessary in these situations, yet it does not appear to cause problems with hyperkalemia because the defect develops early in gestation (Dierdorf et al., 1986).

Airway management, mask fit, and intubation may be difficult for infants with massive hydrocephalus or very large defects. Blood loss may be considerable during repair of a meningocele when large amounts of skin are to be undermined to cover the defect.

Patients with myelodysplasia are at high risk of developing allergic reactions to latex (Holzman, 1997). This is probably a result of repeated exposures to latex products encountered during surgery, including nonneurosurgical procedures required to correct coexisting orthopedic and urologic problems, or repeated bladder catheterizations. Patients who develop latex allergy appear to have an increased incidence of allergic reactions to other substances, including some antibiotics and foods, so anaphylaxis should always be anticipated in these situations. Postoperatively, respiratory status should be carefully assessed. Pulse oximetry is valuable during recovery from anesthesia

■ **FIGURE 22-14.** **A**, Newborn infant with a lumbosacral meningomyelocele. Note the partial epithelialization of the neural tissue, which is exposed to air centrally. ■ **FIGURE 22-15.** **A**, Newborn infant with a lumbar meningocele. No neural elements were in the sac, and neurologic function was normal distal to the lesion. **B**, Schematic of meningocele. (**B**, From Carter S, Gold AP: *Nervous system*. In Rudolph AM, Barnett HL, Einhorn AH, editors: *Pediatrics*, ed 16, Norwalk, Conn, 1977, Appleton-Century-Crofts. Copyright 1977, McGraw-Hill.)

because of difficulty with breathing after a tight closure, and because ventilatory responses to hypoxia are often diminished or absent in these patients when a Chiari malformation coexists (Waters et al., 1998).

Spinal dysraphism is the primary indication for laminectomies in pediatric patients. Patients with myelomeningocele suffer from multisystem diseases that result from a severe injury to the developing CNS early in gestation. The systems involved can include the musculoskeletal system, genitourinary system, and immune system in addition to the CNS. These patients suffer frequent exposures to latex products and are at high risk for developing a hypersensitivity to latex. All these patients should be treated with a latex alert, and a true anaphylaxis to latex must be considered when appropriate. Latex allergy can manifest itself by a severe anaphylactic reaction heralded by hypotension and wheezing with or without a rash and should be rapidly treated by removal of the source of latex and administration of IV fluid and vasopressors (Holzman, 1997). Insertion of an epidural catheter by the surgeon under direct vision can provide a conduit for the administration of local anesthetics and opioids for the management of postoperative pain.

Other spinal anomalies (lipomeningoceles, lipomyelomeningoceles, diastematomyelias, and dermoid tracts) may manifest themselves as tethered cords. Children who have had a meningocele repaired after birth may also develop an ascending neurologic deficit from a tethered spinal cord as growth occurs.

The tethered spinal cord syndrome from spinal dysraphism is associated with conditions such as myelomeningocele, lipoma of the filum terminalis, spina bifida occulta, and adhesions from prior spinal surgery. Persistence of this anatomic anomaly can lead to cord or nerve root distortion and impaired perfusion of the spinal cord, resulting in progressive neurologic deficits and chronic pain. Early detection of a tethered cord is now more common with MRI. Visualization and identification of functional nerve roots may be difficult and may result in an inadvertent injury during the surgical dissection. This can lead to fecal and urinary incontinence and exacerbation of lower extremity neurologic dysfunction. EMG monitoring can be helpful for identifying functional nerve roots, as described earlier.

Severe spasticity associated with cerebral palsy can be surgically alleviated by a selective dorsal rhizotomy, which reduces

spasticity by surgically dividing dorsal rootlets to diminish the afferent input to motor neurons in the spinal cord, thus decreasing the hyperactive active reflexes associated with spastic diplegia. Pathologic rootlets are identified by direct stimulation and noting the corresponding muscle action potential with EMG. Exaggerated action potentials can be elicited in innervated as well as other distal muscle groups. These abnormal rootlets are partially sectioned to decrease afferent nerve conduction. However, these rootlets may contain sensory and proprioceptive fibers. Spinal cord reflexes can be quantified by measuring the HR (as noted earlier). The postoperative care of these patients is completed by severe somatic incisional pain, dysesthesia, and hyperesthesia of the affected limb and muscle spasms. A variety of postoperative pain management techniques have been advocated in these patients. These include IV morphine, midazolam/diazepam infusions, and epidural opioids (Geiduschek et al., 1997).

Chiari Malformations

Chiari malformations are generally anatomic abnormalities of the posterior fossa leading to cephalad displacement of the cerebellar vermis through the foramen magnum. There are four types of Chiari malformations (Fig. 22-16 and Box 22-1). Type I occurs in healthy children without myelodysplasia. These patients, most of them adolescents, generally have much milder symptoms, sometimes presenting with only headache or neck pain. The Arnold-Chiari malformation (type II) almost always coexists in children with myelodysplasia. This defect consists of a bony abnormality in the posterior fossa and upper cervical spine with caudal displacement of the cerebellar vermis and lower brainstem below the plane of the foramen magnum. Medullary cervical cord compression can occur. Vocal cord paralysis with stridor and respiratory distress, apnea, abnormal swallowing and pulmonary aspiration, opisthotonos, and cranial nerve deficits may be associated with the Arnold-Chiari malformation and usually appear during infancy. Patients of any age may have abnormal responses to hypoxia and hypercarbia because of cranial nerve and brainstem dysfunction (Ward et al., 1986). Extreme head flexion may cause brainstem compression in otherwise asymptomatic patients. Type III Chiari malformations are associated with encephaloceles and have the

■ **FIGURE 22-16.** Sagittal and coronal MR images of Chiari type I malformation. Note descent of cerebellar tonsils (T) below the level of the foramen magnum (white line) to the level of the posterior arch (*).

Box 22-1 Chiari Malformations**CHIARI TYPE I**

- Tonsillar herniation > 5 mm below the plane of the foramen magnum
- No associated brainstem herniation or supratentorial anomalies
- Low frequency of hydrocephalus

CHIARI TYPE II

- Caudal herniation of the vermis, brainstem, and fourth ventricle
- Associated with myelomeningocele and multiple brain anomalies
- High frequency of hydrocephalus and syringohydromyelia

CHIARI TYPE III

- Occipital encephalocele containing dysmorphic cerebellar and brainstem tissue

CHIARI TYPE IV

- Hypoplasia or aplasia of the cerebellum

most severe symptoms and long-term disability. Type IV is associated with absent cerebellum, and large posterior fossa CSF spaces.

Tumors

Brain tumors are the most common solid tumors in children, which are exceeded only by the leukemias as the most common pediatric malignancy (Pollack, 1994). Supratentorial tumors account for about 25% to 40% of brain tumors in children. Supratentorial resection usually requires invasive monitoring and techniques to control elevated ICP (Fig. 22-17). The majority of brain tumors in children are infratentorial, in the posterior fossa. These include medulloblastomas, cerebellar astrocytomas, brainstem gliomas, and ependymomas of the fourth ventricle (Fig. 22-18). Because posterior fossa tumors usually obstruct CSF flow, increased ICP occurs early. Presenting signs and symptoms include early morning vomiting and irritability or lethargy. Cranial nerve palsies and ataxia are also common findings, with respiratory and cardiac irregularities usually

FIGURE 22-17. MR image of supratentorial tumor. High-grade gliomas are generally less well circumscribed, with irregular enhancement.

occurring late. Sedation or general anesthesia may be required for radiologic evaluation or radiation therapy.

Surgical resection of a posterior fossa tumor presents a number of anesthetic challenges. Children are usually positioned prone, although the lateral or sitting positions are used by some neurosurgeons. In any case, the head will be flexed, and the position and patency of the endotracheal tube must be meticulously ensured. A nasotracheal tube is preferred when the patient is prone, as it is easier to secure and less likely to be dislodged. Proper positioning of the endotracheal tube is initially done by confirmation of clear bilateral breath sounds with the head flexed as much as possible while the patient is still supine after intubation is performed. Care should be taken to ensure that all other nasal and oral tubes (e.g., gastric, esophageal) do not cause pressure on the nares or lips, which can lead to edema or erosion after lengthy procedures.

Arrhythmias and acute blood pressure changes may occur during surgical exploration, especially when the brainstem is manipulated, so careful observation of the electrocardiogram

FIGURE 22-18. MR image of infratentorial tumors. **A**, Brainstem glioma. **B**, Ependymoma displacing the pons and medulla.

and arterial waveform tracing is important. Altered respiratory control is generally masked by muscle relaxants and mechanical ventilation. Intracranial compliance is presumed to decrease even when ICP is only marginally elevated, thus precautions to minimize increases in ICP should be taken. If ICP is markedly elevated or acutely worsens, a ventricular catheter may be inserted by the neurosurgeon prior to tumor resection to permit emergent drainage of CSF. Fixation pins used in small children can cause skull fractures, dural tears, and intracranial hematomas. Elevation of the bone flap can result in sinus tears, massive blood loss, or VAE. Surgical resection of tumors in the posterior fossa can also lead to brainstem and cranial nerve damage. Table 22-8 lists some of the signs of encroachment on these structures. VAE is a potentially serious complication that is not eliminated by the use of the prone or lateral position because head-up gradients of 10 to 20 degrees are frequently used to improve cerebral venous drainage. In infants and toddlers, large head size relative to body size accentuates this problem. Damage to the respiratory centers and cranial nerves can lead to apnea and airway obstruction after extubation of the patient's trachea.

Tumors in the midbrain include craniopharyngiomas, optic gliomas, pituitary adenomas, and hypothalamic tumors and account for approximately 15% of intracranial tumors (Fig. 22-19). Hypothalamic tumors (hamartomas, gliomas, and teratomas) frequently appear with precocious puberty in children who are large for their chronological age. Craniopharyngiomas are the most common perisellar tumors in children and adolescents and may be associated with hypothalamic and pituitary dysfunction. Symptoms often include growth failure, visual impairment, and endocrine abnormalities. Signs and symptoms of hypothyroidism should be sought and thyroid function tests measured. Steroid replacement (dexamethasone or hydrocortisone) is generally administered because the integrity of the hypothalamic-pituitary-adrenal axis may be uncertain. In addition, diabetes insipidus occurs preoperatively in some patients and is a common postoperative problem. A careful history usually reveals this condition preoperatively, especially if attention is focused on nocturnal drinking and enuresis. Evaluation of serum electrolytes and osmolality, urine-specific gravity, and urine output is helpful, because hypernatremia and

hyperosmolality, along with dilute urine, are typical findings. If diabetes insipidus does not exist preoperatively, it usually does not develop until the postoperative period. This occurs because the reserve of antidiuretic hormone in the posterior pituitary gland is enough to allow functioning for many hours even when the hypothalamic-pituitary stalk is damaged intraoperatively. Postoperative diabetes insipidus is marked by a sudden large increase in dilute urine output associated with a rising serum sodium concentration and osmolality. Treatment can initially be with dilute crystalloid solutions to replace the urine output, with careful attention to electrolyte measurements. However, urine output is usually so prodigious (up to 1 L/hr in an adult) that an infusion of aqueous vasopressin (1 to 10 mU/kg per hour) is best used, with fluid input then carefully restricted to match urine replacement and estimates of insensible losses. If diabetes insipidus persists, intranasal desmopressin can be used to replace IV pitressin, because desmopressin generally needs to be administered only twice daily. Return of antidiuretic hormone activity a few days postoperatively may cause a marked decrease in urinary output, water intoxication, seizures, and cerebral edema if desmopressin is not discontinued and fluid administration not adjusted appropriately.

Transsphenoidal surgery is generally performed only in adolescents and older children with pituitary adenomas. However, this procedure should be treated like other midbrain tumors in terms of monitoring and vascular access. Patients are usually intubated orally to give the surgeon optimal access to the nasopharynx, and preparations for an emergent craniotomy should be anticipated in case unexpected massive bleeding develops. Because nasal packs are inserted at the end of surgery, patients should be fully awake prior to tracheal extubation.

Approximately 25% of intracranial tumors in children involve the cerebral hemispheres. These are primarily astrocytomas, oligodendrogliomas, ependymomas, and glioblastomas. Neurologic symptoms are more likely to include a seizure disorder or focal deficits. Succinylcholine should be avoided if motor weakness is present, as it can cause sudden massive hyperkalemia. Nondepolarizing muscle relaxants and narcotics may be metabolized more rapidly than usual in patients receiving chronic anticonvulsants. Choroid plexus papillomas are rare but occur most often in children younger than 3 years. They usually arise from the choroid plexus of the lateral ventricle and produce early hydrocephalus as a result of increased production of CSF and obstruction of CSF flow. Hydrocephalus usually resolves with surgical resection. When lesions lie near the motor or sensory strip, a special type of somatosensory evoked potential monitoring called *phase reversal* may also be used to delineate these important eloquent locations (Hatipoğlu et al., 2009). If cortical stimulation is planned to help identify motor areas, muscle relaxants must be permitted to wear off. Nitrous oxide and narcotics are usually sufficient to prevent patient movement during these periods.

■ **FIGURE 22-19.** MR image of craniopharyngiomas, demonstrating both cystic and solid components.

Hydrocephalus

Hydrocephalus, the most common pediatric neurosurgical condition, involves a mismatch of CSF production and absorption, leading to increased intracranial CSF volume (Fig. 22-20). The majority of cases of hydrocephalus result from obstruction of CSF flow or inability to absorb CSF appropriately. Hemorrhage

■ **FIGURE 22-20.** Infantile hydrocephalus. CT scan demonstrates a dilated ventricular system and thinning of the cortical mantle. (Courtesy Division of Neuroradiology, University Health Center of Pittsburgh.)

(neonatal intraventricular or subarachnoid), congenital problems (aqueductal stenosis), trauma, infection, or tumors (especially in the posterior fossa) can cause hydrocephalus. Hydrocephalus is classified as nonobstructive/communicating or obstructive/noncommunicating based on the ability of CSF to flow around the spinal cord in its usual manner. Unless the etiology of the hydrocephalus can be definitively treated, treatment entails surgical placement of a ventricular drain or ventriculoperitoneal shunt.

Intracranial hypertension or a decrease in intracranial compliance almost always accompanies untreated hydrocephalus in children. How much intracranial compliance exists and how acutely hydrocephalus develops are both instrumental in how severe the signs and symptoms of hydrocephalus will be. In the young infant, if hydrocephalus develops slowly, the skull will insidiously expand and the cerebral vault will expand. However, in older children, the cranial bones are fused or the cranium cannot expand fast enough, and signs of impending herniation rapidly become apparent. The patient may become progressively more lethargic and develop vomiting, cranial nerve dysfunction, bradycardia, and ultimately death.

The approach to patients with symptomatic hydrocephalus should be directed at controlling ICP and rapidly relieving the obstruction. These patients may be vomiting and at risk for pulmonary aspiration. A rapid-sequence induction of anesthesia with thiopental or propofol followed by a succinylcholine or rocuronium is indicated in these situations. Hyperventilation should be instituted as soon as the trachea is intubated.

Unless the etiology of the hydrocephalus can be definitively treated, treatment entails surgical placement of a ventricular shunt. Most shunts transport CSF from the lateral ventricles to the peritoneal cavity (ventriculoperitoneal shunts). Occasionally the distal end of the shunt must be placed in the right atrium or pleural cavity, usually because of problems with the ability of

the peritoneal cavity to absorb CSF, as in peritonitis. VAE may occur during placement of the distal end of a ventriculoatrial shunt.

Endoscopic third ventriculostomy by way of a percutaneous flexible neuroendoscope is an alternative to extracranial shunt placement (Goumnerova and Frim, 1997). During these procedures, a ventriculostomy may be made to bypass an obstruction (such as aqueductal stenosis) by forming a communicating hole from one area of CSF flow to another using a blunt probe inserted through the neuroendoscope (Fig. 22-21). Common locations for a ventriculostomy are through the septum pellucidum (so the lateral ventricles can communicate) or through the floor of the third ventricle into the adjacent CSF cisterns. Complications such as damage to the basilar artery or its branches or neural injuries can be life threatening, and the anesthesiologist should be prepared for an emergency craniotomy during these procedures. Bradycardia and other arrhythmias have also been reported in conjunction with irrigation fluids and manipulation of the floor of the third ventricle (El-Dawlatly et al., 2000).

There are a few special situations involving shunts that anesthesiologists should be familiar with. For example, children who develop a shunt infection usually have their entire shunt system removed and external ventricular drainage established. They return to the operating room for placement of a new system several days later after their infection has been treated with antibiotics. While an external drain is in place, care must be taken not to dislodge the ventricular tubing. In addition, to avoid sudden changes in ICP, the height of the drainage bag should not be changed in relationship to the patient's head. For example, suddenly lowering an open drainage bag can siphon CSF rapidly from the patient, resulting in collapse of the ventricles and rupture of cortical veins. When transporting patients with CSF drainage, or when moving them from a stretcher to an operating room table, it is best to close off the ventriculostomy tubing during these brief periods.

Slit ventricle syndrome develops in approximately 5% to 10% of patients with CSF shunts and is associated with overdrainage of CSF and small, slitlike lateral ventricular spaces. Patients with this condition do not have the usual amount of intracranial CSF to compensate for alterations in brain or intracranial blood volume. Administration of excess or hypotonic IV solutions should be avoided to minimize brain swelling, because postoperative cerebral herniation has been reported after uneventful surgical procedures in these children (Eldredge et al., 1997).

Postoperatively, the patient's mental status should be monitored because of the possibility of the reobstruction of the shunt, leading to life-threatening hydrocephalus.

Craniosynostosis

Craniosynostosis is a congenital anomaly in which one or more cranial sutures close prematurely. It occurs in approximately one of every 2000 births, with males affected more frequently than females. It can involve one suture, or it may be very complex and be associated with a variety of syndromes. If left uncorrected, the deformed cranium can result in increased ICP and compression of the brain, with potential neurologic consequences (Inagaki et al., 2007). Surgical correction is usually performed within the first months of life to achieve the best cosmetic results, because brain growth is very rapid during

FIGURE 22-21. infancy, “pushing” the skull into a normal shape. Repair of craniosynostosis may involve removal of one small strip of bone from the skull, or it may entail a complete reconstruction of the calvarium (see Chapter 25, Anesthesia for Plastic Surgery).

Although these operations are extradural procedures, significant blood loss from the scalp and cranium make them challenging. It is essential that adequate venous access for rapid blood administration be secured, especially if multiple sutures are involved. Antifibrinolytic drugs (tranexamic acid) may have some usefulness in these procedures. The incidence of VAE is also significant during these procedures (Faberowski et al., 2000). Precordial Doppler ultrasonography and end-tidal

CO₂ monitoring are useful for early detection of VAE. Because neuroendoscopic techniques are designed to minimize surgical incision, dissection, and blood loss, less aggressive fluid replacement and invasive hemodynamic monitoring is becoming the norm. The application of endoscopic techniques for craniosynostosis repair has resulted in significantly less morbidity. Endoscopic strip craniectomies are associated with decreased blood loss, decreased surgical time, and improved postoperative recovery time for neonates and infants (Jimenez and Barone, 1998; Jimenez et al., 2002). Tobias and colleagues (2001) reported a significant decrease in the incidence of VAE during this procedure.

Epilepsy

Epilepsy remains one of the most common neurologic disorders in children. Although new pharmacologic interventions have shown promise in the medical management of childhood epilepsy, a large number of children continue to have intractable seizures, and physicians resort to surgical interventions in such situations. Chronic administration of anticonvulsant drugs, such as phenytoin and carbamazepine, induces rapid metabolism and clearance of neuromuscular blockers and opioids by up-regulating hepatic P450 enzymes (Soriano and Martyn, 2004). General anesthetics can compromise the sensitivity of intraoperative neurophysiologic monitors that are used to guide the actual resection of the epileptogenic focus (Eldredge et al., 1995). If cortical stimulation is used to mimic the seizure pattern or identify areas on the motor strip, neuromuscular blockade should be antagonized.

Advances in neurophysiologic monitoring have enhanced the ability to safely perform more definitive neurosurgical resections in functional areas of the brain. A variety of techniques are used during the entire perioperative period to aid in localization of seizure foci. A major part of preoperative planning should include a thorough discussion of the modality and type of neurophysiologic monitoring to be used during the surgical procedure. In general, ECoG and an EEG can be used when the patient is on low levels of volatile anesthetics. Cortical stimulation of the motor cortex necessitates observation of motor movement of the specific area of the homunculus. Therefore, muscle relaxation should be avoided, or permitted to dissipate, during the monitoring period. ECoG is typically recorded continuously on a polygraph via a grid and strip electrodes placed on the surface of the brain after dural opening. Because some epileptogenic foci are in close proximity to cortical areas controlling speech, memory, and motor or sensory function, monitoring of patient and electrophysiologic responses is frequently used to minimize iatrogenic injury to these areas (Adelson et al., 1995; Ojemann et al., 2003). Cortical stimulation of the motor strip in a child under general anesthesia will require either EMG or direct visualization of muscle movement. Neuromuscular blockade should not be used in this situation. Cortical stimulation is possible using a dual channel stimulator. Epileptogenic activity may be evident by either clearly documented electrographic seizures or EEG spike activity, which consists of either interictal spikes of 50 to 80 msec or sharp waves of 80 to 200 msec. During anesthesia, the use of low concentrations of volatile anesthetics or nitrous oxide and opioids alone should avoid attenuating ECoG and EEG recordings.

In patients with generalized seizures, precise localization of the seizure focus is essential to minimize postoperative functional deficits. This involves serial craniotomies. The first is insertion of an intracranial grid and strip electrodes. EEG grids or strips are placed on the exposed cortical surface to accurately create a map that will localize the seizure focus. The patient is then observed in an electrophysiology unit to map the location of the seizure foci and provide a road map for the neurosurgeon for the resection. In some cases, the patient is monitored over several days. Once a seizure map is generated, the patient returns to the operating room for definitive resection. Depending on the location of seizure foci, age, and development of the patient, the resection is performed under general anesthesia or by an awake craniotomy technique. It is important to avoid administration of nitrous oxide until the dura is opened,

because intracranial air can persist up to 3 weeks after a craniotomy, and nitrous oxide in these situations can cause rapid expansion of air cavities and result in tension pneumocephalus (Reasoner et al., 1994).

Neural function is best assessed in an awake and cooperative patient (Penfield, 1954). Positioning of the patient is critical for the success of this technique, as the patient must remain still for an extended period of time. The patient should be in a semilateral position to allow patient comfort as well as surgical and airway access to the patient. Motor and sensory cortices are localized by inducing motor movements or sensory changes with cortical stimulation. Language function is tested by eliciting speech arrest with cortical stimulation. Verbal memory is tested by stimulating the hippocampus or lateral temporal cortex. A variety of techniques have been advocated to facilitate intraoperative assessment of motor-sensory function and speech. These range from no sedation with local anesthesia, to asleep-awake-asleep techniques involving general anesthesia induced before and after functional testing (Sarang and Dinsmore, 2003; Brunson and Mayhew, 2005). The asleep-awake-asleep technique entails induction of general anesthesia. The airway is secured either by tracheal intubation or by placement of a laryngeal mask airway. General anesthesia is maintained during the craniotomy. The anesthetic is discontinued to permit functional neurophysiologic testing. Once the testing is completed, general anesthesia is reinstated and the airway is secured. The advantage of this technique is that the patient is completely anesthetized during the most painful segments of the surgery. However, a major drawback is the depressant effects of residual anesthetics and the inability to predict the patient's response to emerging from anesthesia under the surgical drapes. Therefore, monitored conscious sedation is the most frequently used technique in pediatric patients. Deep levels of sedation with a variety of IV anesthetic and sedative drugs (propofol and dexmedetomidine) combined with an opioid (fentanyl or remifentanyl) have been shown to be efficient in several clinical reports (Ard et al., 2003; Keifer et al., 2005; Everett et al., 2006). An important factor in the choice of anesthetic drugs is its effect on the intraoperative ECoG. Therapeutic levels of propofol can potentially depress the ECoG. Propofol, when discontinued 20 minutes before monitoring, did not interfere with the ECoG, in awake cooperative children older than 10 years (Soriano et al., 2000a). However, it is imperative that candidates for an awake craniotomy be mature and psychologically prepared to participate in this procedure. Therefore, patients who are developmentally delayed or have a history of severe anxiety or psychiatric disorders should not be considered appropriate for an awake craniotomy.

Postoperative seizures are an uncommon but devastating complication. Prophylaxis in the perioperative period and aggressive treatment of new convulsions are well-recognized mainstays of care. Phenytoin is the agent used most commonly for prophylaxis, but maintaining therapeutic serum levels can be a challenge (Wolf et al., 2006). Levetiracetam (Keppra) is becoming increasingly common and in many instances supplants phenytoin as the choice for prophylaxis. Both drugs can be administered intravenously, but unlike phenytoin, administration of levetiracetam does not require following serum drug levels to monitor for toxicity. Alternative agents frequently used in pediatrics include phenobarbital, carbamazepine, and valproic acid. Status epilepticus can be treated effectively with lorazepam (0.1 mg/kg IV bolus over 2 minutes) or diazepam

(0.5 mg/kg rectally). Lorazepam may be repeated after 10 minutes and accompanied by fosphenytoin (20 mg/kg IV or IM) if initial doses are ineffective. Phenobarbital (20 mg/kg) is also an effective first-line antiepileptic drug.

Vascular Malformations

Vascular anomalies are rare in infants and children. Most are congenital lesions that appear early in life. Large arteriovenous malformations (AVMs) in neonates may be associated with high-output congestive heart failure and require vasoactive support. Initial treatment of large AVMs often consists of several treatments involving intravascular embolization in the interventional radiology suite (Burrows and Robertson, 1998). Operative management is commonly associated with massive blood loss. Ligation of an AVM can lead to sudden hypertension with hyperemic cerebral edema (Morgan et al., 1999) and should be treated with vasodilators such as labetalol or nitroprusside.

Moyamoya syndrome is a rare chronic vasoocclusive disorder of the internal carotid arteries that appears as transient ischemic attacks or recurrent strokes (or both) in childhood. The etiology is unknown, but the syndrome can be associated with prior intracranial radiation, neurofibromatosis, Down syndrome, and a variety of hematologic disorders including sickle cell disease. Medical management consists of antiplatelet medications (e.g., aspirin or calcium channel blockers) and surgical management aims to improve blood flow to the ischemic area. The operation involves suturing a scalp artery onto the pial surface of the brain (pial synangiosis). The anesthetic management of these patients is directed at optimizing cerebral perfusion (Soriano et al., 1993); this includes ensuring generous preoperative hydration and maintaining the blood pressure close to the patient's preoperative levels. Maintenance of normocapnia is essential as well, because both hypercapnia and hypocapnia can lead to steal from the ischemic region and further aggravate cerebral ischemia (Kuwabara et al., 1997). A nitrous oxide and narcotic-based anesthetic provides a stable level of anesthesia for these patients and is compatible with intraoperative EEG monitoring. Once the patient emerges from anesthesia, the same maneuvers that optimize cerebral perfusion should be extended into the postoperative period.

Neurotrauma

Neurotrauma primarily includes TBI and spinal cord injury (SCI). TBI is the leading cause of death and disability in children over 1 year of age. Approximately half of children with cervical spine injury have concomitant TBI, and the presence of TBI increases the risk of spine injury. After TBI, mortality is lower for children than for adults (10.4% versus 2.5%), but certain factors predict worse outcomes (Box 22-2). Because secondary injuries can progressively worsen outcome, basic life support algorithms, such as Pediatric Advanced Life Support (PALS) and Advanced Trauma Life Support (ATLS), and the principles of ATLS, including primary and secondary surveys, should be immediately applied. The spine cannot be "cleared" by radiographic examination alone; a child with normal cervical spine radiographs should be maintained with cervical spine immobilization until a thorough examination can be performed.

Box 22-2 Predictors of Poor Outcome after Traumatic Brain Injury in Children

- Age < 4 years
- Cardiopulmonary resuscitation needed
- Multiple trauma
- Hypoxia ($P_{aO_2} < 60$ mm Hg)
- Hyperventilation ($P_{aCO_2} < 35$ mm Hg)
- Hyperglycemia (glucose > 250 mg/dL)
- Hyperthermia (temperature > 38° C)
- Hypotension (systolic blood pressure < 5th percentile for age)
- Intracranial hypertension (intracranial pressure > 20 mm Hg)
- Poor rehabilitation

In children, cervical spine fractures can occur without neurologic deficit, and neurologic deficit can occur without fracture. Neurologic deficit without fracture has been termed SCIWORA (SCI without radiologic abnormalities). Most children undergo an MRI evaluation. Blunt abdominal trauma and long-bone fractures may occur with TBI/SCI and can be major sources of blood loss. Craniotomies for the evacuation of either epidural or subdural hematomas are at high risk for massive blood loss and VAE. Infants with inflicted trauma often present with a myriad of chronic and acute subdural hematomas (Duhaime et al., 1998). Most inflicted injuries involving death involve TBI. Children with inflicted TBI (iTBI) commonly present with altered consciousness, coma, seizures, vomiting, or irritability, and either injuries out of proportion to history or developmental milestones or incomplete histories. Types of injuries include subdural hematoma, subarachnoid hemorrhage, skull fractures, and diffuse axonal injury with or without cerebral edema. Outcome is poor after iTBI.

Cerebral Hemodynamics after TBI

Cerebral Metabolic Rate, Blood Flow, Autoregulation, and CO₂ Reactivity

During the first 6 to 12 hours after TBI, the brain may suffer poor perfusion and cerebral ischemia. This may be followed by hyperemia and ICP. Finally, vasospasm occurs in up to 19% of patients with TBI, and poor perfusion may occur (White et al., 2001). Compared with children without TBI, children with TBI have a lower V_{MCA} and cerebral hypoperfusion ($CBF < 25$ mL/100 g per minute) is associated with cerebral ischemia and poor outcome (Adelson et al., 1997; Skippen et al., 1997). However, after TBI, CBF and CMR_{O_2} may not be matched, resulting in either cerebral ischemia or hyperemia. As noted before, there are age-related changes in V_{MCA} , CBF, and CMR_{glu} (see Fig. 22-3) (Kennedy and Sokoloff, 1957; Ogawa et al., 1987; Bode and Wais, 1988; Vink et al., 1988). One study of 30 children showed CO₂ vasoreactivity changes of less than 2% to be associated with poor outcome (Adelson et al., 1997). Cerebral autoregulation is impaired more often after severe (42%) than after mild (17%) pediatric TBI (Stoyka and Schutz, 1975; Bouma et al., 1998; Vavilala et al., 2004, 2007), and autoregulation may be more impaired in children with iTBI (Vavilala et al., 2007). Hemispheric differences in cerebral autoregulation are common (40%) after focal TBI (Vavilala et al., 2008). If cerebral autoregulation is impaired, lower blood pressure may passively

■ **FIGURE 22-22.** **A**, Intact cerebral autoregulation. There is relatively little change in cerebral blood flow velocity (CBFV) with increase in mean arterial pressure (MAP). **B**, Impaired cerebral autoregulation. There is a linear increase in CBFV with increase in MAP.

result in diminished CPP and CBF (Fig. 22-22). Autoregulation is not a static condition and may deteriorate in patients with initially intact autoregulatory capacity. Empirically increasing MAP to prevent cerebral ischemia in the presence of unilaterally impaired cerebral autoregulation in the presence of hyperemia could result in cerebral hemorrhage (Bruce et al., 1981; Aldrich et al., 1992; Mandera et al., 2002). Impaired cerebral autoregulation has been associated with poor outcome after pediatric TBI (Vavilala et al., 2006, 2007).

Cerebral Perfusion Pressure

In 2003, pediatric guidelines issued by a number of organizations recommended that a CPP of less than 40 mm Hg be avoided after severe TBI to prevent cerebral hypoperfusion leading to cerebral ischemia (Adelson et al., 2003). However, although it is not well understood, there is probably an age-dependent CPP threshold, with older children with TBI requiring higher CPP (Chambers et al., 2005, 2006). Furthermore, there may be variability (low and high) in CBFV, despite a CPP of greater than 40 mm Hg (Philip et al., 2009). These data suggest that empirical CPP management may not have predictable effects on

CBF. However, today, either systolic blood pressure or CPP is used clinically to estimate cerebral perfusion. The presence of Cushing's reflex and autonomic dysfunction might be the only indicators of increased ICP. Although hypotension is defined by a systolic blood pressure below the fifth percentile, in the absence of ICP monitoring and suspected increased ICP, supranormal systolic blood pressure may be needed to maintain CPP. At a minimum, MAP should not be allowed to decrease below values normal for age by using vasopressors. IV phenylephrine infusion is often used to maintain CPP above 50 mm Hg.

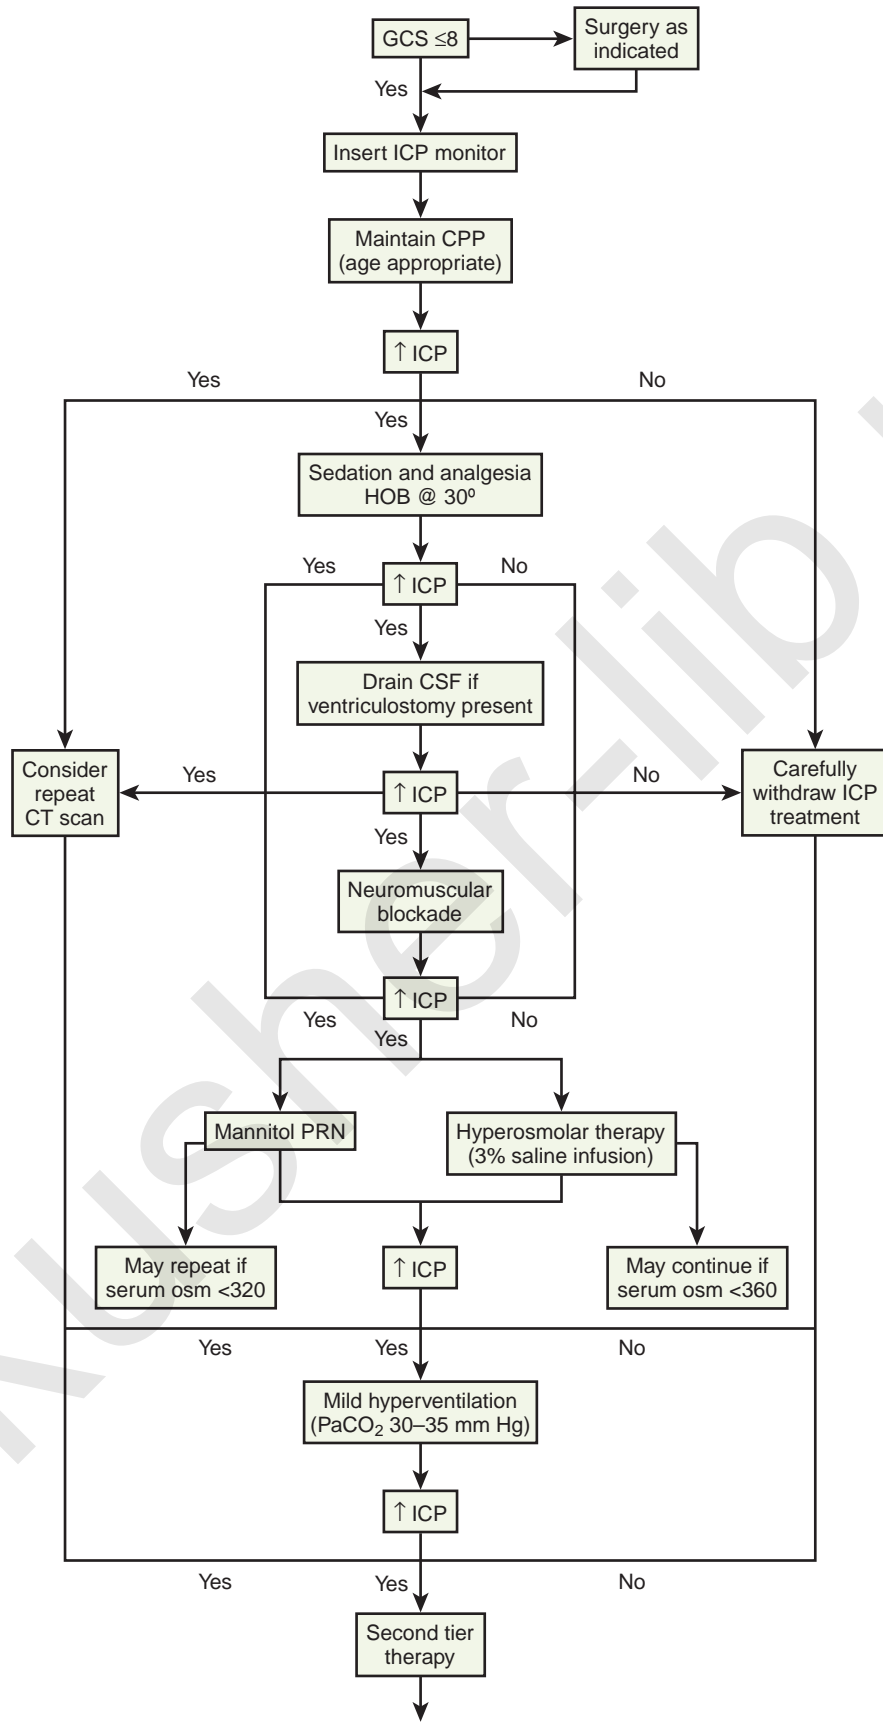

Intracranial Pressure and Intracranial Pressure Monitoring

The management of increased ICP in children is similar to that in adults (Fig. 22-23). The indications for ICP monitoring and the treatment threshold for increased ICP are given in the 2003 pediatric guidelines (Adelson et al., 2003). The use of ICP monitoring for infants and children with severe TBI and a Glasgow Coma Scale of 8 or less varies, but it is supported by several clinical studies (Adelson et al., 2003). Symptoms of increased ICP (>20 mm Hg) are nonspecific in children, and intermittent apnea may be its first sign in infancy (Sharples et al., 1995). ICP measurements from ventricular catheters and fiberoptic intraparenchymal transducers have a good correlation (Gambardella et al., 1993). Ventricular catheters also provide a conduit for withdrawing CSF.

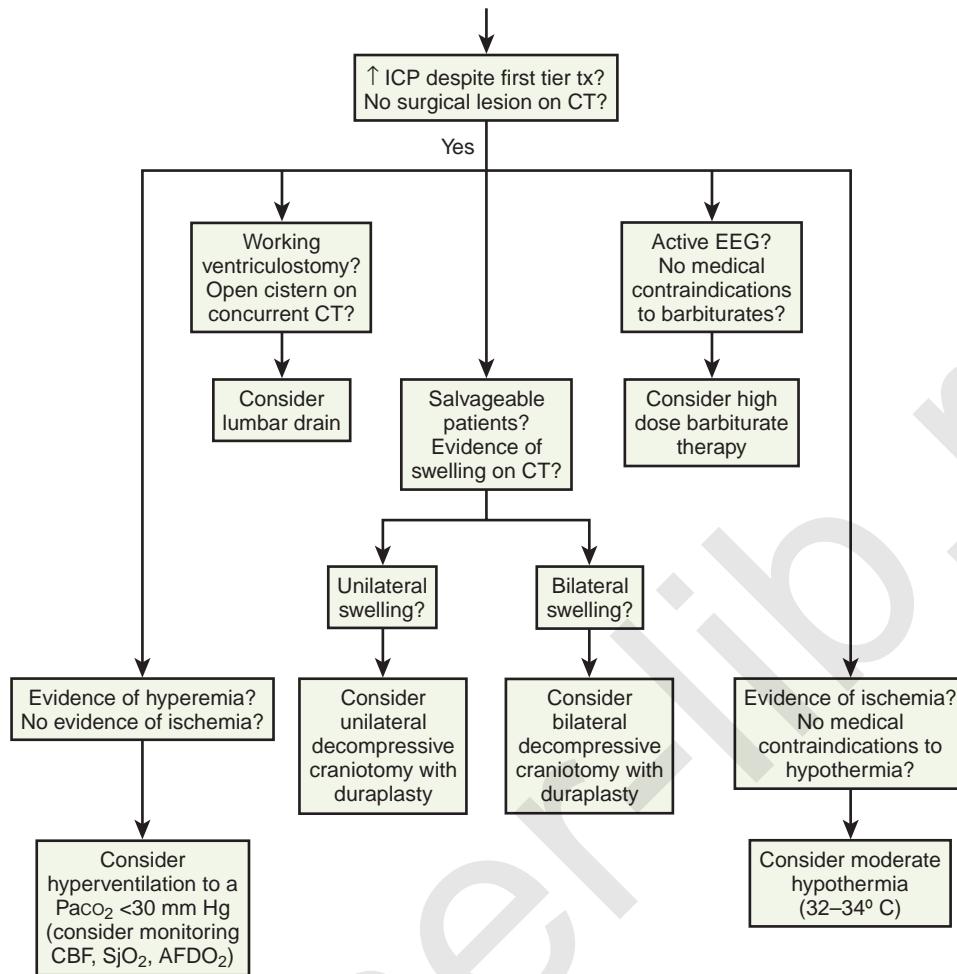

Intracranial hypertension can be initially managed through elevation of the head, neuromuscular blockade, and hyperosmolar therapy. Mannitol can be given at a dosage of 0.25 to 1.0 g/kg intravenously. All diuretics interfere with the use of urine output as a guide to intravascular volume status. Hypertonic saline (3% NaCl) decreases ICP and increases CPP (Khanna et al., 2000). High-dosage barbiturate therapy can be titrated to produce a burst suppression pattern on the EEG, which results in a reduction in CMR. Refractory ICP can be treated with thiopental infusions, but volume loading and inotropic support may be needed to counter myocardial depression and hypotension (Adelson et al., 2003). If these maneuvers fail to control elevated ICP, decompressive craniectomy should be considered. Careful monitoring of blood gasses, minute ventilation, and end-tidal CO_2 tensions are recommended. Current guidelines recommend maintaining normocapnia (Paco_2 , 35 to 40 mm Hg) except in the presence of impending herniation.

Anesthetic Management

The anesthetic approach to the traumatized child is based on the principles outlined in the 2003 pediatric guidelines for managing children with severe TBI (Table 22-9; see Fig. 22-23) and on ATLS guidelines and as previously described. Children with a Glasgow Coma Scale score of less than 9 require tracheal intubation for airway protection, and management of increased ICP. The most common approach to tracheal intubation is direct laryngoscopy and oral intubation with crioid pressure after induction of anesthesia, ventilation with 100% oxygen, and neck in-line stabilization, without traction. Nasotracheal intubations are contraindicated in patients with basilar skull fractures. If increases in ICP occur despite hyperosmolar therapy during surgery, changing from less than 1 MAC volatile anesthesia to TIVA may be considered. Invasive arterial blood pressure monitoring should be used to guide blood pressure management and for hourly sampling of blood gases,

(Adapted from Adelson PD, Bratton SL, Carney NA, et al: Guidelines for the acute medical management of severe traumatic brain injury in infants, children, and adolescents: critical pathway for the treatment of established intracranial hypertension in pediatric traumatic brain injury, *Pediatr Crit Care Med* 4[3 Suppl]:S65, 2003.)

■ FIGURE 22-23—cont'd.

TABLE 22-9. Selected 2003 Pediatric Guidelines for the Management of Severe Brain Injury

Physiologic Parameter	Recommendations
Blood glucose	Avoid dextrose-containing solutions Keep blood glucose level at < 200 to 250 mg/dL
Temperature	Avoid hyperthermia: cool patients to 36° to 37° C Hypothermia (32° to 34° C) may be considered for refractory ICP
Cerebral blood flow (CBF) and Paco ₂	Avoid mild or prophylactic hyperventilation (Paco ₂ < 35 mm Hg) Mild hyperventilation if acute brainstem herniation exists Mild hyperventilation may be considered for refractory ICP
Systolic blood pressure (SBP)	Hypovolemia should be corrected ASAP SBP should be maintained at the 5th percentile, at least, for age May be beneficial to maintain SBP in normal range (≥50th percentile)
Cerebral perfusion pressure (CPP)	Keep CPP >40 mm Hg CPP 40 to 65 mm Hg may represent an age-related continuum for best treatment
Intracranial pressure (ICP)	Monitor if Glasgow Coma Scale score < 9 Treat ICP ≥20 mm Hg Ventriculostomy or intraparenchymal catheter
Hypertonic solutions	3% saline, 0.1 to 1.0 mL/kg/hr Mannitol, 0.25 to 1.0 g/kg

glucose, and coagulation. Central access should be attempted by experienced personnel; intraosseous access is a second-line option if immediate vascular access is required (see Chapter 30, Anesthesia for the Pediatric Trauma Patient). Muscle relaxants should be used in unstable patients, and opioids should be used sparingly in patients with TBI if tracheal extubation is planned for the end of the case. For SCI, when neuromonitoring (including motor evoked potentials) is used, TIVA should be used to maintain anesthesia. Normothermia is currently maintained unless refractory ICP is present.

Indications for Surgery

The major goal of surgery for patients with TBI is to optimize the recovery of viable brain. Most operations deal with the removal of mass lesions to prevent herniation, intracranial hypertension, or alterations in CBF. In general, unless small and deemed likely venous, epidural hematomas should be evacuated in comatose patients. Subdural hematomas that are associated with herniation thicker than 10 mm, or that produce a midline shift of greater than 5 mm, should be removed. Indications on intraparenchymal mass lesions include progressive neurologic deterioration referable to the lesion, signs of mass effect on CT, or refractory intracranial hypertension. Penetrating injury can often be managed with local débridement and watertight closure if not extensive, and if there is minimal intracranial mass effect (see Intracranial Pressure, earlier). Patients with severe brain swelling as manifest by cisternal compression or midline shift on CT, or intracranial hypertension by monitor, are potential candidates for decompressive craniectomy (Taylor et al., 2001). The relatively increased frequency of diffuse swelling in the pediatric population makes children more frequently candidates for such treatment. Generous decompressive craniectomy with duraplasty should be considered when intracranial hypertension reaches or approaches medical refractoriness in salvageable patients when the ICP elevation and its effects are believed to be the major threat to recovery. Unilateral craniectomy is appropriate for lateralized swelling; bifrontal decompression is selected for diffuse disease. In general, surgical removal of mass lesions in comatose patients should be performed as early as safely feasible. As this often involves incompletely resuscitated patients, close collaboration between surgery and anesthesia is critical. Bidirectional communication should be maintained regarding issues such as the stage of the procedure, anticipated and ongoing blood loss, systemic stability, and unanticipated events, so that the procedure can be altered or even terminated if necessary.

Induced Hypothermia

Head cooling and mild hypothermia have been demonstrated to be protective in asphyxiated neonates (Wyatt et al., 2007).

However, induced hypothermia in adult with TBI has mixed results (Clifton et al., 2001). Recently, Adelson and colleagues (2005) demonstrated in a phase II trial that induced hypothermia can be a safe therapeutic option for children with TBI. A National Institutes of Health–sponsored phase III trial is underway. An international multicenter trial of induced hypothermia in pediatric patients reported that hypothermia did not improve the neurologic outcome and may increase mortality (Hutchison et al., 2008). Interestingly, the International Hypothermia in Aneurysm Surgery Trial failed to demonstrate any advantage of hypothermia over normothermia intraoperatively during surgical clipping of intracranial aneurysms (Todd et al., 2005).

Neuroendoscopy

Technological advances in minimally invasive endoscopic surgery have entered the neurosurgical arena. The anesthetic considerations for these evolving techniques are the same as those for other neurosurgical procedures discussed in this chapter. (See the discussion of neuroendoscopic techniques under Craniosynostosis, earlier.) Endoscopic third ventriculostomy is another approach for the treatment of obstructive hydrocephalus in infants and children (Rekate, 2004). A flexible fiberoptic scope inserted through a trocar provides a working channel that allows the neurosurgeon to insert a ventricular catheter or make fenestrations. Despite the relative safety of this procedure, bradycardia and other arrhythmias have been reported in conjunction with lack of egress of irrigation fluids and manipulation of the floor of the third ventricle (El-Dawlatly et al., 2000, 2001).

SUMMARY

The role of the pediatric neuroanesthetist is to provide comprehensive care to children with neurologic pathologies. The cerebral physiology is influenced by the developmental stage of the child. The understanding of the effects of anesthetic agents on the physiology of cerebral vasculature in the pediatric population has significantly increased in the past decade, allowing more rationale decision making in anesthesia management. Although no single anesthetic technique can be recommended, sound knowledge of the principles of cerebral physiology and anesthetic neuropharmacology will facilitate the care of pediatric neurosurgical patients.

		Summary	785

In this chapter, the anesthetic considerations of the most common general abdominal, thoracic, urologic, and bariatric procedures are summarized. Practical suggestions and discussions of anesthetic techniques and anesthetic concerns for common surgical problems are offered.

For the most part, anesthetic considerations for pediatric general surgery are similar to those for adults. Inhalation anesthesia supplemented with muscle relaxants can provide adequate operating conditions. Nitrous oxide should be avoided in the presence of a bowel obstruction and when one-lung anesthesia may render the patient hypoxicemic. When aspiration of gastric contents is a major concern, either rapid-sequence induction or awake intubation should be performed. Because children about to undergo urgent emergency surgery frequently have fluid and electrolyte imbalances as well as underlying hemodynamic instability, a thorough preoperative assessment of the patient is essential. Anesthetic agents are selected to render the patient unconscious, but, in addition, regional anesthesia is used to provide the child with perioperative pain relief. The details of the regional techniques of caudal, lumbar epidural anesthesia, ilioinguinal/iliohypogastric nerve block, penile nerve block, and intercostal nerve block are discussed in Chapter 16, Regional

Anesthesia. The planned operative approach influences anesthetic management. As the frontiers of minimally invasive surgery expand, these new techniques can markedly influence the patient's cardiorespiratory stability and, consequently, the choice of anesthetic agents.

VIDEO ENDOSCOPY

With the development of smaller instruments, the technological progress in video imaging, and the increasing experience among pediatric surgeons, video endoscopic surgery is being performed for a growing number of pediatric surgical indications. Benefits of video laparoscopy and thoracoscopy include small incisions and scars, reduced surgical intervention and postoperative pain, earlier return of bowel function, and more rapid recovery (Box 23-1) (Reddick and Olsen, 1989; Soper et al., 1992; Rogers et al., 1992; Rodgers, 1993; Soper et al., 1994; Steiner et al., 1994; Sawyers, 1996; Hunter, 1997; Danelli et al., 2002). Fiberoptic endoscopes that can be passed through a needle are now manufactured, and digital video signals can be electronically modified to yield sharp, detailed, color images

Box 23-1 Advantages of Video Endoscopic Surgery in Infants and Children

- Improved visualization
- Decreased surgical stress
- Decreased postoperative pain
- Decreased ileus, and earlier return to enteral feeding
- Shorter hospitalization
- Quicker return to normal activity (parents and patient)
- Fewer long-term complications
- Cosmetically superior

with a minimum light intensity. Digital cameras are designed to maintain an image in an upright orientation regardless of how the telescope is rotated. They are also equipped with an optical or a digital zoom to magnify the image or give the illusion of moving the telescope closer to the object of interest. The smallest of telescopes use fiberoptics and are less than 2 mm in diameter. Two-millimeter disposable ports, mounted on a Veress needle, are used for introduction of these small instruments. Larger instruments and ports are used in larger patients and for more complex cases.

Another major advance in video endoscopic surgery is the development of the endoscopic suite in which all necessary wiring is in equipment booms, ceilings, and walls. The manipulation of digital images is controlled by voice or touch-screen command, either from the operative field or at a conveniently located station nearby. High-quality digital images are displayed on flat-panel monitors that can be positioned within a comfortable viewing range. Remote-controlled cameras can direct any view in the room to any of the monitors or to a remote site. Digital radiographs can be routed from the radiology department to the operating room, and consultants in remote locations can be viewed on monitors in the operating room so that the surgeon can see with whom they are speaking.

An additional feature of newer endoscopy suites is voice-controlled bed positioning. Robotic tools can be vocally directed to position telescopes in the surgical field for optimal viewing; these surgical telemanipulators facilitate microsurgery in confined spaces even in small infants. Other endoscopic robots are being developed for a wide range of surgical applications.

GENERAL ABDOMINAL SURGERY

Abdominal and thoracic pathologic conditions requiring surgical intervention can be caused by metabolic or endocrine disturbances, tumors, inflammatory processes, or embryologic disorders. [Box 23-2](#) lists abdominal conditions commonly encountered in pediatric general surgery.

Laparoscopy

Laparoscopic surgery involves the intraperitoneal or extraperitoneal insufflation of carbon dioxide (CO₂) through a Veress needle. A variable-flow insufflator terminates flow at a preset intraabdominal pressure of up to 15 mm Hg. Once the abdomen is filled with CO₂, the Veress needle is replaced by a cannula

- Ovarian cysts or tumors

through which a video laparoscope is inserted. Additional ports are placed according to the surgical procedure undertaken.

The laparoscopic procedures that can be performed in infants and children are virtually unlimited. A list of operations currently being performed is shown in [Box 23-3](#). As surgeons gain more experience with laparoscopic surgery, the time required to complete these operations decreases ([Fig. 23-1](#)). The safety and efficacy of commonly performed laparoscopic procedures compared with alternative approaches (e.g., endoscopic, open surgical techniques) have been compared ([Mattei, 2007; Chertin et al., 2007; Perger et al., 2009](#)).

Laparoscopic gastrostomy involves placement of an umbilical port and a left subcostal cannula (the future site of the gastrostomy). The stomach is pulled to the abdominal wall and the gastrostomy is performed using the Seldinger technique ([Fig. 23-2](#)). Operative time is approximately 30 minutes ([Tomicic et al., 2002](#)). The risks may be lower than in percutaneous endoscopic gastrostomy in small children, because the procedure is done under direct vision. There is less trauma than with open surgery, and feedings are initiated within 24 hours. Laparoscopic fundoplication for the treatment of gastroesophageal reflux disease is associated with a complication and recurrence rate comparable with or less than that for open surgery ([Esposito et al., 2000](#)).

The laparoscopic treatment of appendicitis in children has been controversial, particularly in complicated cases (e.g., gangrene, perforation). Experience indicates, however, that laparoscopic appendectomy is not associated with an increased risk compared with open surgery, even in the presence of perforation ([Meguerditchian et al., 2002](#)). The incidence of wound infections and intraabdominal abscesses may be less in laparoscopic than in open appendectomy ([Paya et al., 2000](#)). Surgical times are comparable, and postoperative pain and length of

hospital stay are diminished (Canty et al., 2000; Lintula et al., 2001). Comparable results have been reported for laparoscopic cholecystectomy (Esposito et al., 2001) and laparoscopic splenectomy in pediatric patients (Danielson et al., 2000; Park et al., 2000). Infants undergoing laparoscopic pyloromyotomy have shorter times to enteral feeding and hospital discharge (Hall et al., 2009). Diagnostic laparoscopy and laparoscope-guided cholangiography are being used in the evaluation of neonatal conjugated hyperbilirubinemia, avoiding the need for laparotomy and operative cholangiography (Hay et al., 2000).

The role of laparoscopy in the treatment of solid neoplasms is evolving. Indications include biopsy of suspected malignancies, staging or determination of resectability, second-look procedures to help determine response to chemotherapy, and diagnosis of recurrent or metastatic disease (Sailhamer et al., 2003).

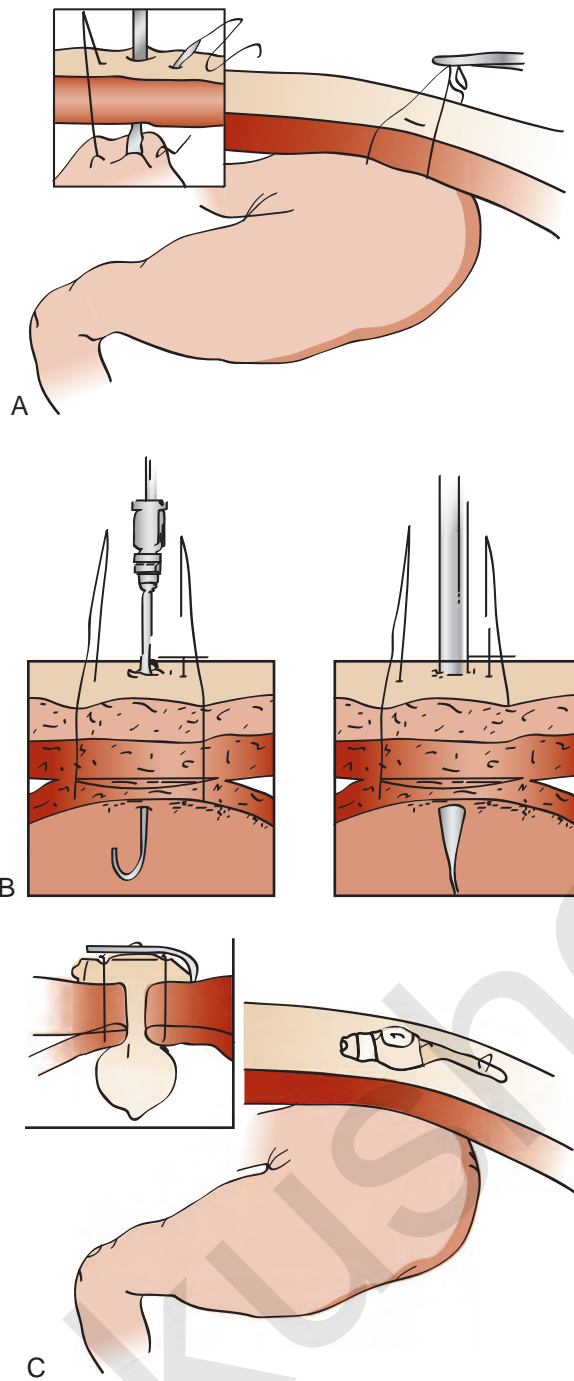

FIGURE 23-1. The learning curve for laparoscopic fundoplication. (Adapted from Georgeson KE, Inge TH, Albanese CT: Laparoscopically assisted anorectal pull-through for high imperforate anus: a new technique, *J Pediatr Surg* 35:927, 2000.)

Laparoscopic tumor ablation or curative resection may have a role in selected cases. Open surgery may be required when complete resection of the intact specimen with delineation of surgical margins is part of the protocol design in patients enrolled in multicenter studies. Although advocates of laparoscopic surgery maintain that it can reduce hospital costs, promote earlier patient discharge, produce less postoperative pain, improve cosmetic results, and allow patients a more rapid return to full activity, evidence for this is questionable so far (Rangel et al., 2003).

Anesthetic Considerations

Although regional anesthesia may be used alone in older children, general anesthesia is nearly always used for laparoscopic procedures. The use of the laryngeal mask airway (LMA) has been described in adults undergoing laparoscopy. The reliability of the standard LMA to provide adequate gas exchange during positive pressure ventilation is controversial (Maltby et al., 2000; Lu et al., 2002). More favorable ventilation and a reduction in inadvertent gastric insufflation have been reported with the LMA-ProSeal (Laryngeal Mask Company Limited, Henley on Thames, UK) (Maltby et al., 2002). The pediatric ProSeal LMA has been shown to be effective for short laparoscopic procedures (Sinha et al., 2007). In infants and children, however, endotracheal tube (ETT) placement remains the standard.

After tracheal intubation, the stomach is suctioned with an orogastric tube to decrease the risk for visceral injury during trocar insertion. The surgeon may prefer to place the patient near the foot of the table, especially for procedures in infants. The table position may need to be changed repeatedly during the operation, and both the Trendelenburg and the reverse Trendelenburg positions are often used. Accordingly, care must be taken to secure the patient to the table (e.g., using rolls of gauze and tape) while ensuring that the extremities are well padded and are not subject to inadvertent movement and untoward pressure during the operation. Inadvertent endobronchial intubation may occur as a result of cephalad displacement of the diaphragm associated with the Trendelenburg position or abdominal insufflation with gas. As a part of routine monitoring, a precordial stethoscope should be placed over the left sternal border at the nipple line of the chest to detect this complication readily.

■ **FIGURE 23-2.** Laparoscopic gastrotomy. The stomach is entered and pulled up to the anterior abdominal wall (**A**) and is sutured in place (**B**). The gastrotomy tube is then placed (**C**). See related video online at www.expertconsult.com.

A variety of general anesthetic techniques have been used for laparoscopic surgery. Regional anesthesia is not commonly used as an adjunct to general anesthesia in pediatric patients unless the laparoscopy is converted to an open procedure. The use of nitrous oxide is controversial. Concerns have been raised that nitrous oxide may cause bowel distention, compromising visibility and exposure during surgery (Eger and Saidman, 1965; Cunningham and Brull, 1993). In addition, nitrous oxide may exacerbate the already increased incidence of nausea and

vomiting after laparoscopy (Lonie and Harper, 1986; Divatia et al., 1996; Tramer et al., 1996), although the findings of several studies have failed to confirm these effects of nitrous oxide (Taylor et al., 1992; Jensen et al., 1993). However, nitrous oxide can also support combustion. Because of its antiemetic effect, propofol has been recommended for maintenance of anesthesia during laparoscopy (Martin et al., 1993; Song et al., 1998). The combination of propofol and remifentanyl has been advocated because the patient emerges rapidly and without an increase in postoperative nausea and vomiting compared with the use of inhalation anesthesia (Grundmann et al., 2001). Because of the increased incidence of postoperative nausea and vomiting associated with laparoscopy, prophylactic treatment with antiemetics and histamine blockers (droperidol, metoclopramide) have been commonly used. Orogastric suctioning at the end of the operation may also help reduce the risk for postoperative nausea and vomiting.

For most surgical procedures, postoperative pain is reduced with laparoscopy compared with open surgery, and postoperative analgesia can usually be achieved with intravenous (IV) and oral agents. Although diminished compared with open surgery, pain after laparoscopic surgery is associated with the incision, visceral manipulation, irritation and traction of nerves, vascular traction and injury, the presence of residual gas in the abdomen, and inflammatory mediators (Alexander, 1997). Pain is frequently localized to the back or shoulder. Laparoscopic repair has been associated with more postoperative pain than open hernia repair (Koivusalo et al., 2009).

A variety of approaches to prevent and treat pain after laparoscopy have been described. Bupivacaine infiltration at incision sites before skin incision has been shown to decrease postoperative pain (Kato et al., 2000; Moiniche et al., 2000). Bupivacaine infiltration has been found to be superior to IV fentanyl or tenoxicam in reducing postoperative pain (Salman et al., 2000). Low-dosage intrathecal morphine and bupivacaine also decrease postoperative pain (Motamed et al., 2000). Intraperitoneal local anesthetic instillation and mesosalpinx block may diminish postoperative pain after laparoscopy and may be beneficial in reducing postoperative shoulder pain (Kiliç et al., 1996). Intraperitoneal instillation of both bupivacaine and meperidine has been shown to be more efficacious than the combination of intraperitoneal bupivacaine and intramuscular meperidine (Colbert et al., 2000).

Caution must be used to avoid toxic plasma concentrations of local anesthetics due to systemic absorption in infants and children, however. Perioperative acetaminophen, nonsteroidal antiinflammatory agents, and other nonopioid analgesics should be used in combination with opioids as needed for postoperative analgesia. Clonidine has been shown to reduce the requirement for postoperative opioids, and it has the advantage of decreasing the tachycardia associated with pneumoperitoneum (Yu et al., 2003).

Physiologic changes during laparoscopic surgery are related to positioning (Trendelenburg, reverse Trendelenburg), increased abdominal pressure resulting from gas insufflation, and increased arterial CO_2 tension associated with insufflation. The magnitude of physiologic changes associated with laparoscopic surgery is influenced by the patient's age, underlying myocardial function, and anesthetic agents. The reverse Trendelenburg position may cause hypotension, especially in the anesthetized patient with intravascular hypovolemia. The Trendelenburg position causes cephalad displacement of the

diaphragm, restricting lung excursion and posing a risk for endobronchial intubation. In addition, central venous pressure and heart rate increase, and systemic arterial pressures and cardiac output decrease (Hirvonen et al., 1995). The pulmonary effects depend on the patient's age, weight, pulmonary function, extent of Trendelenburg position, anesthetic agents, and ventilation technique (Sprung et al., 2002). Atelectasis and a decrease in functional residual capacity and pulmonary compliance may be observed. Ventilation/perfusion mismatch may result in decreased arterial oxygen tension. Neuromuscular blockade, endotracheal intubation, and positive pressure ventilation may help to reduce the pulmonary effects of the Trendelenburg position. As long as intraabdominal pressure is kept below 15 mm Hg, oxygen saturation can generally be maintained during position changes and pneumoperitoneum despite adverse changes in respiratory mechanics (Sprung et al., 2003). Significant hypercarbia may occur despite adjustments in mechanical ventilation, especially in infants.

Both pneumoperitoneum and the Trendelenburg position reduce femoral venous flow, increasing the risk for thrombotic complications (Rosen et al., 2000). Cardiovascular instability associated with laparoscopy has also been attributed to hypercarbia-induced arrhythmias, venous gas embolus, compression of the vena cava, pneumothorax, and pneumomediastinum (Lalwani and Aliason, 2009). Insufflation to an intraabdominal pressure of 12 mm Hg can cause septal hypokinesis and left ventricular wall motion abnormalities (Hoymork et al., 2003; Huettemann et al., 2003). The increase in intraabdominal pressure associated with gas insufflation results in increased intrathoracic pressure and increased pulmonary and systemic vascular resistances and decreased cardiac output (Hirvonen et al., 1995, 2000). Arterial blood pressure may be decreased, maintained, or even elevated by an increase in systemic vascular resistance. Reduction in splanchnic, hepatic, and renal blood flow and increases in the plasma concentrations of catecholamines, cortisol, prolactin, growth hormone, and glucose levels have been reported with CO₂ pneumoperitoneum (Hashikura et al., 1994; Mikami et al., 1998; Ishizuka et al., 2000).

Hypothermia is avoided by warming the insufflating gas or by maintaining insufflating flows of less than 2 L/min.

A new technique, known as gasless laparoscopy, eliminates the risks of pneumoperitoneum by using mechanical retraction (Canestrelli et al., 1999). Reduced visualization is associated with this technique, but its application to pediatrics remains uncertain (Lukban et al., 2000).

Inguinal Herniorrhaphy and Umbilical Herniorrhaphy

During the seventh month of gestation, the testicle descends from the abdomen through the inguinal wall into the scrotum. The processus vaginalis, a peritoneal covering, encloses the testicles during their descent. In term infants, the processus vaginalis is usually closed at birth, but it remains patent in 15% to 37% of people. In premature infants, the incidence of closure is much higher, depending on the gestational age at the time of birth. The continued patency of the processus vaginalis is the principal factor in the development of congenital hernias and hydroceles.

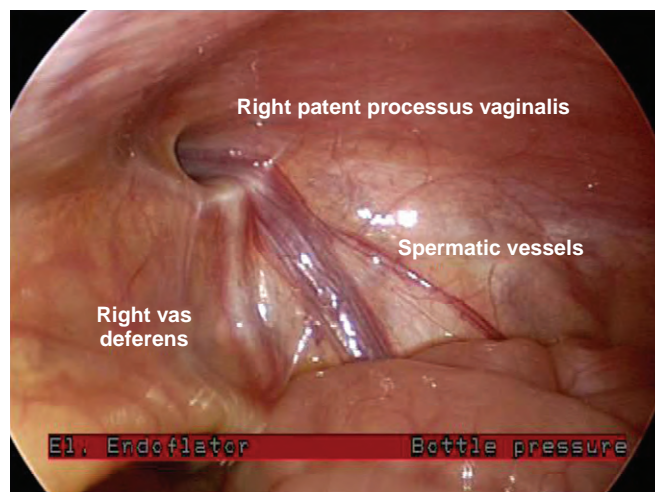

Inguinal hernia repair is the most frequent general surgical procedure performed by pediatric surgeons. Males are more frequently affected than females, and the incidence of inguinal

hernia is highest in the first year of life. Right-sided hernias (60%) occur more frequently than left-sided (30%) and bilateral (10%) hernias. Other risk factors associated with inguinal hernias are prematurity, chronic respiratory illness, and excessive intraperitoneal fluid (ventriculoperitoneal shunts, ascites, peritoneal dialysis).

The surgical technique for this procedure is well described (Rowe and Lloyd, 1986). Laparoscopic techniques have also been described (Lobe and Schropp, 1992; Lee and Liang, 2002; Schier et al., 2002), as well as needlescopic techniques (Prasad et al., 2003). The overall complication rate after an elective hernia repair is about 2%, and it increases to 14% after operations for incarcerated hernia. A major surgical issue in patients with a unilateral inguinal hernia is whether the contralateral side should be explored, thereby subjecting the patient to possible unnecessary damage to the contralateral vas deferens and spermatic cord. In a number of studies, a patent contralateral processus vaginalis occurs about 60% of the time. However, this patency appears to be age related, with the highest rate occurring in infants (63%), and with the incidence decreasing until 2 years of age, when it appears to plateau at 41% (Rowe and Lloyd, 1986). Despite the high incidence of patent processus vaginalis, the incidence of contralateral hernias is about 15%. The development of a contralateral hernia is also age dependent. If the initial hernia developed in the first year of life, there is a fourfold greater chance that a contralateral hernia will develop compared with children whose initial hernia manifested after 1 year of age. In girls with unilateral inguinal hernias, the incidence of positive explorations for contralateral hernias is 60%. Consequently, girls almost always undergo contralateral exploration. Laparoscopy without a separate incision has been advocated to examine the contralateral side for a patent processus vaginalis when the ipsilateral hernia sac is of sufficient width to allow passage of a laparoscope (Yerkes et al., 1998) (Fig. 23-3).

Herniorrhaphies are commonly performed as an elective procedure; however, in children with incarceration and signs of bowel obstruction, a rapid-sequence induction with application of cricoid pressure is needed.

The following discussion pertains to elective, uncomplicated hernias. Anesthesia can be induced by mask inhalation of volatile agents or by IV or rectal technique. Endotracheal

■ FIGURE 23-3. Laparoscopic hernia repair with patent process vaginalis.

intubation is usually unnecessary for herniorrhaphy, except in infants younger than 1 year, in whom it may be difficult to maintain an adequate airway with bag and mask ventilation without distending the stomach. However, the use of the LMA in these patients may make tracheal intubation unnecessary. The patient must be well anesthetized when the spermatic cord is being manipulated. Inadequate depth of anesthesia at this stage can result in laryngospasm or bradycardia. Caudal epidural anesthesia or ilioinguinal/iliohypogastric nerve block can be quite effective, both in providing postoperative pain relief and in diminishing the intraoperative anesthetic requirements (Markham et al., 1986). Premature infants have a particularly high incidence of inguinal hernias. In these infants, for whom an inhalation anesthetic may have increased risks, spinal anesthesia (Harnik et al., 1986) and caudal epidural (Spear et al., 1988) anesthesia have been used successfully to avoid general anesthesia and endotracheal intubation (Williams et al., 2006).

Orchiopexy

Cryptorchidism affects approximately 0.8% of 1-year-old boys. The undescended testicle may lie within the abdomen, the inguinal canal, or the external ring just proximal to the scrotum. Although the undescended testicle is usually associated with a hernia, the most significant medical risk for the patient is the chance of developing a malignancy, which is 10-fold greater than in a normally descended one.

The objectives of repair for undescended testicles are to alter the course of the spermatic artery from the renal pedicle to the internal ring to the external ring, and to create in its place a direct line from the renal pedicle to the scrotum. However, the surgical approach to patients with undescended testes is not uniform (Hinman, 1987; Heiss and Shandling, 1992). The general approach to patients with a nonpalpable testis is inguinal exploration. If neither the testis nor proof of its absence is found, the lower posterolateral surface of the peritoneal cavity is explored. When the testis is found, it is either removed or surgically placed in the scrotum. This can be accomplished by a staged orchiopexy, autotransplantation of the testis, or Fowler-Stephens procedure. The Fowler-Stephens approach takes advantage of the vascular arcades between the deferential and spermatic arteries in the cord. Because of this collateral blood flow, high ligation of the testicular vessels can preserve the testicular blood supply and provide the surgeon with mobility in bringing the testicle down into the scrotum. The Fowler-Stephens approach has undergone modification and is now generally done in two stages. The first stage involves clipping the spermatic vessel, whereas the second stage, performed months later, involves the formal orchiopexy. With the advent of laparoscopic surgery, both stages of the Fowler-Stephens approach can be done with the aid of a laparoscope (Atlas and Stone, 1992; Bogaert et al., 1993).

The anesthetic considerations are similar to those for inguinal hernia repair. Because of the traction and manipulation of the spermatic cord and testicle, the incidence of intraoperative bradycardia and laryngospasm is somewhat increased. Consequently, a deeper level of anesthesia is required. However, the need for a deeper plane of anesthesia and the risk for bradycardia and laryngospasm can be lessened by the use of intraoperative nerve blocks or regional anesthesia. If an intraabdominal

exploration or the use of laparoscopy is anticipated, the trachea is generally intubated. Because the incidence of postoperative nausea and pain is significant, caudal nerve blocks and prophylactic antiemetics, such as ondansetron (0.1 mg/kg) are recommended.

Surgery for Pyloric Stenosis

Pyloric stenosis is one of the most common gastrointestinal abnormalities appearing in the first 6 months of life. This disorder has a polygenic mode of inheritance and occurs four times more commonly in males and more frequently in white infants. The frequency of this disorder ranges from 1.4 to 8.8 per 1000 live births (Zeidan et al., 1988; Dubé et al., 1990; Saunders and Williams, 1990; Bissonnette and Sullivan, 1991; Murtagh et al., 1992). Some controversy exists regarding the associated risk for pyloric stenosis with the maternal postnatal exposure to macrolides (Louik et al., 2002; Sorensen et al., 2003). Pyloric stenosis has been associated with cleft palate and esophageal reflux.

The cardinal features of pyloric stenosis are projectile vomiting, visible peristalsis, and a hypochloremic, hypokalemic, metabolic alkalosis. Although hypokalemia is a frequent finding, Schwartz and colleagues (2003) reported in a retrospective chart review that 36% of patients with pyloric stenosis were noted to have hyperkalemia. Nonbilious vomiting is the classic presenting symptom and generally occurs between 2 and 8 weeks of age. Jaundice occurs in less than 5% of patients and is thought to be associated with caloric deprivation and hepatic glucuronyl transferase deficiency. The jaundice resolves after successful treatment. Diagnosis is made by palpation of an olive-sized mass in the upper abdomen and is frequently confirmed by radiographic studies. Although false-positive studies are rare, false-negative findings can occur in up to 19% of the ultrasound examinations and in 10% of the contrast studies. Preoperative ultrasound measurements of the pylorus correlate well with intraoperative surgical measurements (Muramori et al., 2007).

The pathologic condition involves gross thickening of the circular muscles of the pylorus, resulting in a gradual obstruction of the gastric outlets. Vanderwinden and coworkers (1992) noted a deficiency of nitric oxide synthetase in the muscle layers of infants with pyloric stenosis. The pathophysiology of pyloric stenosis frequently leads to hypovolemia and a hypochloremic metabolic alkalosis.

Winters (1973) outlined the pathophysiology that leads to hypochloremic, hypokalemic, metabolic alkalosis. In pyloric stenosis, persistent vomiting results in a loss of gastric juices rich in hydrogen and chloride ions and, to a lesser extent, sodium and potassium ions. Because the obstruction is at the level of the pylorus, the vomitus does not contain the usual alkaline secretions of the small intestine; the patient develops a metabolic alkalosis. As an increased bicarbonate load is presented to the kidneys, the resorptive capacity of the proximal tubule is overwhelmed, and an increased amount of NaHCO_3 and water is delivered to the distal tubule. Because NaHCO_3 cannot be reabsorbed in the distal tubule, aldosterone secretion occurs. Increased aldosterone increases sodium reabsorption and kaliuresis. Potassium loss is further exacerbated by potassium being exchanged in the tubule for hydrogen in an effort to maintain normal plasma pH.

With persistent vomiting and intravascular volume depletion, the renal response shifts to maintain the patient's intravascular volume, and sodium conservation occurs. Increased secretion of aldosterone promotes sodium conservation and potassium excretion. In the distal tubule, sodium is also conserved in exchange for hydrogen ions. This may result in a paradoxical aciduria and worsening metabolic alkalosis.

Surgical pyloromyotomy, a relatively simple procedure in the hands of skilled pediatric surgeons, is curative (Fig. 23-4). The operative mortality rates of 10% has declined to less than 0.5%. The surgery can be performed either as an open procedure or laparoscopically. In a comparative study, Campbell and colleagues (2002) noted that laparoscopic pyloromyotomy has become the dominant approach. See related video online at www.expertconsult.com. Hall and coworkers (2009) have shown that laparoscopically performed procedures have shorter times for patients to achieve full enteral feeds and faster hospital discharge times than patients having open pyloromyotomy. However, laparoscopic pyloromyotomy is associated with an increased rate of complications, higher hospital charges, and a reduction in the general surgical resident's operating experience (Campbell et al., 2002). Pyloromyotomy for pyloric stenosis is not a medical emergency that requires immediate surgical intervention. The major anesthetic considerations are recognizing and treating dehydration and acid-base abnormalities before beginning anesthesia. In addition, the patient is at risk for aspirating gastric contents.

The initial therapeutic approach is aimed at repletion of intravascular volume and correction of electrolyte and acid-base abnormalities (e.g., 5% dextrose in 0.45% NaCl with 40 mmol/L of potassium infused at 3 L/m² per 24 hours). Most children respond to therapy within 12 to 48 hours, after which surgical correction can proceed in a nonemergent manner. The use of cimetidine has also been shown to rapidly normalize the metabolic alkalosis in patients with hypertrophic pyloric stenosis (Banieghbal, 2009).

Once the child is satisfactorily hydrated and after the appropriate monitors (precordial stethoscope, electrocardiogram, pulse oximeter, and blood pressure cuff) are placed, the infant is ready for induction of anesthesia. The obstructed pylorus and associated vomiting increase the possibility of aspirating gastric contents during induction of anesthesia. A thorough evacuation of stomach contents through a nasogastric or orogastric tube, with proper preoxygenation and monitoring, greatly reduces the chance of regurgitation during induction, although it does not completely eliminate the possibility of aspiration (Cook-Sather et al., 1997). Infants with pyloric stenosis are thus considered by some anesthesiologists to have a status equivalent to that of infants with a full stomach; therefore, a rapid-sequence induction is preferred to secure the airway and minimize the risks of aspiration (Dierdorf and Krishna, 1981; Battersby et al., 1984). On the other hand, mask inhalation induction preceded by careful emptying of the stomach has been used safely in several pediatric centers (MacDonald et al., 1987). In a prospective nonrandomized observational study of 76 infants with pyloric stenosis, Cook-Sather and colleagues (1998) compared three techniques: awake intubation, rapid-sequence intubation, and modified rapid-sequence intubation (ventilation through cricoid pressure). In this study, awake intubation was not superior to anesthetized, paralyzed intubations. Awake intubation prevented neither bradycardia nor oxygen desaturations.

After induction and intubation of the trachea, a nasogastric or an orogastric tube is reinserted and left in place during the

operative procedure. This allows the surgeon to test the integrity of the pyloric mucosa after pyloromyotomy. A small volume of air is injected down the nasogastric tube, and the surgeon manipulates the air bubble into the duodenum and occludes the bowel lumen both proximal and distal to the incision. Mucosal perforation is indicated if there is air leakage. After the operation, which usually requires less than 30 minutes, the effects of any nondepolarizing muscle relaxant are reversed. The infant can then be safely extubated when fully awake and with intact protective airway reflexes. Some believe that opioid analgesia is seldom necessary (Battersby et al., 1984) and may predispose patients to a prolonged emergence from anesthesia (MacDonald et al., 1987). It is not unusual to encounter lethargy or drowsiness in these infants in the immediate postoperative period. Respiratory depression has been noted to occur postoperatively and is possibly related to cerebrospinal fluid pH and hyperventilation (Andropoulos et al., 1994). Rare occurrences of hypoglycemia, apnea, convulsions, and cardiac arrest in the early postoperative period have also been cited. These events have been ascribed to the cessation of IV glucose infusions and the depletion of liver glycogen (Shumake, 1975). Infants usually begin oral feedings 8 hours after the procedure. The choice of maintenance anesthetic agent for infants with pyloric stenosis has been studied (Wolf et al., 1996; Chipps et al., 1999; Davis et al., 2001; Galinkin et al., 2001).

Wolf and coworkers (1996) found that clinical postoperative apnea occurred in 3 of 11 infants anesthetized with isoflurane, and in none of the nine infants anesthetized with desflurane. In a multicenter study comparing halothane and remifentanyl, where both drugs were administered to similar clinical endpoints, remifentanyl was not associated with postoperative respiratory depression. In this study, all infants received both preoperative and postoperative pneumograms, and remifentanyl (as opposed to halothane) was not associated with new pneumogram abnormalities in the postoperative period (Davis et al., 2001; Galinkin et al., 2001).

Wilms Tumor Procedures

Wilms tumor is the most common childhood abdominal malignancy, occurring with an incidence, consistent throughout the world, of 5.0 to 7.8 per 1 million children less than 15 years of age. Wilms tumor accounts for about 6% of all malignancies in childhood. The incidence is equal in the two genders. The peak age at diagnosis is between 1 and 3 years. Wilms tumor occurs bilaterally in 5% of patients. Patients with Wilms tumor frequently have associated anomalies (aniridia, 1%; hemihypertrophy, 2%; genitourinary abnormalities, 5%; ectopic and solitary kidneys [horseshoe kidneys, ureteral duplications, hypospadias]). Other associated conditions include Beckwith-Wiedemann syndrome and neurofibromatosis. The signs and symptoms associated with Wilms tumor are variable. The most frequent finding is an increasing abdominal girth with a palpable abdominal mass (85%). Hypertension occurs in 60% of patients, and hematuria is present in 10% to 25%. Acquired von Willebrand's syndrome with Wilms tumor occurs infrequently (Baxter et al., 2009).

Wilms tumor is generally located in the upper or lower renal pole. It may involve the renal vein (10% of cases) and extend up the vena cava to the right atrium (5% of cases) (Fig. 23-5). Prognosis for patients with the disease is related to its staging (Table 23-1). Patients with favorable staging have an 80% to 90%

TABLE 23-1. Wilms Tumor Staging

Stage	Description
I	Tumor limited to the kidneys and excised
II	Tumor extending beyond the kidneys, but completely excised
III	Residual nonhematogenous tumor confined to the abdomen
IV	Hematogenous metastases Lymph node involvement
V	Bilateral renal involvement at diagnosis

chance of cure, whereas patients with metastasis have a 50% chance of long-term survival. Risk factors for local recurrence of Wilms tumor include an advanced local stage (involvement of the paraaortic lymph nodes), unfavorable histology, and spillage of tumor at the time of resection (Shamberger et al., 1999). Overexpression of HER2, an oncoprotein, has been shown to be a good predictor of overall survival and longer recurrence-free survival (Ragab et al., 2010). Therapy for Wilms tumor includes surgery, chemotherapy, and radiotherapy. Depending on the size of the tumor and the staging, chemotherapy may be started either before or after surgery. Chemotherapy generally involves vincristine, actinomycin, and anthracycline (doxorubicin).

Preoperative evaluation of the patient is related to the presence of metastases and the patient's cardiopulmonary function. If the patient has had prior chemotherapy with Adriamycin, cardiac function should be assessed by echocardiography (see Chapter 4, Cardiovascular Physiology, and Chapter 36, Systemic Disorders). Serum electrolyte levels should be assessed if there is a history of vomiting. Renal dysfunction is unusual even in patients with bilateral Wilms tumor. Although the surgical approach is generally an open incision, laparoscopic nephrectomy has been reported for the unilateral removal of tumor (Barber et al., 2009; Duarte et al., 2009). Anesthetic considerations revolve around the issue of abdominal distention with delayed gastric emptying and potentially large intraoperative blood losses. Abdominal distention may place the patient at risk for aspiration of gastric contents, so full-stomach precautions should be taken at the induction of anesthesia. Intraoperative blood loss can be a significant factor because of the tumor's location and possible involvement of the renal vein and vena cava (Cristofani et al., 2007). Two large-bore IV catheters are recommended. Because of the possibility that the vena cava may be cross-clamped (either to be explored for extension of tumor or to control hemorrhage), the large-bore catheters should be inserted above the diaphragm.

Pulmonary function may be compromised because of metastasis, tumor embolization, abdominal distention, or surgical traction. Monitoring of the patient should include pulse oximetry and capnography, as well as the standard monitors of electrocardiography, blood pressure, and esophageal stethoscope. Arterial catheters are generally reserved for patients with large tumors, patients with previous intraabdominal surgery (increased number of adhesions), and patients with significant cardiorespiratory depression.

After induction, anesthesia is maintained with potent inhalation anesthetic agents. Nitrous oxide is avoided because of bowel distention, and opioids are administered to reduce the anesthetic requirements. An alternative approach that provides excellent operative conditions and postoperative pain control is the use of combined general anesthesia with either a continuous epidural infusion or paravertebral catheters.

Neuroblastoma Procedures

Neuroblastoma, the most common extracranial solid tumor of childhood, involves the postganglionic sympathetic nervous system. Fifty percent of tumors arise in the adrenals, 30% occur below the diaphragm, and 20% occur in cervical or thoracic sites. Neuroblastoma accounts for 8% to 10% of pediatric cancer malignancies. The median age at presentation is 22 months, with 37% of patients presenting at less than 1 year of age, and 51% of new patients being less than 4 years of age. Clinical presentation may be related to the primary tumor, to its metastasis, or to the associated paraneoplastic syndromes (Table 23-2). Metastases from neuroblastoma occur in lymph nodes, liver, cortical bone, bone marrow, orbits, and skin. The paraneoplastic syndromes can exhibit hypertension secondary to catecholamine release, or kidney displacement with renal artery stretching and renin-angiotensin stimulus. The gastrointestinal symptoms (diarrhea, flushing, abdominal distention) are attributed to vasoactive intestinal peptides (VIPs), whereas the etiology of opsoclonus and ataxia is unclear.

TABLE 23-2. Presenting Signs and Symptoms of Neuroblastoma

Primary tumor	Abdominal mass or pain Respiratory distress or dysphagia Vocal cord paralysis Bowel or bladder dysfunction Horner's syndrome Heterochromia of iris on affected side Incidental finding on chest radiograph
Metastatic disease	Hepatomegaly Lymphadenopathy Bone pain Periorbital ecchymoses Subcutaneous nodules Marrow replacement with anemia, fever, or bruising from low blood counts Systemic illness Failure to thrive Fever of unknown origin
Paraneoplastic syndromes	Vasoactive intestinal peptide syndrome (chronic watery diarrhea and abdominal distention) Opsoclonus-myoclonus or cerebellar ataxia syndrome Excessive catecholamine syndrome (hypertension, headaches, flushing, sweating, tachycardia, palpitations)

Tumor prognosis has been related to age at presentation, extent of disease (staging), degree of tumor differentiation, amount of catecholamine metabolites, serum ferritin level, lactate dehydrogenase level, neuron-specific enolase level, serum lymphocyte count, ganglioside presence, *N-myc* amplification, deletion of chromosome 1p, additional copies of chromosome 17q, and TRKA expression (Smith et al., 1989; Hiyama et al., 1991; Berthold et al., 1992; Eckschlager, 1992; Murakami et al., 1992; Qualman et al., 1992; Shuster et al., 1992; Haase et al., 1999). However, patient age and tumor stage are the two most important independent variables (Fig. 23-6). The Evans staging system uses tumor location, lymph node involvement, and presence of metastases, whereas the Pediatric Oncology Group system emphasizes tumor resectability and identification of residual disease to predict survival and treatment.

Treatment involves surgical resection and chemotherapy. Although neuroblastoma is radiosensitive, 45% of patients present with metastasis, so the use of radiation is sometimes limited in primary therapy. In a series of adrenal neuroblastomas less than 6 cm not associated with adjacent vessel or organ involvement, DeLagausie and colleagues (2003) reported successful tumor removal with laparoscopic techniques. The anesthetic considerations depend on the planned surgical procedure, the location and size of the tumor, and the metabolic effects of the tumor. Electrolyte imbalance may result from vomiting and diarrhea caused by excessive production of VIP. Despite the production of catecholamines, significant hypertension has been reported in 9% to 30% of patients (Weinblatt et al., 1983; Haberkern et al., 1992).

Intraoperatively, blood loss and third-space fluid losses can accompany the resection of tumor. Haberkern and coworkers (1992) noted in a retrospective review that 45% of patients had hypotension after the tumor excision, whereas fewer than 3% of the patients had cardiovascular signs of increased

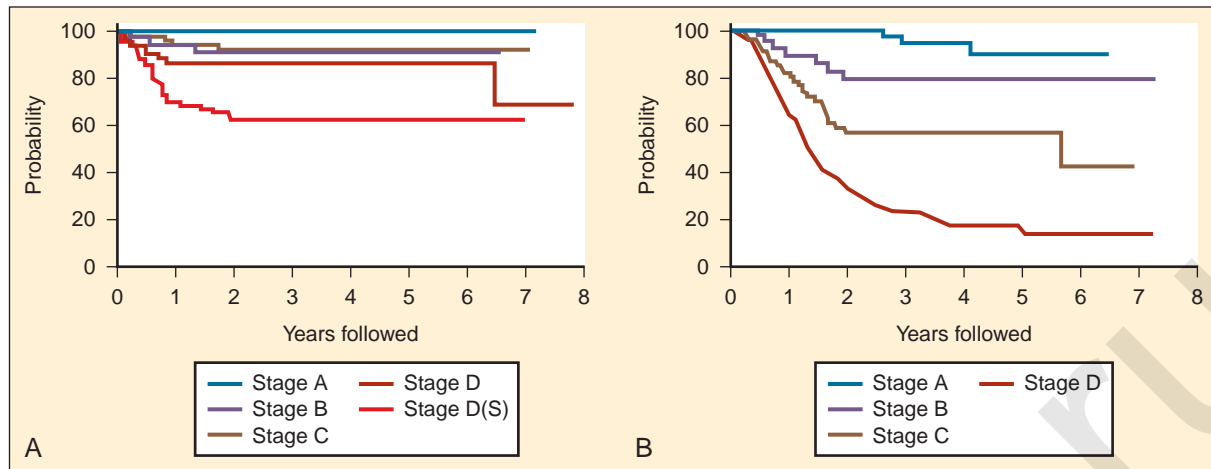

FIGURE 23-6. Prognoses for patients with neuroblastoma as related to age and staging. **A**, Children less than 1 year of age. **B**, Children older than 1 year. Staging is according to the Pediatric Oncology Group (POG) system. *Stage A*: Complete gross resection of primary tumor, with or without microscopic residua. Intracavitary lymph nodes that are not adhered to and removed with primary (nodes adhered to or within tumor resection may be positive for tumor without upstaging patient to stage C) are histologically free of tumor. If primary is in abdomen or pelvis, liver is histologically free of tumor. *Stage B*: Grossly unresected primary tumor. Nodes and liver are the same as for stage A. *Stage C*: Complete or incomplete resection of primary. Intracavitary nodes not adhered to primary histologically are positive for tumor. Liver as in stage A. *Stage D*: Any dissemination of disease beyond intracavitary nodes: extracavitary nodes, liver, skin, bone marrow, bone. *Stage D(S)*: Would be Evans stage I or II except for metastatic tumor in the liver, bone marrow, or skin. *Evans stage I*: Tumor confined to the organ of structure of origin. *Evans stage II*: Tumor extending in continuity beyond the organ or structure of origin but not crossing the midline. Regional lymph nodes on the ipsilateral side may be involved. (Data courtesy Dr. Jonathan J. Shuster and the Pediatric Oncology Group. From Brodeur GM: *Neuroblastoma and other peripheral neuroectodermal tumors*. In Fernbach DJ, Viett TJ, editors: *Clinical pediatric oncology*, St Louis, 1991, Mosby.)

catecholamine release during tumor resection. Although in patients with mediastinal neuroblastoma, airway complications are rare because of the tumor's location in the posterior mediastinum, airway compromise can occur, and evidence of airway compression by the tumor should be evaluated before starting the anesthetic induction. IV or inhalational inductions may be performed. Both volatile agents and opioids have been safely used along with combined regional and general anesthetic techniques (Haber Kern et al., 1992).

Anti-Gastroesophageal Reflux Procedures

Gastroesophageal reflux (GER) involves a dysfunction of the esophageal sphincter mechanism that allows gastric contents to return into the esophagus. Thus, GER may place an anesthetized patient at risk for aspiration. The clinical spectrum of GER can range from patients who are completely asymptomatic to patients with severe esophagitis, esophageal bleeding, esophageal stricture, malnutrition, and respiratory compromise. In the pediatric population, GER can be physiologic, secondary to immature maturation of the lower esophageal sphincter mechanism; however, this aspect of GER generally resolves by 15 months of age. GER is also seen in children who are neurologically compromised, as well as in patients who have survived diaphragmatic hernias, tracheoesophageal fistula, and esophageal atresia repairs (Barry and Auldlist, 1974). GER has also been noted in about 10% of patients who have undergone successful treatment of pyloric stenosis.

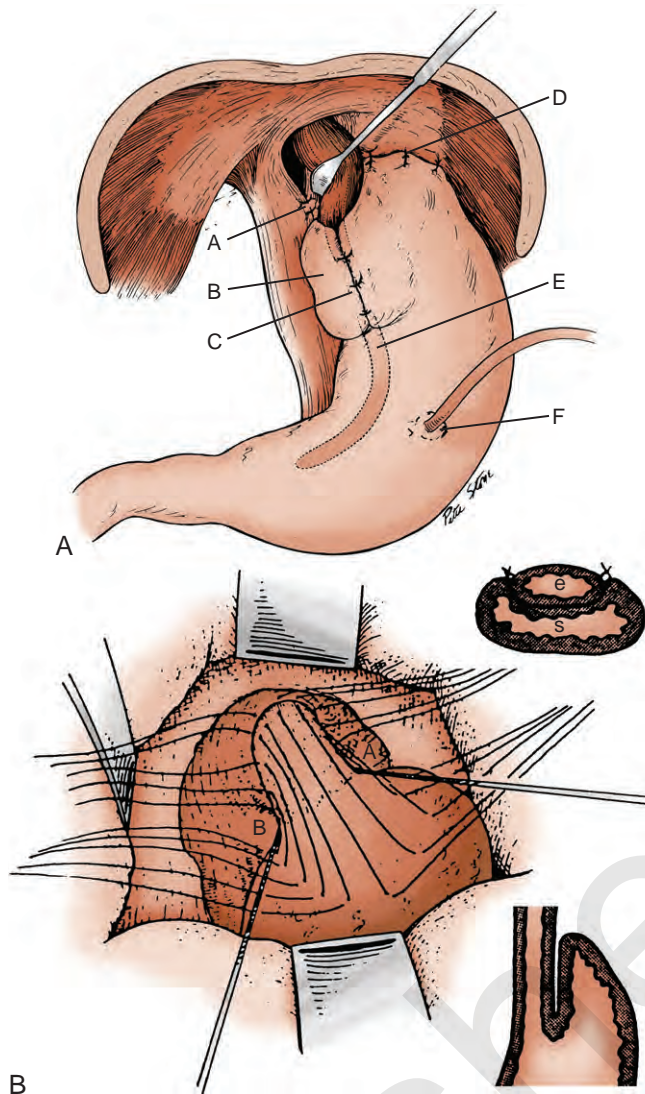

In normal children, reflux of gastric contents is prevented by the gastroesophageal junction. This junction is composed of a lower esophageal sphincter (LES). The LES is a high-pressure zone in the distal esophagus that lies in both the mediastinum

and the abdomen and becomes functionally mature by 6 weeks of postnatal age. Factors that affect the valve mechanism of the LES include the cardioesophageal angle of His, the esophageal hiatus (a sling of muscle that is part of the diaphragm), and the phrenoesophageal ligament. The degree of reflux, the duration of acid exposure in the esophagus, the ability of the esophagus to clear its contents, and the extent of mucosal damage are the primary factors that determine the degree of esophagitis and consequently its clinical and pathologic significance.

In pediatric patients, the complications of GER include respiratory compromise (bronchospasm, chronic aspiration with pneumonitis, reactive airways disease, and apnea) and esophagitis (esophageal metaplasia, Barrett's esophagus, stricture, dysphagia). Diagnostic evaluation includes an upper gastrointestinal series, a nuclear scan, an upper endoscopy, and an esophageal pH probe.

Treatment of GER may involve both medical and surgical therapies. Medical therapy consists of both conservative and pharmacologic interventions (thickened feedings, avoidance of overfeeding, postcibal position therapy). The use of medication is aimed at blocking acid secretions using histamine (H_2)-blocker agents (e.g., ranitidine) and improving gastroesophageal motility and gastric emptying (e.g., metoclopramide, bethanechol). Cisapride, a dopamine antagonist, is also used as a motility drug. Its mode of action is postulated to increase the release of acetylcholine from the myenteric plexus and to increase receptor sensitivity to acetylcholine.

Surgical procedures are aimed at establishing an intraabdominal segment of esophagus and creating a physiologic angle of His (Fig. 23-7). The two common procedures are the 360-degree fundoplication of Nissen and the partial wrap of Thal-Nissen. To avoid the gas bloat syndrome (aerophagia, gastric distention, inability to belch or vomit) associated with Nissen fundoplications, the Thal-Nissen partial wrap is frequently used.

Completed laparoscopic Nissen fundoplication

FIGURE 23-7. A, Salient features of Nissen fundoplication in infants. Crural sutures to reduce hiatus (A). Generous loose, adequate tissue in the wrap (B). Sutures placed through seromuscular depth of both gastric and esophageal walls (C). Sutures to fix the fundus to the diaphragm (D). Appropriately sized mercury-filled dilator to ensure adequate lumen (E). Gastrostomy in all infants and whenever there is any question of gastric outlet problems (F). **B**, The Thal fundoplication. A partial wrap of the fundus is performed anteriorly around the lower esophageal segment. **C**, Laparoscopic view of completed Nissen fundoplication (**A**, From Randolph JG: *Experience with the Nissen fundoplication for correction of gastroesophageal reflux in infants*, *Ann Surg* 198:579, 1983; illustrated by Peter Stone. **B**, from Ashcraft KW: *Thal fundoplication*. In Ashcraft KW, Holder TM, editors: *Pediatric esophageal surgery*, Orlando, 1986, Grune & Stratton.)

The surgical procedure can be performed as either an open or a laparoscopic procedure (Randolph, 1983; Georgeson, 1993; Rothenberg, 1998; Bourne et al., 2003; Esposito et al., 2003; Steyaert et al., 2003). See related video online at www.expertconsult.com. The failure rates of the surgical approaches appear to be similar (Lopez et al., 2008), and laparoscopic fundoplications can be performed in children who have had previous open procedures (Barsness et al., 2009). In children undergoing laparoscopic antireflux procedures, the physiologic perturbations of pneumoperitoneum, increased intraabdominal pressure, and the associated absorption of carbon dioxide need to be considered.

Surgical success rates approach 95% in pediatric patients with normal neurologic development, but in children who are neurologically impaired, morbidity and mortality remain high. It is important to determine if the underlying symptoms of these patients result from GER as opposed to nasopharyngeal incoordination or esophageal or antral dysmotility; (Martinez et al., 1992; Smith et al., 1992). The presence of GER places the patient at risk for aspiration during induction of anesthesia. Preoperative preparation with H₂-blockers and motility drugs should be continued. A rapid-sequence induction should be used if a difficult airway is not anticipated. At least one large-bore IV

catheter should be placed, although fluid and blood losses are minimal. However, pneumothorax, lacerated spleen, puncture, or compression of the vena cava or aorta, and lacerated hepatic veins can occur.

Other anesthesia concerns in patients with GER are the degree of neurologic and respiratory compromise of the patient. Because these children frequently have seizure disorders, preoperative concern should be directed at proper anticonvulsant therapy. Oral anticonvulsants generally cannot be administered for 48 to 72 hours in the postoperative period. Consequently, patients requiring carbamazepine and valproic acid need alternative medicines so that breakthrough seizures do not occur. In addition, a significant number of patients with neurocompromise may also have ventricular-peritoneal shunts. However, the Nissen fundoplication does not appear to increase the risk for shunt infection to more than the risk of placing a shunt (Bui et al., 2007).

For children with severe respiratory compromise or neuromuscular disease, postoperative ventilatory support may be necessary. In children without significant preoperative pulmonary compromise, extubation may be delayed after surgery and supplemental oxygen given as needed. After surgery, the use of

antireflux medication decreased. Within 1 year of surgery, 75% were reported on antireflux medication (Lee et al., 2008).

Surgery for Biliary Atresia

Biliary atresia, characterized by a lack of gross patency of the extrahepatic bile duct, occurs in 1:15,000 live births (Shim et al., 1974). In 10% to 15% of patients, other abnormalities associated with embryologic development are seen, including absent inferior vena cava, intestinal malrotation, polysplenia, and preduodenal portal vein (Lilly and Chandra, 1974). Although biliary atresia is often considered a congenital lesion, it has dynamic properties as well. In microscopic studies of the biliary anatomy obtained from patients at 2 and 4 months of age, the histologic results suggest that biliary structures gradually disappear and are replaced by fibrous tissue. In addition, the success rate for the palliative surgical procedure has been reported as 50% in infants operated on before 4 months of age and 80% in those undergoing surgery before 2 months of age (Ohi et al., 1985). In a study by Serinet and colleagues (2009), among 695 patients who underwent the Kasai procedure, the 2-, 5-, 10-, and 15-year survival rates were 57.1, 32.9, 32.4, and 28.5%, respectively. Increased age at the time of Kasai procedure has been associated with decreased survival rates (Serinet et al., 2009).

Kasai and coworkers (1989), in a review of 245 patients undergoing corrective procedures over a 35-year period, noted that 10-year survival was 74% in infants operated on before 60 days of life. However, Tan and colleagues (1994) have questioned whether earlier corrective surgery is associated with ductal patency. In a series of 205 patients, they noted that survival may be more closely related to the severity of intrahepatic biliary cholangiopathy.

In a 27-year review of 81 patients with biliary atresia, Wildhaber and coworkers (2003) noted that direct bilirubin of less than 2.0, the absence of bridging liver fibrosis, and the number of cholangitis episodes were predictive factors in the success of the Kasai portoenterostomy. Popovic and colleagues (2003) noted that cholinesterase levels can be a useful index of liver function (protein synthesis) early after the Kasai procedure and is independent of albumin synthesis.

Clinically, biliary atresia presents in infants from 1 to 6 weeks of age. About 50% are anicteric until the second or third week of life. The diagnosis of biliary atresia is confirmed either by liver biopsy or by exploratory laparotomy. Surgical palliation for biliary atresia involves hepatic portoenterostomy (Kasai procedure) (Fig. 23-8).

Complications of the surgical repair and from the underlying disease state include cholangitis, portal hypertension, and fat-soluble vitamin deficiency (Kasai et al., 1975). For the anesthesiologist, these complications take on greater significance in patients who return to the operating room for further surgical revision of biliary drainage, treatment of intraabdominal sepsis, or relief of an intestinal obstruction. Because these complications occur frequently and because end-stage liver disease can follow the Kasai procedure, the role of liver transplantation as a primary treatment of biliary atresia has been raised. Kasai and coworkers (1989) suggested that liver transplantation as a primary form of treatment may be indicated for patients older than 3 months with an enlarged, hard liver. Laurent and colleagues (1990) noted that although Kasai's

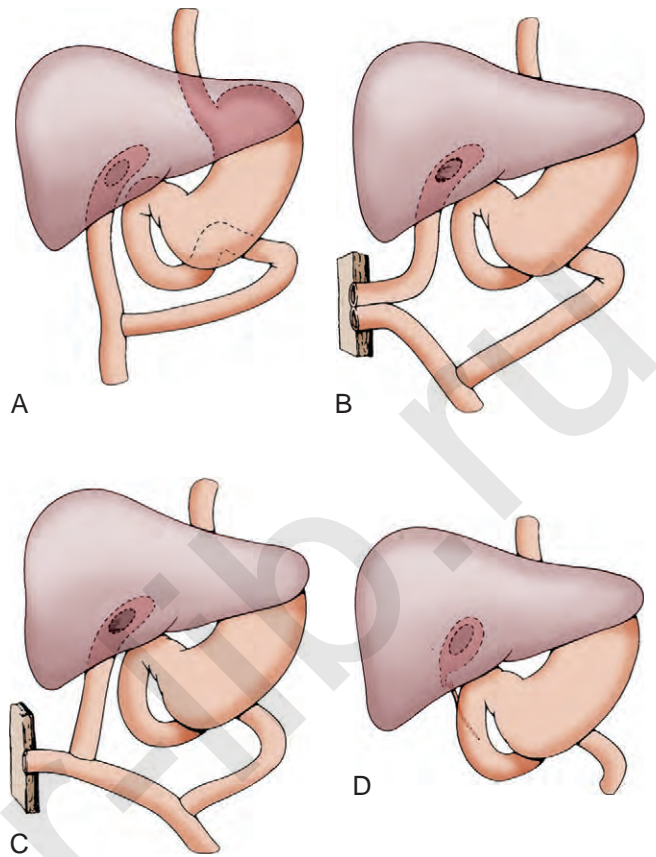

FIGURE 23-8. The Kasai procedure and its various modifications. **A**, Original Kasai. **B**, Kasai H-double-barreled vent. **C**, Bishop-Koop vent. **D**, Gallbladder Kasai. (From Filston HC, Izant RJ Jr: The surgical neonate, evaluation, and care, Norwalk, Conn, 1985, Appleton-Century-Crofts.)

operation does improve the prognosis of biliary atresia, it is not a definitive cure, and 80% of these patients become candidates for liver transplantation.

Anesthetic management for a Kasai procedure (Kasai, 1974) in patients with biliary atresia follows the basic principles of pediatric anesthesia. In infants in whom venous access is already present, induction is achieved with a hypnotic agent, such as propofol (2 to 3 mg/kg), and a muscle relaxant (cisatracurium, 0.2 mg/kg). In infants without an IV catheter in place, inhalation induction is performed with oxygen, nitrous oxide, and sevoflurane. Once the child is adequately anesthetized, an IV catheter is inserted and a muscle relaxant is administered to facilitate endotracheal intubation and to decrease the concentration of potent inhalation anesthetic. After induction, anesthesia is maintained with an oxygen-air-isoflurane mixture along with IV opioids. Because of bowel distention, nitrous oxide is avoided.

Gelman and coworkers (1984) have shown that hepatic blood flow and oxygen supply are better maintained during isoflurane than during halothane anesthesia. Consequently, isoflurane in an oxygen and air mixture is most commonly administered to patients undergoing surgery for biliary atresia.

Anesthesia monitoring for the patient undergoing a Kasai procedure is similar to that used for other pediatric surgical procedures. Arterial cannulation and central venous pressure

monitors are rarely used and are generally reserved for patients with coexisting problems, such as sepsis, pneumonia, cholangitis, and severe cirrhosis. In general, hemodynamic stability is well maintained and the need for intraoperative vasoactive agents is rare. Sometimes the surgical approach involves dividing the triangular and coronary ligaments and displacing the whole liver anteriorly. Although this technique may facilitate exposure, it may compress the inferior vena cava and thereby result in hypotension by decreasing venous return. Ventilation is controlled and end-tidal gases are monitored for carbon dioxide, oxygen, and volatile anesthetic agents. Adequacy of oxygenation is monitored by the pulse oximeter.

The operative procedures generally last 3 to 4 hours, and major blood loss does not occur. Perioperative fluid therapy involves replacement of maintenance and deficit fluids as well as provision for the calculated third-space losses. Third-space losses may vary from 6 to 10 mL/kg per hour. Generally, lactated Ringer's solution is used to restore third-space losses.

Prevention of hypothermia is a major concern for the anesthesiologist. The large surface-to-volume ratio of infants, their relative lack of insulation tissue, coupled with the cold operating room, exposure of body cavities to low environmental temperatures, infusions of cold fluid, and ventilation with dry gases, all increase the potential for hypothermia during surgery. Consequently, great effort must be applied both before and during surgery to protect against heat loss. Methods of preventing heat loss are discussed in Chapter 6, Thermoregulation: Physiology and Perioperative Disturbances.

The pharmacology of anesthetic agents in infants and children with hepatic disease has not been fully evaluated. Although the liver is the major site of drug biotransformation, the effects of hepatic dysfunction on drug elimination and disposition are inconsistent. The degree of liver dysfunction and the drug's ability to bind to plasma proteins are important variables in determining drug kinetics in patients with liver disease.

In general, liver function is fairly well preserved in the first few months of life in children with biliary atresia. As the children get older and ductal fibrosis begins, liver dysfunction ensues. Consequently, in children who return for repeat surgical procedures, the pharmacology of IV anesthetic agents and adjuncts may be altered.

In infants with biliary atresia undergoing the Kasai procedure, if major fluid shifts have not occurred, blood loss has been minimal, and the patient has remained warm, all efforts are made to reverse the muscle relaxation and extubate the trachea at the end of the procedure. In children with other organ system failures (specifically sepsis, cholangitis, or pneumonia), those who are cold at the end of the procedure (<35° C), or those who have undergone transfusion of more than one blood volume, extubation is delayed until warmth and hemodynamic stability are restored. In these children, postoperative recovery and monitoring are carried out in an intensive care setting. The long-term (5-, 10-, and 20-year) survival rates for 80 children after a Kasai procedure, without transplantation, were 63%, 54%, and 44%, respectively. By age 20, almost half had cirrhosis and its sequelae (Shinkai et al., 2009).

Liver Tumor Procedures

Liver tumors in children are uncommon, but 72% of pediatric primary hepatic tumors and 1.1% of all childhood tumors

TABLE 23-3. Malignant Hepatic Tumors

Tumor Type	Tumor	Cases Reported
Hepatomas	Hepatoblastoma	129
	Hepatocellular carcinoma	98

are malignant. Of these malignant tumors, hepatoblastoma and hepatocarcinoma are the predominant tissue types (Table 23-3). Hepatoblastoma commonly affects white boys less than 2 years of age. An abdominal mass that has increased in size is usually the presenting symptom. Anemia, jaundice, and ascites are infrequent findings. Liver function test results are frequently normal. From 2% to 3% of patients may have an associated hemihypertrophy (Geiser et al., 1970). Hepatoblastoma has also been associated with isosexual precocity as a result of the liver's ectopic gonadotropic production and the Beckwith-Wiedemann syndrome (Sotelo-Avita et al., 1976), polyposis coli, Wilms tumor, and fetal alcohol syndrome. An increased incidence of hepatoblastoma has been associated with low birth weight (Ikeda et al 1997; Feusner et al., 1998) (Box 23-4). Between 1973 and 1997, the rate of hepatoblastoma increased. This is in contrast to the decreased incidence observed for hepatocarcinoma (Darbari et al., 2003).

Hepatoblastomas are derived from primitive epithelial parenchyma and are classified by the predominant epithelial component. Among the variants are fetal, embryonal, macrotrabecular, and anaplastic. Survival is related to the histology and complete-

ness of the surgical resection (Table 23-4). Fetal histology has a greater than 90% survival rate, compared with a 50% survival rate for embryonal histology. A few survivors have anaplastic histology. Patients with resectable stages I and II hepatoblastomas have better survival (95%) than patients with unresectable stage III (69%) or metastatic disease (37%). For patients with resectable disease, a 5-year survival rate is 83%, as opposed to 41% for those who had residual tumor after surgery (Finegold et al., 2008) (see Box 23-4). Complete surgical resection offers the only chance for cure in patients with hepatocellular carcinoma, because the tumor is chemoresistant. In patients requiring a liver transplant, the 1-, 5-, and 10-year survival rates are 86%, 67%, and 58%, respectively (Fig. 23-9).

Liver transplantation has been used as both a primary surgical therapy and a rescue for incomplete resection or recurrence of disease. Patients who were rescued had a 30% disease-free survival compared with 82% in the primary treatment group (Otte et al., 2004).

Hepatocellular carcinoma appears to have two age peaks: one at less than 4 years of age and the other between 12 and 15 years of age (Leventhal, 1987). As in adults with hepatocellular carcinoma, the prognosis of survival in children with the disease is 5% to 10%. Typically, patients with hepatocellular carcinoma have the systemic symptoms of weight loss, jaundice, fever, and lethargy. As opposed to adults with this tumor, only about 5% of children have associated cirrhosis (Jones, 1960). Other associated diseases include von Gierke's disease, type I glycogenesis, cystinosis, extrahepatic biliary atresia, α_1 -antitrypsin deficiency, hypoplasia of intrahepatic bile ducts, Wilson's disease, giant cell hepatitis, and Solo's syndrome (Zangeneh et al., 1969; Palmer and Wolfe, 1976; Weinberg et al., 1976; Dehner, 1978) (see Box 23-4). Complete surgical resection offers the only chance for a cure for patients with hepatocellular carcinoma, because the tumor is chemoresistant. In patients requiring a liver transplant, the 1-, 5-, and 10-year patient survival rates are 86%, 67%, and 58%, respectively (see Fig. 23-9).

Anesthetic management for pediatric patients undergoing hepatic lobe resection or tumor resection involves the same principles as for patients with biliary atresia. Efforts at maintaining adequate alveolar ventilation, temperature homeostasis, cardiovas-

FIGURE 23-9. One-year patient survival: United Network for Organ Sharing (UNOS) standard transplant and research file 1989–2007. A total of 8047 patients (age, <18 years) who underwent orthotopic liver transplant between 1989 and 2007 were analyzed from the UNOS database. Of these patients, 237 underwent transplantation for hepatoblastoma, 58 for hepatocellular carcinoma, 35 for hemangioendothelioma, and 36 for other tumors. HB, Hepatoblastoma; HCC, hepatocellular carcinoma; HEH, hemangioendothelioma. cular stability, and fluid management have been described. Some patients receive adjunct chemotherapy before surgery. The chemotherapeutic protocol must be reviewed. Frequently, Adriamycin, an anthracycline, is a major component of hepatic cancer chemotherapy and has been associated with a dosage-dependent irreversible cardiomyopathy. All patients receiving anthracycline chemotherapy should be studied by history, physical examination, electrocardiography, chest radiography, and echocardiography to further evaluate signs and symptoms of cardiac toxicity and cardiac reserve (see Chapters 4 and 36, Cardiovascular Physiology and Systemic Disorders).

Because the potential for massive blood loss exists in patients undergoing hepatic resection, adequate venous access and invasive monitoring are essential to patient management. Two or three large-bore peripheral IV catheters are inserted, and a central venous pressure catheter is placed to monitor cardiac filling pressures. Either the radial or the femoral artery is cannulated, not only to monitor blood pressure but also to determine blood gas levels, chemistry, and coagulation profile. Because of the potential for large fluid shifts, a Foley catheter is placed to measure urine output and assist in assessing the adequacy of fluid resuscitation.

Massive blood volume replacement is a frequent component of the anesthetic resuscitation in children undergoing hepatic resection. Massive blood volume replacement may create physiologic derangements that have anesthetic and surgical consequences. These physiologic alterations include disorders of coagulation, acid-base imbalance, electrolyte imbalance, hypothermia, and decreased tissue oxygen delivery.

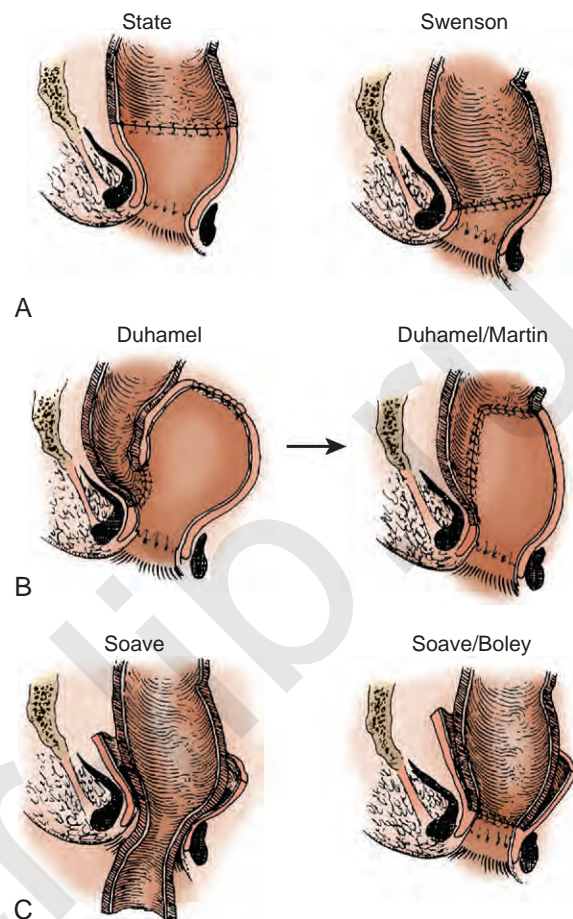

Many children undergoing tumor resection require postoperative ventilatory support. The anesthetic plan should permit early tracheal extubation in the operating room. However, in the event that intraoperative findings reveal unresectable tumor, postoperative care should include observation in the pediatric intensive care unit and attention to changes in intravascular volume and blood pressure. Continued bleeding may require transfusion of blood or fresh frozen plasma, or even return to the operating room for surgical control.

Hirschsprung's Disease Procedures

The basic pathology underlying congenital megacolon, or Hirschsprung's disease, is aganglionosis, or total absence of ganglion cells, in the intrinsic nerve supply of the bowel. The aganglionic area extends proximally from the anal sphincter and involves varying lengths of colon. The normal nerve supply, consisting of Auerbach's plexuses and Meissner's plexuses, which together form the myenteric nerve complex of the bowel, usually becomes an increasingly diffuse network in the descending and terminal portions of the bowel. Absence of the ganglion cells, which occurs in approximately 1 in 10,000 infants, causes a condition resembling spasm in the area without ganglion cells, and the normal bowel proximal to the spastic portion undergoes tremendous distention, with retention of feces and intestinal obstruction or, in less serious cases, prolonged bouts of constipation. Although the cause of Hirschsprung's disease is unknown, defects in nonadrenergic, noncholinergic innervations may prevent relaxation of the aganglionic segment. Bealer and colleagues (1994) demonstrated that nitric oxide synthetase is deficient in the aganglionic colon of patients with Hirschsprung's disease, and that this deficiency may prevent smooth muscle relaxation of the aganglionic segment. On a molecular level, mutations in the RET protooncogene have been found (Sancandi et al., 2000).

In 10% to 20% of patients with Hirschsprung's disease, it is clinically present at birth. Symptomatic infants have delayed passage of meconium, irritability, failure to thrive, and abdominal distention. Older children may present with constipation, fecal soiling, and diarrhea. The major complication from Hirschsprung's disease is acute enterocolitis, a potentially life-threatening event. Diagnosis of Hirschsprung's disease is made by radiographic examination and confirmed by suction biopsy specimens from the rectum. Surgery is usually a two-stage procedure, with the initial procedure being a colostomy. The definitive surgical procedure is generally performed when the child is older (>1 year). The surgical approaches are varied and over time have undergone modifications (Fig. 23-10). Attention has focused on the use of a one-stage transanal endorectal pull-through approach (Elhalaby et al., 2004). Each surgical technique has its own associated intraoperative and perioperative complications, but enterocolitis, wound dehiscence, anastomotic leakage, intestinal obstruction, and fecal soiling are common to all. All of these surgical procedures aim either to excise or to bypass the aganglionic portion of the bowel and to free and advance the remaining normal portion of bowel toward the rectum. These procedures are often long (6 to 8 hours) and involve surgical explorations through the perineum and abdomen.

Laparoscopic surgery has also been used in the treatment of Hirschsprung's disease (Jona et al., 1998; Wulkan and Georgeson, 1998; Georgeson et al., 1999). The minimally invasive assisted pull-through technique is generally used for patients when

■ **FIGURE 23-10.** Lateral views of the three major operative procedures for Hirschsprung's disease. Evolution of each occurs from left to right. Unshaded native rectum is aganglionic. Shaded, pulled-through bowel contains ganglion cells. **A**, State's procedure was a prototypical anterior resection of dilated rectosigmoid. Lengthy aganglionic segment remained. In Swenson's procedure, an oblique anastomosis resulted in ganglion cells within 1 cm of the verge posteriorly. **B**, In the original Duhamel's operation, the oversewn native rectum enlarged as a blind loop, which resulted in a fecaloma that caused partial obstruction. In Martin's modification, the blind loop is obviated by complete division of the septum and anastomosis of the anterior walls of the native rectum and pulled-through colon. Bowel that contains ganglion cells reaches within 1 cm of the anal verge posteriorly. **C**, In the original Soave's procedure, full-thickness colon that contained ganglion cells was advanced through the demucosalized native rectal sleeve. Excess colon extended from the anus for several weeks before transection and delayed anastomosis. In the Boley modification, a primary anastomosis is done 1 cm above the verge. Ganglion cells are present circumferentially at that level. (From Philappart AI: *Hirschsprung's disease*. In Ashcraft KW, Holder TM: *Pediatric surgery*, ed 2, Philadelphia, 1993, Saunders.)

the aganglionic segment is confined to the rectum sigmoid or proximal left colon (Georgeson, 2002). Anesthetic concerns for patients with Hirschsprung's disease are similar to those for any child having surgery. Maintaining body temperature and providing appropriate fluid therapy (for replacement of large third-space losses) are the major challenges for the anesthesiologist.

Anesthesia induction can be either by inhalation or IV means. Because of the surgical bowel manipulation and the relatively obstructive nature of the underlying disease, nitrous oxide is

discontinued after induction, and anesthesia is maintained with a mixture of air, oxygen, and potent inhalation agent. Long-term follow-up of patients with Hirschsprung's disease suggests that 25% of patients will require reoperation, and that 19% to 25% of patients will develop enterocolitis (Fortuna et al., 1996).

Surgery for Appendicitis

Acute appendicitis is a common condition in children. Although the mortality from acute appendicitis is rare (case-fatality ratio, 0.3%) (Addiss et al., 1990), morbidity (peritonitis, abscess formation, wound infection) is related to the state of the appendix at the time of the operation. The highest incidence of appendicitis is found in patients aged 10 to 19 years. The incidence of perforation of the appendix in children appears to be about 30% to 45%, but in preschool children and infants it can be as high as 80%. The incidence of appendicitis appears to be affected by race and gender. The incidence of appendicitis is 1.4 to 1.6 times greater in whites than nonwhites, whereas the perforation rate for nonwhites is 22% compared with 18% for whites (Addiss et al., 1990).

The signs and symptoms of appendicitis are variable. The incidence of negative appendectomy (surgery performed without positive appendicitis) is significant. In males, the negative appendectomy rate is about 9%, whereas in females it is about 22%. In females, diagnostic accuracy decreases during child-bearing years, whereas in males, diagnostic accuracy does not appear to be affected by age. Classically, the patient presents with periumbilical pain that eventually localizes to the right lower quadrant. Anorexia, nausea, and vomiting are frequent, as is a low-grade fever. Continued progression of the inflammatory course results in increased tenderness in the right lower quadrant as well as pain referred to the right lower quadrant on palpation of other areas of the abdomen. With advanced disease, gangrene and perforation of the appendix occur, with ensuing peritonitis and possible abscess formation. Both ultrasound and computed tomographic (CT) imaging have been used to evaluate appendicitis in children. The advantages of ultrasound include cost, lack of exposure to radiation, and its ability to assess ovarian pathology, but CT affords a higher diagnostic accuracy and better delineation of extent of disease where the appendix is perforated.

The pathophysiology of appendicitis is thought to be related to an obstruction of the lumen of the appendix, with subsequent bacterial overgrowth and distention of the appendix (Fig. 23-11). In untreated cases, distention and overgrowth lead to gangrene and rupture. Although there is some urgency in making the diagnosis and surgically removing the appendix, the operation is never so urgent that a proper review of the patient's medical history and physical assessment cannot be performed.

Preoperative anesthetic management of the child with diagnosed appendicitis includes concerns regarding fluid and electrolyte disorders. Because these children may have been vomiting and may be febrile, signs and symptoms of dehydration should be assessed and any fluid or electrolyte deficits corrected.

Once the child has been adequately volume-resuscitated and a normal airway is anticipated, an IV rapid-sequence induction with cricoid pressure is performed. Anesthetic technique (inhalation agents versus opioid-based techniques) may depend on the surgical technique used to remove the appendix. Although frequently the appendix is removed by laparotomy, the role of laparoscopy (especially in female patients) in both diagnosis and management is increasing (Gilchrist et al., 1992; Kuster

■ FIGURE 23-11. Laparoscopic acute appendicitis.

and Gilroy, 1992; Olsen et al., 1993). See related video online at www.expertconsult.com. In a study by McAnena and coworkers (1992), the median postoperative hospitalization stay was one half and the rate of wound infection one third in patients undergoing laparoscopic appendectomy compared with patients undergoing open appendectomy. In a study involving 30 pediatric hospitals, Newman and colleagues (2003) noted significant variability in practice and resource utilization among the institutions. In addition, the length of stay did not differ between those patients who underwent an open or a laparoscopic appendectomy.

Regardless of surgical technique, monitoring of the patient includes electrocardiogram, pulse oximeter, temperature probe, blood pressure cuff, precordial stethoscope, and end-tidal gas measurements. Depending on the patient's body temperature, active cooling techniques (cooling blanket, rectal acetaminophen suppositories, cool IV fluids, and cool intraabdominal irrigations) may be needed to help lower the patient's temperature. The addition of inhalational anesthetics may also augment cooling by promoting cutaneous vasodilation with subsequent increased heat loss.

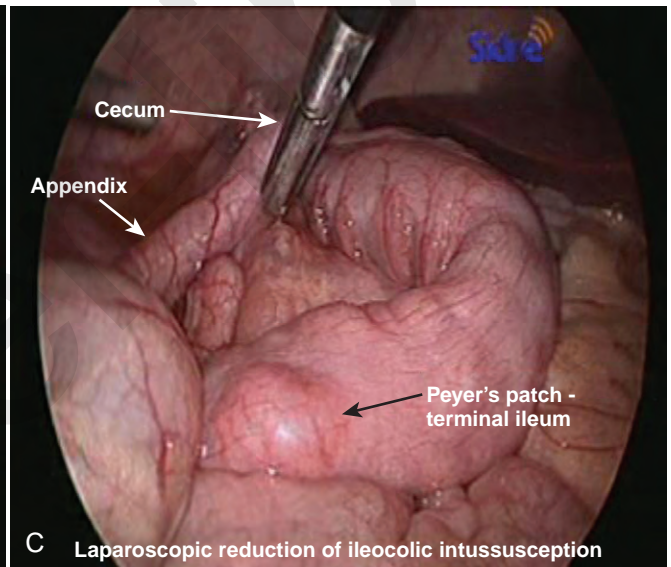

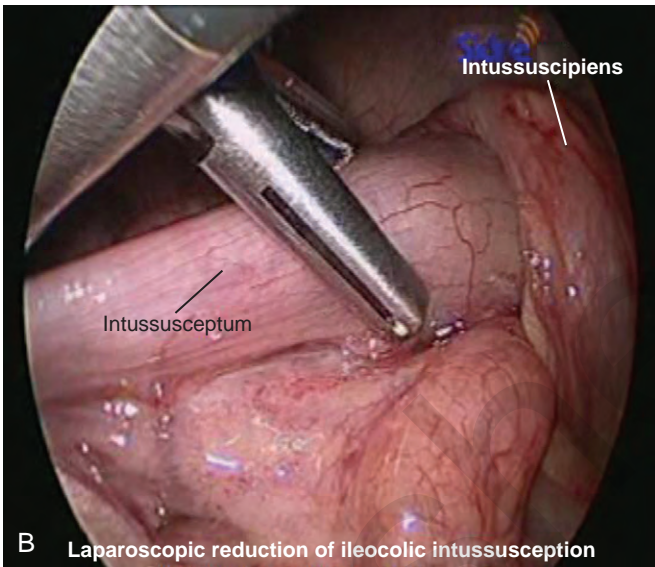

Intussusception Repair

Intussusception is the invagination or telescoping of one portion of the intestine into another (Fig. 23-12). It tends to occur more frequently in males than females. Over 50%

A

■ **FIGURE 23-12.** **A**, Intussusception. **B**, Laparoscopic view of intussusception, **C**, Laparoscopic view of reduced intussusception with hypertrophied Peyer's patch at the lead point. **D**, Diagnostic enema encounters the intussusceptum in the mid-transverse colon (M). **E**, The coiled-spring appearance of an ileocolic intussusception: the contrast material has interdigitated between the intussusceptum and the intussusciens (**A**, From deLorimier AA, Harrison MR: *Pediatric surgery*. In Dunphy JE, Way LW: *Current surgical diagnosis and treatment*, Los Altos, Calif, 1979, Lange Medical. **D** and **E**, From Blickman JG, Parker R, Barnes PD: *Pediatric radiology*, St Louis, 2009, Mosby, p 73.)

of cases occur in children less than 1 year of age, and less than 10% of cases occur in children older than 5 years. Ninety percent of cases have idiopathic causes—frequently seen in children less than 1 year of age. Older children are more likely to have Meckel's diverticulum, intestinal polyps, lymphoma, adhesions, trauma, hemolytic uremic syndrome, or ectopic pancreatic nodule as an etiology. Intussusception has also been reported postoperatively and after blunt abdominal trauma (Komadina and Smrkolj, 1998; Linke et al., 1998). In addition, an association between rotavirus vaccine and intussusception has been reported (Zanardi et al., 2001).

The clinical presentation of acute intussusception involves sudden paroxysms of abdominal pain, bloody stools, and an abdominal mass, although in one series of patients, 18% of the children had painless intussusception (Hutchison et al., 1980). In a review of 14 published reports, Losek (1993) noted that bloody stools were present in 42% of patients. Occult blood was noted in 43% and abdominal masses were present in 62% of patients. Intussusception can also manifest with neurologic findings (lethargy, apnea, seizures, hypotonia, opisthotonus) similar to a picture of septic encephalopathy (Conway, 1993). Other symptoms and signs may include diarrhea, vomiting, fever, and dehydration. In other children, intussusception can be a chronic entity that may mimic gastroenteritis (Shekhawat et al., 1992), whereas in neonates, intussusception may mimic necrotizing enterocolitis (Price et al., 1993).

About 90% of intussusceptions are ileocolic, and the remainder are ileoileal and colocolic. Treatment for intussusception involves the administration of appropriate fluids to combat dehydration, and radiologic or surgical attempts to reduce the invaginated bowel. Hydrostatic enemas with barium or air have been reported to be successful in 80% of patients. However, enemas are contraindicated in patients with evidence of peritonitis, shock, and intestinal perforation. Surgical laparotomy with manual reduction or resection (or both) as well as laparoscopic approaches have been described for surgical management in patients with unsuccessful radiologic reduction and in patients with signs of intestinal perforation, peritonitis, and shock (Hay et al., 1999).

Anesthetic considerations include restoring electrolyte and fluid deficits. Shock should be treated before commencing anesthesia. The intravascular deficits may be further exacerbated by the presence of barium in the gastrointestinal tract. The child with an intussusception should also be considered at risk for aspiration, and because of the intestinal obstruction, nitrous oxide should be avoided. Anesthesia should be induced with IV agents. If hemodynamic instability is a concern, ketamine or etomidate should be used as the hypnotic agent for induction.

GENERAL THORACIC SURGERY

Thoracic surgery in children is performed for a wide variety of congenital, neoplastic, infectious, and traumatic lesions (Box 23-5). The patient may be a few hours old with a congenital cystic adenomatoid malformation (CCAM) and life-threatening respiratory distress or an adolescent with an asymptomatic mediastinal tumor. Regardless of age or disease, four principles are common to all patients undergoing general anesthesia for thoracic surgery, as follows:

- Preoperative evaluation and preparation can minimize intraoperative problems and improve the safety of the anesthetic.

Box 23-5 Childhood Lesions Requiring Thoracic Surgery

- Empyema
- Chest wall deformities
- Chest wall masses
- Lung abscess
- Bronchiectasis
- Lobar emphysema
- Tumor (primary or metastatic)
- Pulmonary sequestration
- Congenital adenomatoid malformation
- Congenital cysts of the lung
- Bronchogenic cysts
- Esophageal lesions
- Mediastinal masses
- Scoliosis

- The anesthesiologist must be aware of potential intraoperative problems.
- Modern monitoring techniques have increased safety with regard to anesthetic management.
- Surgical approaches and techniques are constantly changing as efforts are made by surgeons to use minimally invasive procedures.

A thorough preoperative evaluation is essential in caring for the pediatric patient scheduled for thoracic surgery. Appropriate imaging and laboratory studies should be performed preoperatively according to the lesion involved. Guidelines for fasting, choice of premedication, and preparation of the operating room are used as for other infants and children scheduled for major surgery. After induction of anesthesia, placement of an IV catheter, and tracheal intubation, arterial catheterization should be performed for most patients undergoing thoracotomy as well as for those with severe lung disease having thoracoscopic surgery. This facilitates monitoring of arterial blood pressure during manipulation of the lungs and mediastinum, as well as monitoring of arterial blood gas tensions during single lung ventilation (SLV). For thoracoscopic procedures of relatively short duration in patients without severe lung disease, the insertion of an arterial catheter is not required (Rao et al., 1981). Placement of a central venous catheter is generally not indicated if peripheral IV access is adequate for projected fluid and blood administration.

Inhaled anesthetic agents are commonly administered in 100% O₂ during maintenance of anesthesia. Isoflurane may be preferred because there is less attenuation of hypoxic pulmonary vasoconstriction (HPV) than with other inhaled agents, although this has not been studied in children (Benumof et al., 1987). Nitrous oxide is avoided. Use of IV opioids may facilitate a decrease in the concentration of inhaled anesthetics used and thereby limit impairment of hypoxic pulmonary vasoconstriction. Alternatively, total IV anesthesia may be used with a variety of agents. The combination of general anesthesia with regional anesthesia and postoperative analgesia is particularly desirable for thoracotomy, but it may also be beneficial for thoracoscopic procedures, especially when thoracostomy tube drainage, a source of significant postoperative pain, is used after surgery. A variety of regional anesthetic techniques have been described for intraoperative anesthesia and postoperative

analgesia, including intercostal and paravertebral blocks, intrapleural infusions, and epidural anesthesia (see Chapter 16, Regional Anesthesia).

In awake patients, except for young infants, ventilation is normally distributed preferentially to dependent regions of the lung, so that there is a gradient of increasing ventilation from the most nondependent to the most dependent lung segments. Because of gravitational effects, perfusion normally follows a similar distribution, with increased blood flow to dependent lung segments; therefore, ventilation and perfusion are normally well matched. However, controlled ventilation under general anesthesia with decreased functional residual capacity and absent diaphragmatic contractions results in a reverse distribution of ventilation (see Chapter 3, Respiratory Physiology in Infants and Children). During thoracic surgery, these and other factors act to increase ventilation/perfusion (V/Q) mismatch. Compression of the dependent lung in the lateral decubitus position may cause atelectasis. Surgical retraction, SLV, or both result in collapse of the operative lung. Hypoxic pulmonary vasoconstriction (HPV), which acts to divert blood flow away from under-ventilated lung regions, thereby minimizing V/Q mismatch, may be diminished by the use of inhaled anesthetic agents and other vasodilating drugs. These factors apply similarly to infants, children, and adults. The overall effect of the lateral decubitus position on V/Q mismatch, however, differs in infants compared with older children and adults.

In adults with unilateral lung disease, oxygenation is optimal when the patient is placed in the lateral decubitus position with the healthy lung dependent (down) and the diseased lung nondependent (up) (Bachland et al., 1975; Remolina et al., 1981). Presumably, this is related to an increase in blood flow to the dependent, healthy lung and a decrease in blood flow to the nondependent, diseased lung as a result of the hydrostatic pressure (i.e., gravitational) gradient between the two lungs. This phenomenon promotes V/Q matching in the adult patient undergoing thoracic surgery in the lateral decubitus position.

In infants with unilateral lung disease, however, oxygenation is better with the healthy lung up (Heaf et al., 1983). Several factors account for this discrepancy between adults and infants. Infants have a soft, easily compressible rib cage that cannot fully support the underlying lung. Functional residual capacity, especially in the lower lung, is closer to or at residual volume, making airway closure likely to occur in the dependent lung even during tidal breathing (Mansell et al., 1972).

Finally, the infant's increased oxygen requirement, coupled with a small functional residual capacity, predisposes to hypoxemia. Infants normally consume 6 to 8 mL of O₂/kg per minute, compared with a normal O₂ consumption in adults of 2 to 3 mL/kg per minute (Dawes, 1973). For these reasons, infants are at increased risk for significant oxygen desaturation during surgery in the lateral decubitus position.

Thoracoscopy

During the past decade, the use of video-assisted thoracoscopic surgery has dramatically increased in both adults and children (see Video Endoscopy, p. 745). As with laparoscopy, reported advantages of thoracoscopy include smaller chest incisions, reduced postoperative pain, and more rapid postoperative recovery compared with thoracotomy (Weatherford et al., 1995; Angelillo Mackinlay et al., 1996; Mouroux et al., 1997).

Box 23-6 Thoracoscopic Procedures in Infants and Children

- Patent ductus arteriosus ligation
- Segmentectomy
- Sequestration resection
- Sympathectomy
- Tracheoesophageal fistula ligation
- Thymectomy
- Thoracic duct ligation

Thoracoscopic surgery is being used extensively for pleural débridement in patients with empyema, lung biopsy, and wedge resections for interstitial lung disease, mediastinal masses, and metastatic lesions. More extensive pulmonary resections, including segmentectomy and lobectomy, have been performed for lung abscess, bullous disease, sequestrations, lobar emphysema, CCAM, and neoplasms. Thoracoscopic procedures used in infants and children are listed in [Box 23-6](#).

Thoracoscopy can be performed while both lungs are being ventilated using CO₂ insufflation and a retractor to displace lung tissue in the operative field. However, SLV is extremely desirable during thoracoscopy, because lung deflation improves visualization of thoracic contents and may reduce lung injury caused by the retractors (Benumof, 1995).

Surgery for Chest Wall Deformities

Pectus excavatum (funnel chest) ([Fig. 23-13](#)) and the less common pectus carinatum (pigeon breast) deformities are congenital abnormalities of the sternum, ribs, and costal cartilages. These deformities are usually minimal at birth but progress with age. A higher incidence of both deformities occurs in children with Marfan syndrome or congenital heart disease, and in families in which other children have the defect (Shamberger and Welch, 1987; Robicsek and Lobato, 2000). These children often appear asymptomatic but occasionally have cardiac or pulmonary abnormalities related to the deformity (Malek et al., 2003). Patients with pectus excavatum generally present with normal

■ **FIGURE 23-13.** Pectus excavatum deformity becomes most obvious when the child is in the sitting position.

or modestly reduced forced vital capacity and total lung capacity and, in severe cases, V/Q mismatch. The heart is displaced to the left and compressed, lending to arrhythmias, right-axis deviation on electrocardiogram, a functional murmur, and reduced stroke volume—most noticeable in the standing position and during exercise, explaining the mild exercise intolerance experienced by some patients. The cardiac and pulmonary abnormalities are in most instances benign and may worsen as the child ages but may be improved by surgical repair. There also is an increased incidence of mitral valve prolapse in patients with pectus deformities (Shamberger et al., 1987).

Preoperative assessment focuses on exercise tolerance and other signs of cardiopulmonary compromise, such as lung infections. Laboratory evaluation includes a chest radiograph; pulmonary function tests, arterial blood gases, and electrocardiogram are added only if there is clinical evidence of significant underlying disease. Echocardiography is now commonly performed to detect the presence of mitral valve prolapse, and, if the child has it, prophylaxis for subacute bacterial endocarditis is administered. Patients are often emotionally distressed by the appearance of a chest deformity and may benefit from preoperative counseling and, if needed, premedication.

Classic operative repair involves extrapleural excision of the sternocostal cartilages and mobilization of the sternum and ribs. The most common complications of operative repair are pneumothorax, flail chest, and postoperative atelectasis; blood loss is usually minimal to moderate. Intraoperative monitoring includes temperature, blood pressure, pulse, heart and breath sounds, airway pressure, and oxygen saturation or tension. Capnography is also useful, but arterial catheterization is needed only if there is a specific indication. General anesthesia

with controlled ventilation is the method of choice, with no agents specifically indicated or contraindicated because of the operation itself. Oxygen by face mask is administered in the recovery room, but it is usually not needed after the child fully awakens. Although patient-controlled analgesia is commonly used for postoperative analgesia, both intercostal nerve blocks and thoracic epidural analgesia have become increasingly popular for children undergoing pectus repair (Robicsek, 2000).

A thoracic epidural catheter provides more reliable analgesia to the operative area than a lumbar epidural that has been threaded a great distance. However, thoracic epidural catheters are not as easy to insert as lumbar catheters, and many practitioners are not comfortable with their routine use. Although a technique using electrocardiographic guidance and insertion from the caudal space has been described, it is not widely used (Tsui et al., 2002). An additional issue with the thoracic catheters is the safety of their insertion under general anesthesia (Horlocker, 2003). Although some children allow insertion before induction (McBride et al., 1996), many younger children are not likely to remain cooperative for the procedure, mandating insertion after induction (Hammer, 2002; Birmingham et al., 2003). Moreover, several centers have actively and successfully used thoracic epidural techniques in anesthetized children for thoracic and cardiac procedures without complications related to insertion after induction (Cassady, 2000; Birmingham, 2003). Solutions of both bupivacaine with fentanyl and fentanyl alone have been used successfully, including in the patient-controlled mode for appropriately mature children (Caudle et al., 1993; Birmingham et al., 2003) (see Chapter 16, Regional Anesthesia).

Another approach is to use a minimally invasive technique in which the costal cartilages are preserved and the sternum is elevated with a bar. Under direct vision and through a thoracoscope, a transmediastinal tunnel is created and a prebent bar is passed behind the sternum with the convex side down. The bar is then rotated 180 degrees to elevate the sternum (Fig. 23-14) (Nuss et al., 1998; Nuss, 2002). Borowitz and coworkers (2003) have shown that static pulmonary function and ventilatory response to exercise was normal both before and after surgery, thereby suggesting that placement of the bar does not result in an increased chest wall restriction. In addition, Lawson and colleagues (2003) noted that the surgical repair of the pectus excavatum after the Nuss procedure had a positive impact on the patient's physical and emotional well-being. Complications of this minimally invasive approach include atelectasis, subcutaneous emphysema, pericardial and pleural effusions, myocardial perforation, diaphragmatic perforation, and dislocation of the stabilizing bar (Willekes et al., 1999; Hebra et al., 2000; Molik et al., 2001; Moss, 2001; Hosie et al., 2002; Uemura et al., 2003). Postoperative pain after the Nuss procedure is significant. Thoracic epidural analgesia for 2 to 3 days, followed by oral opioid and nonsteroidal antiinflammatory drug therapy, is appropriate.

Thoracotomy, Lobectomy, and Pneumonectomy

Thoracotomy in the infant or child may be indicated for congenital abnormalities (cysts), tumors (mediastinal teratomas), trauma (gunshot wounds), or infective lesions (bronchiectasis). Subsegmental resection is used for biopsy and removal of

■ **FIGURE 23-14.** CT scan of a patient undergoing Nuss procedure (A). AP (B) and lateral (C) radiographs of a patient with a Nuss bar in place.

metastatic tumors, whereas lobectomy is most commonly used for removal of congenital anomalies and extensive tumor metastasis. Pneumonectomy in children is done for various tumors, congenital abnormalities, and inflammatory lesions such as bronchiectasis. Perioperative management differs dramatically depending on the indication for surgery.

Surgical Lesion

If a space-occupying lesion is present, the patient is examined for signs of decreased cardiac output, diminished lung volume and reserve, and airway compression (Keon, 1981). History focuses not only on general exercise tolerance but also on signs of intermittent airway obstruction (stridor, cyanosis, or wheezing). Physical examination includes checking for a shift in the trachea, asymmetric chest movement, wheezing, and any signs of respiratory distress. Laboratory assessment should include a chest radiograph, but additional studies such as tomography, angiography, or computed tomography often provide more exact data about vascular or airway compression and compromise. It is crucial to determine the extent of airway compression and physiologic compromise, because impairment may worsen with induction of anesthesia as sympathetic and muscular tones are reduced.

If the intrathoracic lesion is a primary or metastatic tumor, the history concentrates on previous treatment (Baldeyrou et al., 1984). Previous treatment for the tumor, especially chemotherapy and radiation, is important to know about. Special attention is given to anthracycline (cardiac toxicity), bleomycin (pulmonary toxicity), and steroid (adrenal suppression) therapy. If there is any question about functional disability caused by this treatment, consultation with the child's oncologist is useful. Anemia, thrombocytopenia, and malnutrition are common in these patients and should be improved before surgery (Beattie, 1984). A special consideration is the immunocompromised patient with an unknown pulmonary infiltrate. This is usually assumed to be an opportunistic infection, but because it may represent metastasis, a biopsy is occasionally requested. These patients are often in poor general condition and may require postoperative ventilatory support, especially if they had only marginal compensation before surgery (Imoke et al., 1983; Prober et al., 1984).

Assessment

General assessment of the child starts with vital signs and overall appearance. Because children tolerate the loss of large amounts of usable lung tissue without obvious distress, the

appearance of dyspnea or diminished exercise tolerance is an ominous sign. The history in older children focuses on complaints of dyspnea, cyanosis, wheezing, coughing, and weight loss. Infants often show less specific signs, such as poor feeding, irritability, choking, or change in sleep habits. If the child has had previous surgery, the perioperative course should be examined. The chest is inspected for asymmetric expansion and use of accessory muscles and then is auscultated for wheezes, rales, rhonchi, and absent breath sounds in both the supine and sitting positions. Physical assessment of the cardiovascular system concentrates on the presence of a gallop, murmurs, arrhythmias, and adequate peripheral pulses.

Preparation

Preparation for surgery starts with a discussion of the proposed anesthetic with the parents and, if appropriate, with the child. The anesthetic plan, including monitoring, possible complications, and potential for postoperative ventilation, is discussed. It is best to delay surgery until any infection or bronchospasm has been brought under optimal medical control with antibiotics, chest physiotherapy, and bronchodilators, as needed (Sutton et al., 1983). It may be difficult or impossible to eradicate infections or bronchospasm completely in destructive lesions such as bronchiectasis. If this is the case, it is acceptable to proceed after reasonable medical therapy has optimized the patient's status so that no further improvement is anticipated.

Monitoring

At a minimum, thoracotomy requires monitoring of inspired oxygen, blood pressure, heart and breath sounds, airway pressure, and temperature, as well as an electrocardiogram. Oxygen saturation by pulse oximeter or, less commonly, by transcutaneous oxygen tension (P_{O_2}) monitor (Harnick et al., 1983) is vital for detection of sudden changes in oxygenation from lung compression or kinking of the airway. Capnography is particularly useful for detecting sudden changes in effective ventilation. Arterial cannulation for pressure and arterial blood samples is useful and is needed if extensive blood loss or resection of lung tissue is expected or if the child is already critically ill. Percutaneous arterial cannulas (24 gauge in neonates, 22 gauge in children up to 8 to 10 years of age, and 20 gauge in preadolescents and older) can be inserted in children and should be used whenever indicated. Central venous monitoring is used less commonly but can be helpful for guiding extensive volume replacement. Urinary drainage is a consideration for particularly long procedures.

Positioning

Positioning of the patient has often been used to minimize spillage of lung contents because double-lumen tubes are impractical in smaller patients (Conlan et al., 1986). Suction through the ETT may not be adequate to control the large quantities of pus freed during surgical manipulation. The prone and lateral positions are the most commonly used. Positioning can cause significant ventilatory changes in children. Functional residual capacity (FRC) decreases during general anesthesia (Motoyama et al., 1982), and it falls dramatically once the pleura is opened (Larsson et al., 1987).

The practical problems of dislodgment of the ETT with movement and adequate padding in these positions are especially important in children. Open-celled foam with adhesive backing (Reston; 3M, St. Paul, MN) can be applied to the thorax, pelvic rim, and other pressure points to minimize the effects of positioning. Also, the tube position must be rechecked each time the patient is moved.

Anesthesia

General endotracheal anesthesia presents various challenges to the anesthesiologist. A quiet, smooth inhalation induction is often used in infants and smaller children, whereas an IV induction is used in the older child. If there is concern about spillage of lung contents, rapid securing of the airway with IV induction is preferred to minimize coughing. The choice of appropriate anesthetic agents depends on both the patient's status and the surgical lesion. Nitrous oxide can accumulate in cysts with air-fluid levels and should be avoided in these patients or in patients requiring a high fraction of inspired oxygen (F_{iO_2}). Volatile agents are especially useful in patients with bronchospastic disorders. The rate of rise of inhalational anesthetics may be slowed in the presence of intrapulmonary shunting. Precipitous hypotension is another potential problem with volatile agents in patients with low cardiac reserve. Muscle relaxants are routinely used along with controlled ventilation employing humidified gases. Although mechanical ventilators are usually acceptable, manual ventilation provides useful information to the anesthesiologist about changes in compliance or airway resistance, especially in infants or in procedures where there is recurrent obstruction of the airway.

Single-Lung Ventilation Techniques

Single-Lung Ventilation Using a Single-Lumen Endotracheal Tube. The simplest means of providing SLV is to intentionally intubate the ipsilateral main stem bronchus with a conventional single-lumen ETT (Baraka, 1987; Kubota et al., 1987; Rowe et al., 1994). See related video online at www.expertconsult.com. When the left bronchus is to be intubated, the bevel of the ETT is rotated 180 degrees and the patient's head is turned to the right (Bloch, 1986; Kubota et al., 1987). The ETT is advanced into the bronchus until breath sounds on the operative side disappear. A fiberoptic bronchoscope (FOB) may be passed through or alongside the ETT to confirm or guide placement (Watson et al., 1982). When a cuffed ETT is used, the distance from the tip of the tube to the distal cuff must be shorter than the length of the bronchus so that the ETT does not occlude the upper lobe bronchus (Lammers et al., 1997) (Fig. 23-15). This technique is simple and requires no special equipment other than a FOB. This may be the preferred technique of SLV in emergency situations such as airway hemorrhage or contralateral tension pneumothorax.

Problems can occur when using a single-lumen ETT for SLV. If a smaller, uncuffed ETT is used, it may be difficult to provide an adequate seal of the intended bronchus. This may prevent the operative lung from adequately collapsing, or it may fail to protect the healthy, ventilated lung from contamination by purulent material from the contralateral lung. The operative lung cannot be suctioned using this technique. Hypoxemia may occur because of obstruction of the upper lobe bronchus, especially when the short right main stem bronchus is intubated.

■ **FIGURE 23-15.** Obstruction of the left upper lobe bronchus with a cuffed endotracheal tube used for left-sided, single-lung ventilation.

Single-Lung Ventilation Using a Balloon-Tipped Bronchial Blocker.

A Fogarty embolectomy catheter or an end-hole, balloon-wedge catheter may be used for bronchial blockade to provide SLV (Fig. 23-16) (Ginsberg, 1981; Lin and Hackel, 1994; Hammer et al., 1996; Turner et al., 1997). Placement of a Fogarty catheter is facilitated by bending the tip of its stylet toward the bronchus on the operative side. A FOB is used to reposition the catheter and confirm appropriate placement. When an end-hole catheter is placed outside the ETT, the bronchus on the operative side is initially intubated with an ETT. A guidewire is then advanced into that bronchus through the ETT. The ETT is removed and the blocker is advanced over the guidewire into the bronchus. An ETT is then reinserted into the trachea alongside the blocker catheter. The catheter balloon is positioned in the proximal main stem bronchus under fiberoptic visual guidance. With an inflated blocker balloon, the airway is completely sealed, providing more-predictable lung collapse and better operating conditions than with an ETT in the contralateral bronchus.

A potential problem with this technique is dislodgment of the blocker balloon into the trachea. The inflated balloon then blocks ventilation to both lungs or prevents collapse of the operated lung, or both. The balloons of most catheters currently used for bronchial blockade have low-volume, high-pressure properties, and overdistention can damage or even rupture the airway (Borchardt et al., 1998). One study, however, reported that bronchial blocker cuffs produced lower cuff-to-tracheal pressures than double-lumen tubes (Guyton

et al., 1997). When closed-tip bronchial blockers are used, the operative lung cannot be suctioned, and continuous positive airway pressure (CPAP) cannot be provided to the operative lung if needed.

When a bronchial blocker is placed outside the ETT, care must be taken to avoid injury caused by compression and resultant ischemia of the tracheal mucosa. The sum of the catheter diameter and the outer diameter of the ETT should not exceed the tracheal diameter. Diameters for pediatric ETTs are shown in Table 23-5.

Adapters have been used that facilitate ventilation during placement of a bronchial blocker through an indwelling ETT (Arndt et al., 1999; Takahashi et al., 2000). For use in children, a 5-F endobronchial blocker designed with a multi-port adapter and FOB has been described (Cook Critical Care, Bloomington, IN) (Hammer, 2001; Hammer et al., 2002). The balloon is elliptical, so it conforms to the bronchial lumen when inflated. The blocker catheter has a maximal outer diameter of 2.5 mm (including the deflated balloon), a central lumen with a diameter of 0.7 mm, and a distal balloon with a capacity of 3 mL. The balloon has a length of 1.0 cm, corresponding to the length of the right main stem bronchus in children approximately 2 years of age (Scammon, 1923). The blocker is placed coaxially through a dedicated port in the adapter, which also has a port for passage of an FOB and ports for connection to the anesthesia breathing circuit and ETT (Fig. 23-17). The FOB port has a plastic sealing cap, whereas the blocker port has a Tuohy-Borst connector, which locks the catheter in place and maintains an airtight seal. Because oxygen can be administered during passage of the blocker and FOB, the risk for hypoxemia during blocker placement is diminished, and repositioning of

■ **FIGURE 23-17.** The Cook 5-F endobronchial catheter is shown inserted in the multiport adapter (Cook Critical Care, Bloomington, IN). The adapter has four ports for connection to (clockwise from bottom) the breathing circuit, fiberoptic bronchoscope (FOB), endobronchial catheter, and endotracheal tube (A). After the FOB and endobronchial catheter have been inserted through the multiport adaptor, the FOB is placed through the monofilament loop at the distal end of the catheter (arrow). The multiport adaptor is then attached to the indwelling endotracheal tube (B) and the breathing circuit (C). The FOB is directed into the main stem bronchus on the operative side. The catheter is then advanced until the monofilament loop slides off the end of the FOB into the bronchus. (From Hammer GB: *Selective bronchial blockade in small infants*, *Anesth Analg* 93(6):1624–1625, 2001.)

the blocker may be performed with fiberoptic guidance during surgery (Bird et al., 2007).

When placement of a bronchial blocker inside the ETT is guided by an FOB, both the blocker catheter and the FOB must pass through the indwelling ETT. The inner diameter of the ETT through which the catheter and FOB are to be placed must be larger than the sum of the outer diameters of the catheter and the FOB. The 5-F blocker catheter and an FOB with a 2.2-mm diameter, for example, may be inserted through an ETT as small as 5.0 mm in inner diameter. For children with an indwelling ETT smaller than 5.0 mm in inner diameter, a blocker catheter can be positioned under fluoroscopy (Fig. 23-18).

Single-Lung Ventilation Using a Univent Tube. The Univent tube (Fuji Systems Corporation, Tokyo, Japan) is a single-lumen ETT with a second lumen containing a small blocker catheter that can be advanced into a bronchus (Fig. 23-19) (Kamaya and Krishna, 1985; Kawande, 1987; Gayes, 1993). A balloon located at the distal end of this small tube serves as a blocker. Univent tubes require a FOB for successful placement. Univent tubes are now available in sizes as small as 3.5- and 4.5-mm inner diameter for use in children older than 6 years (Table 23-6) (Hammer et al., 1998). Because the blocker tube is firmly attached to the main ETT, displacement of the Univent blocker balloon is less likely than when other blocker techniques are used. The blocker of the 4.5-mm Univent tube has a small lumen, which allows egress of gas and can be used to insufflate oxygen or to suction the operated lung.

A disadvantage of the Univent tube is the large amount of cross-sectional area occupied by the blocker channel, especially in the smaller-sized tubes. Smaller Univent tubes have a disproportionately high resistance to gas flow (Slinger and Lesiuk, 1998). The Univent tube's blocker balloon has low-volume, high-pressure characteristics, so mucosal injury can occur during normal inflation (Benumof et al., 1992; Kelley et al., 1992).

Single-Lung Ventilation Using a Double-Lumen Tube. All double-lumen tubes (DLTs) are essentially two tracheal tubes of unequal length, molded longitudinally together. The shorter tube ends in the trachea, and the longer tube, in the bronchus. Marraro (1994) described a bilumen tube for infants (Pawar and Marraro, 2005). DLTs for older children and adults have cuffs located on the tracheal and bronchial lumens. The tracheal cuff, when inflated, allows positive pressure ventilation. The inflated bronchial cuff allows ventilation to be diverted to either or both lungs and protects each lung from contamination from the contralateral side.

Conventional plastic DLTs, once available only in adult sizes (35-F, 37-F, 39-F, and 41-F), are now available in smaller sizes (Table 23-7). The smallest cuffed DLT is 26-F (Rusch, Duluth, GA) and may be used in children as young as 8 years. DLTs are also available in sizes 28-F and 32-F (Mallinckrodt Medical, St. Louis, MO), suitable for children 10 years of age and older.

DLTs are inserted in children using the same technique used in adults (Brodsky and Mark, 1983). The tip of the tube is inserted just past the vocal cords and the stylet is withdrawn. The DLT is rotated 90 degrees to the appropriate side and then advanced into the bronchus. In the adult population, the depth of insertion is directly related to the height of the patient (Brodsky et al., 1996). No equivalent measurements are yet available in children. If fiberoptic bronchoscopy is to be used to confirm tube placement, an FOB with a small diameter and sufficient length must be available (Slinger, 1989).

A DLT offers the advantage of ease of insertion and the ability to suction and oxygenate the operative lung with CPAP. Left DLTs are preferred to right DLTs because of the shorter length of the right main bronchus (Benumof et al., 1987). Right DLTs are more difficult to accurately position because of the greater risk for right upper lobe obstruction. DLTs are safe and easy to use. There are very few reports of airway damage from DLTs in adults, and none in children. Their high-volume, low-pressure cuffs should not damage the

airway if they are not overinflated with air or distended with nitrous oxide while in place. Guidelines for selecting appropriate tubes (or catheters) for SLV in children are shown in Table 23-7. There is significant variability in overall size and airway dimensions among children, particularly among teenagers, and these recommendations are based on average values for airway dimensions. Larger DLTs may be safely used in adult-size teenagers.

Postoperative Care

Tracheal extubation at the completion of surgery is often possible after simple subsegmental resection or lobectomy. However, the patient’s underlying cardiopulmonary reserve, the course of the surgery, and the expected postoperative course may

preclude extubation. Although postoperative pain can cause significant splinting, intercostal or epidural blocks, coupled with judicious parenteral opioids, can minimize the discomfort (see Chapters 15 and 16, Pain Management and Regional Anesthesia). Whether in the operating room or in the intensive care area, before extubation the patient must be awake, breathing well, able to cough and maintain an airway, and able to maintain acceptable oxygenation with no more than 40% inspired oxygen. A chest radiograph should be obtained as soon as possible after surgery to detect any significant pneumothorax or atelectasis. Atelectasis is common and usually responds to humidity, encouragement to cough, CPAP, and if necessary, endotracheal suction.

The expected postoperative course depends on both the surgical procedure and the underlying diseases. After simple lobectomy, most children develop normally and have normal exercise tolerance (McBride et al., 1980). Children who have undergone pneumonectomy may have more problems (Buhain and Brody, 1973). With time, overinflation of the remaining lung occurs, with a demonstrable decrease in vital capacity. These children may have significant exercise intolerance for a prolonged period after surgery.

Surgery for Congenital Lobar Emphysema, Pulmonary Sequestration, and Cystic Lesions

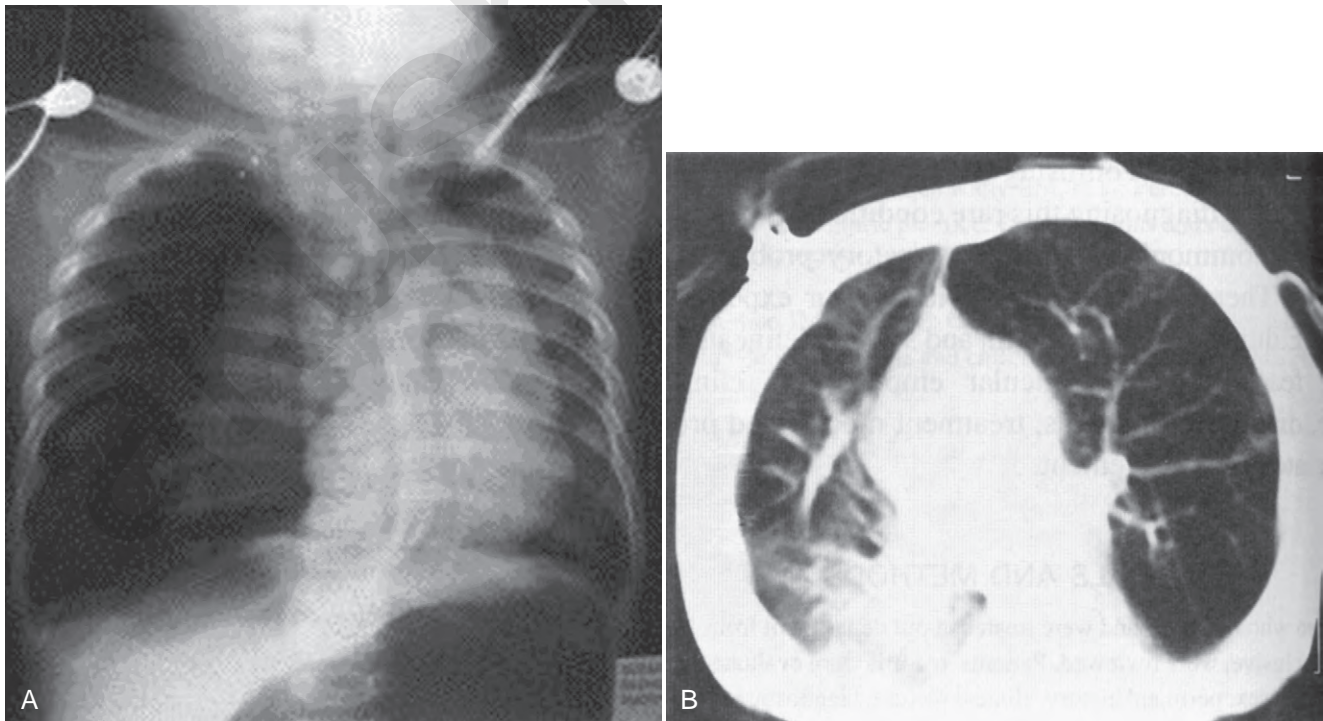

Congenital Lobar Emphysema

Congenital lobar emphysema is a rare cause of sudden respiratory distress in infants (Leape and Longino, 1964; Raynor et al., 1967). Hyperinflation and progressive air trapping cause expansion of the affected lobe, along with compression of

other lung tissue, mediastinal shifting, and impaired venous return. The most commonly affected is the left upper lobe, followed by the right middle and upper lobes. Occasionally, more than one lobe is affected. The cause of the obstruction is unknown in most cases, although many show evidence of deficient and disordered bronchial cartilage. In some cases, there are identifiable causes of bronchial compression, such as aberrant blood vessels, bronchial cysts, and bronchial stenosis. Finally, some patients have widespread lung disease with poor elastic recoil throughout (Ryckman and Rosenkrantz, 1985). See related video online at www.expertconsult.com.

Congenital lobar emphysema usually appears clinically between the newborn period and the first 6 months of life (Murray, 1967) with tachycardia and retractions. The child may have rapid, progressive accumulation of gas in the affected lobe. Physical examination reveals asymmetric expansion of the thorax, wheezing, displacement of the cardiac impulse, hyperresonance to percussion, and diminished breath and heart sounds. Chest radiographs (Fig. 23-20) show overdistention of the affected lobe, mediastinal shift, and atelectasis in other lobes. The chest radiograph can help differentiate lobar emphysema from pneumothorax or congenital cysts by the presence of faint bronchovascular markings and herniation of the affected lobe across the midline.

Infants who show rapid deterioration constitute a surgical emergency to relieve the expanding lobe with its ventilatory and cardiac impairment. Many patients do not have a clear clinical picture, however, but rather have a vague history of intermittent cyanosis or respiratory distress, failure to thrive, or unusual respiratory distress with feeding or a cold. Lobar emphysema is also seen in preterm infants with respiratory distress who are undergoing mechanical ventilation, and it most frequently develops in the right upper lobe.

■ **FIGURE 23-20.** Right-sided congenital lobar emphysema. **A**, The right lung appears hyperinflated and lucent and may be mistaken for a pneumothorax. **B**, CT scan reveals markedly hyperexpanded right lung, mediastinal shift to the left, and compression of the left lung.

Preoperative evaluation depends on the degree of patient distress (Payne et al., 1984). If there is rapid deterioration, evaluation is limited. Chest tube placement, needle aspiration of the trapped air, and vigorous mechanical ventilation have been tried as palliative procedures but are associated with a much higher mortality than thoracotomy and lobectomy. If the patient is stable and there is any question about the diagnosis, procedures such as radioisotope perfusion scans, angiography, or CT imaging can be used before proceeding with definitive surgery. During preanesthesia evaluation, cardiopulmonary stability of the patient is the prime concern. The degree of distress, its progression, and the need for supplemental oxygen are key components of the examination. Cardiac evaluation is important because these patients have a higher incidence of congenital heart disease, especially ventricular septal defect.

Monitoring includes pulse oximetry to detect rapid changes in oxygenation, especially with induction. In deteriorating patients, there may be little time to establish intraarterial monitoring before incision. Doppler-assisted or automated blood pressure cuffs increase the accuracy of measurements and are especially useful in infants. After intubation, capnography is helpful.

Induction of anesthesia in infants with congenital lobar emphysema is a critical phase in the management of anesthesia. The crying, struggling infant can increase the amount of trapped gas, whereas positive-pressure ventilation or positive airway pressure by the anesthesiologist can also increase the emphysema. A smooth inhalation induction with sevoflurane and oxygen is often used, with positive pressure ventilation minimized until the chest is open (Coté, 1978). Controlled or assisted ventilation is added if unacceptable hypoventilation develops, whereas intubation is performed with or without muscle relaxants, depending on the patient's tolerance of positive pressure ventilation. High-frequency ventilation has been used successfully in infants with lobar emphysema (Goto et al., 1987) and should be considered if the practitioner is familiar with the technique. The low airway pressures are especially suitable for these patients. Nitrous oxide is avoided because it can expand the emphysematous areas (Payne et al., 1984). If the lobe expands suddenly, the surgeon should be ready to open the chest immediately and relieve the pressure. Raghavendran and coworkers (2001) described a technique involving a caudal epidural catheter threaded to the thoracic level in spontaneously breathing patients who were anesthetized with potent inhaled anesthetic agents.

An alternative induction approach, especially for unstable infants, is sedation with IV ketamine (1 to 2 mg/kg) and local anesthetic infiltration of the incision site (Coté, 1978). After the intrathoracic pressure has been relieved, general anesthesia can proceed with any technique appropriate to the patient's underlying status. Older children who are stable often undergo bronchoscopy before thoracotomy to rule out a foreign body or other correctable lesions. After induction with oxygen and a volatile agent, thorough topical anesthesia with 2% to 4% lidocaine (not more than 4 to 6 mg/kg) smoothes the course. As with the younger patient, rapid surgical decompression may be needed as the case proceeds.

In most patients, the trachea can be extubated at the end of the lobectomy. Humidity, coughing, and early increases in activity or ambulation minimize atelectasis in the immediate postoperative period. These children do well clinically after surgery but have reduced forced vital capacity and delayed forced

expiration, not only in the immediate postoperative period but throughout childhood (Eigen et al., 1976; McBride et al., 1980).

Pulmonary Sequestrations

Pulmonary sequestrations (Fig. 23-21) result from disordered embryogenesis producing a nonfunctional mass of lung tissue supplied by anomalous systemic arteries. Signs include cough, pneumonia, and failure to thrive and they often appear during the neonatal period, usually before the age of 2 years. Diagnostic studies include CT scans of the chest and abdomen and arteriography. Magnetic resonance imaging may provide high-resolution images, including definition of vascular supply. This may obviate the need for angiography. Surgical resection is performed after the diagnosis. Pulmonary sequestrations do not generally become hyperinflated during positive pressure ventilation. Nitrous oxide administration may result in expansion of these masses, however, and should be avoided.

Congenital Cystic Lesions

Congenital cystic lesions in the thorax fall into three categories: bronchogenic, dermoid, and cystic adenomatoid malformations (Fig. 23-22) (Stocker et al., 1977; Nishibayashi et al., 1981; Kravitz, 1994). Bronchogenic cysts result from abnormal budding or branching of the tracheobronchial tree. They may cause respiratory distress, recurrent pneumonia, or atelectasis due to lung compression. Dermoid cysts are clinically similar to bronchogenic cysts but differ histologically, as they are lined with keratinized, squamous epithelium rather than respiratory (ciliated columnar) epithelium. They usually appear later in childhood or adulthood. CCAMs are structurally similar to bronchioles but lack associated alveoli, bronchial glands, and cartilage (Ryckman and Rosenkrantz, 1985). Because these lesions communicate with the airways, they may become overdistended as a result of gas trapping, leading to respiratory distress in the first few days of life. When they are multiple and air filled, CCAMs may resemble congenital diaphragmatic hernia radiographically. Treatment is surgical resection of the affected lobe. As with the diaphragmatic hernia, prognosis depends on the amount of remaining lung tissue, which may be hypoplastic because of compression in utero (Adelman and Benson, 1976; Schwartz and Ramachandran, 1997).

Surgery for Diseases of the Mediastinum

Surgical problems of the mediastinum fall into three major categories: masses, infections, and pneumomediastinum. The mediastinum is functionally divided into anterior, middle, and posterior segments. This classification is useful diagnostically in evaluating defects, because of the propensity of lesions to develop primarily in only one of the divisions (Table 23-8 and Box 23-7).

Masses in the anterior portion of the mediastinum tend to be lymphomas, lymphangiomas (cystic hygroma), and teratomas. See related video online at www.expertconsult.com. Thymomas and thymic cysts can appear here but are rare in childhood. Lymphomas are primarily of the Hodgkin's type, and biopsies of them are done only for diagnostic purposes. The survival of the child with mediastinal lymphoma depends on the systemic spread of the tumor and not on the amount of

FIGURE 23-21. Extralobar pulmonary sequestration. **A**, Chest radiograph of pulmonary sequestration. **B**, Aortogram of pulmonary sequestration of arterial blood supply coming from aorta. **C**, Thoroscopic resection of sequestration. **D**, Resected sequestration. (From Zitelli BJ, Davis HW, editors: *Atlas of pediatric physical diagnosis*, ed 4, St Louis, 2002, Mosby, p 539.)

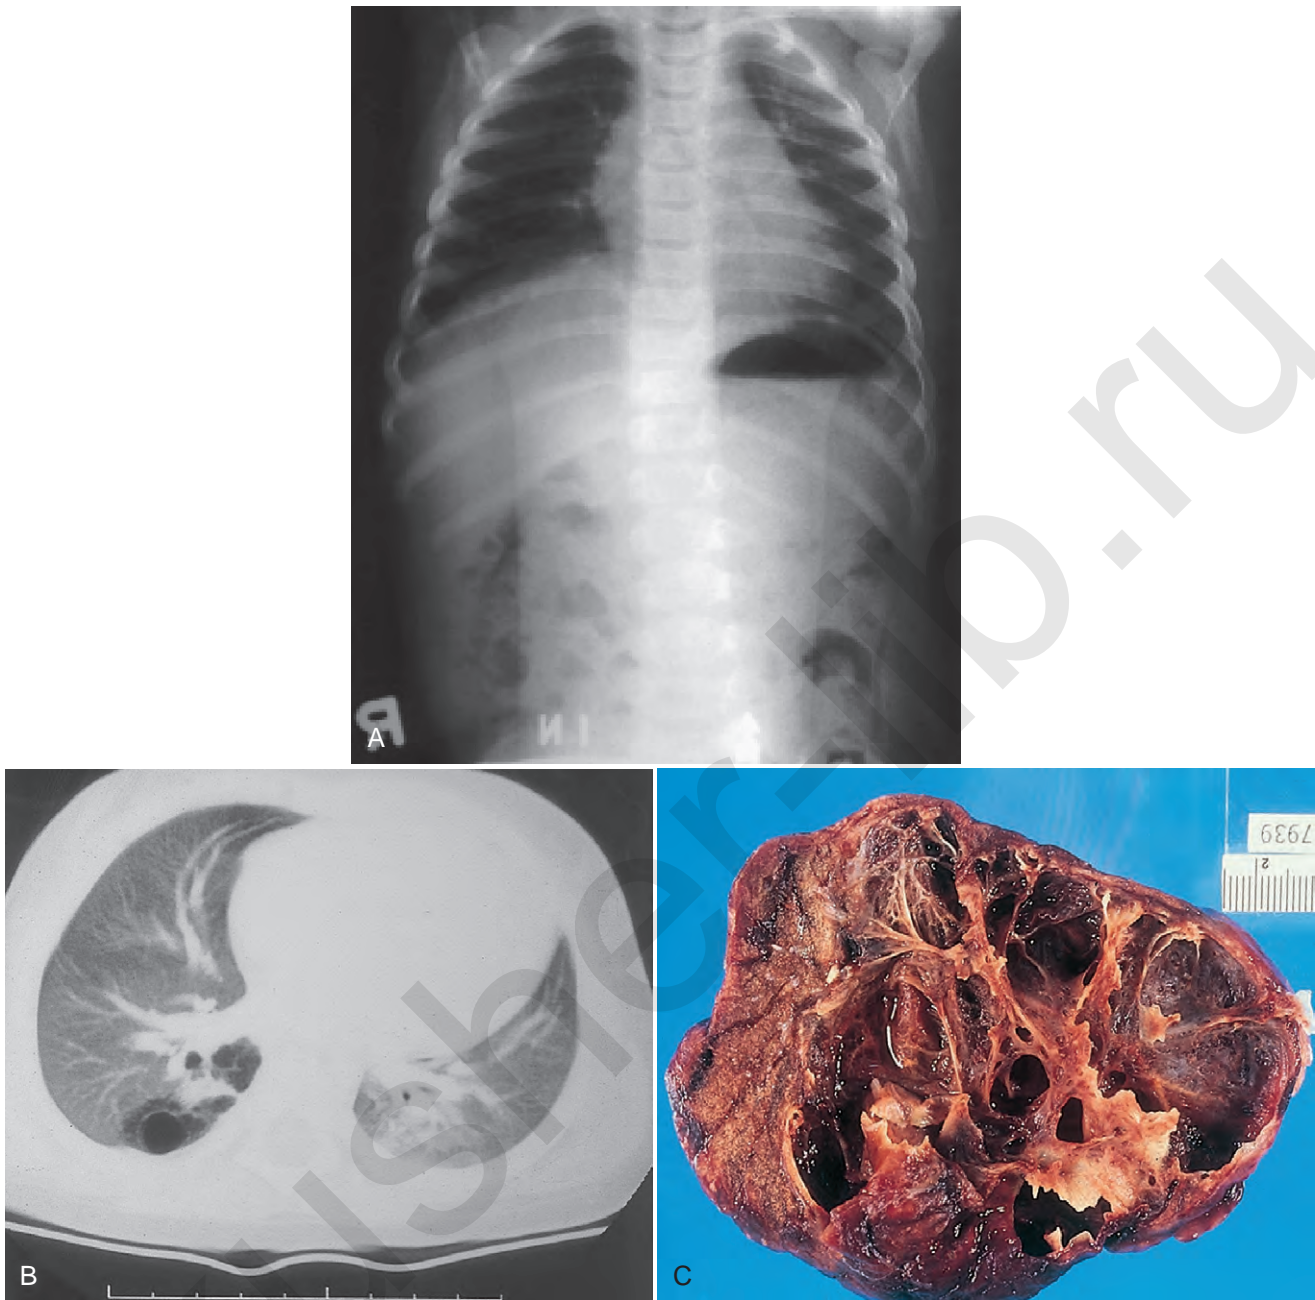

lymphoma present in the mediastinum. Lymphangiomas are often extensions of cystic hygromas from the cervical region into the mediastinum. If not all of the lymphangioma is removed at the initial resection, further extension may occur. Anterior mediastinal masses can appear in various ways. Although they may be asymptomatic and detected incidentally on a chest radiograph, they may also present as compression of pulmonary or vascular structures. Superior vena cava syndrome, cardiac tamponade, and both tracheal and lung compression can be prominent characteristics (Levin et al., 1985; Northrip et al., 1986).

Bronchogenic cysts, granulomas, and lymphomas predominate in the middle division. Bronchogenic cysts make up 7.5%

of all mediastinal masses (Fig. 23-23). They may be asymptomatic or exhibit symptoms of airway obstruction or recurrent pulmonary infection (Birmingham et al., 1993; Landsman et al., 1994). Bronchogenic cysts are usually next to the trachea or main stem bronchi at the level of the carina, but they can also be intrapulmonary. They can produce sudden, life-threatening airway obstruction at any age. Lesser degrees of obstruction appear initially as wheezing, stridor, or unilateral obstructive emphysema (Azizkhan et al., 1985; Azarow et al., 1993).

In the posterior division, enteric cysts and tumors of neurogenic origin (neuroblastoma, ganglioneuroma, neurofibroma) predominate. See related video online at www.expertconsult.com. Enteric cysts and duplications are lined with secretory

■ **FIGURE 23-22.** Microcystic adenomatoid malformation seen on plain film (A), CT scan (B), and surgical specimen (C). (From Zitelli BJ, Davis HW, editors: Atlas of pediatric physical diagnosis, ed 4, St Louis, 2002, Mosby, p 565.)

epithelium and can enlarge rapidly and cause dysphagia, ulceration, or bleeding. In rare cases, they can ulcerate directly into the tracheobronchial tree. Neurogenic tumors are usually asymptomatic and detected on a routine chest radiograph, although they can be responsible for tracheobronchial compression, recurrent pneumonias, and, rarely, stigmata of pheochromocytoma.

Mediastinal infections and inflammation are less common today than in the past (Campbell and Lilly, 1983). Modern antibiotic therapy dramatically reduced the incidence of suppurative mediastinitis caused by *Staphylococcus* and other organisms, whereas the incidence of tuberculosis and other similar infections in the general population has diminished. Although mediastinitis can result from extension of cervical node infections

or hematogenous spread, the more likely cause is perforation of the trachea or esophagus. Foreign bodies can be responsible for perforation of the larynx, trachea, or esophagus; instrumentation of the trachea (endotracheal intubation or suction) or esophagus (esophageal dilation) can also be responsible.

Pneumomediastinum is an accumulation of air, usually in the superior anterior division. This occurs in trauma patients and as a result of mechanical ventilation, especially in newborns who undergo long-term ventilation and children with severe asthma. Pneumomediastinum is usually asymptomatic, but it may be responsible for tamponade and hypotension. These patients need urgent decompression by thoracostomy. Pneumomediastinum can be accompanied by pneumopericardium, which may need

TABLE 23-8. Mediastinal Masses

Location	Presentation
Anterior Division	
Lymphomas	Superior vena cava syndrome
Lymphangiomas (cystic hygroma)	Cardiac tamponade
Teratomas	Tracheal and lung compression
Thymomas and thymic cysts	Thymomas and thymic cysts
Middle Division	
Bronchogenic cysts	Airway obstruction
Granulomas	Stridor
Lymphomas	Obstructive emphysema
Posterior Division	
Enteric cysts, duplications	Airway obstruction
Neuroblastoma	Recurrent pneumonias
Ganglioneuroma, neurofibroma	Dysphagia

to be drained urgently as well. The intrathoracic pressure generated by pneumomediastinum can impede venous drainage of the head and result in increased intracranial pressure (Fig. 23-24).

Anesthetic management of children with mediastinal diseases demands careful preoperative evaluation (Mackie and Watson, 1984). The location and nature of the disease are crucial to both preparation and management (see Fig. 23-24). The airway is considered first (Todres et al., 1976; Keon, 1981). If there is evidence of obstruction, the site and degree must be assessed. History and physical examination should focus not only on signs such as cyanosis and stridor but also on maneuvers or circumstances that change the signs. The practitioner should determine if sleep,

excitement, position, movement of the head and neck, or coughing changes the degree of obstruction. Although chest radiographs and barium studies provide some information, CT scans are best at delineating the obstruction of vascular and airway structures (Angelescu et al., 2007). These scans have the added advantage of demonstrating extension of infection or tumor into structures such as the pericardium.

Signs of lower airway disease can be caused by mediastinal tumors (Sibert et al., 1987). Compression of the lower airways and lung tissue can be responsible for wheezing, atelectasis, obstructive emphysema, and recurrent pneumonias. This is important because wheezing caused by compression of lower airways and lung tissue usually does not respond to bronchodilators, nor will atelectasis caused by compression respond to chest physical therapy. Repeat chest radiographs or pulmonary function tests can help delineate the degree of functional impairment. In older, more cooperative children, maximal inspiratory and expiratory flow-volume loops obtained with the patient upright and supine can quantitate the functional degree of impairment and help distinguish fixed from variable obstructions (Fig. 23-25).

Cardiovascular involvement may be related to direct compression of the heart or of the great vessels. Echocardiography or CT scanning can delineate impingement. The important determination is assessment of functional impairment. If the child has arrhythmias, pulsus paradoxus, hypotension, or superior vena cava syndrome, the risk of general anesthesia increases dramatically.

■ **FIGURE 23-24.** Mediastinal compartmentalization on lateral radiograph (A) and CT scan (B). A, Anterior; M, Middle; P, Posterior. (From Blickman JG, Parker R, Barnes PD: Pediatric radiology, St Louis, 2009, Mosby.)

■ **FIGURE 23-25.** Curves showing maximum expiratory and inspiratory flow versus volume. A, Variable upper airway obstruction caused by papillomatosis of the larynx. B, Variable central (intrathoracic) airway obstruction caused by tracheomalacia. C, Fixed-type obstruction caused by tracheal stenosis. (From Motoyama EK: Physiologic alterations in tracheostomy. In Myers EN, Stool SE, Johnson JT, editors: Tracheostomy, New York, 1985, Churchill Livingstone.)

Induction of anesthesia may remove compensatory efforts by the patient (Neuman et al., 1984). The child's position, pattern of ventilation, or sympathetic tone while awake may have been responsible for barely maintaining adequate cardiopulmonary function (Bray and Fernandes, 1982; Prakash et al., 1988) (Fig. 23-26). In these situations, the anesthesiologist and surgeon must determine alternative approaches to the lesion (Mackie and Watson, 1984). If the child has a better airway, easier ventilation, or less hypotension in one position, efforts are made to keep him or her in this position. Although respiratory compromise is a significant complication in patients with an anterior medial mass undergoing general anesthesia, this complication

is more likely in patients with a tracheal cross-sectional area less than 50% of normal (as predicted by CT) and a peak expiratory flow rate less than 50% of predicted (Shamberger, 1999). Biopsy of accessible lesions under local anesthesia should be considered if there is significant cardiopulmonary compromise. In extreme cases, radiation therapy quickly shrinks the tumor mass, allowing a biopsy to be done later with less risk to the patient (Piro et al., 1976). If general anesthesia is used, the surgeon should be present at induction and prepared for interventions such as passage of a rigid bronchoscope or immediate release of a pneumomediastinum via subxiphoid thoracostomy. Of utmost importance is that the patient, family, pediatrician,

FIGURE 23-26. The effects of anesthesia on tracheal compression in a patient with a mediastinal mass. (From Prakash UBS, Abel MD, Hubmayr RD: *Mediastinal mass and tracheal obstruction during general anesthesia*, Mayo Clin Proc 63:1004, 1988.)

and surgeon all understand the risk for cardiovascular and respiratory compromise that exists in performing tissue biopsies under general anesthesia (Fig. 23-27).

Mask induction with a volatile agent and 100% oxygen is appropriate if there is concern about airway obstruction. The negative intrathoracic pressure of spontaneous breathing and any beneficial effect this has on maintenance of airway patency are preserved (Sibert et al., 1987). In some cases, airway obstruction worsens with positive pressure ventilation; it may be necessary to maintain spontaneous or assisted ventilation. Two important monitors during induction are breath sounds from the precordial stethoscope and continuous oxygen saturation monitoring from a pulse oximeter. Nitrous oxide is avoided in all cases of pneumomediastinum or obstructive emphysema and in patients who have significant V/Q abnormalities

from lung compression (Mackie and Watson, 1984). The role of nitrous oxide in patients with asymptomatic bronchogenic cysts is unclear. Because these cysts are air filled, they may expand on exposure to nitrous oxide and cause airway compromise. In rare cases of severe airway impingement, intubation in the awake, sedated patient may be necessary to secure the airway safely for general anesthesia. If cardiac compression is of primary concern, narcotic-based anesthesia with or without ketamine for induction is a useful technique.

Thoracotomy or thoracostomy is usually the operative procedure performed in these patients. Major complications include massive blood loss, further obstruction or perforation of the airway, and lung compression (Barash et al., 1976; Neuman et al., 1984). There continue to be sporadic reports of death during the induction and maintenance of anesthesia in children

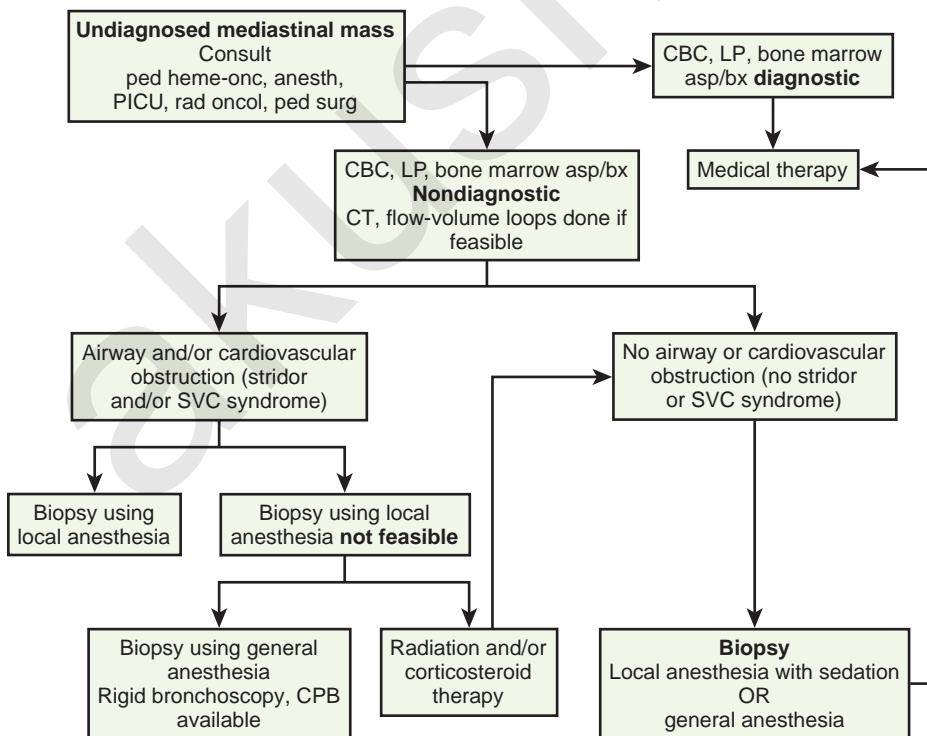

FIGURE 23-27. Algorithm for mediastinal mass.

with mediastinal masses, emphasizing the need for meticulous preoperative evaluation and intraoperative care. After reviewing 44 pediatric patients with mediastinal masses, Ferrari and Bedford (1990) noted that significant anesthesia-related problems occurred in the patients who were symptomatic before surgery. They noted that general anesthesia could be administered with the following caveats: spontaneous ventilation must be performed, induction of anesthesia should be in the sitting position, IV access should be in the lower upper extremity, and a rigid bronchoscope and experienced bronchoscopist must be available. The anesthesiologist not only must be prepared for each complication but also must notify the surgeon immediately if there is loss of airway, difficulty in ventilation, or sudden hypotension.

UROLOGIC SURGERY

A wide range of surgical lesions require the expertise of a pediatric urologist (Box 23-8 and Table 23-9). Although the anesthetic requirements for the different surgical lesions vary, the preoperative anesthetic assessment focuses on several important considerations. First, does the child have a known syndrome that has multiple anesthetic considerations? Second, does the child have other congenital anomalies, such as cardiac abnormalities, that require evaluation? Last, does the child have signs or symptoms of any underlying renal insufficiency? In general, renal failure is divided into acute and chronic components. Acute renal failure is the sudden loss of the kidneys' ability to excrete water, electrolytes, and waste products in sufficient quantities to maintain the body's homeostasis. The causes of acute renal failure are numerous and can be divided into four broad categories: prerenal, renal parenchymal, renal tubule, and obstructive. Regardless of its cause, management of acute renal failure is aimed at ensuring that the patient has an adequate circulating blood volume, and at avoiding fluid overload.

Congestive heart failure occurs when more than insensible fluid losses and urinary output are replaced. Although either a normal or reduced urinary output can occur with acute renal failure, with the onset of anuria or oliguria, hyperkalemia and hypocalcemia can occur. Hyperkalemia is the major life-threatening complication of acute renal failure and therefore must be treated immediately. Because of the kidneys' inability to excrete cellular waste products, acidosis also develops in acute renal failure. Although for most patients, acute renal failure is reversible, some patients go on to develop chronic failure (see Chapter 5, Regulation of Fluids and Electrolytes).

Chronic renal failure or end-stage renal disease results in a 95% loss of creatinine clearance. A 50% loss of nephrons generally results in no biochemical abnormalities and a glomerular filtration rate of about 80%. The biochemical manifestations of end-stage renal disease result in the inability of the kidneys to regulate water and electrolytes and to excrete acid waste products. Because the kidney is also an exocrine organ, progressive renal failure is accompanied by abnormalities in the excretion of vitamin D, parathyroid hormone, and erythropoietin. End-stage renal disease, through its biochemical and hormonal mediators, affects all organ systems (see Chapter 28, Anesthesia for Organ Transplantation).

In addition to being aware of the pathophysiologic problems that accompany patients with renal and urologic abnormalities, the anesthesiologist must be cognizant of potential emotional

difficulties that children have when faced with genitourinary surgery. Not infrequently, some of these patients have deep-seated emotional problems, and the anesthesiologist should be sensitive to their needs. Issues involving the psychological preparation of the patient are explored in Chapter 8, Psychological Aspects of Pediatric Anesthesia.

In the child with normal renal function, anesthesia for urologic surgery is similar to anesthesia for most other types of surgery. In patients with renal insufficiency, nephrotoxic drugs should be avoided or their dosage reduced. The differences in distribution and excretion of drugs that are renally excreted should be remembered. This primarily applies to neuromuscular blockers, because there is little evidence that the volatile agents are materially different in patients with renal insufficiency. There is a well-known risk of prolongation of action with morphine and, especially, meperidine, but the synthetic opioids are used more commonly in this population. Among the muscle relaxants, a delayed onset of and slight resistance to vecuronium have been reported in renal failure patients (Hunter et al.,

TABLE 23-9. Signs and Symptoms of Patients with Renal Insufficiency

Other System Involved	Signs and Symptoms
Cardiovascular	Hypertension Increased cardiac output or high output failure Atherosclerosis or hyperlipidemia Pericarditis Variable increase in 2, 3-diphosphoglycerate levels
Pulmonary	Hypoxemia Pulmonary edema Pleuritis
Hematologic	Anemia secondary to erythropoietin deficiency Anemia secondary to blood loss, decreased iron absorption, and folic acid deficiency Platelet dysfunction Decreased antithrombin III levels Increased factor VIII and fibrinogen
Neurologic	Irritability, confusion, anxiety, memory loss, encephalopathy, and psychosis Seizures, coma Peripheral neuropathy
Gastrointestinal	Anorexia, nausea, vomiting, gastroparesis
Metabolic/endocrine	Renal osteodystrophy secondary to hyperparathyroidism, hyperkalemia, hypocalcemia, metabolic acidosis, hypernatremia, and hyponatremia
Infectious	Hepatitis B or non-A, non-B hepatitis Cytomegalovirus and human immunodeficiency virus

1984), as well as delayed onset of rocuronium (Driessen et al., 2002). However, these differences are modest, even in children with complete renal failure.

Urologic procedures frequently require patients to be positioned in the lateral, prone, or lithotomy position. Each of these positions can be associated with compression-type injuries, as well as with compromise of ventilation and venous return. Consequently, anesthetic management requires not only diligence to patient monitoring but also attention to appropriate patient positioning, padding, and rechecking of positioning.

Cystoscopy

Cystoscopy is commonly performed in children under general anesthesia to evaluate abnormalities of the urethra, bladder, and ureters. This is a relatively brief procedure; however, positioning the patient away from the anesthesia machine, extending the anesthetic tubing and monitor cables, maintaining a possibly difficult airway at the far end of the operating table, and exposing the patient to a cold room and irrigating solutions may complicate the delivery of anesthesia. Mask inhalation anesthesia is usually satisfactory, and endotracheal intubation or laryngeal mask airway is not necessary beyond infancy, as long as a satisfactory airway can be maintained. It is important, however, to maintain a relatively deep plane of anesthesia before insertion of the cystoscope, because the urethral stimulation may precipitate laryngospasm (Breuer-Lockhart reflex) (Stehling

and Furman, 1980). Regional anesthesia is infrequently used as the primary anesthetic for cystoscopy, but it can be used for postoperative analgesia. However, most children experience little discomfort on awakening.

Circumcision

Circumcision is the most frequently performed surgical procedure in the world (Klauber and Sant, 1985). Most circumcisions are performed during the newborn period, and many are done without any anesthesia. However, there is increasing attention paid to providing analgesia for the procedure, including the use of the simple penile nerve block by obstetricians, family practitioners, and pediatricians (Maxwell et al., 1987; Howard et al., 1998). Simple techniques can significantly decrease cardiovascular and behavioral responses to pain in these neonates (Holliday et al., 1999). With increased education, especially at the resident level, there should be an increase in these techniques being used by primary care practitioners.

Beyond the newborn period, circumcision is usually performed under general anesthesia. Mask inhalation anesthesia with sevoflurane or isoflurane in nitrous oxide and oxygen is commonly used. A penile nerve block can be performed either immediately after anesthetic induction or at the end of the operation. It may be advantageous to place the block before the circumcision because the anesthetic requirement is decreased and emergence is more rapid. Caudal epidural anesthesia is also efficacious, although penile nerve block is preferred by some because less local anesthetic is given and less time is taken to perform the block. Others have suggested that the time, expense, and risk of caudal block are not justified for circumcision, because parenteral opioid administration is equally effective (Martin, 1982).

A comparison of different modalities for analgesia, with a focus on caudal analgesia, found that although the need for rescue analgesia is reduced in the early postoperative period when caudal block is compared with parenteral analgesia, there the data in the literature are not sufficient to accurately compare both the short- and long-term effectiveness of caudal block versus other modalities such as parental analgesia, penile block, or topical anesthetic gel or cream (Allan et al., 2003). This analysis points out a problem in analyzing almost all the work on analgesia for urologic procedures—there are insufficient studies available that compare all available modalities in a consistent, uniform manner, thereby allowing direct comparison of risks and benefits.

Ureteral Reimplantation and Bladder Neck Surgery

Reimplantation of one or both ureters is performed for treatment of vesicoureteral reflux, whether it occurs congenitally or results from repeated urinary tract infections. Vesicoureteral reflux occurs in up to 2% of children, and its severity is based on a voiding cystourethrogram. The need for surgical reimplantation is based on the patient's age, gender, grade of reflux, degree of renal scarring, and anatomic abnormalities. In addition to reimplantation, some patients may be amenable to deflux procedures (Fig. 23-28). Deflux procedures involve cystoscopy and injection of compounds (Teflon, and, more recently, polydimethylsiloxane and dextranomer polymer) into the terminal

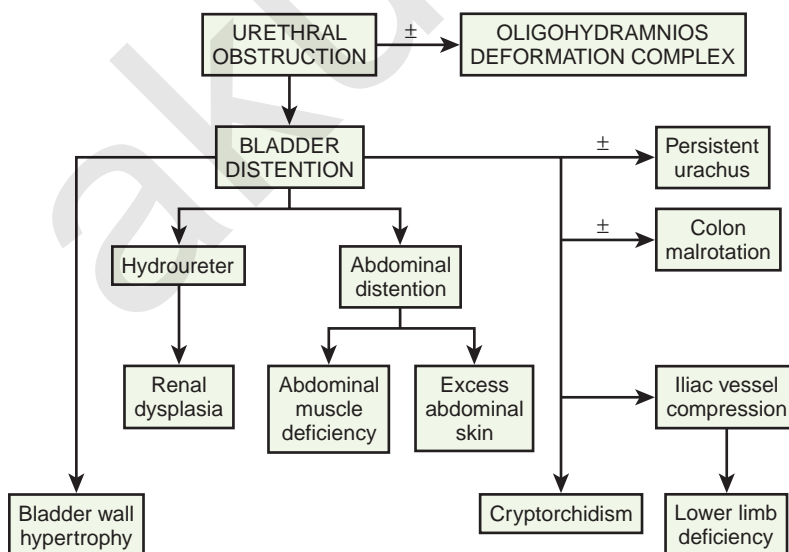

■ **FIGURE 23-28.** *Grade I:* Reflux into the ureter only. *Grade II:* Complete reflux into the ureter, pelvis, and calices without any dilation of the structures. *Grade III:* Complete reflux with mild dilation or tortuosity of the ureter, and mild dilation of the renal pelvis but only slight blunting of the caliceal fornices. *Grade IV:* Complete reflux with moderate dilation of the ureter, renal pelvis, and calices; complete obliteration of the sharp angle of the fornices with maintenance of the papillary impressions of the calices. *Grade V:* Gross dilation and tortuosity of the ureter with gross dilation of the renal pelvis and calices; obliteration of the papillary impressions of the calices. Grades I through III have a high rate of spontaneous resolution and often require surgical correction. (From Zitelli BJ, Davis HW, editors: Atlas of pediatric physical diagnosis, ed 4, St Louis, 2002, Mosby, p 464.)

submucosal area of the ureter as it enters the bladder (Schlussel, 2004). This injection causes a mechanical obstruction just inferior to the ureteral opening and thereby prevents urine from the bladder from refluxing back into the ureter. The duration of the procedure may vary from 2 to 5 hours, so general anesthesia and endotracheal intubation are indicated. A caudal or lumbar epidural catheter can be used to provide supplemental regional anesthesia intraoperatively, minimizing the general anesthetic requirement as well as providing for postoperative analgesia and prevention of bladder spasm. The surgical procedure usually precludes the ability to measure urine output accurately. In those patients for whom the surgery is anticipated to take a long time, a central venous pressure catheter can be placed. For shorter surgical procedures, losses can be estimated by observation of the surgical field and vital signs. Serial hematocrit values should be measured whenever blood loss appears excessive. As with other urologic procedures, regional anesthesia

via the caudal or epidural approach can be very useful for both intraoperative and postoperative pain relief.

Procedures for Prune-Belly Syndrome

The prune-belly syndrome (Eagle-Barrett syndrome) occurs in 1 in 40,000 births, mostly in boys, and results from distal urinary tract obstruction that leads to multiple secondary organ dysfunction (Jones, 1988). Figure 23-29 outlines the proposed sequence of events in the urethral obstruction malformation complex that leads to the classic manifestations—namely, abdominal muscular deficiency, renal dysplasia, excess abdominal skin, and cryptorchidism. Other variable features include colonic malrotation, persistent urachus, and lower limb abnormalities. Figure 23-30 shows the typical physical appearance of a child with prune-belly syndrome.

■ **FIGURE 23-29.** Developmental pathogenesis of early urethral obstruction sequence. (From Jones KL, editor: Smith's recognizable patterns of human malformation, Philadelphia, 1988, Saunders.)

■ **FIGURE 23-30.** Infant with prune-belly syndrome. Note lax abdominal skin. (From Jones KL, editor: *Smith's recognizable patterns of human malformation*, Philadelphia, 1988, Saunders.)

A classification system has been devised according to the severity of disease in prune-belly syndrome (Woodhouse et al., 1982). Children in group I have severe renal disease, pulmonary hypoplasia, or both, which is incompatible with survival. Children in group II are seen as neonatal emergencies with severe uropathy and urinary tract infection and require multiple corrective surgical procedures. Patients in group III have minimal problems in the newborn period but are prone to infections in later childhood. The prognosis for children in groups II and III is good, with as many as half of the children in group II developing normally and exhibiting good renal function.

These patients have a depressed cough mechanism resulting from deficient abdominal musculature, so preoperative sedation is best avoided. Because aspiration is a risk, administration of an H_2 -antagonist (such as ranitidine) and sodium citrate may be indicated to raise gastric pH, and rapid-sequence induction may be recommended. Controlled ventilation is necessary intraoperatively to prevent hypoventilation. Anesthesia can be maintained with inhalation agents or IV techniques, although muscle relaxation is usually unnecessary. Tracheal extubation should be performed only when the patient is awake and meets appropriate criteria. A review of 120 anesthetic cases suggested that intraoperative morbidity was rare, despite allowing spontaneous breathing in half of the cases (Henderson et al., 1987).

Postoperatively, respiratory infections occurred in approximately 7% of cases; one patient died from postoperative aspiration pneumonia (Henderson et al., 1987). These patients require close observation and aggressive pulmonary toilet. Caudal, epidural, or spinal anesthesia in awake or mildly sedated patients may be useful for procedures such as cystoscopy or herniorrhaphy. After abdominal procedures, caudal or lumbar epidural administration of local anesthetic may be indicated to minimize postoperative pain. Postoperative mechanical ventilation may be required for patients who undergo extensive abdominal procedures or when significant pulmonary disease is present.

A wide variety of urologic abnormalities are found in prune-belly syndrome, including renal dysplasia, dilated and tortuous ureters, enlarged and dysfunctional bladder, urethral obstruction, and prostatic hypoplasia (Barratt and Manzoni, 1987). Despite severe urologic abnormalities, renal function may be well preserved. The surgical approach has become more conservative with the appreciation of the relatively good outcome in these patients. The standard surgical approach includes acceptance of the dilated upper urinary tract without extensive ureteral remodeling procedures, and maintenance of adequate bladder drainage with urethral surgery (Barratt and Manzoni, 1987).

Repair of Exstrophy of the Bladder

Exstrophy of the bladder is a rare anomaly, occurring in 1 in 30,000 births, most commonly in boys. This anomaly can be subdivided into classic exstrophy, cloacal exstrophy, and epispadias. Classic exstrophy is most common, with an absence of the anterior wall of the bladder and overlying abdominal wall, epispadias, and separation of the symphysis pubis (Fig. 23-31). Many urologists prefer to perform a staged repair, with the initial stage scheduled during the newborn period. This allows approximation of the symphysis pubis without the need for iliac osteotomies. Multiple procedures are usually necessary in the first years of life to achieve complete repair. To formulate an appropriate anesthetic plan, including an accurate prediction of blood loss, the anesthesiologist must discuss the surgical plan preoperatively with the urologist.

■ **FIGURE 23-31.** **A**, Bladder exstrophy. The bladder extrudes from the abdominal wall and the mucosa is exposed. **B**, Cloacal exstrophy, which occurs along with an omphalocele, as well as anomalies of the colon and rectum.

During the newborn period, blood loss, evaporative losses, and third-space fluid losses can be excessive during bladder exstrophy repair. It is recommended that two IV catheters or a central venous catheter be placed before surgery. An arterial catheter may be useful for monitoring blood pressure and allowing the sampling of blood for measurement of glucose levels, hematocrit, and blood gas analysis. In addition, significant heat loss is common during these procedures, demanding close attention to temperature levels and active warming, usually through a forced-air heating system. A combined general anesthetic-and-epidural technique is increasingly popular for these cases, with the epidural catheter providing excellent analgesia into the postoperative period (Wee et al., 1999). Bupivacaine or ropivacaine is commonly used, but an opioid is not often added in the neonatal period because of the risk for respiratory depression, unless prolonged mechanical ventilation is anticipated. Postoperatively, careful attention must be focused on maintaining fluid and electrolyte homeostasis, as well as on preventing anemia, hypotension, and hypoxia, as in any other case.

Hypospadias Repair

Hypospadias occurs in approximately 8 per 1000 male births (Belman, 1985). Associated anomalies that cause difficulties for the anesthesiologist are rare. Hypospadias is repaired either as a single-stage or a multistage procedure, depending on the complexity of the anatomic abnormality (Fig. 23-32). The surgical procedure usually requires several hours, so most anesthesiologists prefer endotracheal intubation rather than mask anesthesia for patient safety and for convenience. The laryngeal mask airway may also be useful in these procedures. Blood loss is usually not significant, and transfusion is rarely required. Induction of anesthesia can be achieved by any of the techniques commonly used in children. Intraoperatively, anesthesia can be maintained using either an inhalation or a balanced technique. General anesthesia combined with a conduction block provides excellent intraoperative conditions and postoperative pain relief.

Caudal epidural block may be the optimal choice because it provides complete intraoperative and postoperative analgesia. Penile block is less effective than caudal epidural anesthesia for postoperative analgesia after hypospadias repair, especially in cases of proximally located hypospadias (Blaise and Roy, 1986). When only a distal penile hypospadias is present, penile nerve block may be as effective as caudal epidural anesthesia. In children less than 1 year of age, a single caudal epidural injection of bupivacaine (0.25% with 5 mcg/mL epinephrine; 1.2 mL/kg) is administered after the induction of general anesthesia (Hannallah, 1987). Some practitioners prefer 0.2% or 0.125% bupivacaine to give greater volume with less risk for motor blockade. The caudal block is repeated at the end of the surgery if more than 1 hour has elapsed since the first caudal epidural injection. For children older than 1 year, it can be worthwhile to place a catheter for continuous caudal block using a commercially available epidural catheter kit. With the availability of smaller epidural catheters, a continuous infusion of local anesthetic may also be practical for younger patients (see Chapter 16, Regional Anesthesia).

BARIATRIC SURGERY

Obesity in Children and Adolescents

Obesity is the most common health problem facing U.S. children today. Data suggest that the prevalence of obesity continues to increase rapidly. Results from the National Health and Nutrition Examination Survey III reveal that approximately 14% of children in the United States are obese, as defined by body mass index (BMI) greater than the 95th percentile (Centers for Disease Control, 1997). The prevalence is increasing approximately 47% to 73% faster among black and Hispanic children than among non-Hispanic white children. As of 1998, the prevalence of obesity in children had increased to 21.5% among African Americans, 21.8% among Hispanics, and 12.3% among non-Hispanic whites (Strauss and Pollack, 2001).

Childhood obesity has been defined variously by absolute weight, weight-for-height percentiles, percentiles of ideal body weight, triceps skinfolds, and BMI (weight in kilograms divided by height in meters squared). The most recent recommendations from the Centers for Disease Control and Prevention suggest that BMI is the most appropriate and easily available method to screen for childhood obesity. Age and gender cutoffs for BMI have been published (Kuczmarski et al., 2000); patients with a BMI of greater than 30 are considered obese, and those with a BMI of greater than 40 are considered morbidly obese.

Although many of the adverse effects of childhood obesity may not become apparent for decades, even young children may suffer from severe morbidity. Psychological problems include low self-esteem, self-consciousness, helplessness, and depression. Hypertension, hypercholesterolemia, and hyperinsulinism all occur in young, obese children, leading to coronary artery disease and diabetes in adulthood. Obese children may develop gallstones, hepatitis, obstructive sleep apnea, and increased intracranial pressure resulting from pseudotumor cerebri (Strauss, 2002). Obese children are more likely to be admitted to the hospital than their normal-weight peers. In addition, obese children have higher hospital charges and longer lengths of stay (Nafiu et al., 2008). The adverse effects of obesity in childhood are shown in Box 23-9. These complications may result in the need for surgery (e.g., gallstones, slipped epiphysis, bariatric surgery) and complicate anesthetic management during surgery (airway obstruction or reactivity, hyperglycemia, systemic or intracranial hypertension) (Nafiu et al., 2007).

Physiologic Considerations

Obesity is associated with many physiologic disturbances of concern to anesthesiologists. Work of breathing is increased, and fatty chest and abdominal walls decrease chest compliance. FRC is significantly reduced, leading to lower airways closure and atelectasis, causing hypoxemia due to intrapulmonary shunting. Exacerbations of hypoxemia caused by sleep apnea may lead to pulmonary hypertension, cor pulmonale, and heart failure. A small number of morbidly obese patients have somnolence, cardiac enlargement, polycythemia, hypoxemia, and hypercapnia (Pickwickian syndrome). Morbidly obese patients with preoperative pulmonary dysfunction have higher morbidity after bariatric surgery but may subsequently have significant improvement in sleep apnea, gas exchange abnormalities, pulmonary hypertension, and cardiac function (Sugerman et al., 1992).

■ **FIGURE 23-32.** Different locations of hypospadias. **A**, Glans. **B**, Proximal. **C**, Midshaft. **D**, Scrotum.

Cardiac reserve is decreased in obese patients. Even normotensive morbidly obese patients have increased preload and afterload, increased pulmonary artery pressures, and elevated right and left ventricular stroke work compared with nonobese patients. The degree of cardiac abnormality correlates with the degree of obesity. Left ventricular dysfunction is often present in young, asymptomatic obese patients. Right ventricular failure is common in older patients (Brodsky and Vierra, 2000).

Weight loss, whether through diet or bariatric surgery, can reverse cardiac dysfunction and hypertension (Jones, 1996). Hypertension is common among morbidly obese adolescents and adults.

The gastric contents of unpremedicated, nondiabetic, fasting obese patients (BMI ≥ 30) without GER are not increased in volume or acidity compared with nonobese surgical patients (Harter et al., 1998). However, morbidly obese patients (BMI \geq

40) do have large gastric volumes and low pH (Vaughan et al., 1975). Morbid obesity is also associated with a high incidence of GER, with 70% of patients complaining of heartburn (Hagen et al., 1987).

Other gastrointestinal abnormalities in morbidly obese patients include steatohepatitis, cirrhosis, and gallstones (Clain and Lefkowitz, 1987). Approximately 30% of patients who do not have gallstones at the time of bariatric surgery develop gallstones within 3 to 6 months after surgery, prompting many surgeons to perform a cholecystectomy at the time of the bariatric procedure.

Endocrine and genetic abnormalities are associated with obesity and short stature. Hirsutism, increased muscle mass, and acanthosis nigricans are associated with polycystic ovary syndrome. Obesity associated with mental retardation may signify a congenital syndrome such as Prader-Willi, Laurence-Moon-Biedl, or Cohen's syndromes. Female patients with short stature and obesity may be diagnosed with Turner's syndrome. Recurrent headaches, especially if associated with vomiting, may be caused by pseudotumor cerebri; papilledema may be seen on fundoscopic examination.

Bariatric Surgical Procedures

Gastric bypass and other types of bariatric surgery have been considered appropriate for select adults with a BMI of 40, or of 35 in the presence of comorbid conditions (Consensus Development Conference Panel, 1991; National Institutes of Health, 1998). Few data and no guidelines exist for bariatric surgery in adolescents. In 1975, Soper and colleagues reported on 18 morbidly obese adolescents and young adults (age, >20 years) who underwent either gastric bypass or gastroplasty. The median weight loss was approximately 25% of body weight by 3 years after surgery. A similar report in 1980 described an average weight loss of 40 kg at 3 years and 26 kg at 5 years after surgery (Anderson et al., 1980). Major early postoperative complications occurred in more than a third of the patients, including one death from an anastomotic leak. Since these early reports, the gastric bypass procedure has undergone significant modifications. Surgical stapling devices

allow compartmentalization of the stomach without complete transection (Kellum et al., 1998). "Long limb" gastric bypass has also been used in patients with a BMI of greater than 50, with improved weight loss compared with conventional bypass procedures (Brolin et al., 1992).

Strauss and coworkers (2001) reported their results in 10 adolescents, aged 15 to 17 years, who underwent gastric bypass surgery. All patients were highly motivated and had demonstrated serious attempts at weight loss by diet and behavior modification programs. All adolescents were behaviorally and genetically normal and were more than 100% and 100 pounds above their ideal body weight. Obesity-related morbidities included sleep apnea, hypertension, vertebral fracture, and severe school avoidance. No perioperative complications were reported. Satisfactory weight loss was achieved in 9 of 10 patients, with a mean weight loss of greater than 50 kg. Late complications included protein-calorie and micronutrient malnutrition in one patient, an abdominal wall hernia requiring surgical repair in one patient, cholecystectomy in two patients, and small bowel obstruction requiring surgery in one patient.

Abu-Abeid and colleagues (2003) reported their experience with 11 adolescents, aged 11 to 17 years, who underwent laparoscopic adjustable gastric banding (LAGB). Unlike gastric bypass operations, LAGB involves no anastomoses and no bypass of functional bowel, and the operation is reversible. The authors cited no perioperative or late complications; the mean decrease in BMI was from 46.6 to 32.1 kg/m². One patient with heart failure and pulmonary hypertension had significant functional improvement during the 23-month follow-up period.

Anesthetic Management

Preoperative Considerations

In preparation for surgery, a thorough history and physical examination should be performed. Review of systems is focused on medical complications of obesity shown in [Box 23-9](#). Medications taken for weight loss and other conditions are noted. Blood pressure and oxygen saturation should be recorded. Airway examination may reveal large tonsils and a small pharyngeal airway. Cardiac and lung auscultation may reveal signs of heart failure, pulmonary hypertension, wheezing, and low lung volumes. An electrocardiogram may show findings of cor pulmonale. An echocardiogram should be considered if cardiac dysfunction is suspected. In association with frequent urination, nocturia, and fatigue, blood glucose values may confirm the diagnosis of diabetes.

Administration of premedication should be followed by monitoring of oxygen saturation, as ventilatory depression and airway obstruction may occur. An H₂-receptor antagonist and metoclopramide may be given 60 to 90 minutes before anesthetic induction to decrease gastric volume and acidity. A nonparticulate oral antacid may be given immediately before induction.

Intraoperative Management

Many obese patients become hypoxemic in the supine position because of upper airway obstruction and diminished FRC. Elevating the head of the operating room table may diminish these changes.

Noninvasive blood pressure measurements may be inaccurate, prompting the need for intraarterial monitoring. Measurement of arterial blood gases at baseline and during general anesthesia is recommended, especially for lengthy surgeries. Because venous access may be limited, placement of a central venous catheter, although technically challenging, may be required. Meticulous attention to positioning and padding of the head, neck, and extremities is essential to prevent injury during surgery. Patients must be well secured to the operating table in anticipation of the use of the Trendelenburg and reverse Trendelenburg positions, as well as lateral rotation of the operating table.

Because the risk for aspiration is high in morbidly obese patients, tracheal intubation should be performed when general anesthesia is administered even for brief procedures. Rapid-sequence induction or awake fiberoptic-guided intubation should be performed to minimize the risk for pulmonary aspiration of gastric contents. Although most patients can be intubated with appropriate body positioning and direct laryngoscopy, two anesthesiologists and a “difficult airway” cart should be present during induction and intubation. Preoxygenation should be performed until the oxygen saturation has been 100% for several minutes. Patients should be ventilated with 100% oxygen, with 10 to 15 mL/kg tidal volumes based on ideal weight. Moderate levels of positive end-expiratory pressure (PEEP) should be added to minimize airway closure, atelectasis, and oxygen desaturations. High levels of PEEP may depress cardiac output. Hypoxemia may occur as a result of placement of abdominal packs or retractors, gas insufflation during laparoscopic procedures, and use of the lithotomy or Trendelenburg position. In extreme cases, the panniculus may need to be mechanically displaced to improve compliance and reduce physiologic shunt during surgery (Wyner et al., 1981).

Drug and fluid administration should be based on ideal body weight. Dosages of select drugs may need to be increased compared with those administered to lean patients, however, because of increases in blood volume and cardiac output in the obese patient (Brodsky and Vierra, 2000). Thiopental and midazolam have increased volumes of distribution in obese patients. Dosing regimens based on ideal body weight for propofol have been recommended (Servin et al., 1993). A nerve stimulator should be used to guide the dosing of muscle relaxants and to monitor complete reversal of their effect. Excessive fat overlying the nerves may render surface electrodes ineffective, and needle electrodes may occasionally be required.

Although technically more difficult in obese patients, regional anesthetic techniques should be considered with or without general anesthesia. Local anesthetics may eliminate the need for muscle relaxants and their reversal. Even when general anesthesia is used in combination with regional anesthesia, decreased concentrations and dosages of inhalation and IV agents allow more rapid awakening and spontaneous airway control. Postoperative analgesia with epidural infusions facilitates improved pulmonary function.

Regional blocks can be difficult because important anatomic landmarks are often obscured. Long spinal or epidural needles are needed. The depth of insertion is difficult to predict; BMI alone is not an accurate predictor for depth of the epidural space (Watts, 1993). Accordingly, the incidence of inadvertent dural puncture is increased in obese patients. Morbidly obese patients, however, have a decreased incidence of postdural puncture headache. Because the spread of local anesthetics is directly related to BMI, local anesthetic dosages

should be reduced by 20% to 25% for both epidural and subarachnoid blocks in obese patients (Pitkanen, 1987; Taivainen et al., 1990). Insulated needles and a nerve stimulator may be helpful in identifying the appropriate nerves for peripheral nerve blocks.

Postoperative Care

Postoperative mechanical ventilation is infrequently needed except in the presence of significant cardiac disease, massive intraoperative fluid resuscitation, sepsis, or airway trauma during intubation. Tracheal extubation in hemodynamically stable, morbidly obese patients should be performed with the upper body elevated 30 to 45 degrees. The patient should be maintained in this position for transport to maximize FRC and oxygenation (Vaughan et al., 1976). Supplemental oxygen should be administered via nasal cannula or mask for at least 3 days after abdominal or thoracic procedures (Taylor et al., 1985). Nasal CPAP or bilevel positive airway pressure (BiPAP) via nasal mask is used for patients with sleep apnea; these modalities may normalize breathing during sleep and prevent nocturnal oxyhemoglobin desaturation (Series et al., 1992; Rennotte et al., 1995). Nasogastric tubes used during surgery must be removed before the application of nasal CPAP or BiPAP. A potential complication of these therapies is gastric distention and disruption of bowel anastomoses, although this risk appears to be small.

Thromboembolism is a major cause of postoperative morbidity in obese surgical patients. Pulmonary emboli occur in as many as 5% of obese patients after laparotomy (Brodsky and Vierra, 2000). The risk for thromboembolism can be reduced with heparin, pneumatic compression devices, or both (Fasting et al., 1985). If an epidural catheter is to be used, it should be placed before initiation of heparin therapy and removed at least 12 hours after the last dose of heparin (Horlocker et al., 2003).

Deep breathing, coughing, and early ambulation must be encouraged, and effective postoperative analgesia is essential. Patient-controlled analgesia with an IV opioid or epidural opioid with or without local anesthetic may be used. Analgesic drugs should be dosed according to ideal body weight. Vigilant monitoring for signs of excessive sedation and respiratory depression is required.

SUMMARY

The pediatric patient presenting for abdominal, genitourinary, or thoracic surgery spans the pathophysiologic spectrum. Both acute and elective clinical presentations, coupled with age-related nuances of the disease, dictate the perioperative anesthetic care of the patient. Advances in intraoperative techniques and postoperative pain management have enabled the surgical frontiers in those specialties to advance.

Anesthesia for Pharyngeal and Laryngeal Procedures 791	

The care of children requiring anesthesia for otorhinolaryngologic, or ear, nose, and throat (ENT), surgery is described in this chapter. Most pediatric otorhinolaryngologic surgical procedures are of short to intermediate duration, and most of the children who are the patients are in reasonably good health. However, the anesthesiologist often encounters children with potentially life-threatening upper airway obstruction (e.g., acute epiglottitis) or with severe pulmonary insufficiency requiring diagnostic or therapeutic ENT procedures. New surgical techniques, such as laryngeal laser surgery, have challenged pediatric anesthesiologists to develop innovative approaches for the protection and maintenance of the patent upper airway.

The art and science of anesthesia must be well integrated in caring for the child undergoing ENT anesthesia. Many procedures, including adenoidectomy, rigid bronchoscopy, and laser removal of papillomas, require short intervals of deep planes of anesthesia and limited movement of the patient. To effectively manage operating room services, the patient must awake in a timely manner without airway irritability. One of the major changes in pediatric anesthesia over the past decade has been the abandonment of halothane in favor of sevoflurane. Although sevoflurane appears to be a safer anesthetic agent than halothane, sevoflurane-induced postoperative delirium continues to challenge the pediatric anesthesiologist (Vlajkovic and Sindjelic, 2007; Kuratani and Oi, 2008).

Propofol has many properties that make it a useful anesthetic agent for ENT surgery. It causes less airway irritability than thiopental. Propofol may be protective against and therapeutic for laryngospasm (Brown et al., 1991; Scanlon et al., 1993; Allsop et al., 1995; Afshan et al., 2002). Propofol also has useful antiemetic properties and a low incidence of emergence delirium (Uezono et al., 2000; Moore et al., 2003; Voepel-Lewis et al., 2003), making this anesthetic a good choice for ENT anesthesia.

ANESTHESIA FOR OTOLOGIC PROCEDURES

Otitis media is the most frequently diagnosed childhood malady, with the highest incidence occurring among children between the ages of 6 and 18 months. Its frequency decreases after the first year of life. By age 7 years, otitis media is a less frequent pediatric diagnosis. Otitis media is inflammation of the middle ear, without reference to pathogenesis or cause. The other areas of the temporal bone that are contiguous with the middle ear, including the mastoid, petrous apex, and perilyabyrinthine air cells, also may be involved. In those who have had a single episode of acute otitis media, residual middle ear fluid remains in up to 40% of patients at 1 month, 20% at 2 months, and 10% at 3 months (Pelton et al., 1977; Teele et al., 1980; Gluckman, 1990).

Many children with persistent middle ear effusion continue to be clinically symptomatic with recurrent acute otitis media, pain, fever, vertigo, disturbed sleep, or significant hearing loss. These symptoms are the most common indications for middle ear effusion drainage by myringotomy and tympanostomy tubes. Myringotomy and insertion of tympanostomy tubes may also be helpful in patients with recurrent acute otitis or atelectasis of the tympanic membrane. Tympanostomy tubes may prevent permanent structural damage and cholesteatoma. Myringotomy with aspiration of the middle ear effusion, but without tube placement, may be appropriate in children with severe otalgia or when culture of the middle ear fluid is required in the evaluation of a child with fever of unknown origin. If the patient requires multiple myringotomy procedures, placement of a tympanostomy tube may be considered.

Many patients with congenital anomalies are candidates for myringotomy tubes. Patients with cleft palate, craniofacial malformations, Down syndrome, Turner's syndrome, and human immunodeficiency virus (HIV) infection have a higher incidence of otitis media and therefore have a greater need for myringotomy and insertion of tympanostomy tubes than the general population (Bluestone and Klein, 2003). These children have other airway and medical issues that complicate the usual approach to the healthy child requiring myringotomy tubes. Critically ill patients with a history of prolonged nasotracheal intubation have a high incidence of persistent middle ear effusions requiring middle ear ventilation.

Adenoidectomy for chronic otitis media with effusion may benefit some children. The effectiveness of adenoidectomy for chronic otitis media with effusion is not directly related to adenoid size. For children who have recurrent or chronic otitis media with effusion and who had one or more myringotomy and tympanostomy tube insertion procedure in the past, adenoidectomy may be a reasonable option (Paradise et al., 2003). Upper airway obstruction, recurrent acute or chronic adenoiditis, and sinusitis are additional indications for adenoidectomy in children who have chronic otitis media with effusion.

Myringotomy and Insertion of Tympanostomy Tubes

Candidates for myringotomy and tube insertion present with subacute or chronic upper respiratory tract infection with or without fever. In these children, surgical intervention appears to improve the symptoms of upper respiratory infection postoperatively (Tait and Knight, 1987). However, the finding by these investigators is applicable only to myringotomy for children with middle ear effusion; it should not be generalized or applied to children with upper respiratory infection (especially in its acute phase with fever) who are scheduled for other surgical procedures (Hinkle, 1989).

In expert hands, the performance of uncomplicated bilateral myringotomies and tube insertions requires only 5 to 10 minutes of operating time; the procedure, however, may take considerably more time when performed by inexperienced trainees or in patients with narrow ear canals. Myringotomy is almost exclusively performed on an outpatient basis.

Preoperative sedation should be administered based on the child's anxiety level. Mask induction of anesthesia with nitrous oxide, oxygen, and sevoflurane provides effective and smooth induction and maintenance anesthesia with prompt emergence. Preoperative or intraoperative analgesia is advo-

cated for early postoperative pain relief. Because these children are usually anesthetized without intravascular access, preoperative administration of oral acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs) (Watcha et al., 1992) and intraoperative intranasal fentanyl or butorphanol (Bennie et al., 1998; Galinkin et al., 2000; Finkel et al., 2001) or intramuscular ketorolac (Pappas et al., 2003) has been studied and recommended. It appears that intraoperative ketorolac (0.5 mg/kg, up to 30 mg) administered by the intramuscular route provides better analgesia than oral or rectal acetaminophen. Ketorolac is associated with less vomiting and minimal sedation compared with intranasal butorphanol and perhaps with fentanyl. However, ketorolac, along with other NSAIDs, should be used with caution because ketorolac affects platelet function, and increased postoperative bleeding during tonsillectomy or adenoidectomy has been reported (Dahl and Kehlet, 1994; Nikanne et al., 1997).

Because children undergoing myringotomy commonly have adenoidal hypertrophy, they may exhibit signs of nasal and upper airway obstruction (Bluestone and Klein, 2001). These children often require continuous positive airway pressure (CPAP) during inhalational induction and insertion of an oropharyngeal airway after reaching a surgical plane of anesthesia to maintain a patent airway (see Chapter 3, Respiratory Physiology, and Chapter 13, Induction, Maintenance, and Recovery). Although myringotomy and tube insertion may last less than 10 minutes, it should be performed with standard monitoring (i.e., using a precordial stethoscope, pulse oximeter, electrocardiogram, thermometer, and automated blood pressure cuff). Myringotomy is one of a few exceptions in modern pediatric anesthesia practice in the United States for which intravenous infusion is not routinely administered.

Postoperative hypoxemia occurs frequently in infants and children during transport and in the recovery room, even after minor surgical procedures such as myringotomy (Motoyama and Glazener, 1986). After myringotomy, patients are prone to upper airway obstruction, and these children should be transferred to the recovery room in the lateral position while receiving supplemental oxygen (see Chapter 13, Induction, Maintenance, and Recovery).

Mastoidectomy and Tympanoplasty

The clinical importance of the mastoid process is related to its contiguous structures, which include the posterior and middle cranial fossa, sigmoid and lateral sinuses, facial nerve, semicircular canals, and petrous tip of the temporal bone. The distal part of the middle ear and mastoid are connected by the aditus ad antrum, making the mastoid susceptible to infection by infectious processes from the middle ear. With improved medical and surgical management of otitis media, mastoidectomy for mastoiditis has declined considerably over the past several decades. However, mastoidectomies may also be performed in association with cholesteatoma removal and tympanoplasty. Tympanoplasty is performed in patients with chronic perforation or atelectasis of the tympanic membrane (Bluestone and Klein, 2003). Deep retraction pockets may lead to squamous epithelium proliferation in the middle ear and mastoid cavities, causing a cholesteatoma that may grow by the enzymatic activity of the skin tissues and accumulation of squamous debris.

Tympanoplasty is an operation to reconstruct the tympanic membrane with or without grafting. Its primary indications are repair of tympanic perforation; stabilization or improvement of hearing; removal or prevention of congenital, iatrogenic, or primary or secondary acquired cholesteatoma; and removal of atelectatic or diseased areas of the tympanic membrane (Haynes and Harley, 2002). Grafting materials include fat, fascia, perichondrium, periosteum, cartilage, vein, and paper patch.

Mastoidectomy involves the surgical exposure and removal of mastoid air cells. There are several types of mastoidectomy (Bluestone and Klein, 2003). In a complete simple cortical mastoidectomy, the mastoid air-cell system is removed, but the canal wall is left intact. The operation is performed for acute or chronic mastoid osteitis, and it is frequently part of the surgical procedure advocated by some surgeons for cholesteatoma.

Posterior tympanotomy or facial recess tympanotomy involves removal of mastoid air cells, followed by formation of an opening between the mastoid and middle ear created in the posterior wall of the middle ear lateral to the facial nerve and medial to the chorda tympani. This procedure allows better visualization of the facial recess without removing the canal wall, and it is primarily advocated for ears in which a cholesteatoma has formed.

With a modified radical mastoidectomy, a portion of the posterior ear canal wall is removed, and a permanent mastoidectomy cavity is created, but the tympanic membrane and some or all of the ossicles are left intact. The procedure is usually performed when a cholesteatoma cannot be removed without removing the canal wall; some function may be preserved.

Radical mastoidectomy involves removal of all mastoid air cells, the posterior ear canal wall, the tympanic membrane, and the ossicles except part or all the stapes. No attempt is made to preserve function. Removal of the posterior ear canal wall allows communication among the exenterated mastoid cellular area, middle ear, and external auditory canal, forming a common single cavity. The procedure is indicated when there is extensive cholesteatoma in the middle ear and mastoid that cannot be removed by a less radical procedure. The operation may be indicated for a suppurative complication of otitis media.

Tympanomastoidectomy with tympanoplasty is the term used when a tympanoplasty is performed in conjunction with a mastoidectomy. Mastoidectomies that leave the posterior ear canal wall intact are closed cavity, canal wall up, or intact canal wall procedures, whereas those in which the posterior canal is partially removed are open cavity or canal wall down procedures.

Anesthetic Management

All children should be monitored with standard monitoring that includes a pulse oximeter, a capnograph for end-tidal carbon dioxide (CO₂) monitor, precordial stethoscope, electrocardiogram, thermometer, and automated blood pressure cuff. Often, electromyography is used to avoid injury to the facial nerve. In these circumstances, neuromuscular blockade is avoided. Standard no oral intake (NPO) guidelines should be followed in nonemergent situations.

For mastoidectomy and tympanoplasty, the patient is positioned supine, with the head laterally rotated away from the affected side. It is important to carefully rotate the neck of a

patient under general anesthesia because of the risk for atlantoaxial rotational subluxation (Brisson et al., 2000).

Induction of anesthesia can entail inhalational or intravenous induction. The anesthesiologist should consider endotracheal intubation without muscle relaxation or with a short-acting muscle relaxant so the facial nerve can be monitored during surgery. The use of nitrous oxide may be contraindicated during and after placement of the tympanic graft, because nitrous oxide accumulates in a closed gas space and increases the ambient pressure; some surgeons believe this tends to lift the graft away from its new site (Koivunen et al., 1996; Doyle and Banks, 2003).

The most common postoperative complication requiring unscheduled admission to the hospital for children who have undergone tympanomastoidectomy is postoperative nausea and vomiting (PONV) (Megerian et al., 2000). PONV has been attributed to surgical stimulation of the vestibular labyrinth, anesthetic techniques, or a combination of the two (Jellish et al., 1995; Dornhoffer and Manning, 2000). Propofol has antiemetic properties (Ved et al., 1996; Erb et al., 2002b). It appears that propofol used for induction and maintenance of anesthesia is superior to isoflurane or sevoflurane in reducing PONV after middle ear surgery (Jellish et al., 1995, 1999; Moore et al., 2003). The use of intravenous dexamethasone during surgery appears to decrease PONV in patients after undergoing tympanomastoid surgery (Liu et al., 2001).

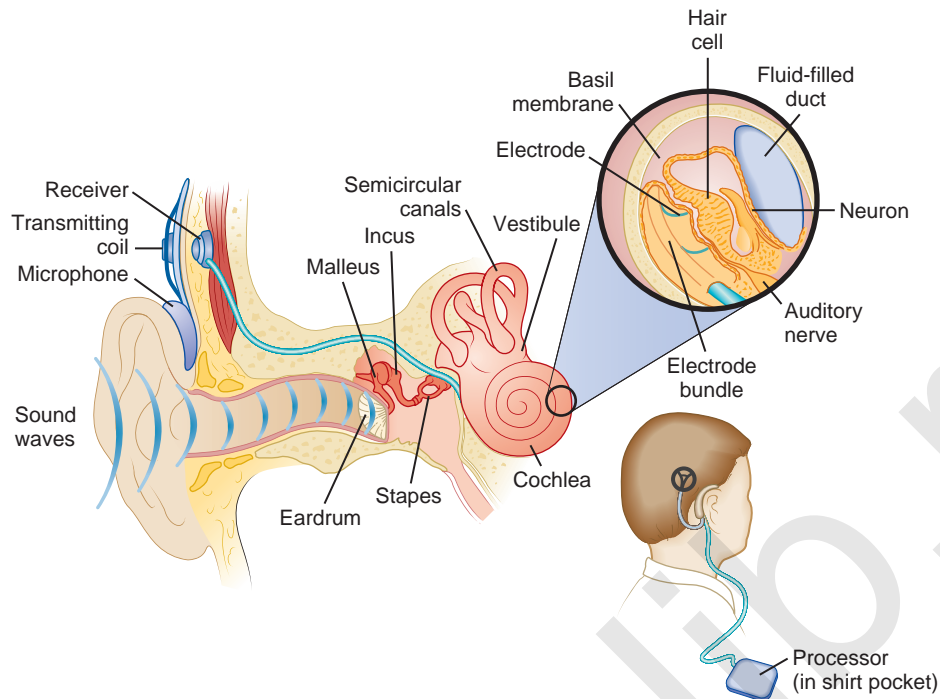

Cochlear Implantation

Cochlear implantation has become a feasible choice for profoundly hearing-impaired children (Figs. 24-1 and 24-2). Profoundly deaf children's auditory nerve fibers remain intact, but the sensory neuroepithelium in the cochlea is absent. This damage occurs because of a genetic defect, infection, cochlear ossification, or aging (Fischetti, 2003). Cochlear implants bypass the damage by receiving and converting sound into signals sent along electrodes to cells adjacent to the auditory nerve. Hearing aids are ineffective because sound cannot be converted into an electrical impulse. Cochlear implants have eight to 22 electrodes that are placed through a cochleostomy. Sounds received from an external microphone are converted to an electrical signal that is received and transmitted by the cochlear nerve (Balkany et al., 2001; Miyamoto and Kirk, 2003). Because the cochlea is full size at birth, there is no anatomic difficulty with electrode insertion in very young children.

Surgery requires 2 to 3 hours, and it is performed through an extended postauricular incision along with a mastoidectomy. Anesthetic considerations are the same as those for mastoidectomy, including the avoidance of muscle relaxants so the facial nerve can be monitored. The anesthesiologist should establish the patient's level of hearing dysfunction so that a method of communication can be established. It is helpful to have a parent or sign language specialist accompany the child to the operating room. If the child reads lips, masks should be kept down from the anesthesiologist's mouth until after induction of anesthesia.

Otoplasty

Otoplasty is a cosmetic procedure to reconstruct or restructure the auricle. Anesthetic considerations are similar to those in other head and neck cosmetic procedures, with one minor

■ **FIGURE 24-1.** The outer ear collects the pressure waves of a sound, which the eardrum converts into mechanical vibrations in tiny bones in the middle ear. The oscillating stapes sets off pressure waves in the fluid in the cochlea, which stimulates nerve cells on the auditory nerve that leads to the brain. The cochlea transmits pressure waves through its duct fluid, displacing the basilar membrane, which bends hair cells to varying degrees. The cells release neurotransmitters that cause attached neurons to fire, telling the brain where along the duct the bending has occurred, which corresponds to the frequency of the original sound, and communicating the amplitude of the bending, which indicates the loudness. The cochlear implant uses a microphone worn behind the ear to pick up sound and send it to a processor, where integrated circuits and algorithms amplify, digitize, and filter the sound into a coded signal sent to the transmitter coil. The coil sends the signal by radio waves through the skin to an implanted receiver. The receiver converts the waves into electrical impulses that travel along electrodes that end at cells at certain points along the cochlea. A magnet in the transmitter holds it against the implanted receiver. (From Fischetti M: *Cochlear implants: to hear again*, *Sci Am* 288:82, 2003.)

■ **FIGURE 24-2.** In the Nucleus 24 Counter implant, the active intracochlear electrode array is precurved to wrap around the modiolus. A stylus is used to straighten the electrode during insertion. (From Miyamoto RT, Kirk KI: *Cochlear implants in children*. In Bluestone CD, Stool SE, Alper CM, et al., editors: *Pediatric otolaryngology*, ed 4, Philadelphia, 2003, Saunders, p 809.)

modification. Otoplasty is frequently bilateral, requiring both sides to be simultaneously prepared and draped. To ensure symmetry, simultaneous visualization requires frequent head motion, and the endotracheal tube must be well secured. PONV is frequent.

ANESTHESIA FOR RHINOLOGIC PROCEDURES

Reduction of Nasal Fracture

A nasal fracture may cause considerable bleeding, and the blood may be swallowed into the stomach. These patients therefore are assumed to have a full stomach, regardless of the time of last food intake. Reduction of a nasal fracture may take only a few moments, but in the acute situation, an oral endotracheal tube is mandatory to protect the airway from pulmonary aspiration. More commonly, surgery is delayed for several days after an isolated nasal fracture to allow swelling to subside. In these cases, a flexible laryngeal mask airway (LMA) can be substituted for an endotracheal tube. The LMA cannot prevent aspiration of stomach contents into the lungs, but it can

prevent blood from the nose from passing through the vocal cords (John et al., 1991; Williams and Bailey, 1993). The LMA may be removed either when the patient is deeply anesthetized or when awake.

Nasal Polypectomy

Nasal polypectomy is performed under general anesthesia, often using a preformed Ring, Adair, Ellwyn (RAE) endotracheal tube, which was originally developed by Ring and associates (1975) (see Chapter 10, Equipment). Packing of the pharynx is indicated in most intranasal procedures. One end of the oropharyngeal gauze packing should be tagged with a hemostat and left hanging externally at one corner of the mouth. A note should be prominently placed in the room for all to see, or a labeled tape should be placed across the exit door, reminding all operating room personnel that a throat pack is in place and needs to be removed. Historically, as much as 10 mcg/kg of epinephrine, usually in a 1:200,000 solution (5 mcg/mL), can be used in children for hemostasis under halothane anesthesia without apparent myocardial irritability (Karl et al., 1983; Ueda et al., 1983). More recently, however, our anesthesia practice has decided to use isoflurane, sevoflurane, desflurane, propofol, or remifentanyl as maintenance anesthetic, without changing the epinephrine dosage (see Chapter 13, Induction, Maintenance, and Recovery).

Special consideration should be given to the management of children with cystic fibrosis, in whom nasal polyps often occur (Hulka, 2000) (see Chapter 36, Systemic Disorders). The polyps are multiple and recur after removal. These children often have severe obstructive lung disease with recurrent pulmonary infection and thick, tenacious secretions. They are frequently hypoxemic in room air. During general anesthesia, the cystic fibrosis patient may require frequent endotracheal lavage with saline and deep suctioning. Secretions can hamper oxygenation and ventilation; a rise in the peak inspiratory pressure intraoperatively may indicate that the endotracheal tube requires suctioning. An inhaled bronchodilator should be immediately available to treat bronchospasm. Inhaled anesthetics and nitrous oxide or opioids and a relaxant may be used for patients with mild to moderate airway obstruction. Nitrous oxide should be avoided in those with severe lower airway obstruction with air trapping, because of possible hyperinflation of trapped air spaces. These patients with lower airway obstruction should be ventilated with an oxygen-air mixture, and appropriate positive end-expiratory pressure (5 to 7 cm H₂O) should be added throughout the procedure to minimize airway closure and atelectasis (see Chapter 3, Respiratory Physiology in Infants and Children). Because of the association of nasal/ethmoidal polyposis with asthma and aspirin sensitivity (Samter's triad), NSAIDs should be used with caution.

In addition to pulmonary pathology, upper airway obstruction frequently occurs in these patients. During induction, the mouth must be kept open because nasal air passages may be completely blocked by the polyp. Nasal packing, usually placed at the completion of the surgical procedure, may lead to further problems in ventilation and oxygenation in the postoperative period. This situation is partially relieved if the surgeon first introduces a nasopharyngeal airway and then packs around it. If preoperative pulmonary function is poor, the physician should consider transferring the patient to the

intensive care unit (ICU), with the endotracheal tube in place, for immediate postoperative respiratory care.

Sinus Surgery

Sinus surgery is indicated for children who have failed maximal medical therapy. Children with allergy or gastroesophageal reflux disease should receive maximal medical therapy and should rarely require surgery (Goldsmith and Rosenfeld, 2003). Children with immune deficiency, immotile cilia syndrome (i.e., Kartagener's syndrome), or cystic fibrosis (Gysin et al., 2000) are at high risk for chronic sinusitis. Unfortunately, because of their underlying disease, these children have a significant surgical failure rate (Herbert and Bent, 1998).

In children with recurrent sinusitis without chronic disease, adenoidectomy should be the initial procedure if the quantity of adenoid tissue visualized on endoscopy is considered sufficient to serve as a reservoir of bacterial pathogens. Adenoidectomy or adenotonsillectomy is usually the first-line surgical intervention for preschoolers, and it is often appropriate in older children. The expected rate of improvement is 70% to 80% (Goldsmith and Rosenfeld, 2003).

Endoscopic sinus surgery (ESS) should be performed only when children have failed previous therapies. In contrast to older traditional techniques of sinus surgery, ESS focuses on enlarging the natural ostia of the maxillary and ethmoid sinuses, while preserving most or all of the sinus mucosa (Goldsmith and Rosenfeld, 2003). In addition to children with chronic sinusitis who fail medical management, Lusk (2003) lists the accepted indications for ESS as complete nasal obstruction in patients with cystic fibrosis, antrochoanal polyps, intracranial complications, mucocoeles and mucopyocoeles, orbital abscess, traumatic injury in the optic canal, dacryocystorhinitis resulting from sinusitis, fungal sinusitis, certain neoplasms, and meningoencephalocele. In properly selected children, the results are good, with an expected improvement of 80% (Lusk, 2003). Preoperative computed tomography (CT) is essential in defining the specific diseased sinuses and in looking for anatomic abnormalities that need to be addressed, including septal deviation, concha bullosa cells, obstructing Haller air cells, and abnormal middle turbinates (Goldsmith and Rosenfeld, 2003).

ESS is performed under general anesthesia using an oral preformed (RAE) or standard endotracheal tube. Many of these children have chronic disease or upper airway obstruction. The anesthetic approach is similar to that described for nasal polypectomy and adenotonsillectomy. The surgeon may elect to use topical oxymetazoline (0.25% to 0.50%) for initial vasoconstriction and then infiltrate the tissue with lidocaine (0.5%) and epinephrine (1:100,000 solution) for hemostasis. The surgeon and the anesthesiologist should be aware that the duration of vasoconstriction usually does not last longer than 1.5 hours, and when surgical procedures are not completed within this period, mild bleeding may make visualization of the surgical site difficult and present a potential problem postoperatively. Some surgeons routinely pack the nose with gauze after the procedure for hemostasis, and the patient becomes an obligate mouth breather. Other surgeons may elect to use Surgicel or FloSeal to obtain hemostasis, and each of these materials has the potential for migration into the lower airway.

Choanal Atresia

Choanal atresia is a congenital malformation in which no connection exists between the nasal cavity and the aerodigestive tract (Prasad et al., 2002); it has an incidence of 1 in 7000 births. The atresia is bony (30%) or mixed membranous and bony (70%). The existence of purely membranous atresia has come into question (Brown et al., 1996). Choanal atresia is unilateral in 50% to 60% of patients. Syndromes associated with choanal atresia include Apert's syndrome, DiGeorge syndrome, trisomy 18, Treacher Collins syndrome, camptomelic dysplasia, and CHARGE association (i.e., coloboma, heart defects, atresia choanae, retardation of growth and development, genitourinary problems, and ear anomalies) (Tewfick et al., 1997).

The symptoms caused by choanal atresia depend on whether the obstruction is unilateral or bilateral. Because neonates are obligatory nasal breathers, those with bilateral disease present with acute respiratory distress. Respiratory distress can be attenuated if the mouth is kept open with an oral airway strapped in place or by a large rubber nipple with a large hole cut in it and kept in place with an umbilical tape around the neck (McGovern, 1961; Hengerer and Wein, 2003). For the neonate with bilateral choanal atresia, surgical nasal correction or tracheostomy must be performed within the first few days of life. Other infants may have only unilateral atresia, with minimal symptoms that can go undiagnosed for months or even years. The most common complaint is intractable unilateral anterior nasal discharge.

A number of surgical procedures have been described for the correction of choanal atresia, including endoscopic, transnasal, transeptal, and transpalatal procedures (Holland and McGuirt, 2001). Timing of surgery for bilateral choanal atresia varies and depends on the infant's ability to adapt to oral breathing and acquire adequate nutrition. Hengerer and Wein (2003) state that some surgeons advocate "a rule of tens" to guide the timing of surgical intervention. The child must reach 10 weeks of age, weigh 10 pounds, and have a hemoglobin level of 10 g/dL. Other surgeons have demonstrated routine success in newborns 48 to 72 hours old and weighing as little as 1900 g (Werkhaven J, 2003, personal communication).

The anesthetic approach depends on the child's condition. In general, intravenous induction with a muscle relaxant of intermediate duration, endotracheal intubation with an oral RAE tube, and maintenance with an inhaled agent and opioid or propofol and remifentanyl infusion suffice. Rarely, algorithms for difficult neonatal intubation must be used for securing the airway in infants with bilateral choanal atresia. After the atresia is surgically corrected, the surgeon is often faced with the problem of restenosis (Pirsig, 1986); however, recent innovations have created optimism that the restenosis rate can be reduced. Newer endoscopic techniques with powered instrumentation have enhanced the safety and efficacy for choanal atresia repair (Prasad et al., 2002). Mitomycin-C, an aminoglycoside and alkylating agent used as an intravenous antineoplastic agent, can be used topically after choanal atresia repair. Topical application inhibits fibroblast growth and migration and granulation tissue formation responsible for restenosis (Holland and McGuirt, 2001). Topical mitomycin has not caused systemic effects and has not contributed to anesthetic complications. Patients with unilateral obstruction usually do well in the postoperative period and require no special monitoring. However, infants undergoing bilateral repair can exhibit partial or intermittent

upper airway obstruction that persists for some time. The infant should be observed closely in the ICU with appropriate monitoring until breathing dynamics have normalized.

ANESTHESIA FOR PHARYNGEAL AND LARYNGEAL PROCEDURES

Tonsillectomy and Adenoidectomy

Tonsillectomy and adenoidectomy (perhaps with the exception of myringotomies) are the most common pediatric surgical procedures performed in the United States. Although tonsillectomy and adenoidectomy are frequently performed procedures, the benefits in relation to cost and risk are still hotly debated (Paradise, 2003). Just about every indication has its advocates and detractors (Bluestone, 2001; Paradise, 2003).

Nocturnal upper airway obstruction, with or without obstructive sleep apnea (OSA), is a common indication for adenotonsillectomy. A mild, partial obstruction in otherwise healthy children is exacerbated by conditions such as achondroplasia, Down syndrome, mucopolysaccharidosis, and obesity. Adenotonsillectomy is considered curative when adenotonsillar hypertrophy is the primary cause of childhood sleep-related breathing disorders (Schechter, 2002). Indications for tonsillectomy include recurrent pharyngotonsillitis, chronic tonsillitis, hemorrhagic tonsillitis, peritonsillar abscess, streptococcal carriage, dysphagia, abnormal dentofacial growth, halitosis, and suspicion of malignant disease (i.e., tonsil asymmetry) (Darrow and Siemans, 2002). Additional indications for adenoidectomy include recurrent or chronic rhinosinusitis or adenoiditis, and recurrent otitis media (Darrow and Siemans, 2002). Adenotonsillar hypertrophy with resultant upper airway obstruction is the most frequent cause of OSA in children (Fig. 24-3).

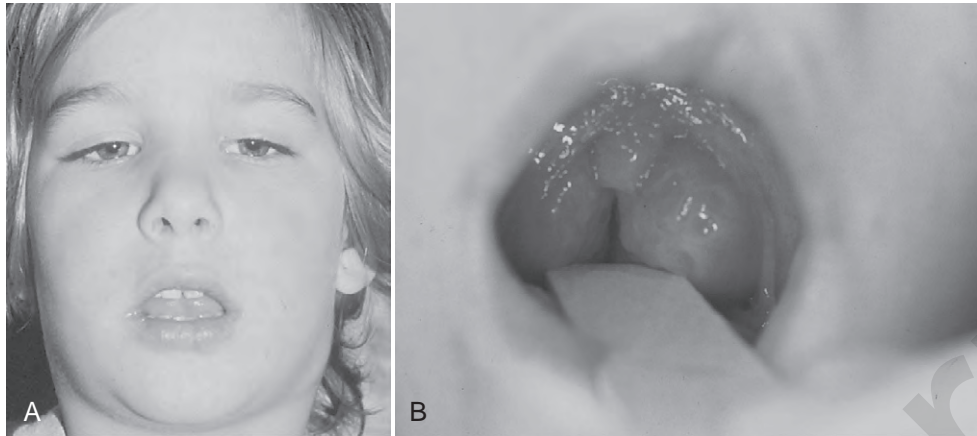

Obstructive Sleep Apnea Syndrome

Obstructive sleep apnea syndrome (OSAS) is a disorder of breathing during sleep characterized by prolonged partial upper airway obstruction (obstructive hypopnea) or intermittent complete obstruction (OSA) with or without snoring and associated with moderate to severe oxygen desaturation that disrupts normal sleep-time breathing and normal sleep patterns (American Thoracic Society, 1996). The most common cause of OSAS among children is upper airway narrowing with adenotonsillar hypertrophy. OSAS also occurs in infants and children with upper airway narrowing resulting from craniofacial anomalies, and in those with neuromuscular diseases, including cerebral palsy and muscular dystrophy (Marcus, 2001; Schwengel et al., 2009) (Box 24-1). See related video online at www.expertconsult.com.

In recent years, the epidemic increase in the prevalence of obesity during childhood seems to be contributing to substantial changes in the cross-sectional demographic and anthropometric characteristics of the children being referred for evaluation of OSAS. Although less than 15% of all symptomatic habitually snoring children were obese (i.e., >95th percentile for age and gender) in the early 1990s, more than 50% fulfilled the criteria for obesity among all referrals to a Kentucky sleep center by the mid 2000s (Gozal et al., 2006; Schwengel et al., 2009).

Adenotonsillar hypertrophy is the most common cause of OSAS in children. Many published papers, primarily case reports

■ **FIGURE 24-3.** Adenoidal and tonsillar hypertrophy. **A**, Dull expression of a child with marked adenotonsillar hypertrophy and nasal obstruction (i.e., adenoid facies). He must keep his mouth open to breathe and shows signs of fatigue as a result of obstructive sleep apnea caused by upper airway obstruction. **B**, On examination of the pharynx, his enlarged tonsils are seen meeting in the midline. and case series, support the idea that tonsillectomy with or without adenoidectomy is often the cure for OSAS (Schechter et al., 2002; Garetz, 2008).

The peak prevalence of OSAS in children occurs between 2 and 8 years, which is the age when the tonsils and adenoids are large in relation to the child's upper airways. The site of collapse is most commonly at the level of the adenoids or velopharynx (Isono et al., 1998; Isono, 2006). Although OSAS is associated with adenotonsillar hypertrophy, there must be other neuromuscular factors involved. These patients usually do not obstruct while awake, implying that sleep induces another dimension to

OSAS. Some otherwise normal children with OSAS but with smaller tonsils and adenoids are cured by adenotonsillectomy, whereas others with larger tonsils and adenoids are not (Marcus, 2001). The patency of pharyngeal airway is maintained by tonic and phasic contractions of the upper airway dilator muscles, such as the genioglossus, geniohyoid, and velopalatine muscles (Isono, 2006). Compared with other inspiratory muscles (i.e., diaphragm and intercostal muscles), these upper airway muscles are preferentially depressed with sleep, sedatives, and general anesthetics (Ochiai et al., 1989, 1992) (see Chapter 3, Respiratory Physiology in Infants and Children). It is hypothesized that children with OSAS may have abnormal centrally mediated activation of their airway muscles, leading to a more collapsible upper airway (Marcus et al., 1994).

Fatty deposits of the upper airway structures, and subcutaneous fat deposits in the anterior neck region are the direct causes of airway obstruction in obese children (mostly adolescents), as well as in obese adults, with OSAS. In addition, increased adipose deposits in the chest wall and abdomen can reduce chest wall compliance as well as cephalad displacement of the diaphragm, causing inefficient ventilation by mass loading and decreased functional residual capacity of the lung (Dayyat et al., 2007; Schwengel et al., 2009). Obese patients have symptoms that differ from those in children with OSAS caused by adenotonsillar hypertrophy. Obese patients tend to have a significantly greater incidence of daytime sleepiness, insulin resistance, and systemic as well as pulmonary hypertension than children with adenotonsillar hypertrophy (Tauman et al., 2004). Furthermore, Tauman and coworkers recently observed a high failure rate for obese children with OSAS undergoing adenotonsillectomy.

Dayyat and colleagues (2007) differentiated between children with OSAS into two types. The type 1 child with OSAS is not obese but has disordered breathing secondary to marked lymphadenoid hypertrophy. The type 2 patient is obese with minimal lymphadenoid hyperplasia. Table 24-1 compares the common symptoms experienced by the two types of patients (Dayyat et al., 2007).

One of the most interesting areas of childhood OSAS research has been on the effects that OSAS has on systemic inflammation. Children with OSAS are at risk for developing inflammatory responses that may lead to endothelial dysfunction and

TABLE 24-1. Clinical Presentation of Pediatric Obstructive Sleep Apnea Types I and II

Symptoms and Findings Seen with Similar Frequencies in Types I and II

- Snoring
- Difficulty breathing during sleep, with snorting episodes
- Restless sleep and frequent awakenings
- Excessive sweating
- Night terrors
- Enuresis
- Breathing pauses reported by parents
- Mouth breathing and limited nasal airflow
- Chronic rhinorrhea
- Frequent visits to primary care physician for respiratory-related symptoms
- Retrognathia
- Pulmonary hypertension and cor pulmonale

Symptoms and Findings that Differ Between Types

	Type I	Type II
Excessive daytime sleepiness	+	++++
Weight gain	-	++
Hyperactive behavior	++++	- or +
Truncal obesity	- or +	+++
Enlarged neck circumference	- or +	+++
Enlarged tonsils or adenoids	++++	++
Depression and low self-esteem	+	+++
Shyness and social withdrawal	+	+++
Left ventricular hypertrophy	++	++++
Systemic hypertension	+	++++
Recurrent ear infections	+++	- or +
Insulin resistance	-	++++
Dyslipidemia	+	++++
Elevated C-reactive protein	++	++++
Elevated liver enzymes	-	++

atherogenesis (Gozal et al., 2008). School-aged children with OSAS have a higher serum C-reactive protein level than controls, and the elevation correlates with the severity of OSAS, and levels decrease after adenotonsillectomy (Gozal et al., 2007). Serum proteomic patterns in children with OSAS differ significantly from those in children who have primary snoring but do not have OSAS (Shah et al., 2006). In the Shah group's study, proteomic profiling of serum samples in children with OSAS revealed differential expression of circulating proteins. Proteomics may play a future role in diagnosing OSAS in the snoring child.

Symptoms of OSAS include nocturnal snoring, breathing pauses, gasping, use of accessory muscles of respiration, enuresis, and excessive sweating (Messner, 2003). In addition, children with OSAS have a host of sequelae, which are usually reversible after adenotonsillectomy but can lead to perioperative complications during and after surgery. Children with OSAS may present with failure to thrive, although the cause of this growth failure is unclear (Sterni and Tunkel, 2003).

TABLE 24-2. Polysomnographic Characteristics of Obstructive Sleep Apnea in Children and Adults

Characteristic	Adults	Children
Apnea duration	10 sec	2 breaths
Hypopnea desaturation	≥4%	≥3%
Hypopnea duration	10 sec	2 breaths
Hypopnea nasal pressure drop	>30%	≥50%
Cortical arousals	Common	Uncommon
Normal apnea-hypopnea index	<5	<1

From Karlson KH Jr: What's new in pediatric obstructive sleep apnea? *Clin Pulm Med* 15:226, 2008.

Many of these children experience a growth spurt after surgery. Children with OSAS may have neurocognitive deficits such as poor learning, behavioral problems, and lower grades in school than non-OSAS children. Adenotonsillectomy improves functioning in these children (Marcus, 2001). Recent studies demonstrate that despite negative polysomnographic findings, the benefits of adenotonsillectomy are still observed in children with symptomatic airway obstruction, including improvements in behavior and quality of life (Leong and Davis 2007).

The diagnosis of OSAS is based on a thorough history and physical examination along with appropriate sleep studies, including polysomnography (Table 24-2 and Boxes 24-2 and 24-3). Snoring, increased respiratory efforts, periodic obstructive apnea, and oxygen desaturation while sleeping are the universal features of OSAS, which must be differentiated from the benign condition referred to as primary snoring.

Box 24-2 Key Questions to Ask Parents

- Does your child have difficulty breathing during sleep?
- Have you observed symptoms of apnea?
- Have you observed sweating while your child sleeps?
- Does your child have restless sleep?
- Does your child breathe through his or her mouth when awake?
- Are you worried about your child's breathing at night?
- Do you have any family history of obstructive sleep apnea, sudden infant death syndrome, or apparent life-threatening events?
- Does your child have behavioral problems?

Box 24-3 Facial and Airway Features Suggestive of Obstructive Sleep Apnea

- Small triangular chin
- Retro position of the mandible
- Steep mandibular plane
- High palate
- Long, oval face
- Long soft palate
- Large tonsils in association with the aforementioned facial features

Polysomnography

Pediatric polysomnography includes measurement of end-tidal CO₂, electroencephalogram, chin EMG, chest wall movement, airflow through the nose and mouth, leg movement, and oxygen saturation via pulse oximetry (Box 24-4). After all events are reviewed and scored, several indices can be calculated. These include the apnea index and the apnea-hypopnea index, which are calculated for the entire sleep period, for both rapid eye movement sleep and non-rapid eye movement sleep. The term *index* refers to the number of events divided by the number of hours of sleep (Table 24-3). This calculation allows the comparison of polysomnograms of varying time lengths. The apnea index is determined using only apneas, whereas the apnea-hypopnea index includes both apneas and hypopneas (Wagner and Torrez, 2007).

Box 24-4 Components of Polysomnography*

- Respiratory effort—assessed by abdominal and chest wall movements
- Airflow at nose, mouth, or both
- Arterial oxygen saturation
- End-tidal CO₂ or transcutaneous CO₂ (recommended specifically for pediatric polysomnography to detect hypoventilation)
- Electrocardiography
- Electromyography (tibial) to monitor arousals
- Electroencephalography, electrooculography, and electromyography for sleep staging

From American Thoracic Society: Standards and indications for cardiopulmonary sleep studies in children, *Am J Respir Crit Care Med* 153:866, 1996.
* As recommended by the American Thoracic Society.

TABLE 24-3. Respiratory Events that Can Be Seen During Polysomnography

Event	Definition
Central apnea	Pause in airflow with absent respiratory effort, scored when >20 sec or 2 missed breaths and a >3% drop in oxygen saturation
Obstructive apnea	>90% reduction of airflow despite continuing respiratory effort, scored when event lasts at least 2 missed breaths in children
Obstructive hypopnea	>50% reduction of airflow with associated respiratory effort, scored when at least 2 missed breaths and >3% drop in oxygen saturation or arousal
Mixed apneas	≥90% reduction in airflow, lasting at least 2 missed breaths, and containing absent respiratory effort initially (a central apneic pause), followed by resumption of respiratory effort without a resumption of airflow (an obstructive apnea)
Obstructive hypoventilation	End-tidal CO ₂ > 50 mm Hg for >25% of the total sleep time, with paradoxical respirations, snoring, and no baseline lung disease

It is helpful to divide the scores into severity-based categories (Table 24-4). OSAS severity can be used to determine the appropriate surgical center where the surgery should be performed and whether the child requires overnight observation (Box 24-5).

Although definitive diagnosis of OSAS is made by a positive polysomnogram, many children are not tested because the polysomnography laboratories specializing in children are few, and the tests are expensive and require an overnight stay (Sterni and Tunkel, 2003). Most children are diagnosed by recommendations set forth by the section of Pediatric Pulmonology Subcommittee

TABLE 24-4. Proposed Classification and Severity Criteria of Pediatric Sleep-Disordered Breathing

	OAHI (per hour TST)	Nadir SpO ₂ (%)	PETCO ₂ > 50 mm Hg (% TST)	RAI (per hour TST)
Normal	≤1	>94	<10	<1
Habitual snoring	≤1	>94	<10	<2
Upper airway resistance syndrome	≤2	>92	10-15	≥2
Obstructive alveolar hypoventilation	≤2	>92	>20	≥2
Obstructive sleep apnea				
Mild	2-5	88-92	10-15	2-5
Moderate	5-10	80-88	15-20	5-8
Severe	>10	<80	>20	>8

OAHI, Obstructive apnea-hypopnea index; PETCO₂, end-tidal carbon dioxide tension; RAI, respiratory arousal index; SpO₂, oxyhemoglobin saturation by pulse oximetry; TST, total sleep time.

Box 24-5 Clinical Features that Predict Respiratory Compromise after Adenotonsillectomy and, in Some Cases, Persistent Obstructive Sleep Apnea

- Severe obstructive sleep apnea on polysomnography
- History of prematurity, especially with respiratory disease
- Age less than years
- Morbid obesity
- Nasal problems (deviated septum, enlarged turbinates)
- Mallampati score of 3 or 4
- Neuromuscular disorders or disordered pharyngeal tone
- Genetic or chromosomal disorders
- Craniofacial disorders
- Enlarged lingual tonsils
- Upper respiratory infection within 4 weeks of surgery
- Cor pulmonale
- Systemic hypertension
- Marked obstruction on inhalational induction
- Disordered breathing in the postanesthesia care unit
- Difficulty breathing during sleep
- Growth impairment resulting from chronic obstructed breathing

Data from McGowan et al., 1992; Gerber et al., 1996; Blum et al., 2004; Fricke et al., 2006; Guilleminault et al., 2007.

on Obstructive Sleep Apnea, sans Polysomnography. This committee's recommendations for otherwise healthy children older than 1 year are as follows (Schechter, 2002):

- All children should be screened for snoring. As part of routine health care maintenance for all children, pediatricians should ask whether the patient snores. An affirmative answer should be followed by a more detailed evaluation.
- Complex, high-risk patients should be referred to a specialist.
- Patients with cardiorespiratory failure cannot await elective evaluation. It is expected that these patients will be in an intensive care setting and will be treated by a specialist; these patients are not covered in this practice guideline.
- A thorough diagnostic evaluation should be performed. History and physical examination have been shown to be poor in discriminating between primary snoring and OSAS. Polysomnography is the only method that quantifies ventilatory and sleep abnormalities, and it is recommended as the diagnostic test of choice. Other diagnostic techniques, such as videotaping, nocturnal pulse oximetry, and daytime nap studies, may be useful in discriminating between primary snoring and OSAS. However, they do not assess the severity of OSAS, which is useful for determining treatment and follow-up.
- Adenotonsillectomy is the first line of treatment for most children. CPAP is an option for those who are not candidates for surgery or do not respond to surgery.

Severe, untreated OSAS may lead to pulmonary hypertension and cor pulmonale caused by nocturnal hypoxia and hypercarbia, resulting in compensatory changes in the pulmonary vasculature. Pulmonary vascular resistance increases, causing increased right ventricular strain. Severe cases may progress to pulmonary hypertension, arrhythmias, and cor pulmonale, which are reversible by performing early adenotonsillectomy (Miman et al., 2000). Children with OSAS also tend to have higher diastolic blood pressures. The cardiovascular changes appear to be the result of an increase in sympathetic tone that results from obstructive respiratory events (Marcus et al., 1998). Fortunately, few children develop clinically significant heart failure. It is prudent to pursue an aggressive cardiac evaluation if the child has a loud second heart sound, exercise intolerance, or diastolic hypertension. Because children are diagnosed earlier today, significant heart disease is rarely an issue (Marcus, 2001).

Preoperative Preparation

A careful review of the history, laboratory data, and physical examination results are essential for the optimal outcome of adenotonsillectomy. Careful evaluation of coagulation status is important before performing this procedure. If there is a history of easy bruising, frequent epistaxis, or positive family history, the prothrombin time, partial thromboplastin time, and platelet count should be obtained to rule out coagulopathies. In many pediatric institutions, a coagulation profile is obtained routinely for patients scheduled for adenotonsillectomy. However, in a prospective study of hemostatic assessment of patients before tonsillectomy, routine measurements of a coagulation profile were not useful predictors of postoperative bleeding (Close et al., 1994).

Although relatively mild, von Willebrand's disease (i.e., reduced factor VIII, decreased platelet adhesiveness because of

deficient von Willebrand factor) is the most common coagulopathy seen among patients scheduled for adenotonsillectomy. Children with von Willebrand's disease or mild hemophilia A are treated preoperatively with desmopressin (1-desamino-8-D-arginine vasopressin [DDAVP]) (Prinsley et al., 1993). DDAVP is a synthetic analogue of vasopressin, which, in addition to its antidiuretic effect, stimulates endothelial cells and releases stored factor VIII and von Willebrand factor (Mannucci, 1988). The intravenous dosage of DDAVP is 0.3 mcg/kg, given over 20 minutes before anesthetic induction.

Patients who receive DDAVP are at increased risk for hyponatremia because of the retention of free water that occurs with DDAVP. Anesthesia care providers need to remember that intravenous fluids for these patients should be isotonic (preferably normal saline) and should be administered at one-half to two-thirds maintenance dosage. Patients who require intravenous fluids postoperatively should have their sodium monitored to assess for the development of hyponatremia.

The examiner should elicit a history of drug ingestion, especially acetylsalicylic acid. If the patient was given such drugs recently, surgery should be postponed, because these drugs cause platelet dysfunction for as long as 10 days and may cause excessive bleeding intraoperatively and postoperatively (Davies and Steward, 1977; Paradise, 2003).

During the preoperative visit, the patency of oral and nasal air passages is carefully examined. The patient's mouth should be inspected for the degree of tonsillar hypertrophy or inflammation. The examiner should also have the child breathe with the mouth closed to evaluate the degree of nasal airway obstruction and estimate adenoidal hypertrophy. It is important to inspect the teeth routinely, because tonsillectomy is often performed on children who are losing their primary dentition. Any teeth missing preoperatively should be noted carefully. A tooth that is loose should be pointed out to the parent and child, with the explanation that it may be necessary to remove it while the child is anesthetized (it must then be saved). It is also possible for the surgeon to dislodge or chip teeth in the application of a mouth gag or during other intraoperative manipulations.

Anesthetic Management

All children should be monitored with a pulse oximeter, end-tidal CO₂, precordial stethoscope, electrocardiogram, thermometer, and automated blood pressure cuff. Oxygen saturation is determined in room air before the induction of anesthesia to establish the baseline value. If neuromuscular blockade is required, a nerve stimulator should be used to track the depth of paralysis. Standard NPO guidelines should be followed in nonemergent situations.

Children who are anxious preoperatively may receive sedation with oral midazolam. In older children scheduled for intravenous induction, EMLA cream (i.e., eutectic mixture of local anesthetics, 2.5% lidocaine and 2.5% prilocaine) is applied to the dorsum of both hands and sealed with plastic adhesives at least 1 hour before intravenous catheter insertion (see Chapter 9, Preoperative Preparation, and Chapter 13, Induction, Maintenance, and Recovery).

Adenoidectomy is a relatively short procedure (15 to 45 minutes), and many centers perform anesthesia without neuromuscular blockade and with less opioid than suggested in the following descriptions. Anesthesia is induced most commonly with oxygen, nitrous oxide, and sevoflurane. As with those

undergoing myringotomies, children with adenotonsillar hypertrophy often have partial or complete nasal airway obstruction. The mouth must be kept open during the induction of anesthesia until the gag reflex is abolished and the oral airway is inserted. If necessary, moderate CPAP (10 to 15 cm H₂O), with jaw thrust during induction (before the patient is deep enough for oral airway insertion) helps to prevent the pharyngeal airway collapse that results from the relaxation of upper airway muscle tone (Reber et al., 2001; Bruppacher et al., 2003).

After the intravenous route is established, atropine or glycopyrrolate may be given for its anticholinergic effects. The patient's trachea is intubated with a preformed oral (RAE) tube under deep inhalational anesthesia supplemented with a topical lidocaine spray to the vocal cords under a direct vision, an intravenous bolus of propofol, or an intermediate-acting, nondepolarizing muscle relaxant (e.g., cisatracurium, vecuronium). In older children, anesthesia may be induced intravenously with propofol (2 to 3 mg/kg) mixed with lidocaine (1 to 2 mg/mL of propofol) to reduce pain at the injection site, with or without anticholinergic agent or a muscle relaxant. Inhalation anesthetic or propofol infusion is continued thereafter with spontaneous or controlled ventilation. A cuffed endotracheal tube is recommended to reduce the chance of aspiration of blood and secretions and to reduce gas leaks around the tube. A cuffed endotracheal tube, 0.5 to 1.0 mm (inner diameter) smaller than the age-appropriate size, should be chosen to accommodate the passage of the cuff through the subglottis (Khine et al., 1997; James, 2001; Fine and Borland, 2004). The endotracheal tube is immobilized with adhesive tape over the middle of the lower lip (Fig. 24-4). The breath sounds on both sides of the chest should be auscultated carefully to avoid endobronchial intubation. The endotracheal tube is then held in place by the groove-bladed tongue depressor that is a part of the Ring adaptation of the Brown-Davis mouth gag (Fig. 24-5).

Anesthesia is maintained with supplemental opioids to reduce the requirement of the anesthesia maintenance agent and to provide postoperative analgesia. The physician may start with a loading dose of 1 to 2 mcg/kg of fentanyl, 50 to 100 mcg/kg of morphine, or 10 to 20 mcg/kg of hydromorphone given intravenously, with additional doses administered as needed. Children with moderate and severe OSAS should receive lower

■ **FIGURE 24-4.** For tonsillectomy or adenoidectomy, an oral Ring, Adaire, Ellwyn (RAE) endotracheal tube is fixed over the middle of the lower lip.

■ **FIGURE 24-5.** Patient in position for tonsillectomy. A Brown-Davis mouth gag holds the mouth open. An oral Ring, Adaire, Ellwyn (RAE) endotracheal tube is fixed to the middle of the lower lip and is held in the groove of the tongue blade.

dosages of opioids to minimize the risk for prolonged apnea during emergence and postoperative upper airway obstruction. Brown and coworkers (2004) have shown that young age and low preoperative oxygen saturation were associated with lower postoperative morphine requirement. It appears that children with a minimal oxygen saturation of 85% or less during preoperative sleep required half the postoperative analgesic dosage required by children whose saturations were 85% or greater (Brown et al., 2006).

The use of NSAIDs during or after tonsillectomy is controversial. A meta-analysis suggested that there is an increased risk for bleeding and increased return to the operating room when NSAIDs such as ketorolac are used (Marret, 2003). Criticism of this meta-analysis focuses on the small number of patients evaluated, the varying types and dosages of NSAID, and the varying surgical techniques used for the tonsillectomy. A Cochrane database review evaluated the role of NSAIDs in posttonsillectomy bleeding and found no significant correlation between NSAID use and increased risk for posttonsillectomy bleeding (Cardwell et al., 2005). Practice among pediatric anesthesiologists varies. Some centers do not use NSAIDs during adenoidectomy or tonsillectomy, whereas others use them routinely (Allford, 2009).

There is evidence that high dosages of dexamethasone (up to 1 mg/kg, 25 mg maximum) reduce postoperative swelling and pain and decrease the incidence of PONV without apparent adverse effects attributable to dexamethasone (Pappas et al., 1998). Children receiving dexamethasone are more likely to advance to a soft-solid diet on the first postoperative day (Steward et al., 2003).

Bleeding during tonsil and adenoid surgery is seldom excessive, but massive hemorrhage has occurred with tearing of the carotid vessels (Smith, 1972, 1980). Homeostasis is usually obtained using electrocautery. There have been several reports of fires due to electrocautery-induced ignition of the endotracheal tube or packing during tonsillectomy. Fires are caused by combustible material in an oxygen-rich environment (Mattucci and Militana, 2003); management of airway fires is discussed later.

Children with OSAS tend to emerge from anesthesia more slowly than children without OSAS. This may be explained by their deficit in sleep arousal mechanisms. They seem to have elevated sleep arousal mechanisms in response to hypercarbia

and increased upper airway obstruction (Marcus et al., 1998, 1999). Other subtle disturbances of sleep architecture may also be present (Bandla et al., 1999).

Techniques of Tonsillectomy and Adenoidectomy

A myriad of surgical techniques are used to perform tonsillectomy and adenoidectomy, and they use a mouth gag to give oropharyngeal exposure. The surgeon should use caution when placing and removing the mouth gag to avoid displacement of the endotracheal tube.

The adenoidectomy is performed either with a mechanical or a thermal technique (Hesham, 2009). Mechanical removal of the adenoids may be performed using curettes, adenotomes, or a micro-debrider. These mechanical techniques require nasopharyngeal packing to prevent bleeding, and the surgeon must remember to remove the packing at the end of the procedure. Thermal removal of adenoid tissue may employ electro-surgical cautery, radiofrequency ablation, or lasers, and it usually results in little bleeding.

Tonsillectomy can also be performed via mechanical or thermal techniques. Intracapsular removal of tonsil tissue is a newer approach that preserves the integrity of the tonsil capsule, and will be discussed later.

Mechanical removal of the tonsil has many technical variations. In general, an incision is made in the anterior pillar mucosa to expose the tonsil capsule, and using sharp or blunt dissection, the tonsil and capsule are removed together. Alternatively, a guillotine, or snare, is occasionally used to remove the tonsil without making an incision. This results in exposure of the underlying pharyngeal musculature with the perforating vascular supply to the tonsil, and hemostasis must be established. At the turn of the previous century, snare tonsillectomy with ether anesthesia was the standard, and hemostasis was achieved after prolonged observation of the surgical field to ensure passive wound clotting. This was less than ideal, and the mortality rate was unacceptably high. Today, active hemorrhage control is performed after removal of the tonsils. Some surgeons use dissolvable suture to ligate the bleeding points, but this is becoming less common. More often, electro-surgical cautery is used for hemostasis. This technique completes an electrical arc between the patient and the surgical instrument and has the potential to ignite flammable gases and combustible materials (such as the sponges in the nasopharynx used for tamponade of the adenoid bleeding). Case reports of airway fires have been reported with the use of electro-surgical cautery in tonsillectomy (Mattucci and Militana, 2003). It is suggested that the inspired oxygen levels be maintained as they are for the use of lasers in the airway (see *Laser Surgery of the Larynx*, later).

Thermal removal of the tonsil uses the electro-surgical unit or a radiofrequency unit for tonsil dissection. The most common radiofrequency unit in use is Coblation (ArthroCare, Austin, TX). Thermal removal of the tonsils and adenoids generally results in less blood loss, but it may be accompanied by slightly more postoperative pain than other techniques. A cuffed endotracheal tube, using moist throat packing and inspired oxygen levels of less than 40%, will minimize the risk for an airway fire (Johnson et al., 2002).

Intracapsular tonsillectomy is a newer technique that uses either the micro-debrider or the radiofrequency ablator to remove the tonsil tissue while preserving the tonsil capsule

(Koltai et al., 2002). In effect, this may be considered a selective removal of the tonsillar mass, which is believed to be the most common cause of OSAS. Preservation of the capsule protects the underlying pharyngeal musculature, resulting in less postoperative pain and hemorrhage. Because the vascular supply is interrupted at a more terminal point, the muscular bed can contract around the vessels, providing better hemostasis. Initially, this technique was recommended only for those patients with OSAS. Recurrent infection is considered a contraindication, because this technique leaves behind residual tonsil tissue that may become reinfected. This technique is especially appropriate in those OSAS children 3 years of age and younger because of the lower postoperative pain scores and thus less opioid need (Solares et al., 2005; Colen et al., 2008). In general, the only risk of an intracapsular tonsillectomy is the rare (<1 in 1500) need to return for a complete tonsillectomy because of tissue regrowth leading to recurrent infectious tonsillitis.

At the conclusion of surgery, the surgeon usually suctions the pharynx and larynx under direct vision to prevent bleeding caused by agitation of raw mucosal surfaces by a suction catheter. Suctioning of the stomach contents may also remove swallowed secretions, blood, or residual preoperative sedative medications. Removal of these preoperative medications may decrease excess sedation in the postoperative period. Some surgeons elect to infiltrate 0.25% bupivacaine or other local anesthetic medications into the tonsillar fossa to aid in postoperative pain relief (Naja et al., 2005), whereas others feel that this analgesic technique may lead to premature discharge of patients who will then experience rebound pain when the local anesthetic wears off. This practice has occasionally been associated with airway obstruction after extubation.

After tonsillectomy, the anesthesia provider should always use a tonsil suction tip and should never blindly suction the nasopharynx or oropharynx after adenoidectomy or tonsillectomy. Suctioning should be directed toward the midline to avoid the lateral tonsil fossa. A soft nasopharyngeal airway may be inserted to facilitate airway patency for extubation. If adenoid hemostasis is adequate prior to insertion of the nasopharyngeal airway, usually no additional bleeding is encountered. Toward the completion of surgery, before a child regains active reflexes, the anesthesiologist should auscultate both sides of the chest to rule out the presence of aspirated blood or secretions and, under direct laryngoscopic visualization, examine the mouth and pharynx for blood and other debris that could cause airway irritation after extubation.

Laryngospasm may occur when the patient is extubated after tonsillectomy. Methods for avoiding this problem include extubating the trachea while the child is deeply anesthetized (not recommended for children with OSAS) or almost completely awake (see Chapter 13, Induction, Maintenance, and Recovery). Although intravenous lidocaine has not consistently proved helpful in preventing laryngospasm, application of local anesthetic before intubation or manipulation of the airway can reduce the incidence of laryngospasm during intubation and after extubation (Leicht et al., 1985; McCulloch et al., 1992; Landsman, 1997). It appears that lidocaine deposited locally in the laryngeal area suppresses laryngeal mucosa neuroreceptor transmission. However, lidocaine's duration of action at laryngeal receptor sites is only 30 minutes, and its administration before intubation may not protect against laryngospasm at the time of extubation (Warner, 1996).

Before extubation, the lungs should be well expanded with an oxygen-air mixture at sustained high positive pressure (35 to 40 cm H₂O) several times (the vital capacity maneuver), to reopen intrathoracic airways and reverse atelectasis, which frequently develops during anesthesia and surgery; the patient should then be extubated under positive pressure (Benoit et al., 2002; Tusman et al., 2003) to prevent postoperative oxygen desaturation. Positive airway pressure at the moment of extubation causes a coughing motion, which helps to expel secretions around the vocal cords. Positive extending pressure on the upper airway walls also attenuates the excitation of the superior laryngeal nerve and may diminish the risk for laryngospasm (Suzuki and Sasaki, 1977; Sasaki, 1979) (see Chapter 3, Respiratory Physiology in Infants and Children, and Chapter 13, Induction, Maintenance, and Recovery).

Postoperative Management

Children with hypertrophic tonsils and adenoids tend to have increased airway obstruction in the immediate postoperative period. The presence of blood and secretions in the pharynx and larynx may provoke upper airway reflexes, leading to laryngospasm. These patients tend to become hypoxemic more often and perhaps more severely during the first several hours after surgery than patients undergoing procedures not involving the upper airways (Motoyama and Glazener, 1986). However, they seem to maintain their preoperative levels of oxygen saturation in room air thereafter, as determined with pulse oximetry (Motoyama and Borland, unpublished observations). Fortunately, serious complications after adenotonsillectomy are infrequent. Postoperative hemorrhage, however, does occur and can become a life-threatening catastrophe (discussed later). Postoperative emesis is relatively common because of pharyngeal mucosal irritation from surgery, which may stimulate the glossopharyngeal nerves, or from bloody secretions that are swallowed. It is therefore prudent for the anesthesiologist to administer antiemetics (e.g., ondansetron or metoclopramide) prophylactically, in addition to dexamethasone before the end of surgery (Pappas et al., 1998). Pain after tonsillectomy is mild to moderate and may be controlled by opioids given intraoperatively as part of anesthetic management or by supplementation (morphine, 50 mcg/kg; fentanyl, 0.5 to 1.0 mcg/kg; hydromorphone, 10 mcg/kg) in the postanesthetic care unit. Postoperative pain after adenoidectomy is relatively mild. Acetaminophen is a good adjunct to pain control in these patients.

It has been reported that children with OSAS have reduced opioid requirements after adenotonsillectomy. In addition, children with OSAS spontaneously breathing during halothane anesthesia are more likely to become apneic than non-OSAS children when treated with the same dosage of fentanyl (Waters et al., 2002). However, others have found no morbidity from opioid or benzodiazepine treatment in OSAS pediatric patients undergoing adenotonsillectomy (Helfaer et al., 1996; Sanders et al., 2006; Leong and Davis, 2007).

Preoperative sedation with benzodiazepines and postoperative treatment with opioids should be tailored to meet the needs of the patient. It would be prudent to titrate opioids, anticipating that the more severe the OSAS, the higher is the risk of opioid and benzodiazepine sensitivity. For patients with moderate or severe OSAS, many anesthesiologists prefer not to administer opioids until the patient has fully emerged from the anesthetic, has regained spontaneous ventilation, has been extubated, and

is able to maintain an open airway with spontaneous ventilation. The patient's opioid therapy may then be titrated carefully to achieve analgesia without respiratory compromise (Leong and Davis, 2007). During the immediate postoperative period, monitoring these patients in a postanesthetic care unit staffed with pediatric recovery room nurses allows a safe postoperative recovery with pain control.

Children with OSAS have a higher incidence of postoperative respiratory complications, including prolonged oxygen requirements, airway obstruction requiring nasal airway, and major respiratory compromise requiring airway instrumentation, than children without OSAS (Biavati et al., 1997; Wilson and Robertson 2002). Because OSAS is a disorder of anatomic and dynamic factors of upper airway function, it is not surprising that a procedure that is curative in many of these children would cause significant postoperative respiratory complications. Because these children are presumed to have impaired neuromuscular control of upper airway patency, residual anesthetic effects combined with blood, edema, and residual lymphoid tissue obstructing the postsurgical airway can lead to postoperative respiratory events (Wilson et al., 2002). McColley and colleagues (1992) reported a 58% incidence of severe respiratory compromise in children younger than 3 years that was associated with severe oxygen desaturation (SpO₂, ≤70%) or hypoventilation from upper airway obstruction. Among children with OSAS undergoing adenotonsillectomy (mean age, 5 years), intraoperative and postoperative complications are particularly high among those who were born prematurely (85% versus 25% to 34% in full-term infants).

Nixon and coworkers (2005) demonstrated that, not infrequently, children with OSAS continue to have polysomnogram-documented airway obstruction the night after adenotonsillectomy. Obstructive apneas and hypopneas were four times as frequent and associated with greater oxygen desaturation in the severe OSAS group as opposed to the mild OSAS group.

The subpopulation of children with OSAS who must be monitored in the hospital is still unknown. Children who are most likely to experience postoperative respiratory complications and have a higher postoperative respiratory disturbance index on their postoperative polysomnogram include children 3 years of age and younger, children with severe OSAS diagnosed by preoperative polysomnography, and those with associated medical conditions such as hypotonia, morbid obesity, failure to thrive, or severe structural airway abnormalities (Statham et al., 2006; Karlson 2008). These children are not candidates for outpatient surgery facilities and should receive medical care in centers with pediatric inpatient facilities and pediatric intensive care support. High-risk patients should be monitored overnight with continuous pulse oximetry, because standard apnea monitoring is unable to detect obstructive apnea and hypopnea. Patients can be discharged when significant oxygen desaturation during sleep has resolved.

A rare complication of adenotonsillectomy in children with severe OSAS is pulmonary edema resulting from relief of upper airway obstruction (Mehta et al., 2006). The exact cause is unknown. Galvis and colleagues (1980) hypothesized that during obstructed breathing, extreme negative pressures occur in the intrapleural and intrathoracic compartments. Intubation results in sudden equalization of pressure. The pulmonary venous pressure is suddenly much higher than intrathoracic pressure, resulting in pulmonary hyperemia and edema.

Furuhashi-Yanaha and colleagues (2000) hypothesized that the abrupt switch from nasal to oral breathing during emergence from anesthesia might create acute obstruction, which creates an increase in negative intrapleural pressure, leading to pulmonary edema. Regardless of the cause, these children require oxygen and possible reintubation to provide CPAP or positive end-expiratory pressure. This condition usually resolves in 24 to 48 hours (Carcillo, 2003), and the use of diuretics is controversial.

Bleeding after Tonsillectomy

Occasionally, bleeding continues or recurs after tonsillectomy, and the child must be anesthetized to suture or pack the bleeding area. Posttonsillectomy bleeding is classified as primary or secondary bleeding. Primary bleeding occurs within the first 24 hours after surgery and is usually more brisk and profuse than secondary bleeding. Most fatal hemorrhages occur within the first 24 hours after surgery (Randall and Hoffer, 1998). Most posttonsillectomy bleeding, however, occurs within the first 6 hours after surgery (Crysdale and Russel, 1986; Carithers et al., 1987; Guida and Mattucci, 1990).

Secondary bleeding usually occurs 24 hours to 5 to 10 days after surgery, when the eschar covering the tonsillar bed sloughs (Verghese and Hannallah, 2001). Allen and coworkers (1973) reported a 0.1% incidence of posttonsillectomy bleeding necessitating repeat exploration in the operating room. Crysdale and Russel (1986) reported a 2.15% incidence of bleeding during the overnight stay in the hospital for 9400 children undergoing tonsillectomy with or without adenoidectomy. Of these, 3% (0.06% of all patients) required reexploration under general anesthesia.

The child with tonsillar bleeding may be brought back to the anesthesia service several hours or even days or weeks after the surgery. Because primary bleeding tends to be more rigorous, bleeding may obstruct the view of the larynx, and emergent tracheostomy may be needed. The otolaryngologist should be present before anesthetic induction. Whether the bleeding is primary or secondary, several issues must be addressed before induction of anesthesia; the child usually is hypovolemic, anemic, agitated, or in shock, with a stomach full of blood clots and often without an intravenous catheter. This is one of the most dangerous and challenging situations in pediatric anesthesia practice, and the failure to initiate prompt action has been one of the main causes of death associated with tonsillectomy (Alexander et al., 1965).

Under these circumstances, intravenous access must be reestablished, unless it is still in place, to rehydrate or transfuse without delay. It is frequently difficult to find a suitable vein for insertion of a large-enough catheter (at least 22 gauge for infants, 20 gauge for children) for rapid hydration and transfusion in an agitated and hypovolemic child with extreme cutaneous vasoconstriction. An intraosseous infusion or surgical cutdown may be indicated in some patients.

It may be difficult to estimate the extent of blood loss and dehydration. The patient may be tachycardic and have an elevated blood pressure caused by the release of endogenous catecholamines from hemorrhage, hypovolemia, or fear and excitement. If the child is sitting up and talking without feeling dizzy, hypovolemia is only mild to moderate; there is enough time to evaluate volume status and to determine hemoglobin, hematocrit, and urine specific gravity and obtain additional

information on overall physical status. The child who is lying down and has pale conjunctivae, hypotension, and diminished consciousness may be on the verge of hypovolemic shock, and volume resuscitation must begin without delay. In most cases, tonsillar bleeding is not massive, and the child should be rehydrated and transfused as needed before the induction of anesthesia. Hematocrit values should be rechecked after rehydration to have a more accurate estimate of blood loss.

The anesthesiologist must be aware that the child and parents are extremely frightened. If the condition permits, the patient may be sedated with intravenous midazolam to relieve anxiety. Before the induction of anesthesia, precautions for a patient with a full stomach should be taken. These include at least one, but preferably two, well-functioning suction apparatuses with large-bore suction tubes, extra laryngoscope handles and blades, and several cuffed endotracheal tubes with lubricated stylets in place. An experienced assistant should always be available to help the anesthesiologist and to apply cricoid pressure during the rapid-sequence induction (see Chapter 13, Induction, Maintenance, and Recovery).

After preoxygenation, atropine (0.02 mg/kg), and a defasciculating dosage of nondepolarizing muscle relaxant in older children, the child is intubated, most commonly with a rapid-sequence technique using propofol (2 mg/kg), sodium thiopental (3 to 6 mg/kg), etomidate (0.3 to 0.4 mg/kg), or ketamine (2 mg/kg), with dosages guided by the patient's hemodynamic status, and succinylcholine (2 mg/kg) with cricoid pressure. Alternatively, rocuronium (1.2 mg/kg) may be used. When using thiopental and rocuronium for induction, significant precipitation occurs if they are given together without flushing the intravenous tubing between the two drugs. If the child is still anemic or dehydrated before induction, ketamine (2 mg/kg) may be used instead of propofol or thiopental, because the latter two drugs may cause profound myocardial depression and hypotension. A cuffed endotracheal tube is used in these cases to prevent blood from entering the trachea around the uncuffed tube.

Management of anesthesia during maintenance and emergence in these patients focuses on hypovolemia and a full stomach. A large-bore gastric tube is introduced through the mouth to decompress the stomach, although it is not possible to evacuate all blood clots and solid food. Both sides of the chest are carefully auscultated, and the endotracheal tube is suctioned to rule out aspiration of blood or gastric contents. When there is doubt, fiberoptic bronchoscopy may be performed before extubation, and a portable chest radiograph is taken in the operating room or in the postanesthetic care unit. The endotracheal tube is left in place until the child is fully awake and normal gag and cough reflexes have returned.

The death of a child as a consequence of hemorrhage after tonsil and adenoid surgery is particularly tragic because the operation in most cases is elective and the child is in relatively good health. Mortality rates reported in the literature range from 1 in 1000 to 1 in 27,000 (10 to 0.37 per 10,000) in old reports (Bluestone et al., 1975; Avery and Harris, 1976). The anesthesia-related mortality unadjusted for age is reported to be 1 in 14,000 (Avery and Harris, 1976). A more recent survey in Europe shows the posttonsillectomy mortality rates of 0.62 to 0.63 per 10,000 (Windfuhr et al., 2009). Windfuhr and colleagues (2008a, 2008b) also reported life-threatening posttonsillectomy hemorrhage in 79 patients between 1980 and 2006. There were 36 children involved in the study. Out of

29 deaths, 18 were children. Nearly 90% of the life-threatening crises were related to secondary hemorrhage (>24 hours), and all deaths were directly or indirectly attributable to posttonsillectomy hemorrhage.

Peritonsillar Abscess

Peritonsillar cellulitis and abscesses occur more frequently in older children and adults than in young children. Most infections appear to originate in the tonsils and spread to the peritonsillar space between the tonsillar capsule and the superior constrictor muscle. The infection may spread upward into the palate, but it usually does not invade the posterior tonsillar pillar or the posterior pharyngeal wall (Teele, 1983). The patient presents with complaints of severe sore throat, difficulty in swallowing, and high fever. Progressive difficulty in opening the mouth may develop because of spasm of the pterygoid muscles. It is therefore imperative to determine the extent of limitation of mouth opening preoperatively. The affected tonsillar area is markedly inflamed and swollen, and the uvula is displaced to the opposite side (Cook, 1982). In older children and adolescents, it is possible to perform incision and drainage of a peritonsillar abscess with intravenous sedation using an opioid and topical or local anesthesia, with the patient in a head-down position and the head turned to the side of the abscess. If this is not possible, general endotracheal anesthesia is necessary.

The child should be well sedated. Anesthesia is induced with oxygen, nitrous oxide, and sevoflurane by mask or with intravenous sodium thiopental or propofol. Anesthesia is deepened in oxygen without nitrous oxide, while spontaneous breathing is maintained and assisted with a head-down tilt and with the head turned toward the affected side. Under deep inhalational anesthesia, the larynx is exposed carefully with the laryngoscope blade for intubation with a cuffed endotracheal tube. It is advantageous to let the patient breathe spontaneously to maintain the upper airway muscle tone and airway patency. Muscle relaxants should not be given until the anesthesiologist is certain that the airway can be maintained by mask and bag. Two large-bore suction catheters and tonsil suction tips should be on hand in case the abscess ruptures during the process of laryngoscopy and intubation.

Use of the Laryngeal Mask Airway During Adenotonsillectomy

Since the early 1990s, several reports (but no scientific studies) have described the use of the armored LMA rather than an endotracheal tube for airway support during tonsil or adenoid surgery. The armored LMA can be held within the Boyle-Davis gag and remain patent (Alexander, 1990) (Fig. 24-6). A reported benefit of using the LMA is avoiding tracheal intubation and its associated complications (trauma, cardiovascular stimulation, endobronchial intubation, coughing, laryngospasm, and subglottic edema) (Hatcher and Stack, 1999). The disadvantages of the armored LMA include the risk for aspiration of stomach contents and the risk of inadequate positioning (Hatcher and Stack, 1999).

Hern and coworkers (1999) reported the surgeon's perspective on the use of LMA for tonsillectomy. In their study, 44 children were anesthetized using an LMA, and 47 patients were anesthetized using an endotracheal tube before tonsillectomy. There was an 11.4% failure rate for the LMA, requiring

■ **FIGURE 24-6.** Armored laryngeal mask airway used for adenotonsillectomy in a child. (From Kretz FJ, Reimann B, Stelzner J, et al: *The laryngeal mask in pediatric adenotonsillectomy: a meta-analysis of medical studies [in German]*. *Anaesthesist* 49:706, 2000. With permission of Springer Science and Business Media.)

change to an endotracheal tube before the end of the procedure. The LMA was reported to hamper the surgeon's visualization of the field and might have led to removal of less tonsillar tissue in the LMA group. It is difficult to suggest that the LMA is a superior choice for airway management during tonsillectomy. Additional objective data must be accumulated before recommending this technique.

Laser Surgery of the Larynx

The laser (light amplification by stimulated emission of radiation) has been used increasingly in otolaryngology since the introduction of the CO₂ laser for laryngeal surgery (Strong et al., 1973). The laser is a beam of coherent electromagnetic radiation that can be focused to a very small spot with precision, resulting in controlled coagulation, incision, or vaporization of the target tissue without affecting the neighboring tissues (Geffin et al., 1986; Keon, 1988). Clinical uses of the laser for upper and lower airways and its anesthetic implications have been reviewed elsewhere (Beamis et al., 1991; Rampil, 1992; Pashayan, 1994).

The principal components of a laser system include a lasing medium (gaseous or solid) that holds the molecules whose electrons create the laser light, resonating mirrors to boost lasing efficiency, and an energy source that pumps the lasing molecules into producing laser light (Rampil, 1992) (Fig. 24-7). Some lasers use a gaseous lasing media, such as CO₂, argon, or helium-neon, whereas others use solid rods of laser-passive material that contain small quantities of ionic impurities, such

FIGURE 24-7. The central component is the lasing medium itself. This may be, for example, a solid crystal of yttrium-aluminum-garnet (YAG) with a small concentration of neodymium (Nd), or a tube containing carbon dioxide. The energy pump provides the means of obtaining a population inversion of orbital electrons. It may consist of a xenon flash lamp or an electric spark generator. A pair of axial mirrors allows separated passes of collimated photons through the media, enabling maximal amplification by stimulated emission. The mirror on the right is not 100% reflective, allowing the beam to escape eventually. The optional Q-switch increases efficiency of pulsed lasers by allowing a small delay to increase the pumping. (*Adapted from Rampil IJ: Anesthetic considerations for laser surgery, Anesth Analg 74:424, 1992.*)

as chromium (for ruby laser) and neodymium (Nd). A synthetic gem crystal, yttrium-aluminum-garnet (YAG), is commonly used as a passive host matrix (Rampil, 1992). Fiberoptic bundles are used for beam delivery of lasers of visible and near-infrared wavelengths. For the CO₂ laser with invisible far-infrared wavelength, the most common delivery system is an articulated arm containing front-surface mirrors at each junction, which is used together with a low-powered visible helium-neon gas laser beam through the same optical path as a beam guide (Rampil, 1992; Pashayan, 1994). Recently, a flexible, hollow waveguide for delivery of the CO₂ has become available. Physical characteristics of commonly used lasers are described in Table 24-5.

The most commonly used laser for laryngeal surgery is the CO₂ laser. This has a long, far-infrared wavelength and is completely absorbed by the bending frequency of the water molecules; it is absorbed completely in the first few layers of cells and produces very little scatter of energy. The powerful, focused CO₂ laser beam therefore produces explosive vaporization of the target tissue surface with minimal damage to the underlying tissues (Beamis et al., 1991; Rampil, 1992). The thermal effect (i.e., coagulation lateral to the zone of vaporization) can be varied between 80 and 400 mcm and is diminished with increasing water content or vascularity of the tissue or by the use of less power. Thermal coagulation also decreases with shorter pulse duration. The CO₂ laser beam is delivered to the target tissue by means of an articulated arm and a micromanipulator attached

to the microscope or a bronchoscope coupler for tracheobronchial applications (Werkhaven, 1995). The micromanipulator allows surgical precision on the order of 250 mcm.

The potassium (kalium) titanyl phosphate (KTP) laser and argon laser operate in the green and blue-green wavelength range of the spectrum. The KTP and argon laser beams are transmitted through clear substances and are well absorbed by pigments in the tissues, especially melanin and hemoglobin. They therefore have widespread application for certain lesions, such as hemangiomas and granulation tissue (Werkhaven, 1995). The energy scatter is intermediate between the CO₂ and Nd:YAG laser beams. Because the depth of thermal damage produced by a laser beam beyond the immediate vaporization site partially depends on scatter, it produces vaporization (but less than that of the CO₂ laser) in addition to coagulation and cutting (Beamis et al., 1991). The depth of tissue penetration is 0.5 to 2 mm (Pashayan, 1994). KTP and argon laser beams, as well as the Nd:YAG beam, can be transmitted by means of fiberoptic bundles through the rigid or flexible bronchoscope to vaporize or coagulate lesions in the tracheobronchial lumen (Geffin et al., 1986; Ward, 1992).

The Nd:YAG laser has a near-infrared wavelength, is transmitted through clear fluids, and is readily absorbed by proteins. It is absorbed much less by water, and the beam is transmitted and scattered through much larger volumes of tissue. The energy of the Nd:YAG laser beam is therefore widely disseminated and produces less vaporization and more thermal coagulation. The depth of tissue penetration may range from 2 to 6 mm (Pashayan, 1994). The Nd:YAG laser is transmitted by means of flexible optic fibers that can be directed through the side suction port of ventilating bronchoscope. The ablation of granulation tissue, mixed capillary-cavernous hemangioma, or obstructive vascular tumor in the tracheobronchial wall may be accomplished successfully with the Nd:YAG laser (Werkhaven, 1995).

Risks Associated with Laser Surgery

Because of the potential danger with the use of laser beams in the operating room, the users and other operating room personnel should follow the safety guidelines established by the American National Standard for the Safe Use of Laser in Health

TABLE 24-5. Lasers Commonly Used for Airway Surgery

Laser Medium	Color	Wavelength (nm)	Tissue Penetration (mm)
CO ₂	Far infrared	10,600	<0.25
Nd:YAG	Near infrared	1064	2 to 6
KTP	Green	532	0.5 to 2
Argon	Blue/green	488/515	0.5 to 2

Data from Rampil IJ: Anesth Analg 74:424, 1992; and Pashayan AG: Anesthesia for laser surgery, Annual Refresher Courses, No. 221, 1994, ASA. *KTP*, Potassium (kalium) titanyl phosphate; *Nd:YAG*, neodymium–yttrium–aluminum–garnet.

Care Facilities and published by the American National Standard Institute (the ANSI Z136 Standard) (ANSI, New York). Doors to operating rooms where laser surgery is in progress should be clearly marked to prevent unprotected personnel from accidentally straying into the path of laser beams. Warning signs should specify the class and type of the laser being used as well as appropriate protective measures specific for the wavelength (Rampil, 1992; Pashayan, 1994).

All laser beams for medical use are transmitted through air and are well reflected by smooth metal surfaces. Patients and health care personnel involved in laser surgery are at risk for laser injury, particularly of the eyes. The nature and extent of eye injury depend on the wavelength of the laser beam and its energy. Because the laser beam of far-infrared wavelength is absorbed by the surface it first encounters, errant CO₂ laser beams can cause serious corneal ulcerations and scar formation (Liebowitz and Peacock, 1980). Visible and near-infrared lasers (e.g., KTP, argon, Nd:YAG) penetrate through the transparent cornea and anterior chamber of the eye, are absorbed by the retina, and cause serious damage. The anesthetized patient's eyes should be taped closed and covered with saline-soaked eye pads or metal shields, or both (Keon, 1988). Operating room personnel must wear safety goggles that are specific for the laser wavelength in use. Safety goggles should provide wraparound protection from reflected beams (Rampil, 1992). For CO₂ lasers, any plastic or regular eyeglasses (not contact lenses or thin plastic splash protection shields) will suffice as protection (provided that lateral aspects of the eye are also covered), because far-infrared beams are completely absorbed. Visible and near-infrared lasers require specific filters for particular laser wavelengths.

Incandescent debris resulting from the explosive vaporization of the tissue in contact with the laser beam produces a plume of smoke with fine particulates (0.1 to 0.8 μm), which may contain infectious or mutagenic viral particles (Nezhat et al., 1987; Kokosa and Eugene, 1989). Fragments of DNA have been found in the smoke plume, but only one study has found viral transmission from the laser plume (Garden et al., 2002). The same risk exists for the smoke plume from electrocautery. Ordinary surgical masks do not effectively filter particles smaller than 3.0 μm; special high-efficiency masks are therefore needed to filter laser plume particles (Rampil, 1992).

A laser beam can ignite inflammable materials used for general anesthesia, such as endotracheal tubes, anesthesia circuits, oil-based lubricants, ointments, sponges, and drapes (Snow et al., 1976; Cozine et al., 1981; Hermens et al., 1983). All materials used for endotracheal tubes, with the exception of special metallic tubes, are quite vulnerable to laser impact (Geffin et al., 1986; Sosis, 1989a, 1989b). Polyvinyl chloride (PVC) tubes appear to be more easily punctured and ignited by CO₂ laser than red-rubber tubes, and to produce more toxic combustion fumes (Ossof et al., 1983), although black smoke from burning rubber is probably just as damaging to the airway mucosa. Wolf and Simpson (1987) found that once PVC is ignited, it is less flammable than silicone or red rubber, with a flammability index (i.e., the fraction of inspired oxygen [FiO₂] at which the material ignites) of 0.26, compared with silicone (0.19) and red rubber (0.18); this means that silicone and rubber tubes continue to burn in room air, whereas PVC tubes do not. Red-rubber tubes, however, are more resistant to puncture than PVC tubes (41 versus 0.8 seconds with PVC, at the same power density) and intramural fires are less likely to occur (Ossof, 1989). For these reasons, metal tubes are preferred overall.

During laser surgery, when a nonmetallic endotracheal tube is used, the FiO₂ should be reduced to 30% or less, as long as the patient is adequately oxygenated, to reduce combustibility of endotracheal tubes (Hermens et al., 1983). Oxygen may be diluted by nitrogen or helium to reduce the flammability of endotracheal tubes (Pashayan and Gravenstein, 1985; Simpson et al., 1990). Oxygen concentrations up to 60% may be used if helium is the diluent gas. Nitrous oxide supports combustion above 450° C and should therefore be avoided (Wolf and Simpson, 1987; Keon, 1988). It is imperative that the patient be immobilized during laser surgery. The choice of anesthetics depends largely on the technique of ventilation during the laser surgery.

Airway Fire

An airway fire is potentially the worst complication to occur with the use of the laser. Although uncommon, the risk should be appreciated by the anesthesiologist and surgeon, and appropriate responses should be planned before the procedure. Airway fires also have been reported with the use of electrocautery for tonsillectomy and tracheotomy.

Although fires can occur in the operating room environment if the laser accidentally contacts flammable material, airway fires may occur only if flammable materials are present in the airway. Materials such as endotracheal tubes or cottonoid pledgets in the airway are the most common sources of combustion. In the absence of flammable materials, an airway fire cannot be sustained. Although the use of the laser on tissue may generate combustible breakdown products such as methane, the amounts are too small to produce enough heat to self-generate other combustible products. As noted, the concentration of oxygen should be kept as low as possible in the presence of combustible materials.

In the unfortunate event of an airway fire, a mnemonic of the 4 Es—extract, eliminate, extinguish, and evaluate (Box 24-6)—may help guide management. In the event of an airway fire, immediately extract all combustible materials from the airway such as pledgets or endotracheal tubes, even if they are still burning. Second, eliminate the source of oxygen being delivered to the endotracheal tube. The continued delivery of oxygen to a combustible source produces a blowtorch effect that can further ignite material in the vicinity. Third, extinguish any other fires in the vicinity. If a combustible material such as a pledget is still in the airway and cannot be removed, saline flush should be used to extinguish the fire. Fourth, evaluate any damage that may have been caused by the fire or the combustion byproducts. The operative field needs to be examined along with the lower tracheobronchial tree. Standards and guidelines for the management of surgical fires, including airway fires, have been published (A Clinician's Guide to Surgical Fires, 2003).

Ventilatory Management During Laser Surgery

Numerous anesthetic approaches have been reported for airway management during laryngeal laser surgery. General trans-tracheal anesthesia, through a preexisting tracheostomy, is the easiest and probably the safest method. It is performed by replacing the preexisting tracheostomy cannula with a metal tracheostomy tube. Manually operated intermittent jet ventilation (Rontal et al., 1980; Scamman and McCabe, 1986; Ravussin et al., 1987) or high-frequency jet ventilation (Smith et al., 1975) by means of a needle or a catheter through the cricothyroid membrane has been used. These techniques, however, have a potential risk for barotrauma to the upper airways and overdistention of lungs (e.g., pneumothorax, pneumomediastinum), particularly when the laryngeal airway is obstructed. Subcutaneous emphysema and pneumomediastinum also may occur because of needle misplacement or a direct leak at the tracheal puncture site (Borland and Reilly, 1987). Without tracheostomy or transtracheal puncture, the maintenance of airways and pulmonary ventilation during laser surgery can be accomplished by means of manual jet ventilation (i.e., Saunder's jet) without an endotracheal tube. A combination of intravenous propofol, topical lidocaine, and small dosages of opioids (i.e., fentanyl or remifentanyl infusion) has been used successfully with the patient breathing spontaneously (Borland LM, unpublished data).

Nonflammable Endotracheal Tubes

Red-rubber tubes wrapped with reflective aluminum or copper adhesive-backed tape, originally described by Snow and colleagues (1974), have been used effectively (Norton et al., 1976), but the use of these homemade, laser-resistive tubes has decreased considerably over the past decade with the advent of commercially available nonflammable endotracheal tubes. Before wrapping a red-rubber tube with a metal tape, the tube should be wiped with alcohol to remove greasy or oily residues that interfere with adhesion. It should also be wiped with tincture of benzoin or an equivalent before spiral wrapping with a metal tape (Rampil, 1992). There should be no windows of exposed tube; care should be taken to prevent wrinkles, which may cause abrasion of the laryngotracheal mucosa.

Certain metallic tapes do not sufficiently prevent the CO₂, Nd:YAG, or KTP laser beams from penetrating the endotracheal tube and igniting a blowtorch fire. The CO₂ laser can ignite the adhesive backing of all these tapes and perforate the aluminum tapes within 0.1 second (Sosis, 1989a). Other aluminum tapes (3M No. 425 and 433; 3M Corp., St. Paul, MN) and a copper foil tape (Venture Tape Corp., Rockland, MA; 3M Corp.) are effective in shielding at least 60 seconds of direct exposure (Sosis and Dillon, 1990). A metallic foil wrap for endotracheal tubes, specifically manufactured for the laser, is also available (Laser Guard, Merocecel Corp., Mystic, CT) and is approved by the U.S. Food and Drug Administration. This metal-based surgical sponge provides protection against CO₂, argon, and KTP lasers but not against Nd:YAG lasers, according to the study by the Emergency Care Research Institute (ECRI, 1990). It also provides a smoother surface than metal tapes on the endotracheal tube for better airway mucosal protection, but it is bulky, adding about 2 mm to the diameter of the endotracheal tube.

FIGURE 24-8. Flexible stainless steel (Laser Flex) tubes. *Top to bottom:* A 3.5-mm-ID, uncuffed tube; a 4.0-mm-ID, uncuffed tube; and a 5.0-mm, double-cuffed tube. ID, inner diameter. (Courtesy Mallinckrodt Medical, Inc., St Louis, MO.)

A number of laser-resistant endotracheal tubes with metal exteriors have become available for clinical use. The Laser Flex tube (Mallinckrodt, St. Louis, MO; Bivona, Gary, IN) is a stainless steel spiral with a PVC tip, with or without two distal saline-inflatable cuffs (Fig. 24-8). This tube is resistant to CO₂ and the Nd:YAG laser. The Fome Cuff tube (Bivona) is an aluminum spiral tube with an outer coating of silicone that is approved by the manufacturer for the CO₂ laser only. This tube has a self-inflating foam sponge-filled cuff. The foam in the cuff prevents deflation of the cuff after puncture, but damage to the filling tube may cause difficulty in deflating the cuff (Rampil, 1992). The Laser Shield II (Medtronic/Xomed, Jacksonville, FL) is silicon-based endotracheal tube wrapped with metal foil and then wrapped in polytetrafluoroethylene tape to smooth the tube. These tubes are available only in two sizes, and the smaller size (5.0) has an outside diameter with a cuff roughly equivalent to a size 5.5 endotracheal tube.

Anesthesia with Nonflammable Endotracheal Tubes

For laser resections of laryngeal papillomas in a child, anesthesia may be induced by mask with nitrous oxide and sevoflurane with the standard monitors, including a precordial stethoscope, pulse oximeter, capnography, electrocardiography, blood pressure cuff, and nerve stimulator. After intravenous access is secured and an intermediate-acting muscle relaxant is given, the child is intubated with a laser-resistant endotracheal tube. Nitrous oxide is then replaced with air or a helium-oxygen mixture (i.e., heliox). Anesthesia is maintained with a volatile anesthetic or propofol infusion with nitrogen and oxygen, and inspired oxygen concentration is kept at 30% or less as long as oxygen saturation can be maintained at or above 98%. The patient's eyes are taped closed and then covered with saline-soaked gauze pads; the portion of the endotracheal tube not metal coated is also covered with saline-soaked towels to avoid the fire hazard of the laser beam while a Jako-type suspension laryngoscope is being positioned. The child is paralyzed, and ventilation is controlled manually or mechanically with a ventilator. Supplemental opioids may be added intravenously to

■ **FIGURE 24-9.** The Venturi ventilation apparatus with injector needle-on-clamp. *A*, High-pressure gas source with optional oxygen–nitrous oxide or helium blender. *B*, High-pressure tubing. *C*, Reducing valve and pressure gauge. *D*, Short piece of high-pressure tubing. *E*, Manual, all-or-none trigger valve. *F*, Tapered metal connector of the pop-off type. *G*, Low-pressure plastic tubing. *H*, Optional Luer-Loc fitting on tapered metal connector of the pop-off type. *I*, An adapted, curved stainless steel needle, 12 to 18 gauge. *J*, Screw clamp to fit on the edge of the operating laryngoscope. *K*, The operating laryngoscope. *L*, Laryngoscope handle that fits the suspension apparatus. It should be possible for fittings *F* and *H* to pop off when high pressure is inadvertently transmitted through the low-pressure tubing (i.e., when *C* or *E*, or both, are failing) or when an obstruction occurs distally. (Adapted from Van Der Spek AF, Spargo PM, Norton ML: *The physics of lasers and implications for their use during airway surgery*, Br J Anaesth 60:709, 1988.)

reduce the need for the inhaled anesthetic. Dexamethasone (0.4 mg to 1 mg/kg) may be used prophylactically to minimize post-operative mucosal swelling.

Anesthesia with Manual Jet Ventilation

A more commonly accepted and practiced method for ventilation during laryngeal laser surgery is the use of a Venturi apparatus (i.e., Saunders' jet injector), originally described by Saunders (1967) and Spoerel and coworkers (Donlon and Benumof (1996) and applied in pediatric patients by Miyasaka and colleagues (1980) as well as others (Johans and Reichert, 1984; Scamman and McCabe, 1986; Borland and Reilly, 1987). The apparatus consists of an injector and tubing, a toggle switch, a reducing valve or regulator, and tubing with a connector to a high-pressure wall oxygen supply (50 psi) (Figs. 24-9 and 24-10). After a precordial stethoscope, a pulse oximeter sensor, electrocardiogram leads, and a blood pressure cuff are positioned on the child, and anesthesia is induced, usually by mask with nitrous oxide, sevoflurane, and oxygen. An intravenous catheter is inserted, an axillary or rectal temperature probe is placed, and a nerve stimulator is positioned. Cisatracurium (or other intermediate-acting muscle relaxant), fentanyl (2 to 3 mcg/kg), and lidocaine (1 mg/kg) are injected intravenously. Midazolam may be given to ensure amnesia during the laser surgery. Alternatively, anesthesia may be switched to intravenous propofol with or without a small dosage of fentanyl. Nitrous oxide is discontinued, and the patient is ventilated with 100% oxygen for several minutes before the mask is removed. The surgeon positions the child's head and inserts a Jako suspension laryngoscope to secure a patent laryngeal airway.

■ **FIGURE 24-10.** A Saunders-type, hand-held jet ventilation apparatus. (Courtesy Manujet III, VBM Medizintechnik, Sulz am Neckar, Germany.)

In children, supraglottic jet ventilation is used. Subglottic jet ventilation is rarely used in children, because it requires extremely delicate skills to access adequate egress of air between pulses, and if this is not accomplished, pneumothorax or pneumomediastinum results (Hunsaker, 1994).

For supraglottic ventilation, a 10-French metal injector is inserted into the side channel of the suspension laryngoscope and secured with the distal end 1 to 2 cm above the glottic opening; the metal injector is readjusted as needed to obtain the optimal distance and direction. Oxygen concentration of the jet injector is adjusted with an oxygen blender

to reduce the inspired oxygen concentration with room air entrainment to 30% or less, provided that oxygen saturation on the pulse oximeter is 98% or higher. The anesthesiologist begins jet ventilation by intermittently squeezing the toggle switch. Short bursts of inspiration with air entrainment (1 to 2 seconds) with a driving pressure of 15 psi or less (the pressure may vary with different setups), followed by enough expiration time (2 to 4 seconds) to complete exhalation, provides adequate pulmonary ventilation. Close observation of the child's chest motion during each breath is crucial to prevent air trapping, hyperinflation, and volutrauma to the lungs (Borland and Reilly, 1987). Inspired oxygen concentration is decreased as low as possible by adjusting the oxygen-blender to maintain SpO₂ between 98% and 100% throughout the procedure. If passive exhalation is unusually prolonged, measures to improve airway patency must be taken immediately. This can usually be accomplished by readjusting or redirecting the injector. Occasionally, when papillomatous growth about the glottis is extensive, the child may require intubation with a small tube and manual ventilation while the surgeon improves the glottic aperture by debulking papillomas on and around the vocal cords.

After the laryngeal surgery is completed, ventilation is maintained with 2:1 or 1:1 ratio of oxygen and air by mask and bag, or the airway is secured by intubation with a small cuffed or uncuffed orotracheal tube. Neuromuscular blockade is reversed in the usual manner. The endotracheal tube is removed after neuromuscular blockade is completely reversed and the child is breathing satisfactorily.

The manual jet ventilation technique offers several advantages in laryngeal laser surgery, including adequate ventilation, excellent surgical access to the larynx (especially to the anterior and posterior commissures where an endotracheal tube obliterates the exposure), and the absence of ignitable material in the surgical field (Norton et al., 1976; Goforth et al., 1983). Potential risks of this technique include pneumothorax, pneumomediastinum, distention of the stomach and regurgitation, aspiration of resected material, and dehydration of mucosal surface (Lines, 1973; Norton et al., 1976; Rontal et al., 1980; Ruder et al., 1981; Keon, 1988).

Anesthesia with Spontaneous Breathing

Anesthesia for airway laser surgery can be managed by experts with a combination of carefully administered intravenous anesthesia and topical lidocaine. Anesthesia may be induced with inhalation of sevoflurane with a nitrous oxide-oxygen mixture while the patient is allowed to breathe spontaneously. After an intravenous catheter is inserted and the patient positioned with a suspension laryngoscope, topical lidocaine is sprayed under the direct vision. Inhaled anesthetics are turned off and an infusion of propofol is started. During laser surgery, high-dosage propofol (300 to 400 mcg/kg per minute) is supplemented with intermittent doses of morphine (up to 0.1 mg/kg) or an infusion of fentanyl (2 to 3 mcg/kg per hour) to prevent tachypnea. The concentration of oxygen insufflations should be limited to less than 30% for safety, while the patient's breathing is continuously monitored with a precordial stethoscope, and oxygen saturation is monitored with a pulse oximeter. A manual jet ventilator (Sanders) should be readily available for supraglottic jet ventilation as needed if the patient's breathing is too depressed or he or she becomes apneic. Alternatively, total intravenous anesthesia

may be administered with a combination of remifentanyl and propofol infusions. This combination appears to make spontaneous breathing more difficult to maintain.

Laser Bronchoscopy

The laser may be used coupled with a ventilating bronchoscope. If the CO₂ laser is used with the rigid ventilating laser bronchoscope, higher oxygen concentrations can be employed, because there is no flammable material in the airway. The fibers used for KTP and Nd:YAG laser delivery may support combustion, and when used through a bronchoscope, the inspired oxygen concentration should be less than 40%. The newer CO₂ laser waveguide has not been tested for combustibility, so prudence suggests limiting the inspired oxygen concentration to less than 40%.

Tracheostomy

Tracheostomy is indicated in numerous situations before development of respiratory distress (Stool and Eavey, 1990). The three primary indications for the creation of an artificial airway are airway obstruction, chronic assisted ventilation, and pulmonary toilet (Wetmore et al., 1999; Carron et al., 2000). [Table 24-6](#) lists the conditions for which tracheotomy has been advocated in pediatric patients (Wetmore, 2003).

The ideal tracheotomy tube conforms to the trachea and neck without causing undue pressure or injury to the skin or tracheal mucosa. Plastic tracheotomy tubes are commonly used because they cause minimal tissue reaction. Tracheotomy tubes should be manufactured in metric sizes that correspond to endotracheal tube sizes. However, metal tracheotomy tubes are still measured in French sizes (Wetmore, 2003). [Table 24-7](#) compares the sizes of the endotracheal tubes and commonly used tracheotomy tubes in infants and children (Wetmore, 2003).

Anesthetic Approach for Tracheostomy

The need for tracheotomy may occur emergently, urgently, or electively. It is essential for the surgeon and anesthesiologist to establish a plan before surgery. Some situations, including laryngeal trauma, massive facial injuries, upper airway obstruction, and oropharyngeal distortion, require emergency tracheostomy for airway management. This procedure is usually performed outside the operating room and, fortunately, rarely in the pediatric population.

Urgent tracheotomy may be required in neonates for congenital airway defects and for older children because of upper airway trauma, corrosive ingestion, infections, and tumors (see [Table 24-6](#)). Although these children may initially maintain oxygenation and ventilation, they are at risk for acute respiratory failure. They may have airway anomalies that contribute to difficult or impossible tracheal intubation. The location of the obstruction dictates the surgical and anesthetic approach. The anesthesiologist must establish whether the child can maintain a patent airway under anesthesia and whether they can be intubated by standard laryngoscopy or fiberoptic bronchoscopy. Sedation with ketamine may also be an option. Otherwise, anesthesia is induced with an inhaled anesthetic agent after preoxygenation in the position in which the child is most comfortable, often

TABLE 24-6. Conditions for Which Tracheotomy Has Been Advocated

	Allergic	Metabolic	Prophylactic	Degenerative or Idiopathic	Sleep Disorders
Upper airway obstruction	Angioneurotic edema Anaphylaxis	—	Head and neck surgery Neurosurgery Cardiac surgery Prolonged endotracheal tube placement	Vocal cord paralysis	Pharyngeal musculature collapse Tonsilloadenoid hypertrophy

the sitting position. If no intravenous catheter is in place, one is inserted, and atropine (0.01 to 0.02 mg/kg) or glycopyrrolate (0.01 mg/kg) may be injected intravenously as indicated after induction of anesthesia. Unless a normal, unobstructed airway can be maintained, muscle relaxants should not be used because total upper airway obstruction may result. After the child is anesthetized but spontaneously breathing, topical lidocaine (up to 5 mg/kg) may be sprayed on the larynx to ablate laryngeal reflexes before laryngoscopy. If intubation is impossible, an LMA may be used to maintain an airway until the tracheotomy is performed. Tracheostomy is best performed in infants with an endotracheal tube or a rigid bronchoscope in place to ensure adequate pulmonary gas exchange. The endotracheal tube also helps the surgeon to identify the trachea. Many surgeons prefer to use a rigid bronchoscope held in place rather than an endotracheal tube. The rigid bronchoscope allows a firmer anatomic reference for the trachea, but it cannot be taped in place and must be held by hand. Elective tracheotomy is usually performed in children already intubated for chronic ventilation or pulmonary toilet or performed in combination with tumor removal or repair of tracheal abnormalities.

For tracheotomy, the patient is positioned with the shoulders elevated by placing a roll under the neck so that the neck is hyperextended. Some surgeons request that the anesthesiologist hold the chin with the left hand to keep the neck stretched so that soft tissue over the trachea is stabilized (Fig. 24-11) (Stool and Eavey, 1990). The surgeon palpates the neck to identify the thyroid and cricoid cartilages, sometimes with difficulty. The trachea is palpated down to the sternal notch, guided by the presence of an endotracheal tube. A skin incision is made about one fingerbreadth above the sternal notch, either horizontally or vertically. When the fascial layer is incised under the subcutaneous fat and the trachea is identified, a pair of stay sutures, one on each side of the tracheal incision, is placed for traction during the cannulation of the tracheotomy tube. The stay sutures also serve to prevent asphyxiation in the event that the tracheotomy tube becomes displaced in the immediate postoperative period before the tract has formed (Myers et al., 1985). Before the tracheotomy cannula is inserted in the tracheal incision, the endotracheal tube or bronchoscope is slowly pulled back to accommodate the insertion. The endotracheal tube or bronchoscope should not be removed completely until successful

*The endotracheal tubes are marked with the inner diameter, usually with the outer diameter, and with the length.

†The Bivona tube is manufactured by the Bivona Corporation of Gray, IN. Both the inner and outer diameters are marked on the tubes.

‡The Franklin tube is of the Great Ormond Street design, manufactured in England and distributed by Inmed Corporation, Norcross, GA. The tubes are stamped with just the inner diameter.

§The Shiley tube is manufactured by Shiley Laboratories, Irvine, CA. The tubes are stamped with the size and inner and outer diameters.

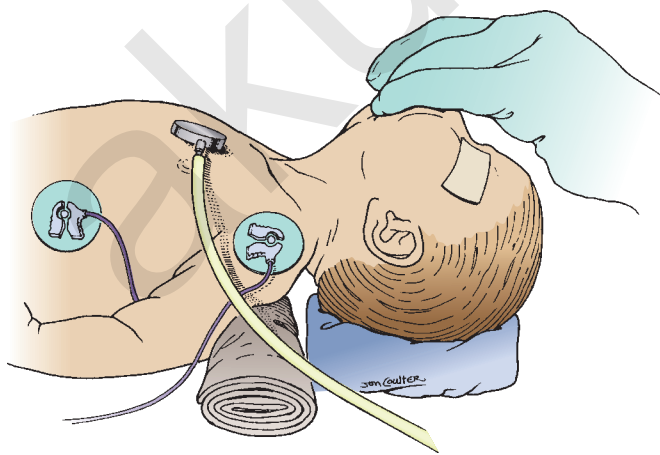

FIGURE 24-11. A child positioned for tracheostomy with the shoulders elevated, the neck hyperextended, and the chin pulled up by hand.

ventilation is demonstrated after placement of the tracheostomy tube. The anesthesia delivery tube is then disconnected from the endotracheal tube under the drapes and reconnected to the proximal universal adapter end of the tracheostomy tube over the operative field.

An esophageal stethoscope or a nasogastric tube has occasionally been misidentified as an endotracheal tube in the trachea by the surgeon, and inadvertent esophageal incision has been made (Schwartz and Downes, 1977); esophageal stethoscopes therefore should be avoided during tracheostomy. The child is monitored with a precordial stethoscope, pulse oximeter, capnography, electrocardiography, automated blood pressure cuff, and rectal or skin thermometer.

Major intraoperative and postoperative complications of tracheostomy include hemorrhage, subcutaneous emphysema, pneumothorax, and pneumomediastinum. The neck and shoulders of the child should be palpated for the typical crepitus to rule out subcutaneous emphysema. Then both sides of the

chest are auscultated. In most hospitals, the patient is transferred to the ICU for observation and a chest radiograph to ensure proper tracheotomy tube positioning and the absence of pneumothorax.

Laryngeal Stenosis

Laryngeal stenosis may occur in the supraglottis, glottis, or subglottis. Clinically, subglottic stenosis is most common. Supraglottic stenosis is rare in children. It usually is a consequence of thermal or chemical injury or iatrogenic injury after previous reconstructive airway surgery.

Subglottic Stenosis

Neonatal subglottic stenosis can be categorized as congenital or acquired. The incidence of congenital subglottic stenosis is 5%; the remaining cases are acquired. Subglottic stenosis in the full-term infant is defined as a subglottic airway diameter of less than 4 mm at the level of the cricoid cartilage, and less than 3 mm in the premature infant (Walner et al., 2001). This narrowing can be compared with the reference point of a neonatal endotracheal tube. The outer diameter of a 2.5 endotracheal tube is 3.6 mm, and the outer diameter of a 3.0 endotracheal tube is 4.2 mm (Rutter et al., 2003). The diagnosis of subglottic stenosis is made by rigid endoscopy while the patient is anesthetized. The extent of the subglottic stenosis is determined by placement of an endotracheal tube that allows an airway leak between 10 and 25 cm H₂O (Table 24-8). This leak allows accurate measure of the airway size. The airway stenosis is then graded as follows: grade I, less than 50% obstruction; grade II, 51% to 70% obstruction; grade III, 71% to 91% obstruction; and grade IV, no detectable lumen (Gerber and Holinger, 2003).

In the absence of trauma, an abnormality of the cartilage or subglottic tissues is usually considered congenital. The cause of congenital subglottic stenosis is thought to be a failure of the laryngeal lumen to recanalize after completion of normal epithelial fusion at the end of the third month of gestation

(Walander, 1955). Congenital subglottic stenosis lies on a continuum of embryologic failure that includes laryngeal atresia, stenosis, and webs. In its mildest form, congenital subglottic stenosis merely represents a normal-appearing cricoid with a smaller-than-average diameter, usually with an elliptical shape. Infants and children with mild subglottic stenosis may present with a history of recurrent upper respiratory infections, often diagnosed as croup, in which minimal glottic swelling precipitates airway obstruction. The location of the stenosis is usually 2 to 3 mm below the true vocal cords (Rutter et al., 2003).

Severe congenital subglottic stenosis can be a life-threatening airway emergency manifesting immediately after the infant is delivered. See related video online at www.expertconsult.com. If endotracheal intubation is successful, the patient may require intervention before extubation. In more severe cases, tracheotomy can be life saving at the time of delivery. Infants with congenital subglottic stenosis may have surprisingly few symptoms and may not present for treatment for weeks or months after birth (Rutter et al., 2003). After the initial management of congenital subglottic stenosis, the larynx will grow with the patient and may not require further surgical intervention.

Laryngomalacia is a congenital condition of excessive flaccidity of the laryngeal structures, especially the epiglottis and arytenoids, most likely caused by the lack of neural control of laryngeal muscles. See related video online at www.expertconsult.com. Laryngomalacia accounts for more than 70% of persistent stridor in neonates and young infants (Fig. 24-12); the remaining 10% of neonatal stridor is caused by vocal cord paralysis (Yellon et al., 2002) (Fig. 24-13).

In the mid-1960s, long-term intubation was introduced as the preferred artificial airway in neonates (McDonald and Stocks, 1965). As neonatal survival rates increased with the advent of neonatology and improved neonatal intensive care, subglottic stenosis occurred as a frequent morbidity caused by long-term tracheal intubation. Acquired subglottic stenosis results from intubation trauma and accompanying inflammatory responses. Factors suspected of contributing to this problem include prematurity, the size and amount of movement of the endotracheal tube, duration of intubation, laryngeal or tracheal injury during intubation, and presence of infection during the course of

tracheal intubation. The incidence of acquired subglottic stenosis has been decreased over the past decade by minimizing the issues known to exacerbate subglottic injury (Walner et al., 2001). Patients presenting to the otolaryngologist for diagnosis or treatment of subglottic stenosis are former preterm infants who were intubated in the neonatal ICU for extended periods and have a tracheotomy in place with an established diagnosis, or are examined on an outpatient basis for symptoms suggesting subglottic stenosis (Cotton, 2000).

Surgical Management of Acquired Subglottic Stenosis in the Neonate

Neonatal subglottic stenosis unresponsive to nonoperative therapy may require tracheotomy or an anterior cricoid split procedure. Tracheotomy is performed if, in addition to severe subglottic injury, there is substantial glottic or tracheal involvement. After tracheotomy and without the endotracheal tube to act as a stent, the stenosis becomes more severe. Over the next 2 years, the airway may heal, allowing for decannulation, but more often, surgical reconstruction of the trachea will be necessary (Rutter et al., 2003).

The anterior cricothyroidotomy, or cricoid split, is an effective treatment for some cases of acquired neonatal subglottic stenosis in the absence of substantial glottic or tracheal or pulmonary pathology (Rutter et al., 2003). The neonate must meet the following criteria (Cotton, 2000):

- Failure of extubation on at least two occasions
- Body weight greater than 1500 g
- Absence of assisted ventilation for 10 days
- Supplemental oxygen requirement of less than 30%
- Absence of heart failure for at least 1 month
- No evidence of an upper or lower respiratory infection
- No antihypertensive medication required

The procedure is performed under general anesthesia with muscle relaxation. The shoulders are elevated, and the neck is extended as in the tracheotomy position (see Fig. 24-11). A horizontal incision is made in the skin over the cricoid cartilage. The cricoid cartilage, upper trachea, and lower edge of the thyroid cartilage are exposed. An incision is made through the cricoid ring and underlying mucosa through the first two tracheal rings and the lower one third of the thyroid cartilage. Stay sutures are placed on both severed edges of the cricoid

cartilage, as in a tracheotomy (Healy, 1995b). The endotracheal tube that was used for anesthesia and airway management is then removed. It is replaced, while the larynx is still split, with a nasotracheal tube that is one size (0.5 mm) larger than that predicted for the patient's age and body size. The surgeon helps guide the nasotracheal tube into position through the open incision, and the wound is closed loosely, with a drain. The nasotracheal tube is left in place for 7 days to stent the subglottic aperture. The patient is kept well sedated with or without mechanical ventilation in the pediatric ICU. A modification of the anterior cricoid split is to place a cartilage graft over the split in an effort to allow the airway to seal more rapidly, leading to earlier extubation. Thyroid alar cartilage and occasionally auricular cartilage are used (Rutter et al., 2003).

Laryngotracheal Reconstruction in Children

Chronically ventilated infants who have undergone tracheotomy because of prolonged intubation and subglottic stenosis will most likely require laryngeal reconstructive surgery. Children with greater than 70% obstruction of their laryngeal lumen usually require this surgery to allow decannulation (Rutter et al., 2003).

Laryngotracheal reconstruction has become the standard of care for symptomatic subglottic stenosis in the pediatric age group. There are five stages: characterization of the stenosis, expansion of the tracheal lumen, stabilization of the framework, healing of the airway, and decannulation (Rothschild et al., 1995). The procedure has evolved to include a variety of techniques for expanding the laryngotracheal complex to provide a stable airway of sufficient size. These include, but are not limited to, anterior cartilage graft with the tracheotomy left in place without stent, long-term (several months) stenting with or without cartilage grafts, and short-term (4 to 6 weeks) stenting with anterior or posterior cartilage grafts (Cotton, 2000).

Anterior cartilage graft with a tracheotomy left in place without a stent is indicated primarily for isolated anterior subglottic stenosis with no or relatively mild posterior subglottic components. A variation of this procedure is to remove the tracheotomy at the time of surgery and perform a single-stage laryngotracheoplasty. Posterior division of the cricoid plate and the introduction of a cartilage graft between the cut ends are indicated particularly for children with persistent posterior glottic pathology or primarily posterior subglottic pathology (Cotton, 2000).

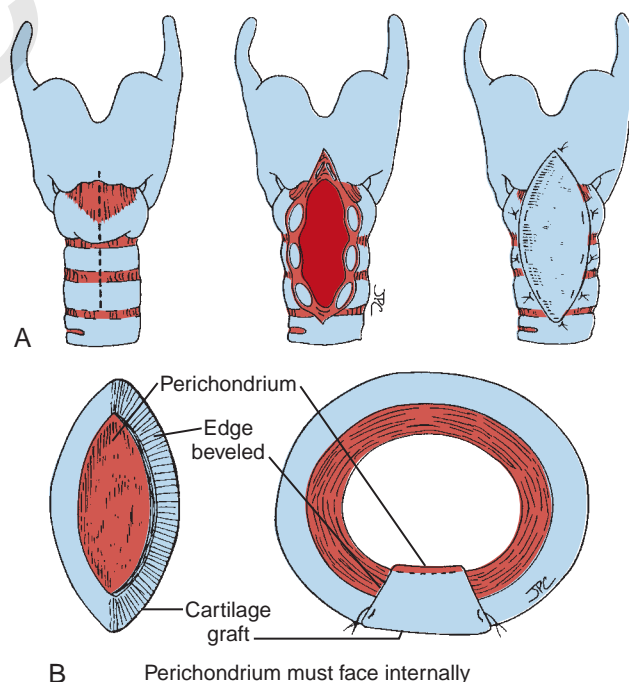

Single-stage laryngotracheal reconstruction (LTR) uses cartilage grafts to obtain stability of the reconstructed airway. Single-stage LTR may include an anterior cartilage graft, a posterior cartilage graft, or both, and reconstruction often includes a cartilage graft at the former stoma site. The grafts are supported temporarily by a full-length endotracheal tube fixed in position through the nasal route (Cotton, 2000). The optimal time for extubation has not been established definitively. In general, children remain intubated for 7 to 10 days for anterior cartilage grafts alone, and 12 to 14 days if a posterior and anterior graft is required (Cotton, 2000).

The patient may be anesthetized by the intravenous route or with inhalation anesthesia through a tracheotomy cannula. Standard monitoring includes pulse oximetry, precordial stethoscope, capnography, anesthetic gas monitoring, electrocardiography, blood pressure apparatus, peripheral nerve stimulator, and axillary or rectal temperature monitor. The patient is placed

in the tracheotomy position with the shoulders elevated and the neck hyperextended. A tracheotomy tube is replaced with a sterile cuffed armored (anode) endotracheal tube through the tracheostomy stoma and is covered under an adhesive drape to minimize contamination of the surgical field.

Through a horizontal skin incision over the cricoid cartilage, laryngeal structures are exposed. A vertical incision is made through the lower thyroid cartilage, the cricoid cartilage, and the upper tracheal rings (Fig. 24-14, A). The rib cartilage graft, which had been taken from the anterior chest wall with the external perichondrium intact, is used for the anterior or posterior grafts (see Fig. 24-14, B). Auricular cartilage and septal cartilage have also been used as graft materials. Toward the conclusion of surgery, the armored tube is removed from the tracheotomy stoma and replaced with a cuffed nasotracheal tube, one size larger than is appropriate for the patient's age and size, to stent the larynx. This intraoperative transition needs to be carefully coordinated between the anesthesiologist and the surgeon.

One requirement of single-stage LTR is meticulous postoperative management of the patient's condition in the ICU. The nasotracheal airway must be maintained securely during the time of extended stenting without accidental extubation. The postoperative management of patients with single-stage LTR is not standardized (Cotton, 2000). Some centers use sedation to prevent agitation and accidental self-extubation and to avoid pharmacologic paralysis (Rothschild et al., 1995). However, many children do not tolerate nasotracheal intubation and require prolonged sedation and neuromuscular blockade to ensure maintenance of an airway

■ **FIGURE 24-14.** Schematic of laryngotracheoplasty for subglottic stenosis. **A**, Laryngotracheal incision with upper and lower extension, depending on the extent of stenosis, and a cartilage graft. **B**, Cartilage graft is shown with the perichondrium internalized. A graft is sutured in position. (From Licameli GR, Healy GB: *Surgery of the larynx and trachea*. In Bluestone CD, Stool SE, editors: *Atlas of pediatric otolaryngology*, Philadelphia, 1995, Saunders, pp 597–632.)

with minimal trauma during healing (Brandom, 1997; Yellon et al., 1997). If neuromuscular blockade is used, daily recovery of neuromuscular function and the avoidance of prolonged use of corticosteroids will be associated with less muscle weakness after extubation (Yellon et al., 1997). Prolonged sedation with benzodiazepines or opioids can lead to withdrawal syndrome, and close observation after weaning from these agents is paramount. The role of dexmedetomidine in pediatric patients for prolonged sedation in the ICU setting continues to be investigated (Chrysostomou et al., 2006, 2009; Bejian et al., 2009).

Acute Supraglottitis or Epiglottitis

Acute infectious epiglottitis or supraglottitis is a relatively uncommon but truly life-threatening disease of childhood. See related video online at www.expertconsult.com. Acute epiglottitis is an acute bacterial infection principally involving supraglottic structures, including the lingular surface of the epiglottis, the aryepiglottic folds, and the arytenoids, with little or no involvement of subglottic structures, including the laryngeal surface of the epiglottis. It is therefore more appropriate to call it *supraglottitis*. Until the late 1980s, before the vaccination became available, *Haemophilus influenzae* type b (Hib) was the causative organism in more than 75% of cases. Group A β -hemolytic streptococci account for most of the rare cases of epiglottitis (Gorelick and Baker, 1994). With the advent of effective Hib conjugate vaccines in 1988, the incidence of Hib disease declined dramatically in the United States (Adams et al., 1993; Hoekelman, 1994). The age-specific incidence of Hib disease among children younger than 5 years old decreased by 71%, and that of Hib meningitis by 82%, between 1985 and 1991 (Adams et al., 1993). Similarly, the incidence of acute supraglottitis, one of the most dreaded childhood emergencies, has declined by 84% (Gorelick and Baker, 1994).

Until the late 1980s, before the era of Hib conjugate vaccination, preschool children between the ages of 2 and 6 years had the highest incidence of supraglottitis, although it occurred in infants, older children, and occasionally adults (Schloss et al., 1979; Blackstock et al., 1987; Crysedale and Sendi, 1988). The highest number of cases is reported in the spring and fall, but sporadic cases are reported in other seasons as well. The condition usually begins with complaints of severe sore throat associated with dysphagia and a thick, muffled voice without a preceding history of runny nose. Rarely is there a croupy or

barking cough, except in atypical cases in infants (Blackstock et al., 1987). The symptoms rapidly progress, and typical pathognomonic signs of dysphagia, dysphonia, dyspnea, and drooling (the 4 Ds) appear (Diaz, 1985).

In most children presenting with stridor in the emergency room, the most common symptoms found in those with acute supraglottitis are drooling, agitation, and absence of spontaneous cough (Mauro et al., 1988). The child looks toxic and usually has a high fever and tachycardia. The disease progresses very rapidly and may be fatal, with severe airway obstruction within 6 to 12 hours, unless immediate steps are taken to restore the patient's upper airway patency. Classically, the child is sitting up, is dyspneic with the mouth open and drooling, and resists attempts to get him or her to lie down. There is forward chin thrust, slight cervical flexion, and forward flexion at the waist, together with tripod placement of the arms to support this posture. The inspiratory phase is slow, with stridor and retraction, whereas the expiratory phase is unobstructed. The inspiratory sound has been compared with that of a quacking duck.

As soon as acute supraglottitis is diagnosed in the emergency room, a pediatric anesthesiologist, an intensive care physician, and an otolaryngologist should be called. The child should never be left unattended by one of these physicians, because the disease can progress so rapidly that complete upper airway obstruction may ensue within minutes. The patient is kept in a sitting or tripod position with an oxygen mask in place and with pulse oximetry monitoring. The child is transferred to the operating room without delay and is accompanied by an anesthesiologist or an intensivist and an otolaryngologist.

A laryngoscope with several blades, endotracheal tubes with stylets, a bronchoscope, and a self-inflating bag with face mask and oxygen must accompany the patient for emergency intubation (Oh and Motoyama, 1977). Throat examination should not be attempted in the emergency room, because the risk for complete airway obstruction is great. If the child's condition permits or when the diagnosis is questionable, the patient may be transferred to the pediatric ICU, where a radiograph of the lateral neck is taken with a portable x-ray machine (Butt et al., 1988). In the ICU, all the help and expertise needed for an emergency should be readily available. In most patients, a swollen epiglottis obstructing the air space (shadow) is seen on the lateral neck radiograph (Fig. 24-15, A). Negative radiographs, however, do not necessarily rule out supraglottitis.

■ **FIGURE 24-15.** Radiographs of the lateral area of the neck. **A**, Supraglottitis. The upper airway is obstructed by marked swelling of the epiglottis and other supraglottic structures. Notice the loss of normal curvature of the cervical spine. **B**, Laryngotracheitis. Arrows point to airway constriction below the vocal cords. (Courtesy Dr. K. S. Oh, Department of Radiology, Children's Hospital of Pittsburgh.)

Compared with acute supraglottitis, the onset of laryngotracheobronchitis (subglottic croup) is insidious. The child starts with the symptoms of upper respiratory infection, with rhinorrhea, cough, sore throat, and low-grade fever for several days before developing the symptoms of upper airway obstruction characterized by inspiratory stridor and barking or seal-like coughs (i.e., croup). The symptoms may last for a few days to more than a week, with varying degrees of severity that is worse at night in the supine position. In severe cases, endotracheal intubation under general anesthesia is required.

A lateral neck radiograph typically shows a narrowing of the airway shadow below the vocal cords (see Fig. 24-15, B). An anteroposterior radiograph of the neck may show a long area of airway narrowing resembling the steeple of a church (“steeple sign”) (Fig. 24-16).

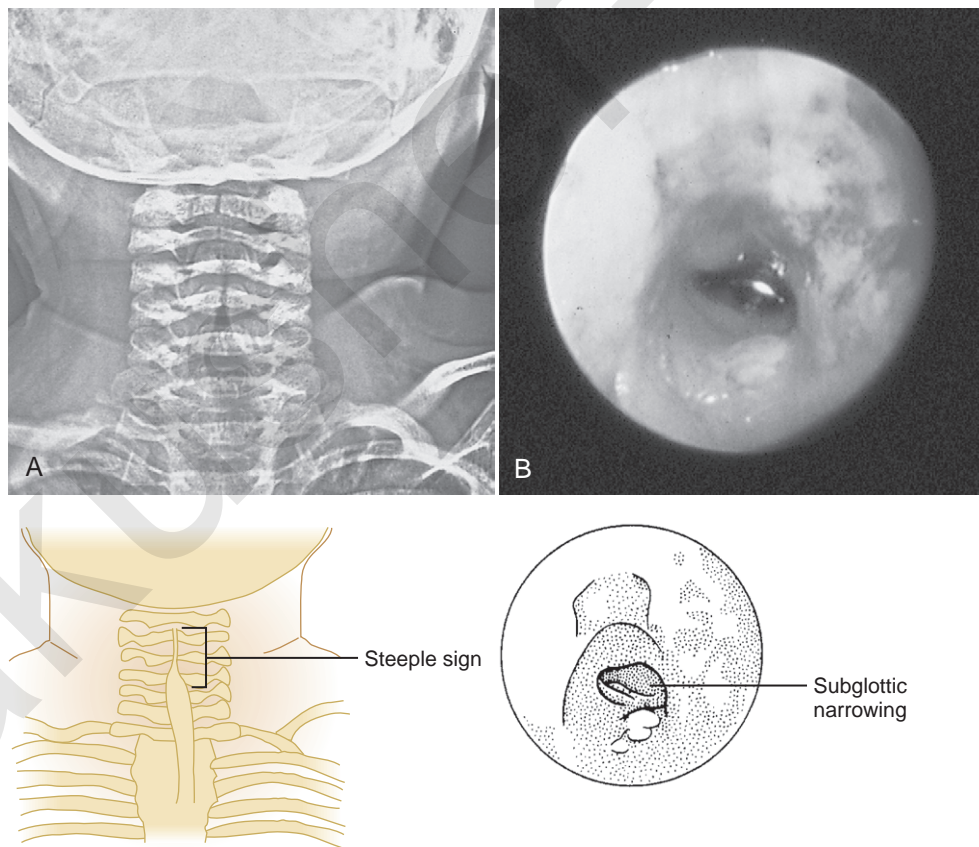

Anesthetic Management of Acute Supraglottitis

In the operating room, anesthesia is induced with sevoflurane and oxygen while the child is in a sitting position and monitored with a precordial stethoscope, pulse oximeter, and electrocardiogram. The child in respiratory distress usually breathes continually, uninterrupted by breath-holding. A moderate continuous positive pressure (10 to 15 cm H₂O) must be

maintained to minimize the inspiratory collapse of laryngeal airways by the Venturi effect, and ventilation must be assisted with moderate continuous positive airway pressure while avoiding inflating the stomach with excessive pressure. An intravenous access is established as soon as the child is sufficiently obtunded, and atropine (0.02 mg/kg) is given to block vagally mediated slowing of the heart; bradycardia in an atropinized child is a sign of severe hypoxia.

The induction may take much longer, even with a higher concentration of an anesthetic, to reach the state where relaxation and centrally fixed pupils indicate that the child is ready for intubation. A moderate CPAP should be applied to expand inflamed pharyngeal soft tissues and prevent the collapse of the airway, especially during the inspiratory phase of assisted ventilation. The use of muscle relaxants is contraindicated, even when the maintenance of the airway with mask and bag seems reasonable, because their use often results in the relaxation of pharyngeal muscles and complete obstruction of the laryngeal airway; frantic attempts to ventilate the child with high pressure cause gastric distention, regurgitation, and further asphyxia.

Endotracheal intubation is performed orally with a stylet-ted tube one or two sizes smaller than usual. Visualization of the classic cherry-red epiglottis under direct laryngoscopy confirms the diagnosis (Fig. 24-17). However, the picture may be

■ **FIGURE 24-16.** Subglottic croup (i.e., laryngotracheobronchitis). **A**, Anteroposterior radiograph of the neck reveals a long area of the airway (*shadow*) narrowing and extending well below the normally narrowed area at the level of the vocal cords. This finding often is called the steeple sign. **B**, In this child, direct visualization using a bronchoscope revealed subglottic narrowing that was so severe that it would require endotracheal intubation or tracheostomy to establish an adequate airway. (From Yellon RF, McBride TP, Davis HW: *Otolaryngology*. In Zitelli BJ, Davis HW, editors: *Atlas of pediatric physical diagnosis*, ed 4, St Louis, 2002, Mosby, p 860; and courtesy Sylvan Stool, MD, Children’s Hospital of Pittsburgh.)

■ **FIGURE 24-17.** A bright red and swollen epiglottis in a patient with acute supraglottitis. It may retain its omega shape (**A**) or resemble a cherry (**B**). (From Yellon RF, McBride TP, Davis HW: *Otolaryngology*. In Zitelli BJ, Davis HW, editors: *Atlas of pediatric physical diagnosis*, ed 4, St Louis, 2002, Mosby, p 858.)

atypical or only part of the epiglottis may be inflamed or swollen. Inflammatory swelling of other supraglottic structures, including the uvula, arytenoids, aryepiglottic folds, and false vocal cords, also causes severe obstruction. To visualize the vocal cords for intubation, the epiglottis is lifted by the curved tip of a straight laryngoscope blade (e.g., Phillips 1). In children with severe obstruction and mucosal swelling, identification of supraglottic structures and glottic opening with a laryngoscope blade may be extremely difficult. Under these circumstances, forcible manual chest compression by the assistant may open up the expiratory passages momentarily (or produce a few bubbles of expired air). By aiming the tip of the endotracheal tube at that spot and advancing the tube with a gentle twisting motion, the physician may be successful in inserting the tube in the glottis (Smith, 1980). In case intubation proves to be impossible, a surgeon who can perform an emergency tracheotomy in the operating room with the surgical instruments and various tracheotomy tubes should be immediately available.

After the endotracheal tube is in place, breath sounds are checked on both sides of the chest, and the tube is fixed with adhesive tape. The breath sounds are monitored carefully with the precordial stethoscope while continuous positive pressure (10 to 15 cm H₂O) is maintained, because pulmonary edema may occur after the relief of severe upper airway obstruction (Travis et al., 1977; Galvis et al., 1980), with an incidence of about 7% (Davis et al., 1981). Throat and blood cultures are taken during this period of stabilization but not before the intubation and restoration of adequate pulmonary gas exchange.

After the child's condition is stabilized and adequate alveolar ventilation is reestablished, some anesthesiologists replace the orotracheal tube with a nasotracheal tube that has a leak, at or below 30 cm H₂O, for postoperative management in the ICU with minimal sedation of the patient (Oh and Motoyama, 1977). This is not a necessary step, and the physician should be confident that the switch could be made without losing the airway. Because acute epiglottitis has become an uncommon phenomenon, many anesthesiologists are happy with the oral intubation and leave the tube in place. The child can be deeply sedated for 24 hours to avoid premature extubation.

Since the mid 1970s, the management of epiglottitis with tracheotomy has been replaced by the less invasive long-term

nasotracheal or orotracheal intubation as the standard treatment of choice. This has significantly reduced the duration of hospital stay for children with acute supraglottitis (Oh and Motoyama, 1977; Schloss et al., 1983). Accidental or self-extubation is a potentially disastrous complication. Careful taping of the tube and proper restraint of elbows and hands can prevent untimely extubation. Because most children are bacteremic, antimicrobial therapy, consisting of ampicillin with sulbactam, cefotaxime, or ceftriaxone, is started after blood and throat cultures are obtained. Any fluid deficits should be corrected parenterally. After emergence from anesthesia, the child often falls back to sleep for some time because of sleep deprivation and exhaustion. After this period, most patients require minimal or no sedation (Oh and Motoyama, 1977), although deep sedation has been used in some centers. Usually, it is possible to extubate these patients in 24 to 48 hours. A return of normal body temperature and increased leaks around the nasotracheal tube are major signs of recovery. The epiglottis may be examined under direct vision, with intravenous propofol to determine the time for extubation. Alternatively, a flexible fiberoptic bronchoscope may be used transnasally with intravenous sedation.

ANESTHESIA FOR ENDOSCOPY

Anesthesia for rigid and flexible bronchoscopy in infants and children requires meaningful cooperation and communication between the endoscopist and anesthesiologist (Donlon and Benumof, 1996). The surgeon and the anesthesiologist are both working in the same anatomic field. The anesthesiologist is concerned about maintaining a patent airway, oxygenation, adequate ventilation, preventing aspiration, minimizing laryngeal motion, and preventing cardiac dysrhythmias, and the surgeon needs a clear view of a motionless field for a reasonable time. Sometimes, these goals conflict. Donlon and Benumof (1996) described the anesthetic goals during bronchoscopy:

- Control of the airway
- Decreased airway reflexes
- Topical anesthesia
- Amnesia

- Unobstructed view of immobile surgical field
- No time restriction on surgeon inherent in the anesthetic technique
- Prevention of aspiration
- Smooth emergence
- Safe extubation
- Minimization of secretions
- Prevention of adrenergic reflexes

To achieve these goals, anesthetic management must be individualized based on the patient's age, concurrent illnesses, goals of endoscopy, skill of the anesthesiologist, and the proven track record of the anesthetic technique.

Rigid bronchoscopy has broad applications in the diagnostic and therapeutic arenas. Common indications for pediatric patients include investigation of stridor, upper and central (tracheobronchial) airway obstruction, gastroesophageal reflux disease, and removal of airway foreign bodies (Hoeve and Rombout, 1992; Cohen et al., 2001). Flexible bronchoscopy is frequently used for examination of the nasal cavity, nasopharynx, larynx, trachea, and bronchi in motion. Technological advances, such as smaller instruments and improved forceps, will continue to expand the diagnostic and therapeutic role of the flexible bronchoscopy (Cohen et al., 2001). Flexible and rigid bronchoscopies are used complementarily, and these procedures are often performed during the same examination. **Box 24-7** lists the common indications for fiberoptic and rigid bronchoscopy. In many scenarios, either instrument can be used for the same indication.

The Storz-Hopkins rigid bronchoscope, with a ventilating sidearm, provides excellent visibility for pediatric bronchoscopy (Szekely and Farkas, 1978; Johnson et al., 1986). This bronchoscope consists of several components: Storz bronchoscope (sizes 3.0 to 6.0); Hopkins glass rod telescope (2.8 and 4.0 mm outer diameter); antifog sheath for the telescope; adapter for anesthesia circuit connecting to the sidearm, which shares the same narrow channel for aspiration and instrumentation; glass obturator cap; and the light source attached to the telescope and prism (Fig. 24-18). Pediatric Storz rigid bronchoscopes are available in three lengths and various diameters (Fig. 24-19). A variety of forceps is available for biopsy and foreign body removal.

It is important to use the smallest optical telescope through the rigid bronchoscope to not completely occlude or unduly increase airflow resistance. For example, use of the standard optical telescope (4-mm outer diameter), as recommended in the literature (Szekely and Farkas, 1978), almost completely occludes the lumen of small bronchoscopes (sizes 3.5 and smaller). The total airway resistance increases sixfold to sevenfold (Widlund, et al., 1982) unless a smaller telescope (2.8-mm outer diameter) is used (Table 24-9). When airway resistance is too high, neither spontaneous nor controlled ventilation is sufficient for adequate gas exchange during rigid bronchoscopy. High airway resistance would be expected to cause hyperinflation of the lungs, and hypercapnia or respiratory acidosis (Rah et al., 1979). Spontaneous breathing during rigid bronchoscopy, especially in neonates and infants, should be limited primarily to evaluations of the larynx and documentation of tracheobronchomalacia in the patient with stridor. The high resistance caused by the telescope in the bronchoscope, together with central respiratory depression caused by general anesthesia, makes spontaneous breathing nearly impossible in these young children (Motoyama, 1992).

With the advances in fiberoptic technology, diagnostic bronchoscopy can be performed with a flexible fiberoptic bronchoscope

Box 24-7 Indications for Flexible or Rigid Bronchoscopy

INDICATIONS FOR FIBEROPTIC LARYNGOSCOPY

- Evaluation of stridor
- Hoarseness or weak cry
- Difficult preextubation of epiglottitis

INDICATIONS FOR RIGID MICROLARYNGOSCOPY AND BRONCHOSCOPY

- Stridor
- Tracheotomy surveillance
- Foreign body evaluation or management
- Interval evaluation after laryngotracheal reconstruction
- Chronic cough
- Severe hemoptysis
- Management of severe laryngotracheal infections
- Airway trauma
- Assessment of toxic inhalation or aspiration
- Evaluation of laryngeal pathology
- Management of mass lesions of the airway, including recurrent respiratory papillomatosis

INDICATIONS FOR FIBEROPTIC BRONCHOSCOPY

- Diagnosis
- Stridor
- Tracheotomy surveillance
- Persistent wheezing
- Persistent atelectasis
- Persistent pneumonia or diffuse infiltrates
- Chronic cough
- Infiltrates in the immunocompromised host bronchoalveolar lavage
- Mild hemoptysis
- Lung lesion of unknown cause
- Selective bronchography
- Assessment of toxic inhalation or aspiration
- Monitoring after lung transplantation
- Therapeutic
- Confirmation of endotracheal tube position
- Acute lobar atelectasis
- Cystic fibrosis management
- Removal of mucus plugs

From Hartnick CJ, Cotton RT: Stridor and airway obstruction. In Bluestone CD, Stool SE, Alper CM, et al., editors: *Pediatric otolaryngology*, ed 4, Philadelphia, 2003, Saunders, p 1437.

during spontaneous breathing with topical anesthesia and minimal sedation even in the sick premature infant. Bronchoscopy also may be performed under general anesthesia through an endotracheal tube or LMA by means of a right-angle adapter with a diaphragm (Maekawa et al., 1981; Wood and Postma, 1988). The use of the flexible fiberoptic bronchoscope for difficult intubation is described in Chapter 13, Induction, Maintenance, and Recovery, and Chapter 12, Airway Management.

Laryngoscopy and Bronchoscopy for Stridor

Stridor in pediatric patients may be congenital or acquired (Fig. 24-20). Most cases are of extrathoracic origin, but some originate in the large intrathoracic airways (i.e., trachea or

FIGURE 24-18. Storz-Hopkins pediatric bronchoscopy assembly. 1, Hopkins glass rod telescope. 2, Antifog sheath for the telescope shown in 1. 3, Storz ventilation bronchoscope, which accommodates the telescope and antifog sheath. 4, Adapter for the anesthesia circuit. 5, Prism. 6, Glass obturator cap.

major bronchi) (Maze and Bloch, 1979) (Box 24-8). See related video online at www.expertconsult.com. Stridor may be caused by fixed obstruction (i.e., airway cross-section does not change with transmural pressure) or varying degrees of obstruction (i.e., airway caliber responds to changes in transmural pressure). These children must be examined while they are actively breathing to document underlying pathophysiology.

The anesthesia approach should be individualized, with good communication between the endoscopist and anesthesiologist. All children should be monitored with a pulse oximeter, end-tidal CO₂ monitor, precordial stethoscope, electrocardiogram,

TABLE 24-9. Flow Resistance of Storz Bronchoscope in Relation to Estimated Airway Resistance in Infants and Children

Age	Airway Resistance (Raw) (cm H ₂ O/L per sec)	Bronchoscope Size (mm)	Bronchoscope Resistance

and automated blood pressure and thermometer. Oxygen saturation is determined in room air before the induction of anesthesia to establish the baseline value. Standard NPO guidelines should be followed.

In the newborn infant, flexible and rigid forms of bronchoscopy are used to determine the cause of stridor. Flexible bronchoscopic examination of the infant's larynx by the nasal approach is possible when the child is awake. The infant should be swaddled for restraint. Information about cord mobility and laryngeal dynamics can be made without much stress to the infant. Atropine or glycopyrrolate can be used as an anti-sialagogue

FIGURE 24-19. Different bronchoscope sizes (3.5 to 6.0) (left) and lengths (20, 26, and 30 cm) (right). (From Casselbrant ML, Alper CM: *Methods of examination*. In Bluestone CD, Stool SE, editors: *Pediatric otolaryngology*, ed 4, New York, 2003, Saunders, p 1379.)

■ **FIGURE 24-20.** Causes of stridor are numerous. More common causes include laryngeal web (**A**), supraglottic or glottic cyst (**B**), and postextubation granulomas (**C**).

Box 24-8 Causes of Stridor in the Pediatric Patient

Congenital stridor	Congenital tumors and cysts
Craniofacial dysmorphism (with micrognathia and glossoptosis)	Congenital subglottic hemangioma
Pierre Robin syndrome	Laryngeal lymphangioma and cystic hygroma
Treacher Collins syndrome (mandibulofacial dysostosis)	Cysts and laryngoceles
Hallerman-Streiff (oculomandibular) syndrome	Miscellaneous congenital tumors
Moebius' sequence	Birth trauma: edema
De Lange's syndrome	Metabolic stridor: laryngismus stridulus
Freeman-Sheldon syndrome (whistling face)	Immunologic stridor: hereditary angioneurotic edema
Macroglossia	Neurogenic stridor: reflex laryngospasm
Beckwith's syndrome	Acquired stridor
Congenital hypothyroidism	Infectious stridor
Glycogen storage diseases	Supraglottitis
Down syndrome	Subglottic group
Diffuse muscular hypertrophy of the tongue	Acute spasmodic laryngitis
Localized lingual tumors	Diphtheria
Laryngomalacia	Retropharyngeal abscess
Congenital subglottic stenosis	Immunologic stridor—juvenile rheumatoid arthritis
Congenital laryngeal webs	Foreign bodies
Laryngotracheoesophageal cleft	Postintubation stridor
Congenital vocal cord paralysis	Laryngeal trauma: mechanical, thermal, chemical
Vascular rings and slings	Neoplasia
Congenital tracheal anomalies	Laryngeal papillomatosis
	Miscellaneous tumors and nodes

Modified from Maze A, Bloch E: Stridor in pediatric patients, *Anesthesiology* 50:132, 1979.

and to prevent vagally mediated bradycardia. The nasal mucosa can be anesthetized with topical lidocaine to prevent discomfort during the transnasal approach, but the vocal cords should not be sprayed, because topical anesthesia affects their motion. Midazolam, dexmedetomidine, or low-dosage propofol may be helpful to reduce the infant's excessive movement while

still maintaining breathing dynamics. Because the upper airway muscles, including the vocal cords (i.e., cricoarytenoid muscles), are extremely sensitive to the depressant effect of sedatives and anesthetics (Ochiai et al., 1989, 1992), anesthesia should be maintained at a minimal level; otherwise, the vocal cord motions will cease.

Alternatively, anesthesia is induced with an inhaled agent (i.e., sevoflurane or halothane) without assisted ventilation, and intravenous access is established. After atropine or glycopyrrolate is infused and a nasal topical decongestant (e.g., oxymetazoline) and lidocaine are sprayed, the anesthetic is discontinued while flexible nasopharyngoscopy is performed. As the infant starts to wake up and the motion of the vocal cords begins to return, the diagnosis of vocal cord paralysis can be made. This approach is superior, especially for the diagnosis of laryngomalacia. The infant breathes actively and may move but is still unconscious during the flexible laryngoscopy. The patient is then reanesthetized with an inhaled anesthetic or with propofol for rigid tracheobronchoscopy.

Only by rigid bronchoscopy under the controlled conditions of general anesthesia can a magnified clear view of the larynx and lower airways be achieved (Hartnick and Cotton, 2003). The use of the rigid bronchoscope allows lower airway inspection while maintaining complete and secure control over oxygenation and ventilation. After airway dynamics are inspected by fiberoptic or rigid bronchoscopy, the child may be paralyzed with an intermediate muscle relaxant. Anesthesia can be maintained with an inhaled anesthetic agent or total intravenous anesthesia. Communication must continue with the bronchoscopist to maintain adequate oxygenation and ventilation. When the lower airways are explored, the endoscopist may need to be reminded to intermittently return to above the carina for the anesthesiologist to ventilate and oxygenate both lungs. In older infants and children, spontaneous breathing may be maintained during the entire procedure.

This technique for laryngoscopy and bronchoscopy with spontaneous breathing is useful for the evaluation of stridor, laryngomalacia, and tracheobronchomalacia. It is also a technique some anesthesiologists advocate for foreign body removal from the airway. Maintenance of spontaneous breathing can be achieved with an inhalational or an intravenous anesthetic technique. For example, after inhalational induction, the concentration of sevoflurane in oxygen is maintained at a minimum alveolar concentration (MAC) of 2 or 3 for about 5 minutes to establish a sufficient tissue level of anesthesia to allow endotracheal instrumentation (Smith, 1980). An alternative is to discontinue the inhaled anesthetic, slowly provide a bolus (2 to 3 mg/kg) of propofol, and begin a propofol infusion between 200 and 400 mcg/kg per minute while maintaining spontaneous breathing. Supplementation with fentanyl or morphine can further ablate laryngeal responses. Before endoscopy, the glottis and trachea are topically anesthetized with 2% to 4% lidocaine (up to 5 mg/kg) under direct vision.

The otolaryngologist then proceeds, using a ventilating bronchoscope and a telescope in situ. Initially, the endoscopist inspects the appearance and motion (widening) of vocal cords with inspiration and the motion of the soft tissues surrounding the inlet to the larynx. The tip of the bronchoscope is held above the inlet to the larynx without touching the pharyngeal or laryngeal soft tissues. After the bronchoscope is introduced past the vocal cords, the anesthesia circuit is connected to the side arm of the bronchoscope, allowing continued assisted ventilation or controlled ventilation. At the end of bronchoscopy, the bronchoscope is removed, and the anesthetic agents are discontinued. If the patient has been spontaneously breathing throughout the anesthesia, the patient can be maintained with oxygen by means of a mask and CPAP. If the patient is apneic or

neuromuscular blockade was required, the child may be intubated and ventilated until clinically ready for extubation.

Bronchoscopy for Foreign Body Aspiration

Foreign body aspiration occurs most frequently in children between 1 and 3 years of age. See related video online at www.expertconsult.com. Commonly aspirated objects include peanuts, seeds, and other food particles and less frequently plastic and metal particles (Baraka, 1974; Blazer et al., 1980). Foreign bodies are embedded more commonly in the right main bronchus than in the left, and less frequently in the larynx and trachea (Blazer et al., 1980; Cohen et al., 2001). Symptoms and signs associated with bronchial aspiration include coughing, wheezing, dyspnea, and decreased air entry in the affected side, whereas dyspnea, stridor, coughing, and cyanosis are more common with laryngeal or tracheal foreign bodies (Blazer et al., 1980).

In addition to the usual preoperative assessment, physical examination should focus on the location, degree of airway obstruction, and gas exchange. A review of the latest chest radiographs is helpful in determining the location of the foreign body and for evidence of secondary pathologic changes such as atelectasis, air trapping, or pneumonia (Fig. 24-21). If significant hyperinflation of one lung or lobe exists, nitrous oxide should be withheld because of the potential danger of further increase in gas volume and possible rupture of the affected lung. Although it is desirable to keep the child NPO (waiting 6 or more hours for solids and 2 hours for clear liquids), the patient's condition determines the timing of the bronchoscopic examination. If foreign body aspiration causes life-threatening respiratory distress, its removal takes precedence over NPO guidelines.

A major controversy in the anesthetic management of patients undergoing bronchoscopy for foreign body removal

■ **FIGURE 24-21.** Foreign body in the left bronchus with hyperinflation of the ipsilateral portion of the lung. (Courtesy Dr. K. S. Oh, Department of Radiology, Children's Hospital of Pittsburgh.)

is whether to control ventilation or to maintain spontaneous ventilation (Verghese and Hannallah, 2001; Chen et al., 2009). There are few data to justify one technique over the other. Woods (1990) prefers spontaneous ventilation, and Kosloske (1982) advocates neuromuscular blockade and controlled ventilation. The risk of controlled ventilation is to force the foreign body deeper into the small airways, and the risk for the spontaneously breathing patient is unexpected movement or cough (Donlon and Benumof, 1996). In a report of four patients in whom the bronchoscopist had the foreign body slip from the forceps back into the airway, neither controlled ventilation with muscle paralysis nor spontaneous breathing under a deep plane of anesthesia played a role in the mishaps. It was thought that the experience of the endoscopist and the availability of proper equipment were more important factors than the method of ventilation (Pawar, 2000).

Muscle relaxation is particularly useful for bronchoscopy involving the removal of a foreign body distal to the carina, especially because the duration of these procedures can extend to more than an hour. If the spontaneous ventilation technique is employed, meticulous topical anesthesia of the vocal cords with lidocaine can decrease the risks for coughing and laryngospasm. Propofol-based total intravenous anesthesia would be a better choice than inhalational anesthesia because propofol provides a steady level of anesthesia regardless of ventilation and perfusion mismatches (Verghese and Hannallah, 2001).

The anesthetic approach to the child who has aspirated a foreign body must be individualized. All children should be monitored with a pulse oximeter, end-tidal CO_2 , precordial stethoscope, electrocardiogram, thermometer, and automated blood pressure. Oxygen saturation is determined in room air before the induction of anesthesia to establish the baseline value. If neuromuscular blockade is required, a nerve stimulator should be used to track the depth of paralysis.

Foreign bodies in the larynx are more likely to cause total airway obstruction than foreign bodies below the glottis. Foreign bodies located in the bronchi may dislodge from cough or change in position and cause total obstruction (Woods, 1990). In case of acute respiratory distress and hypoxemia with a laryngeal foreign body, anesthesia is induced with the patient in a sitting position with an inhaled anesthetic and oxygen while the patient is monitored with a precordial stethoscope, pulse oximeter, and electrocardiogram. Spontaneous breathing is preferable; positive pressure ventilation may cause the foreign body to be displaced and further obstruct the airway (Darrow and Holinger, 2003). After inhalational induction, intravenous access is established (if not already available), and a vagolytic dose of atropine (0.02 to 0.03 mg/kg) is administered. After intravascular access is established, inhalational anesthesia may be switched to total intravenous anesthesia with propofol with or without opioids (e.g., fentanyl, remifentanyl). For children in stable condition with a foreign body presumed to be in the bronchus, an intravenous catheter is inserted before the induction, and the child is monitored in the usual manner. If a full stomach is suspected, the physician must weigh the risk for aspiration against loss of a patent airway before rapid-sequence induction with succinylcholine and cricoid pressure is considered.

As soon as the child is anesthetized, the endoscopist must ensure that no foreign body is present above the vocal cords. If the laryngeal outlet is clear, the larynx is sprayed with 2% to 4% lidocaine, and a bronchoscope is inserted through the laryngeal

inlet. Fortunately, it is rare for an anesthesiologist to encounter a foreign body in the larynx and upper trachea that causes dyspnea and life-threatening hypoxia.

Immediately after the bronchoscope passes the glottis, the anesthesia circuit is connected to the breathing sidearm of the bronchoscope, and manual ventilation, or spontaneous breathing with manual assist, is resumed. It is important to remember that, with extremely high flow resistance through the side arm of the bronchoscope, spontaneous breathing is all but ineffective and the respiratory rate (especially the expiratory phase) must be kept very slow to allow sufficient time for passive exhalation. Inspiratory gas flow is adjusted to accommodate for the leak around the bronchoscope.

During the procedure, the anesthesiologist's attention should be focused on the breath sounds detected by the precordial stethoscope, the symmetry of respiratory excursion, and oxygen saturation measured by a pulse oximeter. Close communication and cooperation between the bronchoscopist and the anesthesiologist are essential throughout bronchoscopy. It is important to remember that the lumen of the bronchoscope is narrowed by the telescope and other instruments, especially when a suction catheter is inserted through the side port, the same narrow channel through which the patient must be ventilated (Cotton and Reilly, 1990). The rate of rise in end-tidal Pco_2 in apneic infants and young children is extremely high—approximately 9 mm Hg/min (Motoyama et al., 2001). The period of apnea or severe hypoventilation therefore should be closely observed and communicated to the endoscopist. The physician must make sure that after each period of hypoventilation or apnea the telescope, forceps, and endobronchial suction catheter through the bronchoscope's side arm are removed. The distal end of the bronchoscope should be pulled above the carina, and the proximal open end of the bronchoscope is occluded with the endoscopist's thumb or a glass obturator cap (see Fig. 24-18), so that the child can be hyperventilated before instrumentation is resumed. During the crucial moment of foreign body retrieval, ventilation must sometimes be held until the oxygen saturation begins to fall.

When the foreign body or its fragment is successfully grasped with the forceps, the forceps and the bronchoscope are carefully pulled out of the trachea and the larynx together as a single unit. It is imperative that the upper airway and glottis be totally relaxed, allowing the foreign body to pass through without being dislodged prematurely. The patient is mask ventilated until the bronchoscope is reintroduced into the trachea. This maneuver can be repeated when the foreign body is fragmented. If a large, obstructive foreign body is removed from the bronchus but is dislodged into the trachea or larynx during the process of retrieval, it can cause serious obstruction of the entire respiratory system unless it is removed immediately. If prompt removal is not possible, the foreign body should be pushed back into one of the main bronchi so that ventilation can be resumed with at least one lung.

Intraoperative complications include laryngospasm, bronchospasm, hypoxia, arrhythmias, and pneumothorax. They are preventable by maintaining adequate anesthesia, oxygenation, ventilation, and muscle relaxation. Premature ventricular contraction, although rare (and most commonly associated with halothane anesthesia in the past), can usually be treated with oxygenation, hyperventilation, and intravenous lidocaine (1 mg/kg), and by reducing the anesthetic concentration. Pneumothorax, although infrequent, must be considered

if acute deterioration of ventilation and gas exchange occurs. A portable chest radiograph is diagnostic, and a chest tube is inserted to reexpand the lung.

After the completion of bronchoscopy for foreign body retrieval, the child is usually intubated with an endotracheal tube. Tracheal intubation allows tracheobronchial suction, lung expansion, and oxygenation and ventilation until adequate reversal of muscle relaxation and return to spontaneous breathing. Dexamethasone (0.4 to 1.0 mg/kg, up to a total of 20 mg/kg) is given prophylactically to prevent laryngeal edema (Tunnessen and Feinstein, 1980; Postma et al., 1987). Postoperative croup is treated with inhalation of racemic epinephrine (0.5 mL of 2.25% solution diluted in 3 mL of saline solution) (Adair et al., 1971).

Endoscopy for Foreign Body Ingestion

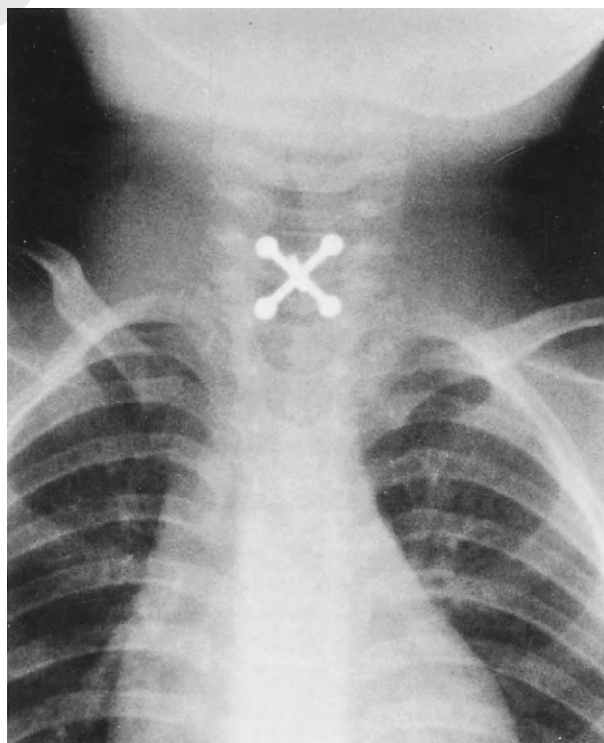

According to the National Safety Council, suffocation from foreign body ingestion and aspiration is the third leading cause of accidental death in children younger than 1 year and the fourth leading cause in children between 1 and 6 years old. Ingestions are often asymptomatic, unrecognized, and self-resolving. Because retained esophageal foreign bodies are so much more common than aspirations, procedures for their removal outnumber those for aspirated foreign bodies (Manning and Stool, 2003). The most commonly ingested foreign body is a coin, followed by food or bones. Other foreign bodies include buttons, batteries, pins, safety pins, thumbtacks, and small toys (McGahren, 1999). Once in the stomach or bowel, coins usually pass through the remainder of the gastrointestinal tract. Many coins, however, become lodged in the esophagus. The most frequent symptoms of upper esophageal foreign body include dysphagia, drooling, gagging, retching, and vomiting. The child may also experience coughing, choking, and significant airway compromise. Serious complications, such as esophageal erosion, caused by retained esophageal coins are rare and occur only after a coin has been lodged for more than 24 hours. Soprano and coworkers (1999) recommend that children with a single coin in any part of the esophagus who have no history of esophageal disease, or respiratory compromise on presentation to the emergency department, be observed for 12 to 24 hours. These authors found that within 24 hours there is a 28% chance of spontaneous passage of the coin into the stomach, regardless of esophageal location.

A chest radiograph should be obtained in all cases of suspected foreign body ingestion. Ingested foreign bodies are predisposed to lodge in three areas of anatomic constriction in the esophagus: the proximal esophagus at the level of the cricopharyngeal muscle and thoracic inlet (the foreign body is seen at the level of the clavicles on chest radiograph), the middle esophagus at the level of the carina and the aortic arch, and the distal esophagus just proximal to the esophageal gastric junction (the foreign body is seen two to four vertebral bodies above the stomach bubble on chest radiography). The most common site for foreign bodies to lodge is at the upper esophagus at the level of the thoracic inlet. If the foreign body is a coin, it will be oriented in a transverse position because the opening of the esophagus is widest in a transverse position (McGahren, 1999).

Removal of a foreign body from the esophagus is not usually a complicated procedure. As long as the child is not

dyspneic, the physician should wait 4 to 6 hours after the last meal, depending on the child's age, until the stomach is empty. The child should be well sedated, and anesthesia is induced with inhaled or intravenous anesthetics. During esophagoscopy, the mucosa over the cricoid cartilage may be traumatized by compression between the endotracheal tube anteriorly and the rigid esophagoscope posteriorly. A prospective review involving more than 50,000 general pediatric anesthetic cases revealed that the incidence of postintubation croup after esophagoscopy was 20 times higher than that of the general pediatric surgical population during the same time period (Moro, Borland, and Motoyama, unpublished observations). A reduced-size endotracheal tube may be helpful to minimize subglottic swelling (Smith, 1980). Dexamethasone (0.4 to 1 mg/kg, up to 20 mg) may also reduce the incidence of postoperative stridor.

The only potential major hazard with foreign body ingestion is when the foreign body, usually a coin, is held in the hypopharynx, and on gagging and coughing, it dislodges and slips into the larynx, completely occluding the airway. When a radiograph of the neck demonstrates a foreign body high in the esophagus (Fig. 24-22), the child is sedated heavily with an opioid and a sedative to avoid excitement, gagging, and coughing. After intravenous access is established and atropine is given, the trachea is intubated under deep sevoflurane anesthesia or propofol, with or without muscle relaxation. The use of neuromuscular blockade is determined by the ability to ventilate the child with positive pressure. Cricoid pressure is avoided under these circumstances because it may irritate the upper airway or dislodge the foreign body.

■ **FIGURE 24-22.** A jack is lodged high in the esophagus of a 4-year-old boy. (Courtesy Dr. J. Medina, Department of Radiology, Children's Hospital of Pittsburgh.)

SUMMARY

Surgical procedures involving the ear, nose, and throat are the most frequently performed procedures requiring general anesthesia in infants and children. Most procedures are of short duration and involve relatively healthy patients. However, there is a subset of patients with congenital abnormalities and OSAS who present with difficult airways and significant upper airway obstruction. Improved monitoring technology, newer anesthetic agents (e.g., sevoflurane, propofol), and shorter-acting muscle relaxants have made care of these patients safer and more efficient.

Over the past two decades, a drastic decline of acute supraglottitis, the most dreaded of childhood emergencies for

pediatric anesthesiologists, has been witnessed with the development of the Hib vaccine. Technological advances in laser surgery and laryngoplasty have continued to challenge pediatric anesthesiologists to develop approaches to meet the needs of advancing otolaryngologic technology.

Plastic and reconstructive surgery for the pediatric patient can involve any part of the body, and some of the children have pathologies related to coexisting diseases and syndromes. They may require surgery on the face, skull, thorax, and extremities, sometimes involving other surgical specialties such as pediatric neurosurgery and otolaryngology. This chapter focuses on reconstruction as it relates to the craniofacial skeleton, extremities, and skin defects involving nevi and vascular malformations.

For the pediatric plastic surgeon, a significant portion of reconstructive surgery involves pathologies of the craniofacial skeleton and soft tissue, and these may be of significant concern for the pediatric anesthesiologist. In this chapter, the pathologies that result in surgery are set in the framework established by Whitaker and associates in 1979. The anesthesiologist who cares for these children will find it easier to organize the varied syndromes and sequences when they are structured in this manner.

CRANIOFACIAL SURGERY

Craniofacial anomalies are characterized by congenital or acquired deformities of the cranial or facial skeleton. Although rare, they comprise a diverse group of defects, and the goal of surgical intervention is to restore both form and function. The classification of craniofacial anomalies is difficult because of their variability, rarity, and degree of severity, and often because of our lack of understanding of their etiology and pathogenesis. The Committee on Nomenclature and Classification of Craniofacial Anomalies of the American Cleft Palate Association has proposed the following categories: synostosis, clefts, hypoplasia, hyperplasia, and unclassified (Whitaker and Bartlett, 1990).

Craniosynostosis

Craniosynostosis is defined as premature closure of one or more of the cranial sutures. It is a relatively common defect, occurring

in one in 2000 to 2500 live births (Posnick, 2000). It can result in abnormalities in the size and shape of the calvarium, cranial base, and orbits, and can cause dental occlusion, and thus it constitutes a diverse group of deformities. Craniosynostosis is not only a cosmetic issue, for it can also affect brain growth, intracranial pressure (ICP), and vision, resulting in developmental delay and vision impairment (Slater et al., 2008).

Premature fusion of a cranial suture results in an abnormal head shape. Growth of the skull perpendicular to the suture is impaired. Compensatory growth parallel to the suture creates the characteristic abnormal skull shape. The shape of the skull defines craniosynostosis. [Figure 25-1](#) shows the different types of abnormal skull shapes and the corresponding synostotic sutures.

Craniosynostosis can occur by itself (simple) or as a major component of a syndrome (complex, or syndromic). Over 100 craniosynostosis syndromes have been described, but six are more common than the others (Slater et al., 2008). These are Apert, Pfeiffer, Saethre-Chotzen, Carpenter's, Crouzon, and Muenke's syndromes. Of these, Apert and Crouzon syndromes are the most common. [Table 25-1](#) lists the various syndromes and their associated anomalies and anesthetic concerns. The timing of surgery usually occurs before 1 year of age. The importance of early intervention is related to improved ability of the infant to reossify, the malleable nature of the calvaria during infancy, and the rapid brain growth that occurs during the first year of life (Panchal and Utchin, 2003). The motivation for and goal of surgical intervention are to reduce ICP, prevent brain injury, and enhance appearance. Repair of syndromic craniosynostosis may be more complicated and appears to be associated with increased blood loss. The etiology of the increased bleeding is unclear, but it might be related to the length of surgery (Fearon and Weinthal, 2002).

Apert Syndrome

Apert syndrome, also referred to as acrocephalosyndactyly, occurs at a frequency of 1 in 160,000 live births (Cohen et al., 1992). Acrocephalosyndactyly, a defect involving the cranium

TABLE 25-1. Anesthetic Considerations for Craniofacial Syndromes—cont'd

Syndrome	Suture(s)	Clinical Features	Anesthesia Issues
Carpenter's syndrome	Coronal and others	HEENT: Tower skull, down thrust eyes, orbital hypertelorism, low set ears, small mandible. Cardiac: cardiac defects common (VSD, ASD). Genitourinary: hypogonadism. Musculoskeletal: Syndactyly of hands and feet. Neurologic: Developmental delay common but variable, may have increased ICP. Other: Obesity.	Preoperative labs: HCT, blood type and screen. Airway management: The small mandible may make intubation difficult. Obesity may make ventilation difficult. Musculoskeletal: Syndactyly may make IV access difficult. Neurologic: Caution with premedication if elevated ICP.
Crouzon syndrome	Coronal, lambdoid, others	HEENT: Frontal bossing, tower skull, midface hypoplasia, beaked nose, hypertelorism, ocular proptosis, airway obstruction can occur. Neurologic: Occasional mild developmental delay, may have increased ICP.	Preoperative labs: HCT, blood type and screen. Airway management: May be a difficult intubation (uncommon), airway obstruction with sedation or anesthesia, caution with premedication. Neurologic: Caution with premedication if elevated ICP, eyes require protection if ocular proptosis present.
Muenke's syndrome	Coronal	HEENT: Wide-set eyes, hearing loss. Neurologic: Developmental delay uncommon.	Preoperative labs: HCT, blood type and screen. Neurologic: Caution with premedication if elevated ICP.

ASD, Atrial septal defect; HCT, hematocrit; HEENT, head ears eyes nose throat; ICP, intracranial pressure; IV, intravenous; VSD, ventricular septal defect.

and the extremities, occurs in Apert, Pfeiffer, Carpenter's, and Saethre-Chotzen syndromes. The characteristic features of Apert syndrome include turribrachycephaly (high steep flat forehead and occiput), mid-face hypoplasia, and orbital hypertelorism (Fig. 25-2). Cleft palate occurs in approximately 30% of these patients. Choanal atresia and occasionally tracheal stenosis have been reported and can cause airway obstruction. Congenital cardiac disease is one of the more common associated visceral anomalies, occurring in approximately 10% of patients. Genitourinary anomalies (hydronephrosis, cryptorchidism) also occur in 10% of patients with Apert syndrome (Cohen and Kreiborg, 1993). Severe synostosis can result in increased ICP and, if uncorrected, developmental delay. Syndactyly of the hands and feet with the fusion of digits two to four can occur and can make intravenous (IV) access difficult. Kreiborg and

■ **FIGURE 25-2.** Apert syndrome.

coworkers (1992) have reported cervical spine fusion, and they have suggested that cervical spine films prior to anesthesia may help predict difficult intubation. Although infants and children with Apert syndrome are often difficult to intubate, many have been intubated uneventfully. In some cases, suboptimal laryngoscopic views secondary to abnormal anatomy may require flexible fiberoptic intubation. The laryngeal mask airway (LMA) may be a reasonable adjunct in those patients who are difficult to ventilate or intubate. However, to date there are no reported instances of their use in infants and children with Apert syndrome. The clinical features and anesthetic implications of Apert syndrome and the other acrocephalosyndactylies are outlined in Table 25-1. Unlike Apert syndrome, the other acrocephalosyndactylies are not typically associated with difficult airways. However, midface hypoplasia is common in these infants and may cause significant upper airway obstruction intraoperatively and postoperatively (Perkins, 1997).

Pfeiffer Syndrome

Pfeiffer syndrome is another example of an acrocephalosyndactyly. The incidence of Pfeiffer syndrome is approximately 1 in 100,000 live births. This syndrome is characterized by bicoronal synostosis, proptosis, midface hypoplasia, and broad thumbs and great toes (Moore et al., 1995). Patients with Pfeiffer syndrome can also present with hydrocephalus, which may contribute to increased intracranial pressure. There are three types of Pfeiffer syndrome, and typically the clinical features, degree of airway obstruction, and mortality rates increase with types 2 and 3 (Moore et al., 1995).

Saethre-Chotzen and Carpenter's Syndromes

The clinical features of Saethre-Chotzen include brachycephaly, facial asymmetry, low hairline, proptosis, beaked nose, large halluces (great toes), and pectus excavatum. Some patients may have renal anomalies, cryptorchidism, developmental delay, and epilepsy. It can be difficult to differentiate it from the other acrocephalosyndactylies because there can be significant clinical

variability (Nascimento et al., 2004). Carpenter's syndrome is the most rare of the syndromic craniosynostosis, with only 45 reported cases since the mid 1990s. As with all of the syndromic craniosynostosis, patients with Carpenter's syndrome have synostosis, midface hypoplasia, and musculoskeletal deformities. They may also have hypogonadism, developmental delay, and obesity (Idestrand et al., 2009).

Crouzon Syndrome

Crouzon syndrome, also known as craniofacial dysostosis, is one of the syndromic craniosynostoses. These infants present with craniosynostosis, proptosis, and midface hypoplasia but without visceral or extremity involvement (Fig. 25-3). As in other patients with midface hypoplasia, significant airway obstruction can occur and may require early tracheostomy (Sirotnak et al., 1995). Table 25-1 outlines the main clinical features and anesthetic issues as they relate to patients with Crouzon syndrome. During infancy, patients with Crouzon syndrome may come to the operating room for tracheostomy or cranial vault remodeling.

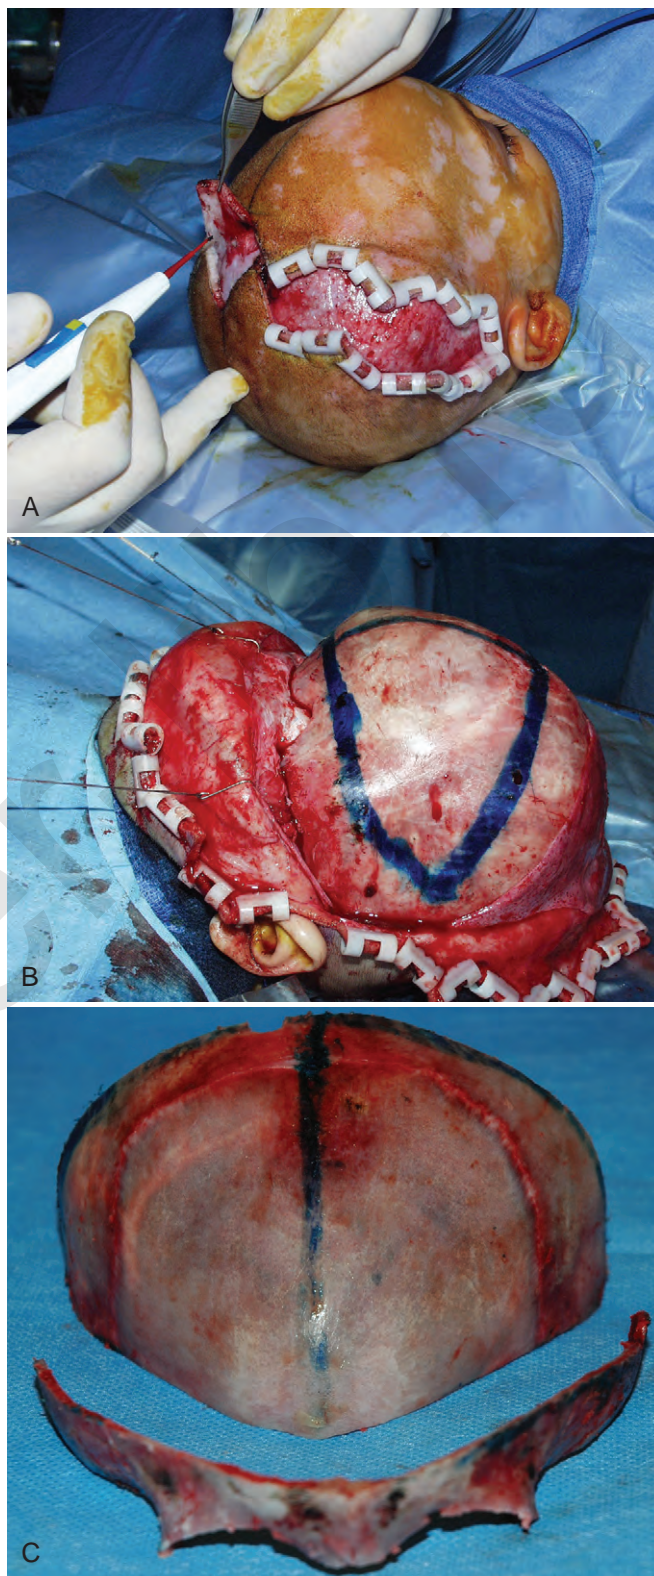

Surgical Management

Cranial Vault

Surgical correction for craniosynostosis can be performed with an open or an endoscopic procedure. The calvarial vault reconstruction typically involves both plastic surgery (by craniofacial surgeons) and neurosurgery. The surgical approach for an open cranial vault reconstruction is through a bicoronal incision (Fig. 25-4, A). A blocking stitch or clips may be applied to the skin flaps to minimize blood loss. The clips may be more effective in preventing bleeding, but some surgeons have expressed concern about the risk for ischemia of the underlying hair

■ FIGURE 25-3. Crouzon syndrome.

■ FIGURE 25-4. Bicoronal skin incision. **A**, A bicoronal incision is made for access to the calvarium. Note the skin clips on the scalp flap to minimize bleeding. **B**, The skin flap is mobilized off the forehead to expose the orbits. **C**, The calvarium and the supraorbital rim are seen in approximation.

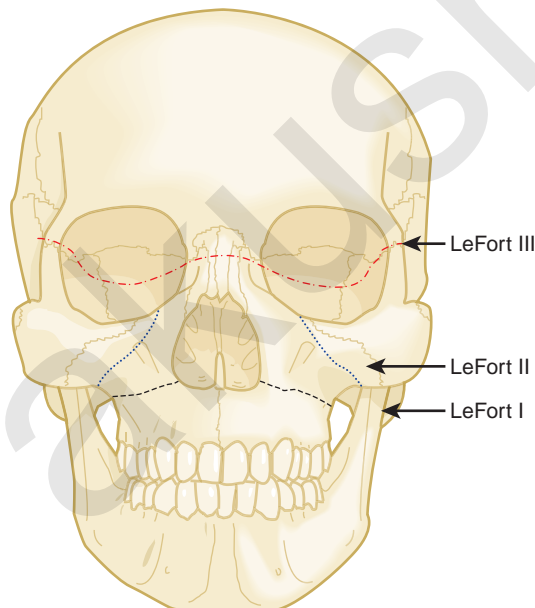

follicles (Ray Harschberger, personal communication, 2009). The scalp flap is dissected off the forehead and mobilized down to expose the superior orbital rim (see Fig. 25-4, B). The calvarium is typically removed by the neurosurgeons in one or several pieces. A bandeau osteotomy is then performed along the lateral temporal bones and the nasion to mobilize the superior orbital rim (see Fig. 25-4, C). Once the osteotomies are complete, the surgical field is protected with moist gauze. The calvarium and the orbital bandeau are sectioned and the pieces are reshaped and replaced in a manner that replicates a normal head shape. The bone is secured with a craniofacial plating system, the scalp flaps are replaced, and the coronal incision is closed.

Strip Craniectomy with Helmet

The endoscopic approach is less invasive and has been reported to cause less blood loss (Jimenez et al., 2002). This procedure is more commonly used for sagittal synostosis, although it has been described for the repair of other single suture and even multiple-suture synostosis. The surgical approach is through smaller incisions. As with open approaches, significant blood loss can occur if the sagittal sinus is entered. Jiminez reported a small percentage of patients who required transfusions, and most were discharged on the first postoperative day. Unlike those who had an open calvarial reconstruction, these patients do require helmet therapy after this repair.

Midface Advancement

Midface advancements are performed to correct midface hypoplasia. The different types of advancements include the Le Fort I maxillary advancement, the Le Fort III maxillary and upper face advancement (Fig. 25-5), and the monobloc advancement, which includes the maxilla, upper face, orbits, and forehead. The

■ **FIGURE 25-5.** Le Fort osteotomies. Le Fort I mobilizes the maxillae. Le Fort II mobilizes the nose. Le Fort III mobilizes the entire midface.

Le Fort I osteotomy is typically performed for patients with midface hypoplasia secondary to cleft lip and palate. The Le Fort III and monobloc osteotomies are typically performed for patients with midface hypoplasia secondary to syndromic craniosynostosis (Apert, Pfeiffer, Crouzon syndromes). The surgical approach for the Le Fort III and monobloc osteotomies are through bicoronal, intraoral, and often eyelid incisions. Significant blood loss can occur during the surgical dissection and osteotomies. Once the midface is mobilized, the advancement can be performed immediately with rigid fixation or gradually with internal or external distraction osteogenesis. Distraction osteogenesis became a common in craniofacial surgery in 1997, and the advantages include less morbidity, more long-term stability, and improved aesthetic outcome (Fearon, 2001; Shetye et al., 2007). The external distraction device has a frame that is anchored to the skull, with a distraction bar positioned perpendicular to the face. The distraction bar is anchored to the newly mobilized midface with wires (Fig. 25-6). Once in place, the midface may be distracted at a rate of 1 to 2 mm a day.

Anesthesia Management

The anesthetic management of infants with craniosynostosis begins with a complete preoperative evaluation. The history should define the cranial sutures involved, the planned surgical procedure, and previous craniofacial reconstruction, and it should identify any associated syndrome. Infants and children with syndromes may have difficult airways, other organ involvement, and more complicated surgical repair with more bleeding. Associated anomalies that can present a challenge to the anesthesiologist include facial and airway features that make mask ventilation and intubation difficult. Airway pathology can also cause obstruction, and some of these children have obstructive sleep apnea (OSA) (Mixer et al., 1990; Pijpers et al., 2004).

■ **FIGURE 25-6.** Midface distraction. An adolescent boy with Apert syndrome, in a midface distractor.

Children with OSA may present with daytime somnolence, enuresis, behavioral changes, and snoring. As many as 40% to 50% of infants and children with syndromic craniosynostosis have clinical features of OSA. This compares with the 0.2% to 0.7% incidence of OSA in the general pediatric population (Lo and Chen, 1999; Pijpers et al., 2004). The most common treatment for OSA is adenotonsillectomy. If this fails to reduce the symptoms, the sequence of recommended steps in this population includes nasal continuous positive airway pressure (CPAP), Le Fort III osteotomy with midface advancement, and as a last resort, tracheostomy. Several studies have demonstrated a reduction in the symptoms of OSA after midface advancement. In one study by Nelson and colleagues (2008), all of the patients reported a decrease in snoring, and five of the six patients with a tracheostomy could be decannulated.

A history of fatigue (or sweating with feedings), cyanosis, and syncope are suggestive of an underlying cardiac anomaly. Cardiac pathology is associated with some of the syndromes (e.g., Apert, Pfeiffer, Carpenter's). Congenital heart disease is most common in Apert syndrome, and the most common cardiac defect is ventricular septal defect (Hidestrand et al., 2009). Infants and children with clinical signs or symptoms suggestive of heart disease or a heart murmur should be preoperatively evaluated by a pediatric cardiologist.

Some infants and children with craniosynostosis may have increased ICP. The incidence of increased ICP in nonsyndromic craniosynostosis varies from 8% to 47%, depending on the number of sutures involved (Arnaud et al., 1995; Renier et al., 2000; Mathijssen et al., 2006). The incidence appears to be higher in syndromic craniosynostosis, with approximately 50% having funduscopic evidence of papilledema (Bannink et al., 2008). This may manifest as headaches, vomiting, and somnolence. However, infants and children with chronically elevated ICP may be asymptomatic. Elevations in ICP manifest as papilledema on ophthalmologic examination, so all patients with craniosynostosis should have a funduscopic examination by an ophthalmologist.

A thorough airway examination may be difficult to perform on an infant. Features that predict difficulty with mask ventilation include midface hypoplasia and enlarged tongues. In addition, a small mandibular space, decreased jaw opening and translocation, and decreased neck flexion and extension predict difficult intubation. The rest of the examination should focus on identifying heart murmurs and, in infants with syndactyly, identifying potential IV and arterial access sites. For reconstructions that involve significant blood loss (cranial vault reconstruction, midface advancement), a preoperative hematocrit level should be obtained, and blood typing and cross-matching should be performed. Former premature infants and infants less than 2 month old should have perioperative glucose monitoring. Premedication can be performed for most children over the age of 1 year but is rarely necessary in those less than 9 months old. Children with evidence of airway obstruction or acute elevations in ICP should not receive a premedicant agent. Endocarditis prophylaxis is not necessary in those patients with congenital heart disease.

Airway

Airway management in these patients can be very challenging during attempts at ventilation, intubation, or both. Fortunately, difficult airways are not common. However, the incidence is

higher in those patients with syndromes and in those patients who have had previous reconstruction. Successful techniques described for infants and children include using the Bullard laryngoscope, laryngeal mask airway, flexible fiberoptic scope, and retrograde intubation (Cooper and Murray-Wilson, 1987; Blanco et al., 2001; Brown et al., 1993, 2004) (see Chapter 10, Equipment, and Chapter 12, Airway Management). A combination of techniques may be required to secure the airway. For example, the LMA has been used to facilitate the passage of the fiberoptic scope and endotracheal tube (Inada et al., 1995) (Fig. 25-7). Although those authors report this technique in a patient with Treacher Collins syndrome, it could be used for any craniofacial patient with a difficult airway. An endotracheal tube and LMA size chart helps in choosing the appropriate equipment (Table 25-2, and see also Table 10-3 in Chapter 10, Equipment). Cuffed endotracheal tubes may be more challenging, because the cuff on the endotracheal tube may not fit through the smaller LMAs. However, the air-Q (Trudell Medical Marketing, London, Ontario, Canada) has its short stalk and detachable adapter that make it easy to pass a cuffed endotracheal tube with the pilot balloon. If an uncuffed endotracheal tube is used, it can be secured while removing the LMA by telescoping a smaller

FIGURE 25-7. A, Once the laryngeal mask airway (LMA) is positioned in the mouth, the fiberoptic scope is placed through it, and the endotracheal tube is fed over the fiberoptic scope into the trachea. **B**, Another uncuffed endotracheal (one-half size smaller) is used as a pusher to facilitate LMA removal without extubation.

TABLE 25-2. Equipment Sizes for Airway Management

Laryngeal Mask Airway (size)	Endotracheal Tube (mm)
1.0	3.0 uncuffed
1.5	4.0 uncuffed
2	4.5-5.0 uncuffed
2.5	5.5 uncuffed
3	6.0 uncuffed
4	6.0 cuffed

endotracheal tube through the top of the larger tube (see Fig. 25-7, B). When passing an endotracheal tube through an LMA that is a size 3 or smaller, an uncuffed endotracheal tube is easier to use, but it runs the risk for creating a large air leak.

The airway for patients having craniosynostosis surgery can be secured with a standard oral endotracheal tube. For these patients, a nasal intubation may be easier to perform when using the flexible fiberoptic scope. A standard endotracheal tube may be preferred to a nasal RAE (Ring, Adaire, Ellwyn) tube because of the surgical approach, which involves a bicoronal incision.

Patients having Le Fort osteotomies require a nasal or an oral intubation depending on the type of Le Fort. Those having a Le Fort I osteotomy (for clefts) will need a nasal endotracheal tube so the maxillae and the mandible can be aligned properly. Nasal endotracheal tubes have been damaged during Le Fort osteotomies, resulting in difficulty with ventilation (Bidgoli et al., 1999), so care must be taken by the surgeons when mobilizing the maxillae. Patients having a Le Fort III osteotomy for midface distraction can be intubated orally with an oral RAE tube.

Some infants with craniofacial anomalies require tracheostomy because of significant upper airway obstruction (Perkins, 1997; Sculerati et al., 1998). Adequate preparation entails having all the necessary equipment available and having personnel who are trained and experienced in the use these airway instruments. It may also mean having a pediatric otorhinolaryngologist immediately available.

Intracranial Pressure

Patients with craniosynostosis may develop intracranial hypertension. Typically this is diagnosed by the presence of papilledema during an ophthalmologic examination. Clinically, increased ICP may range from being asymptomatic to complaints of visual changes, headaches, somnolence, and vomiting. Children with chronically elevated ICP may be relatively asymptomatic and active. Chronically elevated ICP can have anatomic and physiologic consequences that may affect the surgical and anesthetic management. Computed tomography scans and magnetic resonance imaging (MRI) will show a beaten-copper-pot appearance of the skull in patients with chronically elevated ICP. The close proximity of the brain to the skull may make removal of the calvarium difficult. Mannitol (0.25 to 0.75 g/kg) and mild hyperventilation may facilitate this process.

Hemodynamic instability can occur in patients with chronically elevated ICP after the calvarium is removed. The probable physiologic cause is the sudden reduction in blood pressure required to maintain cerebral perfusion pressure once the calvarium is

removed and the ICP equilibrates with atmospheric pressure. Patients may require transient hemodynamic support with vasoactive medication (e.g., epinephrine or phenylephrine).

Blood Conservation and Transfusion Medicine

Craniofacial procedures are often long, exposing infants to the risks of hypovolemia, hypothermia, blood loss, and venous air emboli. The craniofacial procedures typically performed during the first year of life include cranial vault remodeling (including fronto-orbital, posterior, and total vault advancement) and strip craniectomy. One of the most pressing concerns related to anesthesia care in craniofacial surgery is the management of intraoperative bleeding. The cranial procedures can involve significant blood loss because of the duration of the procedure, the many exposed skin and bone surfaces, and the rare complication of entering large vessels such as the sagittal sinus. Blood loss during these procedures has remained an issue since Whitaker and colleagues' description of perioperative blood loss in 1979. Blood loss is often as high as half to one blood volume, and nearly 90% to 100% of the infants undergoing these procedures may require a blood transfusion (Faberowski et al., 1999; Tuncbilek et al., 2005; Stricker et al., 2010). Even the strip craniectomy, which is typically performed to correct nonsyndromic isolated sagittal synostosis and results in less blood loss, can produce significant hemorrhage. In a recent study by White and others (2009), predictors of blood loss during craniofacial surgery included surgery time greater than 5 hours, age less than 18 months, the presence of multiple-suture craniosynostosis, and syndromic craniosynostosis. Infants undergoing strip craniectomy usually experience less blood loss, but this population may be at increased risk because they come to the operating room at the nadir of their physiologic anemia (i.e., at 2 to 3 months of age). Preparation for these procedures requires a baseline hematocrit, and blood typing and cross-match. Some centers also obtain coagulation studies. Adequate IV access needs to be obtained for resuscitation. In an infant, at least two large-bore (22- to 20-gauge) peripheral IV catheters should be placed to provide adequate access. Arterial pressure monitoring is recommended for beat-to-beat analysis of blood pressure and intravascular volume status, as well as for blood gas monitoring. A central venous catheter may be placed for central venous pressure monitoring, or in patients with difficult IV access.

Recently, some centers have reported significant success with minimizing blood loss and exposure to allogeneic blood products during craniofacial surgery. Surgical techniques that minimize blood loss include infiltrating subcutaneous epinephrine, needle tip cautery, scalp clips for the scalp flap, and bone wax for the osteotomy edges. Several medical and pharmacologic blood conservation techniques have been described in the older pediatric patient, but less information is available for the infant having cranial vault reconstruction.

Preoperative blood donation has been described in children as small as 8 kg (Mayer et al., 1996), but this technique has significant limitations in the infant. Their young age, small size, and lower hematocrit may make blood collection more challenging and less feasible. Acute normovolemic hemodilution has been described in older children and adolescents and may be effective. Hemodilution is relatively contraindicated in the infant less than 6 months old. The normal physiologic advantage with hemodilution (increased preload, increased stroke volume, and decreased systemic vascular resistance, increased

tissue oxygenation) may be lost in the infant because of fetal hemoglobin, which more avidly binds oxygen, and a naturally less compliant myocardium.

Because most infants presenting for cranial vault reconstruction have a normal physiologic anemia, erythropoietin was proposed as a therapy to address this concern. Preoperatively, recombinant erythropoietin decreases the transfusion requirements in infants having craniosynostosis repair. Fearon and Weinthal (2002) reported the dosage of erythropoietin as 600 units/kg given subcutaneously once per week along with oral iron supplementation. Erythropoietin was started 3 to 4 weeks before surgery, and the incidence of blood transfusions in infants having craniosynostosis repair decreased from 93% to 57%.

In March of 2007, the U.S. Food and Drug Administration placed a black-box warning on synthetic erythropoietin because of the concern of increased death, deep venous thrombosis, and cancer spread in adult patients receiving synthetic Epogen (Singh et al., 2006; see also www.fda.gov/forconsumers). These concerns have occurred only in the adult population, but some centers have stopped using synthetic erythropoietin for craniofacial surgery. A multicenter retrospective review of 396 pediatric craniofacial patients receiving erythropoietin did not reveal an increase in perioperative complications, specifically death or deep venous thrombosis (Naran et al., 2010).

Antifibrinolytic therapy has been described in pediatric surgery, but the data for craniofacial surgery are limited. Aprotinin, a serine protease inhibitor, decreases perioperative blood loss and transfusion requirements during craniofacial procedures. In a prospective, randomized, and blinded placebo-controlled study evaluating the effect of aprotinin in infants and children having cranial vault remodeling and frontal orbital advancements, D'Errico and colleagues (2003) noted a reduction in the amount of packed red blood cells being transfused intraoperatively and postoperatively in those receiving aprotinin. However, aprotinin did not reduce the number of patients requiring transfusion. Although no adverse events were reported, the option of aprotinin has been curtailed with its removal from the market. Tranexamic acid and aminocaproic acid are two antifibrinolytics that remain available for potential pediatric use. The data to guide the use of tranexamic acid and aminocaproic acid in this population are limited, but a small study by Durán de la Fuente and colleagues (2003) demonstrated a reduction in estimated blood loss and transfusion requirements. The tranexamic acid was not infused continuously but instead was administered every 8 hours at a dosage of 15 mg/kg. Table 25-3 shows standard dosage regimens for tranexamic acid and aminocaproic acid.

In the past, the use of a cell saver was reported as being impractical for small pediatric patients because of the size of the collection reservoir (De Ville, 1997). Recently, the cell-saver reservoirs are available in sizes as small as 25 mL. This technology may reduce the rate of autologous blood transfusion in infants having craniofacial surgery. In fact, the most significant

benefit may occur when cell-saver technology is combined with erythropoietin pretreatment. In a prospective analysis evaluating the use of cell saver with a 55-mL pediatric bowl for patients pretreated with erythropoietin, only 30% of those infants having cranial vault remodeling required allogeneic blood (Fearon, 2005). Krajewski and coworkers (2008) in a prospective randomized trial describe a 5% transfusion rate in infants having elective craniosynostosis surgery when both cell saver (25-mL collection reservoir) and erythropoietin were used, compared with a 100% transfusion rate for those not receiving cell-saver techniques or erythropoietin.

Temperature and Positioning

Craniofacial procedures can be very long—sometimes several hours. Complications resulting from long surgical procedures include skin breakdown, neuropathic injury, and hypothermia. Attention must be paid to the initial setup to ensure adequate positioning and padding to minimize these intraoperative injuries. Infants having cranial vault remodeling may be positioned prone, and attention to protecting the face and eyes is important. Patients with midface hypoplasia and proptosis may present a challenge when placed prone, because adequately protecting the face and eyes may be more difficult. The infant is placed on a full-access forced-hot-air blanket to minimize hypothermia, and the surgical site (head) is then isolated from the body using plastic drapes (Fig. 25-8). This not only minimizes convective and radiant heat losses but also prevents conductive heat loss to a bed wet from irrigation and blood. Blood products should be warmed through a fluid warmer before administration (except for platelets). Intravenous fluid warmers may be used, particularly if large volumes of cold allogeneic blood are being administered.

Venous Air Embolism

Venous air embolism (VAE) is a potential complication of craniofacial and neurosurgical procedures (see Chapter 22, Anesthesia for Neurosurgery). VAE can present with hemodynamic instability

■ **FIGURE 25-8.** The head is isolated from the torso with plastic drapes. The drapes are placed in opposite directions and sealed to minimize moisture and thus hypothermia from blood and irrigation fluids.

TABLE 25-3. Dosage Guidelines for Antifibrinolytic Therapy

Drug	Dosage
Aminocaproic acid (Amicar)	Load 100 mg/kg Infuse 10 mg/kg per hr
Tranexamic acid	Load 10-100 mg/kg Infuse 1-10 mg/kg per hr

and can result in death. VAE occurs commonly in pediatric patients having cranial procedures. A prospective study using precordial Doppler in infants and children having craniosynostosis repair detected VAE in 82% of the patients; 31% percent developed hypotension secondary to VAE, but none developed cardiovascular collapse (Faberowski et al., 2000). This is higher than the previously reported incidence of 66% (Harris et al., 1987). Infants may be at increased risk for VAE, because significant hemorrhage during cranial vault remodeling can result in low central venous pressures. In addition, the relatively large size of the infant head may raise the surgical site above the level of the heart, thereby increasing the pressure gradient for air entrainment. Some advocate the placement of central venous catheters to monitor the trend of central venous pressures and minimize the risk for air embolism. However, no data suggest that central venous pressure monitoring decreases the risk for VAE.

Management of VAE begins with preventing hypovolemic states by providing adequate volume resuscitation and using a precordial Doppler for early detection of VAE. The precordial Doppler should be placed over the left or right parasternal border between the third and sixth intercostal spaces (Schubert et al., 2006). Lowering the head of the bed, left lateral positioning, flooding the surgical field with saline, applying bone wax, discontinuing nitrous oxide, and providing inotropic support are all measures that have been used to acutely manage VAE. Pediatric advanced life support with chest compressions and epinephrine is required for patients who develop symptomatic low blood pressure, bradycardia (heart rate < 60 bpm), or pulseless electrical activity.

Postoperative Care

The postoperative treatment of infants having craniofacial surgery depends on coexisting morbidities and the procedure performed. Most infants and children presenting for cranial vault reconstruction or midface advancement can be extubated in the operating room at the completion of surgery. Factors that may preclude extubation include intraoperative complications resulting in hemodynamic instability, known difficult airway, significant tongue swelling, and intranasal cerebrospinal fluid drainage after Le Fort III osteotomy. Infants in whom distractors were placed may have a more difficult airway after extubation (Fig. 25-9). Mask ventilation can be very difficult with mandibular distractors and impossible with midface distractors. Airway equipment, including oral and nasal airways and appropriately sized LMAs, should be available after extubation. Equipment and personnel to remove part of the distractor device are also important in the operating room (Wong et al., 2004).

Infants having cranial vault remodeling and frontal orbital advancements can experience significant blood loss intraoperatively. If these patients are adequately resuscitated and are hemodynamically stable, they can often be extubated in the operating room. Infants with difficult airways or significant airway obstruction, or those who have experienced intraoperative complications, may benefit from delayed extubation in the intensive care unit (or in the operating room) after their condition has stabilized. Ongoing blood loss is common after major craniofacial surgery, and infants may require repeat transfusions in the immediate postoperative setting. Other complications include cerebral edema (Levine et al., 2001), visual changes (Lo et al., 2002), cerebrospinal fluid leak (Fearon, 2003), infection (Fialkov et al., 2001), metabolic acidosis, and transfusion reactions.

■ FIGURE 25-9. Mandibular distractors.

Hyponatremia has been reported after major intracranial procedures in pediatric patients. This was originally attributed to syndrome of inappropriate diuretic hormone (SIADH). However, this diagnosis has come into question. Although it is not entirely clear, cerebral salt wasting syndrome (CSW) may be the more likely cause. Both SIADH and CSW manifest with hyponatremia. CSW is differentiated from SIADH by hypovolemia, high urine output, and low or normal antidiuretic hormone levels (Levine et al., 2001) (Table 25-4). The proper diagnosis is important because the two are managed differently. SIADH is treated with free water restriction, whereas CSW is managed with isotonic fluid replacement (normal saline) to cover maintenance requirements and urine losses. Frequent sodium evaluations are important to guide therapy.

Hypoplasia

Hypoplasia of the craniofacial skeleton is a category of craniofacial anomalies characterized by hypoplasia or atrophy of a portion of the craniofacial soft tissue and skeleton. Pierre Robin sequence, hemifacial microsomia (including Goldenhar syndrome), and Romberg's disease are examples of these anomalies.

TABLE 25-4. Comparison of Syndrome of Inappropriate Antidiuretic Hormone (SIADH) and Cerebral Salt Wasting (CSW)

Monitoring	SIADH	CSW
Central venous pressure	High (>5)	Low (<5)
Urine output	Decreased	Increased

Pierre Robin Sequence

Pierre Robin syndrome (PRS) is characterized by retrognathia, glossoptosis (tongue falling to the back of the throat), and airway obstruction. It is referred to as a sequence rather than a syndrome because the small mandible and subsequent airway obstruction is secondary to a fixed fetal position in utero that inhibits mandibular growth. PRS occurs with an incidence of 1 in 20,000 to 50,000. The sequence is often associated with a syndrome such as Stickler syndrome, the syndrome most commonly associated with PRS, which is characterized by micrognathia, poor vision, and a collagen disorder with hyperflexible joints. Other syndromes and facial anomalies seen with PRS include velocardiofacial syndrome, fetal alcohol syndrome, and bilateral hemifacial microsomia.

Neonates and infants with PRS will have some degree of airway obstruction. They often also present with significant reflux and feeding difficulties. Mild airway obstruction may require only lateral or prone positioning to relieve the airway obstruction; however, as many as one quarter of infants with PRS have more severe obstruction, necessitating surgical intervention (Bijnen et al., 2009). The optimal surgical intervention is not clear, and there is significant regional variation. Preoperative evaluation by a pediatric plastic surgeon and pediatric otolaryngologist is essential to completely evaluate the airway and identify coexisting airway pathology. The management options include tongue-lip adhesion, mandibular distraction, and tracheostomy. A tongue-lip adhesion involves suturing the inferior portion of the tongue to the lower lip to prevent the tongue from falling to the back of the pharynx and causing obstruction (Fig. 25-10). Once the mucosal flaps from the tongue and the lower lip are approximated, a temporary retention suture with a button is placed through the floor of the mouth and around the mandible to secure the repair. The infant is intubated postoperatively for several days to ensure the success of the adhesion. The goal of the tongue-lip adhesion is to relieve the airway obstruction and improve feeding until the mandible has had a chance to grow. Some evidence suggests that this repair is effective at decreasing airway obstruction and improving feeding (Kirschner et al., 2003). Bijnen and coworkers

■ **FIGURE 25-10.** An infant after a tongue-lip adhesion. Note the temporary retention suture placed through the floor of the mouth and fixed in place with a button.

(2009) found that 73% of their patients had improved airway patency, based on sleep studies, and improved feeding. The tongue-lip adhesion is left intact until the patient is approximately 1 year old. At that time, the mandible has had time to grow and the adhesion can be taken down.

An alternative therapeutic approach involves mandibular distraction. In infants with severe obstruction, mandibular distraction can be performed to rapidly distract the jaw. It can be performed in infants less than 6 months old. Genecov and colleagues (2009) recently described their 10-year experience with mandibular distraction for PRS. Of the 67 patients that had preoperative polysomnography, 65 experienced an improvement. Also, several of the patients who required tracheostomy for PRS could be decannulated after their mandibles were distracted.

Tracheostomy is a final option for those patients who fail conservative treatment, tongue-lip adhesion, or distraction. Some have advocated for early tracheostomy for PRS, but there is evidence that it involves increased morbidity and mortality. Also, once infants receive a tracheostomy, it takes on average 3 years for decannulation to occur (Tomaski et al., 1995).

Anesthesia Management

Airway management in the infant with Pierre Robin sequence can be very challenging because of difficulty with mask ventilation and intubation. The laryngeal mask has been successfully used to ventilate and to assist in the intubation of these patients (Markakis et al., 1992). The LMA has even been placed in the awake patient with PRS after regional nerve blockade (Stricker et al., 2008). Nasal intubation with the flexible fiberoptic scope has also been described (Blanco et al., 2001). Other airway devices used for patients with PRS and difficult intubation include the Storz video laryngoscope (KARL STORZ Endoscopy-America, Inc.) and the Airtraq optical laryngoscope (PRODOL MEDITEC S.A.). In addition, when infants have significant difficulty with ventilation or intubation, aside from oral pharyngeal and nasal airways, a suture (0-silk) can be placed at the base of the tongue to displace the tongue anteriorly to assist with ventilation or intubation.

Infants presenting for tongue-lip adhesion or mandibular distraction will require nasal intubation. After inhalation induction with spontaneous ventilation, a flexible fiberoptic nasal intubation can be performed. After the tongue-lip adhesion is completed, infants typically recover in the intensive care unit, where they remain intubated, relaxed, and sedated for several days. Extubation can be performed in the operating room when both the anesthesiologist and pediatric otorhinolaryngologist can be present. When extubation fails, patients may require direct laryngoscopy, bronchoscopy, and tracheostomy. After mandibular distraction, the airway may become even more challenging because once the distractors are in place they may prevent effective mask ventilation.

Hemifacial Microsomia

Hemifacial microsomia is characterized by unilateral or asymmetric development of the facial bones and muscles and frequently involves the ear. This manifests as hypoplasia of the malar-maxillary-mandibular region and usually involves the temporomandibular joint. The vertebral pathology can involve the cervical vertebrae and can significantly reduce the cervical range of motion. Other associated anomalies of hemifacial

microsomia include cardiac (ventricular septal defect, tetralogy of Fallot, coarctation), renal, and neurologic defects (hydrocephalus). Patients with hemifacial microsomia can have significant upper airway obstruction and OSA. Most patients with hemifacial microsomia are nonsyndromic, but a small percentage have Goldenhar syndrome, which is characterized by hemifacial microsomia, eye colobomas, and vertebral or scapular anomalies. These patients may be very difficult to intubate.

Anesthesia Management

As with PRS, the most significant anesthetic challenge with hemifacial microsomia is airway management (see Pierre Robin Sequence, Anesthesia Management, earlier). Mask ventilation may be difficult because of facial asymmetry. Intubation may be more challenging because of micrognathia and asymmetric mandibular hypoplasia, and also potentially because of decreased cervical range of motion. This difficulty may decrease with age, but it may increase after surgical reconstruction. Successful ventilation and intubation of the infant have been reported with an LMA and fiberoptic laryngoscopy (Johnson, 1994).

Parry-Romberg Syndrome

Parry-Romberg syndrome is a rare disorder characterized by progressive hemifacial atrophy. Many believe this is a form of linear scleroderma. The process often starts in infancy or later childhood as a pigmented line (*coup de sabre*) on the forehead, and then progressive atrophy (which ultimately burns itself out) affects the subcutaneous tissues and skeleton of the hemiface. Reconstruction, which occurs after the atrophy is complete, is often complicated and may require multiple surgeries. Microvascular flaps and fat injections are surgical options (Hunt and Hobar, 2003).

Clefting

Historically, repair of the cleft lip and palate was performed with no anesthesia (Jones, 1971). It consisted of reapproximating pared tissue edges. These simple and quick procedures were performed on older children or adults who could tolerate the pain and inconvenience of the procedure. At most, patients were allowed to gargle with ice water to produce local numbing. In 1847, Snow described using ether for a cleft lip repair. Later in 1850, chloroform was reported for the repair of a bilateral lip and palate in a 7-year-old (Jones, 1971). The airway was unprotected, and blood could drain into the posterior pharynx. In 1921, Magill provided the first endotracheal insufflation technique on an infant and later applied this technique for the repair of a cleft palate in 1924 (Jones, 1971).

Today, general anesthesia is routinely and safely used for infants, children, and young adults having cleft lip or palate repairs. Typically, surgical repair of the cleft lip is performed at 3 to 6 months and the repair of the cleft palate at 9 to 18 months. Pharyngoplasty, performed for velopalatal insufficiency, is usually performed later, at 5 to 15 years of age. The safe age for cleft lip repair was established to be 6 to 12 weeks in 1964 by an audit of American plastic surgeons (Lewin, 1964) and later supported in 1966 by a large retrospective review (Wilhelmsen and Musgrave, 1966) that showed an increased rate of complications in children with a weight of less than 10 lb, hemoglobin level

less than 10 g/dL, and white cell counts higher than 10,000. More recent studies have highlighted the safety of anesthesia for full-term and preterm neonates (Rudolph, 1974; Van Boven et al., 1993). The authors of these studies stress the importance of having a team of surgeons, anesthesiologists, and nursing staff that are experienced and comfortable with the intraoperative and postoperative care of the neonate. The preoperative preparation of the infant for cleft lip and palate surgery begins with a sound understanding of their anatomy, physiology, and associated anomalies.

Lip and Palate

Surgical Management

Palatoplasty. Many techniques describe the repair of a cleft palate, but all include a hard palate procedure and a soft palate (velar) procedure. Palatoplasties are performed with the intention of obtaining velopharyngeal (VP) competence and normal speech and are typically performed before the first year of age. Hard palate repairs include raising oral mucoperiosteal flaps and mobilizing them to the midline of the cleft defect. These oral flaps are raised on the greater palatine neurovascular bundles. Nasal lining flaps, often harvested from the vomer (the posterior bony portion of the nasal septum), are used to repair the nasal lining of the hard palate. After the nasal lining repair, the oral mucoperiosteal flaps are closed in a straight line.

Velar repairs include straight line and z-plasty techniques. Modern velar repairs include dissecting free the abnormally positioned levator palatini muscle and reconstructing the muscular sling in the velum, thus performing an intravelar veloplasty. The soft palate tissue is mobilized to the midline by use of lateral relaxing incisions, which are left open at the conclusion of the procedure. These raw areas are expected to heal by granulation during the first few postoperative days, with serosanguineous drainage during the early postoperative period. At the conclusion of the procedure, a tongue stitch is often placed, as well as a nasopharyngeal airway for prophylaxis, should postoperative tongue swelling result from pressure placed by the mouth retractor.

Pharyngoplasty. Pharyngoplasties are performed to treat an incompetent velopharyngeal sphincter that allows inappropriate nasal air escape during speech, or hypernasality, defined as VP insufficiency. Pharyngoplasties, often performed as secondary speech procedures after a palatoplasty that failed to result in VP competence, alter the anatomy of the posterior pharynx and the VP port. The VP port is the muscular sphincter connecting the posterior nasal cavity and pharynx, and it is made up anteriorly by the posterior free edge of the soft palate (velum), posteriorly by the posterior pharyngeal wall, and laterally by the tonsillar pillars or lateral pharyngeal walls. Pharyngoplasties include the posterior pharyngeal flap and the sphincter pharyngoplasty.

The *posterior pharyngeal flap* (PPF) is a superiorly based flap of tissue raised off the posterior pharyngeal wall. It includes pharyngeal mucosa and a portion of the superior constrictor muscle. The PPF is superiorly based at the level of C2 or the adenoid pad, and it is inset into the posterior free edge of the velum. The PPF is sewn to the middle of the velum creating VP ports on either side of the PPF. These VP ports function as nasal airways.

■ **FIGURE 25-11.** Cleft palate repair complete. The mouth retractor is in place. Cotton rolls are placed on either side of the oral RAE tube to prevent compression from the metal tongue blade of the mouth retractor.

The *sphincter pharyngoplasty* significantly narrows the VP port by elevating the anterior tonsillar pillar bilaterally with the underlying palatopharyngeus muscle. The bilaterally elevated anterior tonsillar pillars are rotated 90 degrees medially and sewn to a horizontal incision made in the posterior pharyngeal wall. Because the tonsillar pillars are a continuation of the posterior free edge of the velum, this technique creates a much smaller muscular sphincter, thereby greatly narrowing the natural VP port.

Because pharyngoplasties alter the anatomy of the VP port and posterior pharynx, they carry the lifetime risk for overcorrection, hyponasality, and, more importantly OSA.

Anesthesia Management

Most patients with a cleft lip or palate can be induced with a standard inhalational induction. If an IV catheter is in place, an IV induction can also be performed. Induction for patients with orofacial clefting can be achieved with an inhalation agent such as sevoflurane. Airway management for most of these children is straightforward, but difficulty with mask ventilation and intubation can occur in infants with craniofacial anomalies or retrognathia. Airway obstruction can usually be managed with the insertion of an oropharyngeal airway and CPAP.

For the patient with an isolated cleft lip and palate, difficulty with laryngoscopy is common. Some studies have described the incidence of difficult laryngoscopy (laryngoscopic view of Cormack and Lehane laryngoscope view grades 3 and 4) to be as high as 4% to 7% (Xue et al., 2006). Factors predicting a more difficult laryngoscopic view include bilateral clefts and retrognathia. Despite this high percentage of poor laryngoscopic view,

only 1% of the patients were difficult to intubate, and only one patient had a failed intubation (Gunawardana, 1996).

Cleft patients with associated craniofacial anomalies or retrognathia may be difficult to ventilate or intubate. In these patients, preparations for alternative airway management need to be made. If general anesthesia is induced, the patient should remain spontaneously ventilating until the trachea is secured with an endotracheal tube. Successful intubation through a laryngeal mask with the aid of a fiberoptic scope has been described for pediatric patients with difficult airways (Inada et al., 1995). Other intubating devices include the Shikani Optical Stylet (Shukry et al., 2005; Clarus Medical). Surgical repair of the cleft palate using an LMA has even been described (Beveridge, 1989). However, disruption of a previous cleft palate repair during the placement of an LMA has also been described, suggesting that care should be taken when placing an LMA in a patient with a history of cleft palate repair (Somerville et al., 2004).

The oral RAE reformed tracheal tube is routinely used for the intubation because the preformed bend in the tube facilitates the use of the mouth retractor. Care should be paid to securing the tube and protecting it from unintentional extubation. Surgical preparation of the field can result in removal of the tape from the tube if it is not secured well (Fig. 25-12). Because of the fixed length of the preformed oral RAE tube, there is a risk of main stem intubation in a smaller infant. Cotton rolls can be placed in the Dingman-Dott retractor to minimize this risk. There is also an increased risk of extubation if an unexpectedly small endotracheal tube is required. An armor-reinforced endotracheal tube (see Fig. 10-11 in Chapter 10, Equipment) can be used to secure the airway in this situation. These reinforced endotracheal tubes do not kink with flexion, making them ideal for infants or children who require a smaller than expected endotracheal tube. Breath sounds should be reevaluated after the mouth gag is in place because of possible compression of the tube, and because advancement may cause single-lung ventilation.

There is no standard technique for the maintenance of anesthesia. Both inhalation and total IV anesthetics have been described for patients having cleft lip and palate surgery. A balanced anesthetic of an inhalation agent (with or without nitrous

■ **FIGURE 25-12.** Securing an oral RAE endotracheal tube for cleft lip or palate surgery. Note the normal midline position of the oral RAE tube. A Tegaderm dressing is placed over the tube and the double-sided adhesive stickers (or tape) to protect against the liquid preparation.

oxide), an opioid, and a muscle relaxant (optional) is effective and safe. For patients having palate surgery, keeping the mean arterial pressure at 50 to 60 mm Hg may prevent excessive bleeding from the surgical site. This can be achieved by deepening the anesthetic with inhalation agents, opioids (remifentanyl), or α_2 -agonists (clonidine or dexmedetomidine). Some studies (Rolla et al., 2003; Steinmetz et al., 2007) have attempted to determine whether the IV or the inhalation technique is better. However, there does not appear to be a clear benefit of either one.

The surgeon infiltrates the palate with epinephrine to prevent excessive bleeding and to facilitate mucosal dissection. It has been demonstrated that inhaled anesthetics sensitize the myocardium and decrease the arrhythmia threshold of epinephrine. Katz and others (1962), almost 50 years ago, described ventricular dysrhythmias when epinephrine was infiltrated during halothane anesthesia. The safe dosage of epinephrine is different for adults and for children. Dosages as low as 1 mcg/kg were found to be arrhythmogenic in adults under halothane anesthesia (Katz et al., 1962). In contrast, a 1983 study found that 10 mcg/kg was safe in children under halothane anesthesia (Karl, 1983). The children in this study ranged from 3 months to 17 years old and were ventilated to maintain an end-tidal CO_2 of 40 mm Hg. The other inhaled anesthetics appear to be as safe or safer than halothane. In adults, the arrhythmogenic dosage of epinephrine was greater than 5 mcg/kg and did not differ between isoflurane, sevoflurane, or desflurane (Moore et al., 1993; Navarro et al., 1994). In children, 10 mcg/kg appears to be a safe maximal dosage of epinephrine for infiltration (see Box 7-3 in Chapter 7, Pharmacology of Pediatric Anesthesia).

Positioning and padding are critical during long periods of anesthesia. In particular, attention should be paid to protecting the infant's chest wall and extremities from the breathing circuit and the tight monitoring leads. The patient is often rotated 90 to 180 degrees, and a straight adapter can facilitate the positioning of the circuit.

Precautions with the airway management should be taken before extubation, especially for patients with difficult airways. Airway obstruction has been described after palatoplasties (Anthony and Sloan, 2002). Patients undergoing a palatoplasty who have a history of a difficult airway or have an associated congenital anomaly should have a nasopharyngeal airway placed by the surgeon before emergence. This may help maintain a patent airway and decrease the work of breathing after extubation (Fig. 25-13). Throat packs can result in airway obstruction if unintentionally left in place, and confirmation of their removal must take place before extubation.

Tongue edema is a particular concern for the anesthesiologist taking care of an extubated patient after cleft palate surgery. Profound tongue, palate, and pharyngeal edema can occur from venous engorgement after use of the Dingman-Dott mouth retractor. It is prudent for surgeons to release the retractor repeatedly throughout the procedure to minimize this risk (Anthony and Sloan, 2002; Oste et al., 2004). Patients experiencing respiratory distress need to be reintubated and mechanically ventilated (Fig. 25-14). It may take several days for the edema to resolve (Anthony and Sloan, 2002).

Postoperative pain management for cleft lip and palate repair should provide analgesia without respiratory depression, nausea, or vomiting. The best solution seems to be a combination of different medications, usually acetaminophen with the occasional addition of an opioid. Acetaminophen, when

■ **FIGURE 25-13.** Nasopharyngeal airway for airway patency for emergence from cleft palate repair.

■ **FIGURE 25-14.** Tongue edema secondary to the Dingman-Dott retractor. Note the tongue stitch placed to help displace the tongue anteriorly and relieve the airway obstruction.

administered rectally, is given at an initial dosage of 20 to 40 mg/kg, followed by 20 mg/kg every 6 hours. The oral dosage is 10 to 15 mg/kg every 4 to 6 hours (Birmingham et al., 1997, 2001). Acetaminophen may have an opioid-sparing effect, and some infants after cleft lip repair require none, or very small amounts, in the postoperative period (Stephens et al., 1997).

Nonsteroidal antiinflammatory agents have been described for analgesia after cleft palate surgery (Sylaidis and O'Neill, 1998). Although some evidence suggests there may be no increased risk for bleeding, many surgeons and anesthesiologists choose not to use them routinely. Dosages of opioids, if administered, should be appropriate for weight, to minimize the risk for respiratory compromise in infants. A safe starting dosage of morphine for infants is 0.02 mg/kg every 3 to 4 hours, as needed. Infants undergoing cleft surgery and being given postoperative parenteral narcotics should be appropriately monitored (e.g., for apnea and bradycardia, electrocardiography, oxygen saturation).

The bilateral infraorbital nerve block works very well as an adjunct or as the sole analgesic technique for cleft lip repair

(Eipe et al., 2006). The block, which can be performed by anesthesiologists or surgeons, provides better analgesia than perineuronal infiltration or opioids alone (Pradeep et al., 1999; Rajamani et al., 2007). The infraorbital nerve block has been described for all age groups including neonates (Bosenberg and Kible, 1995).

The maxillary division of the trigeminal nerve exits from the infraorbital foramen. The nerve provides the sensory supply to the upper lip, the choana, the maxillary sinus, and part of the nasal septum. This block can be used to provide analgesia for cleft lip surgery, nasal septal repair, and endoscopic sinus surgery. There are two approaches to the maxillary division of the trigeminal nerve: extraoral (percutaneous) and intraoral. For the extraoral approach, the needle is directed toward the infraorbital foramen externally through the skin. The location of the foramen varies with the age. In children and adults, the foramen is located approximately 5 to 10 mm below the infraorbital rim in a vertical line from the pupil of the eye (Fig. 25-15). The thumb or a finger of the hand not holding the syringe can be placed on the inferior orbital rim as a guide and to protect the eye during the injection. The needle is placed just inferior to finger. Once it makes contact with the bone, it is withdrawn slightly and the local anesthetic is injected.

The intraoral route is accessed through the subsulcal area in the buccal mucosa. The point of insertion is the upper incisor or the second bicuspid on the side to be blocked. A needle is passed through the subsulcal route toward the location of the

infraorbital foramen. As with the transcutaneous approach, it is suggested that the thumb or a finger of the hand not holding the syringe be placed on the infant's inferior orbital rim and used as a guide and to protect the orbit and eye. Infants scheduled for cleft lip repairs require 0.5 to 1 mL of local anesthetic solution on each side; for older children and adolescents, 1.5 mL to 2 mL can be used. Bupivacaine (0.125%, 0.25%, or 0.5%, with or without epinephrine [5 mcg/mL]) or ropivacaine (0.2% or 0.5%) can be used for the block.

The duration of postoperative analgesia depends on the local anesthetic and its concentration. For children and adults, 0.125% bupivacaine provided analgesia for approximately 4 to 8 hours (Pradeep et al., 1999). Bupivacaine (0.5%) provides analgesia for 6 to 24 hours (Nicodemus et al., 1991; Eipe et al., 2006). In neonates, the block may be shorter (2 to 3 hours) (Bosenberg and Kible, 1995).

Anesthesia in Developing Countries. Medical missions are performed in developing countries for a variety of procedures including cardiac, orthopedic, and genitourinary. Cleft lip and palate missions are some of the most common and are carried out by multiple organizations around the world. The barriers to providing safe effective surgical and anesthesia care in developing countries include lack of hospital resources (electricity, lighting), medical resources (anesthesia machines, ventilators, oxygen, surgical equipment, medications), personnel resources (lack of training, temperament), standards of care, language skills, and cultural and social differences (Ward and James, 1990; Hodges and Hodges, 2000; Fisher et al., 2001). Despite these barriers, many health care providers volunteer their time and skills to help children with cleft deformities.

There is no standard of care for anesthetizing patients in a developing country, so care must be tailored to the limited available resources. Difficulties include limitations in preoperative evaluations, number of anesthetizing agents, ventilators, monitoring, and postanesthesia care units. The preoperative screening process should identify children with obvious cardiovascular and respiratory pathologies. Because of the high volume and limited ability to preoperatively prepare these patients, many are not selected for surgery.

Pathologies that occur in developing countries and complicate anesthesia care include malnutrition, anemia, and parasitic infections, to name a few. Unfortunately, many of these pathologies are not identified, and it is not clear what impact this has on outcomes. Also, families may withhold information for fear of having the surgery cancelled, which may result in increased morbidity and even mortality (Fisher et al., 2001).

The induction of, maintenance of, and emergence from anesthesia need to be tailored to the available resources. Patients who present for isolated lip repair, and who are old enough, can have the procedure under local anesthesia (Hodges and Hodges, 2000). Patients who require general anesthesia are induced with either an inhalational or an IV technique. Halothane is a commonly used inhalational agent because of its cost. The airway is secured with an endotracheal tube in most circumstances; however, endotracheal tubes may have to be reused. Muscle relaxants in some practices (Fisher et al., 2001) are rarely used because of the lack of mechanical ventilation. In this population, spontaneous ventilation may be safer for the patient, and the anesthetist's hands are free. Some groups preferred muscle relaxants because it facilitated rapid recovery in a setting that had no recovery area (Ward and James, 1990).

■ **FIGURE 25-15.** Infraorbital nerve block. **A**, The extraoral route. **B**, The intraoral route.

Outcome data for patients having cleft repairs in developing countries are limited. In a recent survey, (Fisher et al., 2001) identified complications associated with surgical patients from Operation Smile. Most of the surgeries were for cleft lip and palate repair, but other common plastic and orthopedic procedures were included. The data, collected from voluntary submission of perioperative data sheets, were collected on 6037 of the 9422 patients. Complications in the operating room, which included laryngospasm, bronchospasm, and unintentional extubation, occurred in 5% of these patients. In the recovery area, complications such as upper airway obstruction, postextubation croup, bronchospasm, and delayed discharge (pain, agitation) occurred in 3.3%. Cardiovascular complications including ventricular ectopy and supraventricular tachycardia occurred in 1.5%. The complications from arrhythmias are most likely underreported because not all patients had electrocardiographic monitoring. Significant negative events that occurred in 1.8% of the patients included return to the operating room for bleeding, intraoperative reintubation, cancellation of surgery after induction, blood transfusion, cardiac arrest, and death. The age of the patient predicted respiratory complications. A significantly larger percentage of children less than 1 year old experienced intraoperative respiratory complications. Death was an uncommon event; during the 18-month collection period, there were four deaths among all of the Operation Smile patients. This death rate of 0.4 per 1000 (Fisher et al., 2001) is higher than some other reports of pediatric perioperative deaths (<1 per 10,000) (Tiret et al., 1988; Morray et al., 2000), but it is difficult to compare the different patient populations. Despite this information, countless lives have benefited from medical missions to developing countries, and most of these procedures are accomplished safely. However,

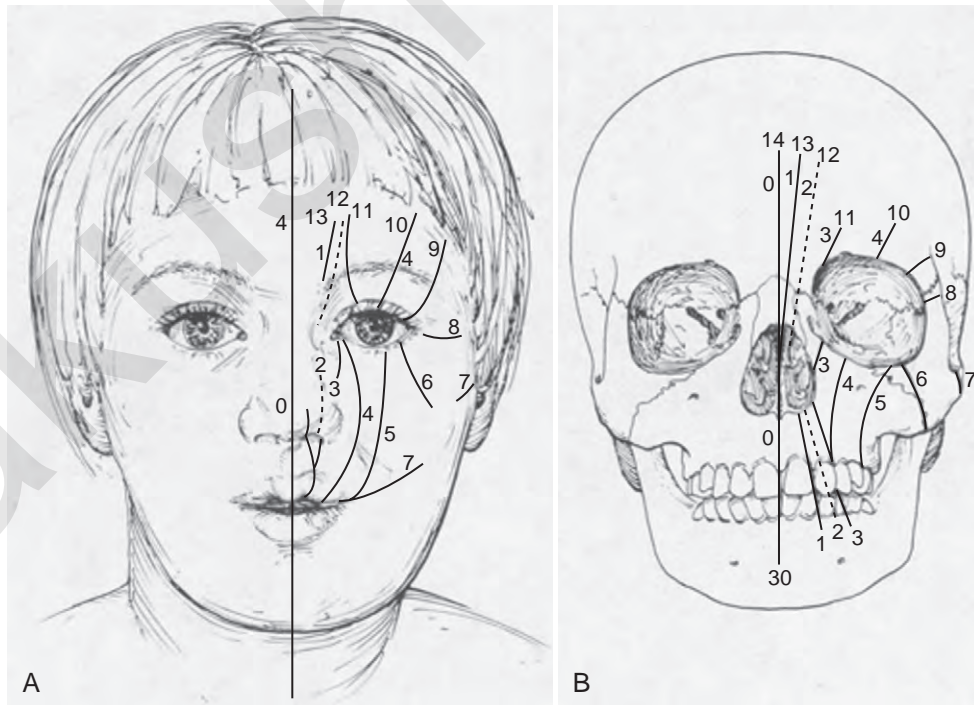

it must be recognized that performing surgery and anesthesia in these environments poses unique cultural, patient care, and system-based challenges for the entire surgical team.

Facial Clefting

Craniofacial clefts involve a defect of the underlying cranial or facial skeleton (or both), as well as the soft tissue envelope, and they can involve the entire face. Tessier classified these defects by the location of the facial clefts. In his classification, the orbit is the center of the defect, and the clefts radiate out like the spokes of a wheel (Whitaker and Bartless, 1990) (Fig. 25-16).

Treacher Collins Syndrome

Treacher Collins syndrome (TCS), also known as mandibulofacial dysostosis, is an example of a bilateral 6, 7, and 8 craniofacial cleft (Fig. 25-17). It was first described in 1846 by Thompson and was further elaborated on by Treacher Collins. Inheritance is as an autosomal dominant pattern with variable penetration. The syndrome is characterized by poorly developed supraorbital ridges, aplastic/hypoplastic zygomas, ear deformities, hearing loss, cleft palate (in one third), and mandibular and midface hypoplasia. From birth, the adequacy of the airway is of primary concern. The degree of airway obstruction is related to the degree of maxillary and mandibular hypoplasia, choanal atresia, and glossoptosis. Tracheostomy may be required during infancy for those at highest risk for OSA and sudden infant death syndrome. The morbidity associated with tracheostomy is significant and some have advocated distraction osteogenesis or tongue-lip adhesion for these patients (Genecov et al., 2009; Thompson et al., 2009). Approximately 50% of patients with

■ **FIGURE 25-16.** Topographic map of craniofacial clefting. Treacher Collins syndrome is a facial cleft located at 6, 7, and 8. (From Whitaker LA, Bartlett SP: *Craniofacial anomalies*. In Jurkiewicz J, Krizek T, Mathes S, et al, editors: *Plastic surgery: principles and practice*, St Louis, 1990, Mosby, p 99.)

■ **FIGURE 25-17.** Treacher Collins syndrome.

TCS have hearing loss, which occurs secondary to anomalies of the inner ear. They also suffer from external ear anomalies (microtia) (Marres, 2002). Congenital heart disease has been described in patients with TCS but it is uncommon (Gollin, 1976). Developmental delay is also uncommon in this population. These patients are followed by a multidisciplinary craniofacial team and can come to the operating room for a variety of procedures. Aside from cleft lip and palate repair, the timing of major reconstruction typically occurs during childhood or adolescence when the cranioorbital zygomatic bony development is nearly complete.

Surgical Management. The focus of care of the patient with TCS during the first 1 to 2 years of life is on the airway and feeding. These patients may have significant airway obstruction and may require positioning, tongue-lip adhesion, mandibular distraction, or tracheostomy. Patients with an associated cleft palate ideally have it repaired before 1 year of age. After 2 years of age, the surgical care of these patients focuses on restoration of hearing, and on reconstruction of the upper face. Ear surgery can involve the external ear (microtia repair) for cosmesis and the middle ear for hearing. Several surgical procedures have been described to reconstruct the upper face. Autologous and vascularized bone flaps are used to reconstruct the zygoma and orbits, and local flaps have been described to repair the eyelid defects. Unfortunately, good cosmetic results are very difficult to achieve and do not last long. Repeat surgery is common. Once dental development is complete, orthodontic and orthognathic surgery is scheduled. These procedures usually involve a sagittal split osteotomy, with or without a Le Fort I (Thompson et al., 2009).

Anesthesia Management. Anesthetic concerns specific to this syndrome primarily involve the airway. Infants and children with Treacher Collins syndrome may be very difficult or impossible to mask ventilate or intubate, and this airway difficulty may increase with age (Nargozian, 2004). Several techniques have been successfully used to manage the airway safely in these patients. Direct laryngoscopy regardless of the blade used may be difficult. However, the Bullard laryngoscope has been used to successfully intubate a child with TCS (Brown et al., 1993). The LMA has also been used successfully to assist in the

intubation of these children (Ebata et al., 1991; Inada et al., 1995). In one series, the LMA was placed in neonates with PRS and TCS awake, and it was then used to guide intubation (Asai et al., 2008). The LMA has even been used successfully to ventilate a newborn with TCS for an extended period of time (Bucx et al., 2003). Other techniques used to intubate infants and children with TCS include the GlideScope (Verathon) (Bishop et al., 2009), a video-assisted laryngoscope (Sugawara et al., 2009), and the Airtraq optical stylet (PRODOL MEDITEL S.A.) (Hirabayashi et al., 2009). Given the potential for difficult mask ventilation and intubation, this population may be best managed with a sedated fiberoptic intubation. Successful sedation in a 6-year-old with TCS using dexmedetomidine and ketamine has been described (Iravani and Wald, 2008).

Another concern for the anesthesiologist is protecting the patient's eyes. Because of the maxillary and zygomatic hypoplasia, prone positioning may increase the risk for orbital compression and perioperative blindness. Infants and children with TCS can have congenital cardiac defects and require prophylaxis for subacute endocarditis when indicated. Those most affected by upper airway obstruction and OSA may have reduced opioid intraoperative and postoperative requirements (Brown et al., 2004).

Hypertrophy and Vascular Anomalies

Vascular anomalies—disorders of the arteries, veins, capillaries, and lymphatics—were classified by Glowacki and Mulliken (1982). They are divided into two groups: vascular tumors and vascular malformations. The most common vascular tumor is the hemangioma. Vascular malformations are further divided into arterial, venous, capillary, and lymphatic malformations.

Hemangiomas

Hemangiomas, the most common vascular tumor, are characterized by endothelial proliferation and angiogenesis and then postnatal regression. Examples include “strawberry” and capillary hemangiomas. Hemangiomas develop after birth and can be common, with 4% to 12% of infants having one by the first year of life. There is a higher incidence in female children. By 9 years of age, most have involuted. A rule of thumb is that 50% involute by 5 years of age, 70% by 7 years of age, and 90% by 9 years of age (Bruckner and Frieden, 2003). Most hemangiomas appear on the head and neck (60%) or the trunk (24%) (Finn et al., 1983). Airway hemangiomas, although rare, can be seen in infants. The typical clinical findings are cough and stridor. Many airway hemangiomas (60%) have associated cutaneous lesions on the preauricular region, chin, lower lip, and neck (Orlow et al., 1997).

Observation is the most common treatment for hemangiomas, as most resolve on their own, but 10% to 20% require some treatment. Medical therapy includes steroid injections or systemic steroids. Laser therapy with flashlamp pulsed dye lasers can be used for superficial hemangiomas. The neodymium yttrium-aluminum-garnet (Nd:YAG) laser can be used for deep hemangiomas. Lesions that involve the airway, affect vision, or cause a consumptive coagulopathy may need to be embolized. Embolization may also be indicated for hemangiomas that need to be surgically removed, because it may facilitate surgical excision.

Some hemangiomas have associated anomalies. For example, facial hemangiomas can be associated with central nervous system vessel anomalies, coarctation of the aorta, right-sided aortic arch, and eye abnormalities. Some hemangioma-associated syndromes are of importance to the anesthesiologist. PHACES syndrome occurs with facial hemangiomas and is composed of posterior fossa abnormalities (Dandy-Walker), hemangiomas, arterial anomalies (coarctation), congenital heart disease (patent ductus arteriosus, ventricular septal defect), eye abnormalities (cataracts), and sternal defects (Poetke et al., 2002).

Vascular Malformations

Vascular malformations occur because of an error in the embryonic vascular structure. Unlike vascular tumors, these malformations are present at birth and grow with the child. The malformation can be arterial, venous, capillary, or lymphatic. Arterial vascular malformations are referred to as high-flow lesions, whereas capillary, venous, and lymphatic malformations are low-flow lesions. MRI is one of the best ways to define the internal structure of these malformations.

Arterial. Arterial malformations are often asymptomatic. However, when they do become symptomatic they may have systemic sequelae. These malformations may cause limb hypertrophy or if extensive may result in a consumptive coagulopathy or congestive heart failure. Treatment is more effective with staged excision and embolization (Upton et al., 1985).

Capillary. Capillary malformations occur in 0.3% to 0.5% of infants. They often appear on the face and neck. Port-wine stains and nevus flammeus are examples. Facial port-wine stains typically occur in the trigeminal nerve distributions V1 (ophthalmic) and V2 (maxillary). Glaucoma and retinal arterial venous malformations are associated findings, and these patients need to be evaluated by an ophthalmologist. Head and brain MRI may also be required to identify underlying leptomeningeal malformations and choroidal angioma. Associated syndromes of capillary malformations include Sturge-Weber and Klippel-Trénaunay. Sturge-Weber syndrome consists of port-wine stain in the V1 trigeminal nerve distribution, glaucoma, overgrowth of the facial skeleton, leptomeningeal malformations, choroidal angiomas, and seizures (Fig. 25-18). Klippel-Trénaunay syndrome consists of capillary, venous, and lymphatic malformations. These lesions may involve the trunk and the extremities (Fig. 25-19). Treatment for capillary vascular malformations consists of multiple treatments with flashlamp pulsed dye lasers (Garzon et al., 2007).

Venous. Venous malformations are low-flow lesions that typically appear on the extremities and are often asymptomatic. However, they may occur in the gastrointestinal tract and can cause bleeding. Because most venous malformations are asymptomatic, treatment is conservative and consists of compressive garments. Treatment for symptomatic lesions includes embolization, sclerotherapy, and surgical excision (Hein et al., 2002).

Lymphatic. Lymphatic malformations are low-flow lesions that can involve the skin and underlying muscle. They typically appear on the head, neck, axillae, and chest. Lesions in the neck can be massive and can cause airway compromise, especially if they become infected and enlarged (Greinwald et al., 2008). These lesions do not regress spontaneously. They can be associated with

■ FIGURE 25-18. Sturge-Weber syndrome.

■ FIGURE 25-19. Klippel-Trénaunay syndrome.

syndromes including Klippel-Trénaunay, Turner's, Noonan's, and trisomies 13, 18, and 21. Intralesional sclerotherapy, laser treatment (CO₂, Nd:YAG), and surgical excision have been described for their treatment (Padwa et al., 1995).

Anesthesia Management

Anesthesia for patients with vascular tumors or malformations can range from routine and uncomplicated to difficult and life threatening. For many patients with a small vascular malformation in an anatomic location of minimal clinical consequence,

anesthesia for radiologic evaluation, radiologic intervention, or surgery can be safe and uneventful. However, anesthesia for vascular malformations can be more complicated because of anatomic location (airway), size and systemic involvement (congestive heart failure, thrombocytopenia, blood loss), and sequelae from therapeutic interventions (ethanol sclerotherapy).

Patients with hemangiomas or capillary malformations such as the port-wine stain may present for repeat laser treatments. For those patients with few or no comorbidities, these treatments can be performed in the outpatient setting. Typically, an inhalational anesthetic via a mask with or without IV access is all that is required. Lesions on the face or back may require an LMA or an endotracheal tube to secure the airway (Isago et al., 2006). Nitrous oxide, although safe for induction, may pose a fire hazard when laser treatments are near the face. Postoperative analgesia can be achieved with acetaminophen.

Vascular malformations involving the airway can lead to respiratory obstruction and OSA (Arneja and Gosain, 2008). In the anesthetized patient, there may be problems with ventilation and intubation (Nargozian, 2004; McLoughlin and McBrien, 2009). Some of the vascular malformations may not initially be obstructing lesions, but after sclerotherapy treatment or dependent positioning may swell dramatically leading to an obstructed airway (Sun et al., 2009). These patients may require alternative techniques to secure the endotracheal tube, such as a fiberoptic scope, the GlideScope, esophageal intubating devices, or intubating through an LMA. A hallmark of the management of the difficult pediatric airway is to secure the airway under general anesthesia while preserving spontaneous ventilation. When preservation of spontaneous ventilation under general anesthesia is not feasible, an awake or sedated intubation or tracheostomy is required. Patients with a consumptive process (Kasabach-Merritt syndrome) may be predisposed to intraoperative bleeding secondary to thrombocytopenia, and they may not be candidates for a regional anesthetic technique. However, regional anesthesia (intrathecal block) has been described in patients with Kasabach-Merritt syndrome when their platelet count is stable (Holak and Pagel, 2010).

Congenital Melanocytic Nevi

Congenital melanocytic nevi are pigmented, plaque-like skin lesions that are typically present at birth and persist and become more pigmented with age. They are classified by their size, which ranges from small to giant. Small nevi are 1.5 cm or less in diameter. Medium-sized nevi measure 1.5 to 19.9 cm in diameter, and large nevi have a diameter of greater than 20 cm. The giant nevi are significantly larger, with a diameter of greater than 50 cm. Small and medium nevi are more common and occur in approximately 1 in 1000 live births. Large nevi are less common and occur in 1 in 20,000 live births. Giant nevi are far less common and occur in only 1 in 50,000 births (Zaal et al., 2005). Besides the cosmetic concerns about congenital melanocytic nevi, there is the risk for malignant transformation, and this is an important consideration for removing these lesions. (Zaal et al., 2005) demonstrated in a large Dutch study that patients with congenital melanocytic nevi have a higher risk for developing malignant melanoma (15 cases in 19,253 person-years versus 1.2 expected cases), and the risk appears to be even higher in those with giant congenital melanocytic nevi. Some have reported melanoma rates as high as 10% in large

■ **FIGURE 25-20.** Tissue expanders placed circumferentially around the waist.

nevi, with the majority of the malignant transformations in the largest lesions occurring by puberty (Tromberg et al., 2005).

Prophylactic removal of large nevi is typically performed early in life. The complexity of the surgical management of congenital nevi depends on the size and the location of the lesion. Large nevi may require a staged excision or the use of tissue expanders (Fig. 25-20). Placement of tissue expanders may occur at as early as 6 months of age. The expanders can be placed in the scalp, forehead, trunk, back, and lower extremities. Expansion is performed gradually over weeks to months and may allow complete closure after the nevi is surgically removed. Other treatment modalities include dermabrasion, lasers (CO₂), and curettage. All of these techniques typically require general anesthesia. Patients with large congenital nevi may also require anesthesia for MRI evaluation for neurocutaneous melanosis. Patients with large nevi in axial locations (head, neck, back) are at increased risk for having melanocyte proliferation in the leptomeninges (pia and arachnoid mater). These melanocytes may malignantly transform and require radiologic surveillance (Lovett et al., 2009).

Anesthesia Management

Many surgical excisions for small and medium nevi in children and adolescents can be performed under local anesthesia in an office setting. Younger patients, or patients who are uncooperative, may require a general anesthetic to facilitate excision. For healthy patients, excisions can typically be performed in an office setting or an ambulatory surgical center. An inhalational anesthetic will achieve appropriate surgical conditions. Depending on the size of the lesion and its location, an IV and an LMA or endotracheal tube may be required. Larger lesions are more likely to require a general anesthetic because of the degree of tissue resection and undermining, the duration of the procedure, and the location of the lesion. Regional anesthesia can be combined with general anesthesia to ensure a pain-free postoperative course. The regional technique can be a neuraxial (single-shot caudal) or peripheral block, depending on the location and size of the surgical excision.

Trauma

Facial Fractures

Trauma to the facial skeleton may result in one or more fractures and may require surgical fixation. Typical facial fractures include zygoma fractures, Le Fort II, Le Fort III, mandible, orbital, nasal, and panfacial fractures. Depending on the mechanism of injury, there may be associated injuries, the most concerning of which is traumatic brain injury. In one study, 25% of patients diagnosed with facial fractures had associated injuries, including limb, brain, chest, spine, and abdominal injuries. Up to 10% of these patients had a brain injury (Thoren et al., 2010). Although only 2.7% of the patients had spinal injuries, almost all of these involved the cervical spine. Another study demonstrated that up to 69% of patients with mandible fractures had an associated traumatic brain injury. Although most of these patients had mild traumatic brain injury, up to 40% of them had a moderate to severe injury (intraparenchymal hemorrhage, epidural or subdural hemorrhage). Of concern, 20% of the patients with mild brain injuries had minimal signs or symptoms (Glasgow Coma Scale [GCS] 15, or no loss of consciousness), but they had an injury documented by computed tomography scan (Czerwinski et al., 2008). The hazard is that these brain injuries may be missed.

Anesthesia Management

Anesthesia management for the pediatric facial fracture patients begins with a complete trauma assessment to identify airway pathology and then to identify associated injuries. Patients at risk for a brain injury with an underlying intracranial lesion (mandible, facial fracture with GCS < 15 or loss of consciousness) should have a neurosurgical evaluation prior to anesthesia for their facial fractures.

Facial fractures involving the midface commonly result in airway compromise because of the displacement of the midface posteriorly into the oropharynx. Blood and secretions may also contribute to airway obstruction. One third of adult patients in one study with midface fractures required intubation (Ng et al., 1998). Patients with Le Fort III fractures developed more severe airway obstruction than patients with Le Fort I or II fractures. In fact, up to 40% of Le Fort III fractures required tracheostomy in one study of adults, compared with 9% of Le Fort I and II fractures (Bagheri et al., 2005).

The airway management of pediatric patients with facial fractures can be challenging. Those with mild injuries like an isolated zygoma or orbital floor fracture typically do not present a significant challenge. However, those patients with complicated midface fractures (Le Fort III) or panfacial fractures can present a dilemma. Children not properly fasted require either a rapid-sequence induction or a sedated fiberoptic intubation. All patients with suspected or known cervical injuries require cervical immobilization.

Facial fractures that result in malocclusion (mandible or Le Fort I) require maxillomandibular fixation (MMF). Intubation options that allow MMF include nasal or retromolar intubation. If there is concern for a full stomach and aspiration, the airway can be initially secured with an oral endotracheal tube after a rapid-sequence induction. The oral endotracheal tube can then be changed to a nasal endotracheal tube using direct laryngoscopy or fiberoptic guidance. The nasal

endotracheal tube can also be placed initially in the awake patient with sedation and topical local anesthetic.

This technique, however, is not an ideal option for the injured pediatric patient. The retromolar approach has been described for patients requiring MMF. This technique requires placing the endotracheal tube in the retromolar space, and it is meant for short-term intubation. The endotracheal tube can be sutured or wired in place by the surgeon. A smaller tube is recommended, and the anesthesiologist needs to be aware of the peak airway pressures once the tube is manipulated into this space (Lee et al., 2009).

The airway options for the patient with midface fractures or panfacial fractures include the placement of an oral endotracheal tube, submandibular airway, or tracheostomy. If MMF is not required, an oral intubation can be performed. In the patient who requires either MMF or long-term intubation, a submandibular airway or tracheostomy is recommended. A nasotracheal intubation is relatively contraindicated in patients with significant midface fractures (Le Fort II and III) because of concern for neurologic injury in those with a skull base (cribriform plate) fracture.

Traditionally, a short-term tracheostomy was recommended for patients with panfacial fractures because of the prolonged intubation in a patient with a potentially difficult airway or MMF. However, tracheostomy has an associated morbidity, and some have advocated a submental or submandibular approach to the airway (Amin et al., 2002; Anwer et al., 2007). The technique is performed after the patient is anesthetized and orally intubated. An armor-reinforced tube is recommended to prevent kinking. A small submandibular incision is made by the surgeon and bluntly dissected until it communicates with the floor of the mouth. The endotracheal tube cuff and then the end of the endotracheal tube (without the adaptor for the circuit) can be passed through this opening with the assistance of curved forceps or hemostats. The tube is sutured in place (Fig. 25-21). The submandibular airway can be removed at the end of surgery or can be left in place for several days (Amin et al., 2002; Anwer, 2009). This technique has been described for young adolescents (12 years old) (Eipe et al., 2005) and children as young as 6 years (Amin et al., 2002). Patients that are placed in MMF should have wire cutters at the bedside to release the fixation in case of an airway emergency. Even in skilled hands, this may

■ FIGURE 25-21. Submandibular intubation.

not be quick. In one study, surgeons were able to remove the fixation in 30 seconds, but nonsurgical hospital staff took more than 2 minutes (Goss et al., 1979).

EXTREMITY SURGERY

Hand Surgery

Congenital hand anomalies are numerous and varied. A classification of hand anomalies and descriptions of specific defects follow. Approximately 1 in 600 infants is born with some form of congenital hand anomaly. The terminology of hand anomalies (Table 25-5) reflects the type, classification, and degree of the defect (Netscher and Baumholtz, 2007). Surgical correction is needed for many of them. The American Society of Surgery of the Hand has created a classification of these anomalies (Box 25-1).

Most anomalies can be surgically managed after the first year of life, but there are a few indications for neonatal hand surgery. Neonates with a superficial extra digit (attached by skin) can have it removed easily with local anesthesia and ligation without general anesthesia or sedation. Constriction bands that compromise circulation or lymphatic drainage often require urgent surgical correction in the neonatal period.

Anomalies that require surgical correction after the neonatal period but before 1 year of age are the syndactylies that occur between fingers of unequal length (Fig. 25-22). Hands exhibit a growth spurt by 2 years of age. Digits of unequal length that are fused together may need to be separated before significant hand growth occurs, because the anomalous growth of one of

■ FIGURE 25-22. Hand syndactyly.

the digits may alter the growth of the other digit if they remain tethered together. Also, surgeries that affect critical hand function, such as opposition, need to be performed early so the development of grasping skills is not delayed. Thus, pollicization, movement of the index finger into the thumb position for a baby without a thumb, may be done on the early side, so that the child can grasp things with the thumb and perform the critical function known as opposition.

Brachial Plexus Palsy

Obstetric brachial plexus palsy is defined as an injury or a disruption to one or more of the trunks (C5 to T1) of the brachial plexus. The injury occurs at an incidence of 0.4 to 4 per 100 vaginal births and decreases significantly for cesarean sections but does not decrease to zero. Usually the injury occurs during passage through the birth canal. Perinatal risk factors for a brachial injury are thought to include large size for gestational age, shoulder dystocia, breech presentation, prolonged labor, and history of previous brachial plexus injuries (Waters, 2005). Patients present with varying degrees of motor and sensory loss of the upper extremity, depending on the type of injury.

The injuries are categorized into four groups, and the groupings predict outcome and guide recommendations for surgical intervention. Group one, involving an injury to the C5 to C6 trunks only, is the most common injury and accounts for approximately 50% of brachial plexus injuries. This upper trunk lesion is commonly called an Erb's palsy. This group has the best prognosis. Group two involves an injury or disruption to the C5 to C7 trunks. Nearly 30% of patients with brachial plexopathy have this injury, and its prognosis is worse than for group one. Group three involves the entire brachial plexus (C5 to T1), with complete loss of function of the entire upper extremity. This injury pattern is seen in 20% of patients. Group four is the most severe, with injury to the entire brachial plexus, including the sympathetic chain. This injury most likely involves an avulsion at or near the spinal cord. These patients have complete loss of motor function of the upper extremity and Horner's syndrome (ptosis, miosis, and anhydrosis). They may also have other motor injuries involving the phrenic, long thoracic, dorsoscapular, and suprascapular nerves (Hale, 2010).

TABLE 25-5. Terminology for Hand Anomalies

Term	Definition
Brachy-	Short
Clino-	Bent
Campto-	Flexed
Phoco-	Shortened or "seal-like"
-Melia-	Extremity
Syn-	Side-to-side fusion
Sym-	Longitudinal fusion

From Netscher DT, Baumholtz MA: Treatment of congenital upper extremity problems, *Plast Reconstr Surg* 119:101e–129e, 2007.

Box 25-1 Types of Congenital Hand Anomalies

Failure of formation of parts (amelia, phocomelia)
 Failure of differentiation (syndactyly, clinodactyly)
 Duplication (polydactyly)
 Overgrowth (macrodactyly)
 Undergrowth (hypoplastic thumb)
 Constriction band syndrome
 Generalized skeletal deformity (dwarfism)

From Netscher DT, Baumholtz MA: Treatment of congenital upper extremity problems, *Plast Reconstr Surg* 119:101e–129e, 2007.

Most brachial plexus injuries are transient and resolve with time alone. Physical therapy often helps to keep the shoulder joint supple while the nerves are recovering. Surgical repair is recommended for patients with group four injuries who are less than 3 months old. The timing and role of brachial plexus surgery become more controversial in those patients in groups one to three who do not demonstrate clinical recovery by 6 to 9 months of age. Surgical repair often involves exploration and resection of the neuroma and placement of a nerve graft. Nerve grafts can be harvested from several locations but the sural nerve is most often used (Waters, 2005; Hale et al., 2010). Neurolysis may be performed if the nerve appears completely normal but is encased by scar (Clarke, 2007).

Anesthesia Management

The anesthesia management of the pediatric patient presenting for upper extremity surgery begins with a thorough preoperative evaluation. Infants and children with hand anomalies may have underlying systemic disorders. Some of the syndromic craniofacial anomalies (Apert and Pfeiffer syndromes) may have associated upper extremity anomalies that need hand surgery. The anesthesia issues concerning these syndromes are outlined in [Table 25-1](#). Patients with epidermolysis bullosa present for hand surgery because of the pseudosyndactyly from dermal loss. Anesthesia for these patients is described in Chapter 36, Systemic Disorders.

Other syndromes involving the hand may also involve the heart. Holt-Oram syndrome, otherwise known as hand-heart syndrome, exhibits varying degrees of congenital cardiac disease and arrhythmias (Shono et al., 1998). The degree of hand pathology does not predict the degree of cardiac involvement. A history consistent with cardiac pathology (poor feeding, sweating with feeding, cyanosis, syncope) or a heart murmur on examination warrants a cardiac evaluation before surgery. Patients with radial anomalies (aplasia) may have an associated VATER (vertebral defects, imperforate anus, tracheoesophageal fistula, radial and renal dysplasia) association. These patients require a preoperative evaluation to identify cardiac, renal, and vertebral anomalies. Radial anomalies also occur with the TAR (thrombocytopenia-absent radius) syndrome. The Poland sequence, also associated with upper extremity anomalies, starts with an initial chest wall deformity and then subsequent ipsilateral upper extremity anomalies. These patients may have significant thoracic insufficiency (Sethuraman et al., 1998).

Patients with brachial plexus injury should be evaluated for the degree of injury. Many patients presenting for surgery have a group four injury, which involves injury to the entire brachial plexus and the sympathetic chain. Horner's syndrome should be noted preoperatively. A small number may have injury to the phrenic nerve as well. This may affect respiratory reserve, and the anesthesia team should be aware of this preoperatively. Often the surgeon will have obtained a preoperative ultrasound of the diaphragm to diagnose this before the operation.

When patients having hand surgery are otherwise healthy, general anesthesia can be used, with or without peripheral nerve blockade. Older patients can have hand procedures with a regional technique as the primary anesthetic (see Chapter 16, Regional Anesthesia). Anesthesia can be achieved with an inhalation or IV induction. Airway management depends on the size of the patient, coexisting disease, and duration of surgery. Infants having procedures with surgical field avoidance most likely require endotracheal intubation. Otherwise, larger healthy children can have their airway managed with an LMA. Patients with congenital heart disease do not require subacute endocarditis prophylaxis for hand surgery.

Patients presenting for surgical repair of the brachial plexus require a general anesthetic. The airway is managed with an endotracheal tube, as the surgery is long and the surgical field is close to the airway. It is important to secure the endotracheal tube well, because the head and shoulder may be moved during the operation. Use of a transparent drape for the uppermost sterile drape can help the anesthesiologist monitor the endotracheal tube position (Clarke, 2007). Neuromuscular blockade may be used for intubation, but a short- or intermediate-acting agent should be used and should not be repeated if the surgeons are using neuromuscular monitoring. Remifentanyl with an inhalation or IV anesthetic will help produce a profound level of anesthesia and akinesia in those patients where neuromuscular blockade is avoided. The surgical repair of the brachial plexus may be lengthy and may require exposure of large areas of the infant. Sometimes both lower extremities are exposed and prepared so as to harvest the sural nerve. Proper padding is essential to minimize risk for pressure injuries, and multiple warming devices (forced hot air devices and warming lamps) may be required to maintain normothermia.

SUMMARY

The anesthetic management of the pediatric patient receiving plastic surgery can be varied and complex. Many of these patients have minimal coexisting disease and can be treated in an outpatient or third-world setting. However, some have multisystem involvement and life-threatening pathologies requiring intensive intraoperative and postoperative care. Also, these patients are cared for by multiple pediatric subspecialties including neurosurgery and otorhinolaryngology. Having an appreciation of the range of clinical disease states and surgical interventions required for the pediatric plastic surgery patient is essential for the pediatric anesthesiologist.

	Summary 869

The topic of anesthesia for pediatric orthopedic surgery encompasses the entire age and medical spectrum of pediatrics and includes the newborn and adolescent, the otherwise normal, the chronically ill, the patient with multiple complex congenital anomalies, the patient with emergent trauma, the elective inpatient, and the outpatient. Orthopedic surgeons operate on virtually every area of the body from the cervical spine to the pelvis to the toes. In many instances, the perioperative anesthesia plan for pediatric orthopedic patients depends more on their ages, on the site and emergent nature of surgery, and on the need for perioperative analgesia and sedation, than it does on the underlying disease or the specifics of the surgical procedure. In other cases, the underlying medical condition, associated anomalies, pathophysiology, and surgical procedure dictate the anesthesia plan. Positioning the patient on the operating room table may be difficult because of deformities or contractures, and often patients require special operating tables or frames to achieve the best posture for surgery. The anesthesiologist must be aware of unusual associated syndromes that have clear orthopedic implications, and syndromes with underlying clinical significance unrelated to the orthopedic condition. Conditions that are commonly encountered in pediatric orthopedic surgery and their anesthesia implications are listed in [Table 26-1](#), but the list is by no means comprehensive (Campbell, 2009). The Online Mendelian Inheritance in Man website (www.ncbi.nlm.nih.gov/omim) is a good source for this information.

Orthopedic surgery is among the most common types of surgery performed in the United States. Technological advances permit more sophisticated orthopedic diagnoses, and they have vastly expanded the range of treatment options and operations available to the orthopedic surgeon. Moreover, technological, physiologic, and pharmacologic advances in anesthesiology have allowed the orthopedic surgeon to contemplate longer, more extensive, and more innovative operations on younger and sicker patients than were ever before possible. Regardless of the underlying condition, almost all orthopedic surgical procedures have recurring anesthesia concerns, including positioning, airway management, blood loss and fluid replacement, conservation of body temperature, and postoperative pain and sedation management.

A common feature of children with orthopedic diseases, particularly patients with congenital anomalies, generalized constitutional diseases of bone and cartilage, or connective tissue disorders, is the significant disability that affects their everyday lives. Some of these children must undergo multiple hospitalizations, anesthetics, and surgical procedures. A single bad anesthesia experience can have an impact on care for years, and an individualized approach is necessary. Sometimes, these children are overwhelmingly fearful and may be completely terrorized by the hospital experience. Simply approaching these children in hospital clothing may elicit screams of terror. Others are seasoned veterans and have

TABLE 26-1. Anesthetic Implications of Commonly Encountered Orthopedic Disorders

Disease	Surgical Interventions	Anesthetic Implications
Congenital Malformations		
Amniotic band constriction	Soft tissue release	May have facial clefts
Clubfoot	Tendon lengthening, release	Dictated by associated malformations
Klippel-Feil syndrome	Release, scoliosis	Hemifused or fused vertebra; limited cervical spine mobility; possible difficult intubation; heart defects
Radial dysgenesis	Tendon lengthening, pollicization release	Episodic thrombocytopenia; congenital heart disease
Sprengel's deformity	—	Associated only with Klippel-Feil syndrome
Trisomy 21 (Down syndrome)	Cervical spine fusion	Large tongue; usually easy intubation; in-line stabilization during intubation; congenital heart disease; opioid sensitivity
Acquired Conditions		
Charcot-Marie-Tooth disease	Tendon transfer	Possible sensitivity with nondepolarizing muscle relaxants; succinylcholine may result in hyperkalemia
Legg-Calvé-Perthes disease	Osteotomies, pinning	None known
Osteomyelitis	Culture, aspiration	Systemic bacterial infection
Septic arthritis	Culture, irrigation	Systemic bacterial infection
Slipped femoral capital epiphysis	Pinning	Obesity
Tumors, benign	Excision, curettage	Possible significant blood loss; pathologic fracture
Tumors, malignant	Radical excision, amputation	Blood loss; metastasis: CNS, lung; chemotherapy; cardiotoxicity
Syndromes, Inherited Conditions		
Apert syndrome and Crouzon's disease	Syndactyly repair; craniosynostosis; hypertelorism	Airway usually normal, but occasional mandibular hypoplasia; cardiac defect
Ellis-van Creveld syndrome	Polydactyly	Cardiac defects; bronchial collapse
Holt-Oram syndrome	Tendon lengthening, pollicization release	Cardiac defects (ASD, VSD)
Jeune syndrome (asphyxiating thoracic dystrophy)	Chest reconstruction, scoliosis	Respiratory failure, prolonged mechanical ventilation; renal failure
Marfan syndrome	Scoliosis	Cardiac (AI, MR), aortic aneurysm
Moebius sequence	Syndactyly	Micrognathia; cleft palate; cranial nerve palsy
Osteogenesis imperfecta	Pathologic fractures, scoliosis	Fractures on positioning or intubation; hypermetabolic fever, platelet dysfunction; blood pressure cuff may cause fractures
VATER (vertebral, anal, tracheal esophageal fistula, renal, cardiac)	Tendon lengthening, pollicization release	Cardiac defects; tracheoesophageal fistula
Short-Stature Syndrome		
Achondroplasia	Spinal fusion, cervical decompression, Ilizarov	Poor cervical mobility, difficult arterial catheterization
Morquio-Ullrich disease	Cervical spine fusion	Poor cervical mobility, difficult airway
Mucopolysaccharidoses (Hurler's, Hunter's, Morquio's syndromes)	Kyphoscoliosis, bony abnormalities	Very difficult intubations; unstable necks; respiratory failure perioperatively
Systemic Disease		
Juvenile rheumatoid arthritis	Varies	TMJ ankylosis; cervical spine immobility or instability; carditis; occasional pulmonary involvement; difficult airway
Neurofibromatosis	Scoliosis	CNS tumors; occasional pheochromocytoma
Sickle cell anemia	Osteomyelitis, Legg-Calvé-Perthes disease, pathologic fracture	Anemia; vasoocclusive crisis; acute chest syndrome; stroke; hypothermia; hypoxia; hypovolemia; immunocompromised host; avoid tourniquet when possible

TABLE 26-1. Anesthetic Implications of Commonly Encountered Orthopedic Disorders—cont'd

Disease	Surgical Interventions	Anesthetic Implications
CNS Diseases		
Arthrogryposis multiplex	Tendon releases (multiple congenital contractures), scoliosis	Difficult intubation (TMJ ankylosis, cervical spine immobility); GE reflux; postoperative upper airway obstruction; congenital heart disease
Cerebral palsy	Tendon releases	GE reflux; postoperative upper airway obstruction
Myelomeningocele	Lower extremity tendon releases, scoliosis, kyphosis	Hydrocephalus
Werdnig-Hoffmann disease	Scoliosis	Respiratory insufficiency; bulbar involvement (poor secretion handling); succinylcholine-induced hyperkalemia
Myopathies		
Duchenne's muscular dystrophy	Tendon releases, scoliosis	Respiratory insufficiency; cardiomyopathy; succinylcholine-induced hyperkalemia; anesthesia induced rhabdomyolysis
Myotonia dystrophica	Tendon releases	Succinylcholine-induced myotonic spasm; cardiac conduction system involvement; avoid direct muscle stimulation

very specific desires about who should treat them and how they are to be anesthetized. For example, some may prefer an intravenous (IV) induction to a mask induction, or have specific sites in which they want their IV placed. Thus, the anesthesiologist must have knowledge of the particular surgeon, the procedure, the positioning of the patient, and the expected duration of the procedure.

SCOLIOSIS

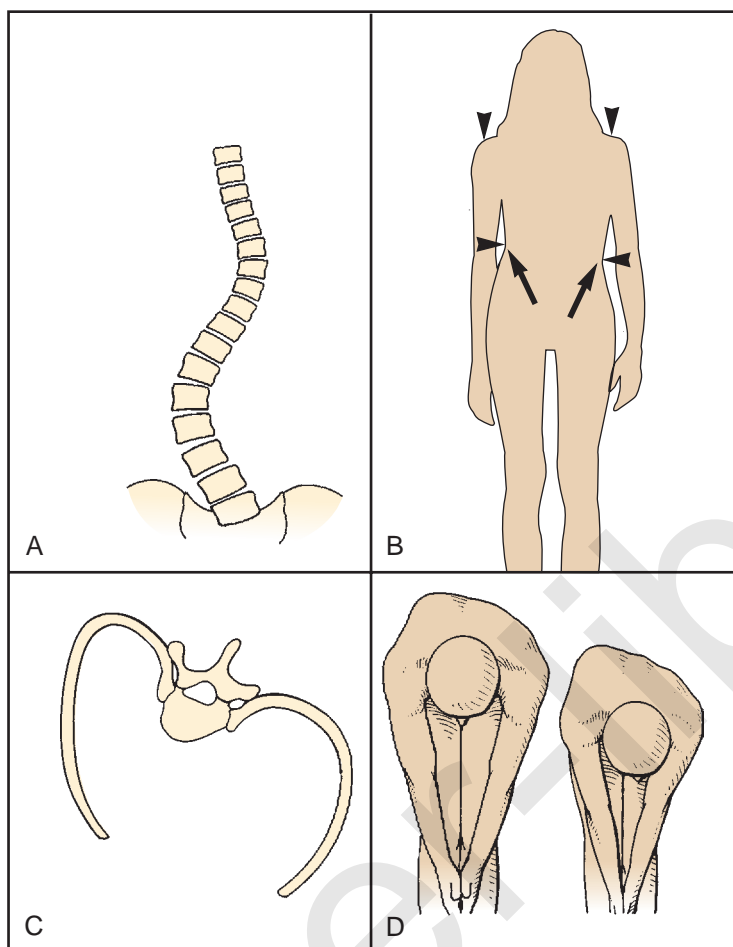

Scoliosis, derived from the Greek root meaning “crooked,” is a lateral and rotational deformity of the thoracolumbar spine. With progression of the lateral spinal curvature, the spinous processes rotate toward the concave side of the curve. The ribs on the convex side are pushed posteriorly by the rotating spine, forming the characteristic gibbous deformity. The ribs on the concave side become prominent anteriorly and are crowded together. Occasionally, scoliosis is associated with kyphosis (“humpback”) or lordosis (“bent backward”) (Fig. 26-1).

The progression of scoliosis and the severity of its systemic manifestations correlate with the angle of curvature measured by the Cobb method (Table 26-2)—that is, the angle between the upper surface of the top vertebra and the lower surface of the bottom vertebra. The end vertebrae are those that are maximally tilted. Perpendicular lines are extended from these end vertebrae to the center of the curve. The angle formed by the intersecting perpendiculars determines the angle of curvature (Fig. 26-2). The curve is defined as facing to the right or to the left, depending on the convexity of the curve. A lateral curve of greater than 10 degrees is abnormal. Respiratory impairment rarely occurs with a curvature of less than 60 degrees.

Epidemiology and Etiology

The overall prevalence of spinal deformities in the North American population is between 1% and 2% (Weinstein et al., 2003). Curves can be described on the basis of their anatomic configurations, age of onset, and associated pathology. In the past, polio and tuberculosis infection were the most common causes. Today, most cases of scoliosis are classified as idiopathic because the basic pathophysiology is unknown. Pedigree analysis suggests that scoliosis is a sex-linked trait with variable expression and incomplete penetrance (Xiong and Sevastik, 1998; Lowe et al., 2000). The most common types of scoliosis are listed in Box 26-1.

Congenital scoliosis is a curvature of the spine that is the result of a rib or vertebral anomaly. *Idiopathic scoliosis* is the most common of the spinal deformities and has three periods of onset, all coincident with periods of rapid growth spurts: infantile (<3 years old), juvenile (3 to 10 years old), and adolescent (>10 years old). Progression of the deformity depends on the age of onset. *Infantile idiopathic scoliosis* is associated with an increased incidence of mental retardation, inguinal hernias, congenital dislocation of the hip, and congenital heart disease. *Juvenile idiopathic scoliosis* can usually be managed conservatively (Lowe et al., 2000). *Adolescent idiopathic scoliosis* is the most common form of scoliosis and occurs most commonly in girls (Weinstein et al., 2003). The curve may resolve, remain stable, or progress in severity. The most significant prognosticators of curve progression in girls are age at onset, premenarchal status, and bone age (Table 26-3) (Lowe et al., 2000; Ahn et al., 2002). Postulated mechanisms for the progression of adolescent idiopathic scoliosis include abnormal vertebral ossification, leptin-induced increased sympathetic nervous system activity, and increases in platelet-derived calmodulin (Lowe et al., 2004; Burwell et al., 2008; Burwell et al., 2009; Gu et al., 2009). *Exotic*

■ **FIGURE 26-1.** Structural changes in idiopathic scoliosis. **A**, As curvature increases, alterations in body configuration develop in the primary and compensatory curve regions. **B**, Asymmetry of shoulder height, waistline, and elbow-to-flank distance are common findings. **C**, Vertebral rotation and associated posterior displacement of the ribs on the convex side of the curve are responsible for the characteristic deformity of the chest wall in scoliosis patients. **D**, In the school screening examination for scoliosis, the patient bends forward at the waist. Rib asymmetry of even a small degree is obvious. (From *Scoles PV: Spinal deformity in childhood and adolescence*. In Behrman RE, Vaughn VC III, editors: Nelson textbook of pediatrics, ed 5, Philadelphia, 1989, Saunders, pp 925–933.)

scoliosis is a term introduced by Campbell and Smith (2007) to describe the spinal deformity found in rare pediatric conditions that pose special challenges beyond simply correcting the spinal curve. These very complicated patients with early-onset spinal deformity often tax the multisubspecialty resources of even the

most sophisticated pediatric centers. Examples include patients with Jeune and Marfan syndromes.

Natural History

The natural history of scoliosis varies according to the cause and the pattern of vertebral involvement. Uncorrected, scoliosis results in curve progression, cosmetic deformity, back pain, and physiologic compromise (Weinstein et al., 2003). In most cases of idiopathic scoliosis, the spinal curvature remains small, and conservative nonoperative management is appropriate (Richards et al., 1976). In 0.2% to 0.5% of cases, the curve increases, necessitating surgical intervention (Ahn et al., 2002). In patients with idiopathic scoliosis, only those with thoracic apices and curves of greater than 100 degrees are at increased risk for death from cor pulmonale and right ventricular failure (Asher and Burton, 2006). The grim prognosis of early death and respiratory failure is untrue in most patients with idiopathic scoliosis (Weinstein et al., 1981). The timing of surgery for this condition is controversial. The worse the curve and the more compromised the cardiorespiratory function, the greater

TABLE 26-2. Correlation of Angle of Curve and Symptoms in Patients with Scoliosis

Angle of Curvature	Significance
<10	Normal
>25	Echocardiographic evidence of increased pulmonary artery pressures
>40	Surgical intervention
>65	Restrictive lung disease
>100	Symptomatic lung disease, dyspnea on exertion
>120	Alveolar hypoventilation

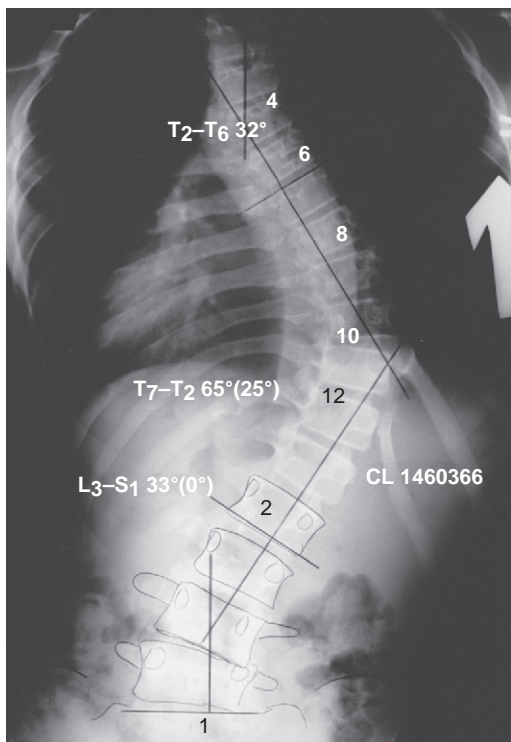

FIGURE 26-2. Standing posteroanterior radiograph from a 13-year-old girl with a severe right thoracic section. Notice the Cobb measurement technique. The Cobb angle is derived by drawing lines parallel to the superior surface of the proximal-end vertebra and the inferior surface of the distal-end vertebra. Perpendiculars to these lines are erected, and the angle of intersection of these lines is measured. The numbers in parentheses indicate the degree of correction of the deformity on side-bending radiographs. (From Thompson GH: *The spine*. In Behrman RE, editor: Nelson textbook of pediatrics, ed 16, Philadelphia, 2004, Saunders, pp 2280–2284.)

the risk for perioperative morbidity and mortality. The pulmonary hypertension of progressive uncorrected idiopathic scoliosis often results in life-compromising respiratory failure in the fourth or fifth decade (Taylor and Gropper, 2006).

Respiratory Sequelae

Even asymptomatic scoliotic patients have demonstrable abnormalities in pulmonary function. As the degree of curvature progresses, vertebral rotation leads to thoracic cage asymmetry and deformation; lung volumes and pulmonary compliance are often but not always inversely related to the degree of this curve (Newton et al., 2005). When the scoliotic curve is greater than 65 degrees, pulmonary function tests demonstrate the characteristic pattern of restrictive lung disease. The first manifestation of this restrictive lung disease is a reduction in vital capacity; in many cases, the vital capacity (normal, 60 mL/kg) is severely reduced, often to less than 60% of predicted. Of the subdivisions of vital capacity, inspiratory capacity is affected to a greater extent than expiratory reserve volume. Functional residual capacity and residual volume are not as severely affected. These alterations in lung volumes are referable to the scoliotic changes in chest wall compliance and the resting position of

TABLE 26-3. Incidence of Scoliotic Curve Progression at Time of Diagnosis of 10-Degree Curve

Age	Menarchal Status	Bone Maturity
<11 yr (88%)	Premenarche (53%)	Immature (68%)
>15 yr (29%)	Postmenarchal (11%)	Mature (18%)

the thoracic cage, rather than to parenchymal changes. The thoracic deformity of early-onset scoliosis damages pulmonary vascular development and inhibits physiologic alveolar growth, also producing decreases in pulmonary volumes (Charles et al., 1976; Fernandes and Weinstein, 2007).

The pulmonary impairment that results from the scoliosis of neuromuscular disease is exacerbated by coexisting abnormalities in central respiratory drive, coordination of swallowing, and innervation of the upper airway and respiratory musculature. Pulmonary dysfunction in these patients is exacerbated by an increased frequency of respiratory infections, a predilection to aspiration, and an impaired ability to clear pulmonary secretions. Patients who have abnormal results on their pulmonary function test, particularly a forced vital capacity (FVC) of less than 30%, or those who have hypercapnia preoperatively will probably require postoperative (or chronic) ventilation (Almenrader and Patel, 2006). Maximum inspiratory and expiratory mouth pressures ($P_{i_{max}}$, $P_{e_{max}}$) that the patient can generate against airway occlusion are the important indices for his or her ability to reexpand the lungs ($P_{i_{max}} \leq 40$ cm H₂O)

and to expel secretions (coughs, $P_{e_{\max}} > 40$ cm H₂O). Unless the patient can generate more than these threshold pressures preoperatively, postoperative admission to the intensive care unit for ventilatory support should be anticipated.

Cardiovascular Sequelae

Mitral valve prolapse is found in 25% of patients with scoliosis but in less than 10% of age-matched controls. Echocardiographic evidence for increased pulmonary artery pressures has been demonstrated in individuals with only modest degrees of scoliosis in the absence of abnormal pulmonary function. Patients with angles of curvature greater than 70 degrees develop pulmonary hypertension on exercise; those with curves greater than 110 degrees have mean pulmonary artery hypertension at rest. Kafer (1980) proposed that this increase in pulmonary vascular resistance is not just the result of lung compression from thoracic cage abnormalities but is also the result of an increased incidence of hypoxic pulmonary vasoconstriction (Schur et al., 1984). In addition, development of the pulmonary vascular bed may be impaired, resulting in a fundamental reduction in the number of functional vascular units per lung (Kafer, 1980; Schur et al., 1984). Chronic hypoxia induces pulmonary vascular remodeling, which contributes significantly to the pulmonary hypertension in these patients (Morrell et al., 2009).

Any child with a myopathy or borderline respiratory status should have an electrocardiogram and an echocardiogram performed to assess the presence of cor pulmonale, ventricular wall motion, ejection fraction, and ventricular wall thickness. Many myopathies, particularly Duchenne's muscular dystrophy, involve cardiac muscle and skeletal muscle (Manzur and Muntoni, 2009; Strehle, 2009). Duchenne's muscular dystrophy is the most common muscular dystrophy in children who present for surgery. An X-linked recessive disorder, this progressive, debilitating disease affects skeletal, cardiac, and smooth muscle. Typically, afflicted boys become wheelchair dependent by the age of 10 years, and in the past, death from respiratory or cardiac failure occurred in this population before the age of 20. With the introduction of contemporary cardiopulmonary interventions, including noninvasive home ventilation, these men are living to previously unprecedented ages (Birnkrant et al., 2007; Birnkrant, 2009). Scoliosis is common, and surgery is often performed to improve the quality of life (see Chapter 3, Respiratory Physiology in Infants and Children).

Numerous anesthesia challenges are presented by patients with Duchenne's muscular dystrophy. Clinically significant cardiomyopathies and rhythm disturbances manifest by 10 years of age (see Chapter 36, Systemic Disorders). Many of these children are obese because of muscle weakness, fatty degeneration of muscle fibers, and lack of exercise. Succinylcholine can cause a fatal hyperkalemia in these patients, who may present for surgery before the diagnosis has been definitively made; therefore, the routine use of this muscle relaxant is no longer recommended in all children (Birnkrant et al., 2007; Birnkrant, 2009; Gurnaney et al., 2009).

Preoperative Evaluation

The most important aspects of the preoperative evaluation include determination of the location and degree of spinal

curvature, the cause of the scoliosis, the patient's history of exercise tolerance, respiratory symptoms, and the presence of coexisting diseases. A directed physical examination of the cardiorespiratory system should evaluate the presence of tachypnea, crackles, wheezing, and signs of right heart failure, such as hepatomegaly, jugular venous distention, and peripheral edema. Any preoperative neurologic deficits should be recorded. Based on the severity of the curve and the degree of respiratory impairment, the preoperative laboratory studies listed in Box 26-2 should be requested.

Right heart involvement is reflected in the findings of right ventricular hypertrophy and right axis deviation on the electrocardiogram. Estimates of the degree of pulmonary hypertension may be made by evaluating the right systolic time interval and the velocity of tricuspid regurgitation on the echocardiogram. Pulmonary function tests are useful in establishing the risk for pulmonary complications in the immediate postoperative period. An FVC of less than 30 mL/kg (or <50% of predicted), or a forced expiratory volume at 1 second (FEV₁) that is less than 50% of predicted, usually indicates postoperative respiratory insufficiency and the need for prolonged postoperative mechanical ventilation. With the airway occluded, peak inspiratory and expiratory forces of at least -30 cm H₂O and +40 cm H₂O, respectively, are necessary for effective sighs and postoperative coughing and expulsion of secretions.

Children with myelodysplastic syndromes are likely to develop an allergy to latex products (Kelly et al., 1994; Maxwell, 2004; Dewachter et al., 2009). All children with any of these syndromes should be considered allergic to latex, and nonlatex products (e.g., tourniquets, sterile and nonsterile gloves) should be substituted for the latex equivalents. Corticosteroids and antihistamines are not administered prophylactically.

Surgical Techniques

The treatment of spinal curvature is dictated by the type of scoliosis and by the surgeon's expertise and preferences. Very few cases of congenital scoliosis can be managed conservatively. The mainstay of therapy is posterior spinal fusion without instrumentation, followed by prolonged immobilization.

Box 26-2 Preoperative Tests for Scoliosis Surgery

- Chest radiography
- Electrocardiography
- Echocardiography
- Pulmonary function tests
 - Arterial blood gas
 - Spirometry
 - Forced vital capacity (FVC)
 - Forced expiratory volume at 1 second (FEV₁, FEV₁/FVC)
 - Peak expiratory flow rate (PEFR)
 - Peak inspiratory pressure ($P_{i_{\max}}$)
 - Peak expiratory pressure ($P_{e_{\max}}$)
- Coagulation studies
 - Platelet count
 - Prothrombin time, partial thromboplastin time
 - Electrolyte panel
 - Liver function tests

Instrumentation in these patients has been associated with a prohibitively high rate of paraplegia, which is presumed to be the result of coexisting cord and vertebral anomalies. Although conservative therapy is the most frequently used treatment for idiopathic scoliosis, when rapid curve progression is anticipated, surgical intervention is used for severe truncal deformities and for pain unrelieved by medical therapy (Weinstein et al., 2003).

Posterior Spinal Fusion

The goal of scoliosis surgery is to achieve a spinal fusion and stabilization of the curve. After incision through the supraspinal ligament, the paraspinous musculature is reflected. The vertebral laminae are decorticated, the facet joints are destroyed, and the spinous processes are removed so that raw cancellous bone is exposed. Bone graft obtained from the iliac crest, ribs on the convex side, or the bone bank is cut into matchstick-size strips and packed over the decorticated surfaces, mainly on the concave side. The fusion extends from one vertebra above the curve to the second vertebra below. Instrumentation is usually inserted to hold the spine in the best possible position while fusion is accomplished. Without a properly performed fusion, the instrumentation ultimately fatigues.

Several instrumentation techniques are available for treatment of the scoliotic spine. The *Harrington rod*, the original instrumentation system, consists of a stainless steel rod that is connected to the inferior facets and pedicles of the spine by multiple ratchet hooks placed at the terminal aspects of the curve. Distraction is adjusted using the ratchet principle (Harrington and Dickson, 1976; Harrington, 1988). The incidence of neurologic complications after this technique is 0.23%. The disadvantages of the Harrington rod include two-dimensional correction, curvature distraction by the end hooks, and the need for prolonged postoperative immobilization. Because of these problems, this technique is rarely used.

Segmental spinal instrumentation was introduced to provide three-dimensional correction and to achieve differential distraction at multiple levels. The *Luque instrumentation system* consists of sublaminar wires on each side of the spinous process and a long, L-shaped rod that can be contoured three dimensionally. The curve is corrected as the wires are tightened (Luque, 1986; Luque and Rapp, 1988). The internal fixation achieved is more rigid than that obtained with the Harrington system, and it can be extended to the pelvis. The most common deficit after Luque rod instrumentation is a dysesthesia, which is usually observed late (2 to 6 days) in the postoperative period. The proposed mechanism for these findings is expansion of an epidural hematoma in the area of the sublaminar wires (Johnston et al., 1986).

The *Cotrel-Dubousset segmental spinal instrumentation system* uses multiple laminar and pedicular hooks attached to a double-rod frame (Richards and Johnston, 1987). This system enables three-dimensional correction of complex curves and obviates the need for postoperative immobilization. It is more time consuming than the Harrington system, increases intraoperative blood loss, and has a lower incidence (0.6%) of neurologic complications than Luque rods. Double-curve patterns are more complex and require multiple hooks at multiple fixation sites, necessitating more extensive decortication and contributing to additional blood loss.

Pedicle screws are the most recent advance in posterior spinal fusion (Kim and Noonan, 2009). Initially used for lumbar curves, they are now used for total curve correction. The limitation of posterior spinal fusion with or without instrumentation is that the anterior growth plates, which play a major role in the development of the deformity, are not affected. Late torsional deformities can result.

Anterior Spinal Surgery

The anterior approach to spinal deformities has been advocated for several specific deformities, including severe kyphosis and lordotic paralytic curves in patients with cerebral palsy. Surgery consists of discectomies with or without instrumentation, performed alone or in combination with a posterior spinal fusion. Video-assisted thoracoscopic surgery can be used for this procedure if instrumentation is not being used (Sucato, 2003). The surgical approach used to expose the anterior portion of the spine depends on the exact spinal deformity. Thoracic curves are usually approached through a left thoracotomy, and the procedure is facilitated by insertion of a double-lumen endotracheal tube and one-lung ventilation. Alternatively, single-lung ventilation in young children is performed by advancing a tracheal tube into the main stem bronchus opposite the side of surgery, or by positioning a bronchial blocker into the main stem bronchus on the operative side.

Many techniques for placing a variety of bronchial blockers outside the tracheal tube have been described for use in children (see Chapter 23, Anesthesia for General Abdominal, Thoracic, Urologic, and Bariatric Surgery) (Hammer, 2001, 2004; Hammer et al., 2002). The combined curve of the thoracolumbar spine is exposed transdiaphragmatically by means of a high subcostal incision that necessitates taking the diaphragm down from its bony insertion. Lumbar curves can be approached extraperitoneally or transabdominally. In general, complications of the anterior approach include great vessel disruption, hemothorax, pneumothorax, paralytic interruption of spinal cord perfusion, and excessive angulation or compression of the spinal cord by rapid distraction of the curvature. Spinal cord injury can result from mechanical damage by a screw or disruption of segmental spinal arteries. At the beginning of the 21st century, performance of anterior scoliosis surgery diminished because of the corrective power of pedicle screw constructs and better surgical methods designed to improve flexibility, such as posterior release, posterior osteotomy, and vertebral resection (Kim and Noonan, 2009).

As an alternative to open thoracotomy, a video-assisted thoracoscopic surgery (VATS) approach is being used to perform anterior thoracic spine release in patients who require both anterior and posterior procedures to correct their scoliosis. The appropriate use of pedicle screws has resulted in a 50% to 66% curve correction, with good maintenance of the curve correction for a minimum of 3 years (Lehman et al., 1976).

Anesthesia Management of Scoliosis Surgery

Overview

Dramatic hemodynamic instability and substantial blood and heat loss are the hallmarks of scoliosis surgery. In addition to the monitors routinely used in conducting pediatric general

anesthesia, large-bore IV access and intraarterial, central venous, and bladder catheterization are recommended. These invasive catheters allow monitoring of beat-to-beat changes in blood pressure, adequacy of oxygenation, ventilation, organ perfusion, and intravascular volume. Additionally, central venous catheterization provides a direct route for administering cardiotoxic medications. Body temperature will decrease during the course of a spinal procedure, and continuous monitoring and meticulous thermoprotective strategies are required to prevent intraoperative hypothermia.

Monitoring and Intraoperative Complications

Scoliosis surgery is very high-risk surgery. Common intraoperative problems are listed in Table 26-4. Complications are related to the surgery (blood loss and its therapy), the prone position, and cardiovascular collapse from myriad causes. Practiced crisis management is essential if patient survival is to be ensured.

Hypotension and cardiovascular collapse are common during this surgery, making it among the highest-risk procedures performed in pediatric surgery and anesthesia. *Physicians should always presume that hypotension is caused by hypovolemia until proven otherwise.* Other causes are far less common and include latex (or rarely, drug) anaphylaxis, anesthetic overdose,

pneumothorax or hemothorax (particularly in a single-staged anterior posterior procedure), and impaired venous return resulting from the prone position, surgical manipulation, and venous air embolism. Air embolism can occur because the epidural veins are exposed during surgery and are above the level of the heart. The outcome from a massive air embolus is almost uniformly fatal.

Because cardiopulmonary resuscitation is virtually impossible to perform with the patient in the prone position, a plan to turn the patient supine must be well established and rehearsed. As in any emergency, it is the anesthesiologist's responsibility to declare the emergency and to call for help. Because the surgeon needs time to pack and cover the open wound with sterile towels and adhesive plastic, it is always better to begin the process early rather than waiting until the last possible moment.

Neurologic Monitoring

Postoperative paralysis or sensory loss is the most feared, devastating, and often unpredictable complication of scoliosis surgery (Owen, 1999). Neurologic injury may result from direct injury to the spinal cord or nerves during instrumentation, from excessive traction during distraction, or from compromised perfusion of the spinal cord. Because the ramifications

TABLE 26-4. Potential Intraoperative Complications During Scoliosis Surgery

Problem	Monitoring Solution
Endotracheal tube malposition	Securely tape tube before turning Benzoin Waterproof tape Bite block (rolled 4×4 gauze pads) After turning prone Hand ventilate and listen to both lung fields DO NOT ALLOW STRETCHER TO LEAVE THE OPERATING ROOM until you are satisfied that the endotracheal tube has not migrated Hourly arterial blood gas determinations Esophageal stethoscope
Alteration in pulmonary compliance in the prone position	Proper position on bed frame: ensure chest can expand unimpeded Hourly arterial blood gas determinations
Alteration in cardiac function in the prone position	Proper position on bed frame to ensure that venous return is not compromised Indwelling arterial catheter Central venous catheter Bladder catheter
Hypotension	<i>Blood loss until proven otherwise</i> Ensure that typed and cross-matched blood is available when surgery starts. Two large-bore peripheral IV catheters and blood warmer Central venous catheter Hourly measurement of hemoglobin/hematocrit Consider Amicar
Coagulopathy	Platelet count Prothrombin time, activated partial thromboplastin time, fibrin split products Thromboelastogram
Electrolyte abnormalities (usually from blood transfusions)	Frequent measurements of sodium, potassium, and ionized calcium Avoid using "old" packed red blood cells NEVER use hypotonic solutions (including for maintenance fluid requirements)
Excessive heat loss	Measure core temperature Heat conservation Active warming (forced air)
Neurologic injuries	Proper positioning, with particular attention to eyes and elbows (brachial plexus) Intraoperative assessment of cord function (e.g., sensory and motor evoked potentials)

associated with motor deficit are significantly greater than those associated with sensory deficit, surgically induced paraplegia has always been the major concern of scoliosis surgery.

Spinal Cord Blood Flow

The organization of the spinal cord blood supply is segmental in a cross-sectional and rostral-caudal fashion (Fig. 26-3). The intrinsic spinal cord vasculature consists of the *anterior median* and the *paired posterior spinal arteries*. The vasculature supplying these vessels arises from the segmental arteries of the aorta and branches of the subclavian—the vertebral arteries—and the internal iliac arteries. The solitary anterior median spinal artery runs along the entire length of the cord in the anterior sulcus, giving off penetrating branches that supply the ventral two thirds of the spinal cord. Blood flow in the anterior spinal artery is not continuous throughout its span; instead, the anterior spinal artery functions as an anastomotic channel between the terminal branches of successive radicular arteries. Blood that leaves the terminal aspects of

these radicular arteries courses upward and downward in the anterior spinal artery. At points between adjacent radicular arteries, blood flows in either direction. The paired posterior spinal arteries, which supply the dorsal third of the cord, also have discontinuous segments and appear more like a plexus of pial vessels than paired arteries.

The three perimedullary vessels give rise to the intramedullary arterial system: the central arteries that supply the gray matter and the deep portions of the white matter and the radial arteries that supply most of the white matter. Nonfunctional anastomotic links exist between the central arterial supply and the radial arterial supply at a given spinal segment. This border zone and the radial circulation appear to be at highest risk for ischemic insult.

The regional circulation of the spinal cord is divided into four segments. The cervical and lumbosacral regions each receive double the blood flow received by the thoracic region (see Fig. 26-3). Although each vertebral level has paired segmental arteries, only six to eight important medullary arteries are formed. These medullary arteries join the spinal arteries.

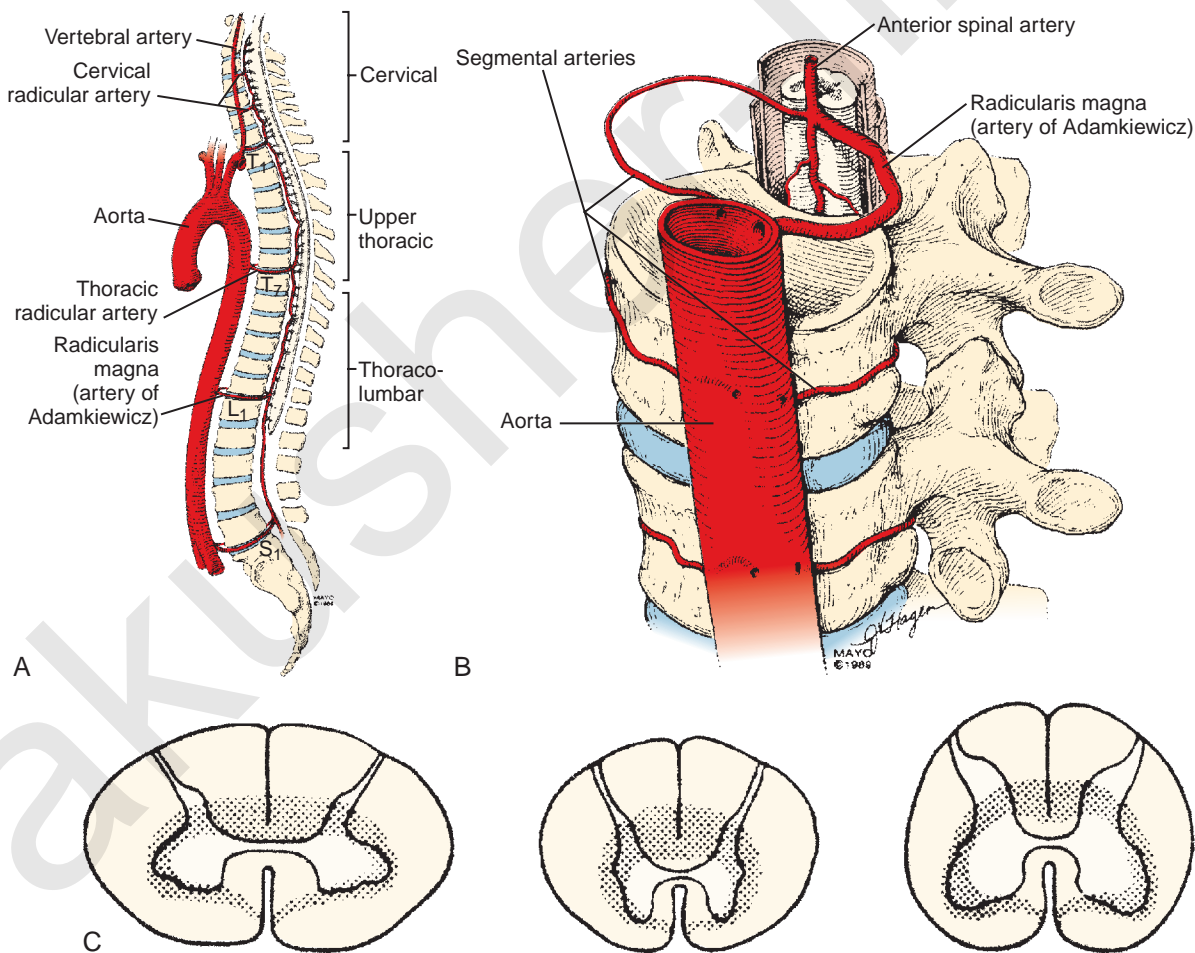

FIGURE 26-3. The anatomy of blood flow to the spinal cord is distinctive in the vertical and horizontal distributions. **A**, Segmental blood flow along the cord axis. **B**, The thoracic cord depends on flow from a number of thoracic radicular arteries, principally the artery of Adamkiewicz. **C**, The cross-sectional distribution of blood flow is distinctive. The outer zone of the cord (white matter) is supplied by the radial arteries; the inner zone (gray and white matter) is supplied by the central arteries. Tissue in the shaded region is supplied by both sources. (A and B, From Cucchiara RF, Michenfelder JD, editors: *Clinical neuroanesthesia*, New York, 1990, Churchill Livingstone; C from Vinken PJ, Bruyn GW, editors: *The handbook of clinical neurology*, vol 12, New York, 1972, North Holland.)

The segmental arteries at all other levels are functionally non-suppliers of blood to the spinal cord itself. The vertebral arteries form the rostral origins of the anterior and posterior spinal arteries and represent the principal supply to the cervical cord. Branches of the thyrocervical and costovertebral arteries supply the lower cervical and upper thoracic cord. A radicular artery arising from T7 provides perfusion for the middle thoracic cord. The most consistent and important of the anterior medullary arteries is the artery of Adamkiewicz—the arteria radicularis magna—which usually joins the anterior spinal artery between T8 and L3. This artery is the predominant source of blood supply to the lower two thirds of the spinal cord. The implications of this design dictate the clinical manifestations of impaired cord perfusion. Watershed areas, which are subject to ischemia during low-flow states, exist between the anterior and posterior circulations and between the four different spinal segments. The segments of T4 to T7 appear to be highly susceptible to injury during periods of hypoperfusion. The dependence of the lower two thirds of the cord on the artery of Adamkiewicz puts this region at particular risk during surgical manipulation of the thoracolumbar aorta and spinal column, and this is referred to as the *lumbar artery enlargement syndrome*. Although the clinical picture of this syndrome is not constant, it is marked by the development of flaccid paraplegia or quadriplegia (depending on the level of the lesion) and dissociated sensory impairment in which heat and pain sensations are affected but deep sensation is spared.

The same principles that regulate the cerebral blood flow apply to spinal cord blood flow. Thus, cord blood flow depends on the perfusion pressure (i.e., mean arterial pressure [MAP] minus cerebrospinal fluid pressure), integrity of the circulation, microcirculatory autoregulation, and intrinsic regulation. If the perfusion pressure falls below 50 mm Hg, spinal cord blood flow is reduced. Spinal cord blood flow autoregulates within the range of a MAP of 60 to 150 mm Hg. Spinal cord blood flow is also regulated on an intrinsic basis in response to arterial oxygen and carbon dioxide tensions, pH, and cord temperature in a fashion identical to that of the cerebral circulation. Hypercapnia increases flow, whereas a P_{aO_2} below 60 mm Hg results in a vasodilation that overrides the effects of hypocarbia and autoregulation (see Chapter 22, Anesthesia for Neurosurgery).

Minimizing Postoperative Neurologic Complications

The estimated risk for postoperative neurologic injury in patients undergoing spinal instrumentation is 0.72% to 1.6% (Cervellati et al., 1996). In a study of 7885 patients who underwent instrumentation or fusion without instrumentation, 87 patients developed acute neurologic changes, and 36% of these patients recovered without sequelae. Individuals with non-idiopathic scoliosis are at higher risk for neurologic injury. Children with congenital scoliosis suffer neurologic complications disproportionately (Cervellati et al., 1996).

To minimize the risk for these devastating neurologic injuries, a variety of methods of intraoperative neurologic monitoring have been used. The goal of this monitoring is to identify and herald the onset of neurologic impairment and to provide the surgeon and anesthesiologist with the opportunity to implement appropriate interventions that may minimize permanent damage. These approaches include wake-up tests and neurophysiologic monitoring.

Wake-Up Test

Vauzelle and colleagues (1973) first described the use of the wake-up test to assess the integrity of the spinal cord. In this technique, patients are awakened intraoperatively to assess spinal cord motor function. The wake-up test requires an anesthetic that allows rapid recovery of consciousness and motor function. Ideally, the test is rehearsed preoperatively. During rehearsal, patients are informed that they will be momentarily awakened at the time of rod insertion to test the function of the spinal cord. Patients must be reassured that they will neither remember the event nor experience pain while they are “awake.” Preoperative preparation increases the speed and success of the test. The effectiveness of neurophysiologic monitoring during spinal deformity surgery is now so well established that the wake-up test is rarely used except to confirm monitoring changes (Schwartz et al., 2007).

When a wake-up test is performed, the operating room must be quiet, the surgeon must stop operating, and an observer is positioned (usually under the drapes) to look for foot movement. After discontinuation of the anesthetic, the patient is first asked to move the hands (“squeeze my fingers”) to evaluate the level of consciousness and is then asked to move the feet (“wiggle your toes”). If the patient is unable to move the feet but can move the hands, spinal cord compromise is presumed, and the spinal rod instrumentation is removed immediately. Spinal cord perfusion is maximized by raising the MAP, increasing the hemoglobin concentration, and normalizing arterial carbon dioxide and oxygen tensions. In one series of 166 patients in whom the wake-up test was used, three patients had demonstrable neurologic deficits when awakened (Hall et al., 1978). These deficits disappeared immediately on release of the distracting force (i.e., rods) (Hall et al., 1978).

Hazards associated with the wake-up test include dislodgment of spinal instrumentation rods and vascular catheters, accidental extubation, air embolization produced by deep inspirations, the patient falling off the operating room table, and recall with subsequent psychological trauma. This test has many other limitations: it tests only the anterior spinal cord (motor function) and not the dorsal column (sensory); it requires patient cooperation and has limited use in patients with baseline cognitive dysfunction; it provides a snapshot of a single moment of spinal cord function and can realistically be performed only once or twice during a procedure; a spinal injury may be missed because it occurred after the wake-up test was performed; depending on the anesthesiologist’s skill and the anesthesia technique employed, it may take 5 to 45 minutes after a wake-up test is requested by the surgeon before wake-up status can be achieved.

Neurometric Monitoring

Sensory-Evoked Potentials. Electrophysiologic (neurometric) monitoring provides real-time, continuous assessment of spinal cord function and does not require patient movement, arousal, or cooperation (see Chapter 11, Monitoring) (Gonzalez et al., 2009). The most common technique uses somatosensory evoked potentials (SSEPs), in which the cortical and subcortical responses to peripheral nerve stimulation are monitored (Banoub et al., 2003). Typically, a peripheral mixed nerve (i.e., posterior tibial nerve, peroneal nerve, or median nerve) is stimulated at fixed intervals during a procedure. SSEPs are recorded

repeatedly during surgery, and their amplitude (height) and latency (time of occurrence) are compared with baseline values (Gonzalez et al., 2009; Mendiratta and Emerson, 2009). Based on changes in these characteristics, it is possible to determine the functional status of the spinal cord sensory tracts. SSEP monitoring requires specialized technology and expertise. To resolve the very low amplitude evoked potentials from background, random, or spontaneous cortical activity, computer signal averaging of repetitive sensory responses is required. The processed evoked-potential waveform is plotted as voltage against time and is characterized by the poststimulus latency and amplitude. The poststimulus latency reflects the time required for impulse transmission from the site of sensory stimulation. A reduction in amplitude of greater than 50% or an increase in latency of less than 10% relative to baseline values is generally considered significant (Banoub et al., 2003; Gonzalez et al., 2009; Mendiratta and Emerson, 2009).

SSEPs monitor only the dorsal columns of the spinal cord and provide no direct evidence of loss of motor function or anterior spinal cord injury. Motor deficits may occur in the absence of alterations in SSEPs, and numerous case reports have recorded the postoperative finding of paralysis despite unchanged intraoperative SSEPs (i.e., false-negative results). In the setting of spinal cord ischemia, the time to loss of SSEPs was almost three times longer than the time to motor evoked potential (MEP) loss (Banoub et al., 2003; Shine et al., 2008). The most comprehensive information regarding the false-negative rate of SSEPs comes from a survey of spine surgeons by the Scoliosis Research Society and the European Spinal Deformity Society, in which definite neurologic deficits, despite stable SSEPs, occurred during surgery in 0.063% of patients (Nuwer et al., 1995). Children with neuromuscular scoliosis frequently have unreliable SSEP data. Despite these limitations, SSEP monitoring reduces postoperative paraplegia by more than 50% (Nuwer et al., 1995). When SSEP monitoring is equivocal, many recommend an intraoperative wake-up test to assess motor function (Grundy, 1983).

Many pharmacologic and physiologic variables affect the latency and amplitude of SSEPs and have been estimated to account for up to 44% of intraoperative SSEP changes. The most important of these are the anesthesia agents, blood pressure, and body temperature (Table 26-5) (Grundy, 1983; Banoub et al., 2003; Gonzalez et al., 2009). All of the potent inhaled anesthesia agents produce dosage-dependent increases in latency and decreases in amplitude. These effects are less for sevoflurane and desflurane, permitting dosages of 1.5 minimum alveolar concentration (MAC) with minimal SSEP changes. Nitrous oxide compounds the effects of volatile anesthetics on cortical SSEPs (Banoub et al., 2003). Alone, nitrous oxide has no effect on SSEP latency but does decrease its amplitude by 50% (Schwartz et al., 2007). Substantial recovery of latency and amplitude is achievable with discontinuance of nitrous oxide and the inhaled vapors (da Costa et al., 2001). In general, the IV agents affect SSEP less than inhaled agents do; at high dosages, they produce slight to moderate decreases in amplitude and increases in latency. Midazolam has no effect on latency (Laureau et al., 1999; Banoub et al., 2003). Ketamine (Langeron et al., 1997) and etomidate (Thakor et al., 1991) augment SSEP amplitude. Propofol has no effect on amplitude or latency and is highly recommended as a component of total IV anesthesia for scoliosis surgery (Laureau et al., 1999; Boisseau et al., 2002). Opioids given in either analgesic or anesthetic dosages

TABLE 26-5. Effects of Anesthesia Agents on Somatosensory Evoked Potentials

Agent	Amplitude	Latency
Desflurane	↓	↑
Isoflurane	↓	↑

produce minimal SSEP effects (Banoub et al., 2003). In a very small study, dexmedetomidine had no effect on SSEP or MEP (Tobias et al., 2008).

The amplitude and latency of the waveform are also affected by age, preexisting neurologic deficits, body temperature, P_{aO_2} , hypoxia, and blood pressure (Fig. 26-4) (Banoub et al., 2003). The reliability of spinal cord monitoring may be dramatically affected by the variability of the evoked responses. Muscle relaxants have no direct deleterious effects on the SSEP but may produce a more reliable recording by providing “quieter” conditions.

An anesthesia milieu that is compatible with adequate neurometric monitoring and that allows rapid awakening can be created using a variety of approaches. Combining desflurane or sevoflurane with a remifentanyl infusion produces ideal SSEPs and still allows for rapid wake-up if a wake-up test is required. Alternatively, the physician can substitute a continuous propofol infusion for the potent inhaled anesthetics in combination with an opioid (Kalkman et al., 1991a; Kalkman et al., 1991b). Because etomidate augments SSEP amplitude, it is particularly useful in patients with abnormal preoperative SSEPs. These individuals are at greatest risk for the development of postoperative neurologic catastrophes (Sloan et al., 1988; Samra and Sorkin, 1991).

Baseline SSEP recordings are made after turning the patient to the prone position. After the patient is prone, the anesthesia depth, end-tidal carbon dioxide (CO_2) levels (35 to 45 mm Hg), temperature, and blood pressure (MAP >60 mm Hg) should be maintained to minimize their effects on the SSEPs during surgery. Throughout the surgical procedure, a physiologic and pharmacologic steady state must be maintained so that SSEPs can be used effectively as monitors of spinal cord function. Deepening the anesthesia depth during critical operative moments when the risk for neurologic compromise is highest must be avoided to minimize the potential for pharmacologically induced false-positive changes. The intraoperative changes of increased latency, decreased amplitude, or complete loss of waveform must be attributed to spinal cord injury rather than to an anesthetic-induced effect.

■ **FIGURE 26-4.** Somatosensory evoked potentials (SEPs) change with hypotension and hypoxia. **A**, During the combination of distraction and hypotension, distal SEPs were unchanged. Resumption of normotension restored the SEP to baseline. **B**, SEP responses are exquisitely sensitive to hypoxia ($P_{O_2} \leq 41$ mm Hg). Resumption of normoxia restored the SEP to baseline.

When the baseline is being established, knowledge of the various effects of anesthesia drugs on SSEPs can be advantageously used to produce optimal signal acquisition. In the setting of less-than-optimal baseline SSEP acquisition, a strategic change in the anesthesia regimen may result in improvement of the quality of the SSEP signal. For example, discontinuing nitrous oxide or desflurane, or both, and substituting an etomidate or propofol infusion can significantly improve SSEP acquisition.

Using the criterion of a decrease in amplitude of greater than 40% amplitude as a significant change, excellent specificity and sensitivity are achievable. In patients with idiopathic scoliosis (i.e., neurologically intact), SSEPs are reliable and can be obtained in more than 98% of patients (Padberg et al., 1998). However, in patients with preexisting diseases such as neuromuscular scoliosis, the reliability of the SSEP is less than 75% but can be improved with the addition of MEP monitoring (Sarwark and Sarwahi, 2007). Precise communication and coordination of efforts among the surgeon, anesthesiologist, and neurometric specialist are imperative when a change in SSEP is observed. Normalization of the SSEPs may occur spontaneously with relaxation of the distraction instrumentation or by improving spinal cord perfusion (e.g., increasing blood pressure and P_{aCO_2} levels).

Motor Evoked Potentials. SSEPs are not the modality of choice for monitoring motor tract function or for detecting the presence of a surgically induced motor deficit. The motor pathways can be activated by transcranial stimulation of the motor cortex or by spinal cord stimulation. Transcranial MEPs (TcMEPs) are exquisitely sensitive to compromised spinal cord function and should be used in combination with SSEPs to improve the accuracy of spinal cord monitoring. In a series of 1121 adolescents with idiopathic scoliosis, nine children awoke with a post-operative neurologic deficit, seven had motor or sensorimotor deficit, and two had pure sensory impairment. All seven patients with motor impairments had significant TcMEP changes; only three of the seven had significant SSEP changes. When changes were detected by both modalities, SSEPs lagged behind TcMEPs by approximately 5 minutes (Schwartz et al., 2007). As a result, some centers have abandoned using SSEPs entirely. Finally, the false-positive rate attributed to MEP monitoring during spinal surgery is less than 10% (Langeloo et al., 2003).

Anesthesia agents have profound effects on MEP recordings. Volatile anesthetics, benzodiazepines, etomidate, barbiturates, and even high-dosage propofol affect MEP fidelity (Sloan and Heyer, 2002; Sloan et al., 2008). A maintenance anesthesia that is based on a continuous infusion of propofol and remifentanyl is titrated to maintain a MAP of at least 65 mm Hg, and that avoids nitrous oxide and muscle relaxants, provides adequate conditions

for uncompromised TcMEP monitoring. Alternatively, high-dosage remifentanyl in combination with low-dosage sevoflurane (0.4 to 0.7 MAC), or continuous infusions of propofol, fentanyl, and dexmedetomidine, are also regimens compatible with reliable monitoring (Joseph et al., 1976; Langeloo et al., 2003, 2007; Ansel et al., 2008).

Blood Loss

Exposure of a vast area of decorticated, raw, cancellous bone during spinal surgery results in extensive blood loss that can exceed 25 mL/kg, even in uncomplicated surgery. Children with neuromuscular scoliosis often require more extensive procedures, including pelvic stabilization, than children with idiopathic scoliosis and can easily have blood loss that exceeds a blood volume (Kannan et al., 2002; Meert et al., 2002). However, even if the extent of surgery is controlled, patients with neuromuscular diseases have an almost seven times higher risk for losing greater than 50% of their estimated total blood volume during scoliosis surgery than do normal controls (Edler et al., 2003).

An estimation of circulating blood volume should be made before the induction of anesthesia. The estimated blood volume (EBV) is calculated by multiplying the patient's weight by the approximate blood volume based on age (Table 26-6). From the EBV, the initial hematocrit, and the minimum acceptable hematocrit, the maximum allowable blood loss can be estimated before packed red blood cell transfusion is indicated.

The decision to transfuse red blood cells should be based on the balance between oxygen supply and demand, which depends on the oxygen content of the blood, cardiac output, regional distribution, and metabolic needs. The trigger to transfuse is then based on the patient's risk of developing inadequate oxygenation. Because blood loss may be difficult or impossible to assess accurately, blood loss is estimated by measuring the hemoglobin concentration hourly and by assuming that changes in central venous pressure reflect ongoing blood loss. As blood loss progresses and exceeds a blood volume, it becomes increasingly important to know the medical causes of bleeding (e.g., dilutional thrombocytopenia or loss of clotting factors V and VIII) so as to account for the inability of the surgeon to achieve hemostasis. Platelet counts and coagulation profiles (i.e., prothrombin time, partial thromboplastin time, fibrinogen, and fibrin split products) should be obtained at regular intervals when extensive blood loss occurs.

Multiple strategies have been described to reduce intraoperative blood loss and the need for blood transfusions of homologous blood in the perioperative period (see Chapter 14,

Blood Conservation). Techniques that may decrease intraoperative blood loss include induced hypotension, alteration of the operative position, changes in surgical technique, and administration of antifibrinolytic agents such as ϵ -aminocaproic acid (Amicar) or tranexamic acid (Cyclokapron). Techniques aimed at decreasing the use of homologous blood products include intraoperative blood salvage, preoperative autologous blood donation, and perioperative normovolemic hemodilution and apheresis (Joseph et al., 1976). Each of these techniques has demonstrated efficacy in some clinical situations.

Preoperative autologous donation with and without erythropoietin treatment has been used extensively in children (Helfaer et al., 1998; Vitale et al., 1998). As this has become more widespread for pediatric scoliosis, 70% of children and adolescents have been able to donate sufficient units for their procedures, a figure similar to that for adults (Murray et al., 1997). Using preoperative autologous donation as the sole blood conservation method limited the number of adolescents undergoing scoliosis surgery who required allogeneic transfusions to 11% to 23%. The addition of autologous donation to deliberate hypotension further reduced allogeneic exposure to 10% (Murray et al., 1997).

Alternatively, perioperative hemodilution and apheresis, isovolemic hemodilution, or acute normovolemic hemodilution can substitute for or augment autologous blood donation (Bryson et al., 1998; Copley et al., 1999). Before incision, the patient's blood is withdrawn through a large-bore peripheral IV cannula or through a central venous catheter and replaced with an isotonic balanced salt solution or colloid in a ratio of 3:1. When using this technique, cardiac index and oxygen extraction increase, and systemic vascular resistance, oxygen delivery, and mixed venous saturation decrease. Lactic acidosis develops when oxygen delivery falls to critical. Moderate acute normovolemic hemodilution, with a minimum hematocrit of 17%, did not result in changes in either oxygen delivery or oxygen consumption in healthy children. The removed blood is stored in anticoagulated bags and is administered as needed to maintain the hematocrit at a predetermined level, usually greater than 20%. Complications of this technique include postoperative pulmonary edema, anasarca, and prolonged postoperative mechanical ventilation.

Perioperative salvage of blood (i.e., use of a cell-saver system) allows blood lost in the operative field to be returned to the patient during the perioperative period (Huet et al., 1999). The efficiency of this technique, its benefits in limiting blood transfusion, and the survivability of red blood cells are unclear (Vitale et al., 2002). When using salvaged blood, it is imperative that the blood be processed and washed adequately to avoid life-threatening bleeding and pulmonary complications caused by transfusion of cellular and tissue debris. Salvaged blood can also cause profound hypotension (e.g., citrate, air embolism) and hemolytic and bleeding complications from centrifugation, cellular debris, or anticoagulant overdose.

Pharmacologic manipulation of the hemostatic mechanism is effective in limiting perioperative blood loss. A series of prospective, randomized, double-blind studies demonstrated that the antifibrinolytic agent ϵ -aminocaproic acid significantly reduces perioperative blood loss and transfusion requirements in patients with either idiopathic or neuromuscular scoliosis who are undergoing spinal fusion (Florentino-Pineda et al., 1976; Thompson et al., 1976a, 1976b). Similarly, tranexamic acid, 100 mg/kg over 15 minutes, followed by an

TABLE 26-6. Approximate Blood Volume Based on Age

Age	Total Blood Volume (mL/kg)
Premature infant	90-105
Term newborn	80-85
1 to 12 months	70-80
Older child	70-80
Adult	55-65

infusion of 10 mg/kg per hour, significantly reduces blood loss during posterior spinal surgery in children and adolescents with idiopathic and secondary (congenital and neuromuscular) scoliosis but may not affect the actual amount of blood transfused (Sethna et al., 2005). The main safety issues related to antifibrinolytic drugs are hypersensitivity reactions, effects on the kidneys, potential for thrombotic events, and effect on mortality.

Deliberate Hypotension

The most common blood-preservation technique is deliberate hypotension (see Chapter 14, Blood Conservation) (Yaster et al., 1986; Tobias, 2002). Numerous techniques to reduce blood pressure have been used, typically with drugs that are direct venous and arterial vasodilators such as nitroprusside and nitroglycerin. Ganglionic blocking drugs (e.g., trimethaphan), α_2 -adrenergic agonists (e.g., clonidine), β - and α_1 -antagonists (e.g., propranolol, esmolol, prazosin, hydralazine), dopamine agonists (e.g., fenoldopam), inhaled anesthetics (e.g., halothane, isoflurane, sevoflurane, desflurane), major conduction blockade (i.e., epidural), and calcium-channel blockers (e.g., nifedipine) are used alone or in combination with the direct-acting venous and arterial vasodilators to lower blood pressure (Yaster et al., 1986; Tobias, 2002; Hammer et al., 2008).

Deliberate hypotension can be used in any patient who is otherwise healthy. It is contraindicated in the presence of evidence of end-organ injury or ischemia. Blood pressure is usually lowered to an MAP of 60 mm Hg. In the past, the most commonly used technique was a continuous infusion of nitroprusside (1 to 8 mcg/kg per minute) combined with β -blockade, using propranolol (1 to 2 mg), labetalol, or an esmolol infusion. β -Blockade is necessary when hypotension is induced with nitroprusside, because nitroprusside produces a reflex tachycardia and increases cardiac index. These effects combine to limit the ability of nitroprusside to lower blood pressure (Yaster et al., 1986). Nitroglycerin, which is often used for deliberate hypotension in adults, fails to reduce MAPs to below 60 mm Hg in children when administered in dosages as high as 40 mcg/kg per minute (Yaster et al., 1986). Potent inhalation agents such as sevoflurane can also be used to induce hypotension in children and adolescents, but they interfere with intraoperative monitoring and delay the ability to rapidly perform a wake-up test. When combined with low-dosage sevoflurane or desflurane, remifentanyl is extremely effective. Regardless of the technique used to induce deliberate hypotension, the appropriate use of adjuvants in the anesthesia technique can aid in achieving the desired effect of hypotension (Tobias, 2002). Children can be premedicated with oral clonidine (4 to 8 mcg/kg) 2 hours before surgery to reduce anxiety and to facilitate the induction and maintenance of hypotension during surgery (Hackmann et al., 2003).

Although deliberate hypotension clearly reduces blood loss, provides a relatively bloodless surgical field, and facilitates surgical dissection, its use in scoliosis surgery is controversial. Animal studies have suggested an additive effect of hypotension and surgical pressure on the spinal cord in producing neurologic injury (Brodkey et al., 1972). In dogs, Griffiths and colleagues (1979) showed that cord compression can alter dorsal column conduction at perfusion pressures that did not affect blood flow. Use of deliberate hypotension mandates normocarbida and adequate oxygen-carrying capacity.

Invasive monitoring is essential when deliberate hypotension is used. An arterial catheter for beat-to-beat monitoring of blood pressure and for frequent hematocrit determinations and sampling of arterial blood gas are essential. Because patients must remain normovolemic at all times, a central venous pressure catheter is a useful monitor. Nitroprusside has been shown to decrease arterial oxygen tension in children and to increase the alveolar to pulmonary artery (P_{aO_2} -to- P_{aO_2}) pressure difference (Yaster et al., 1986). We can assume that the lowered oxygen-carrying capacity of low-hematocrit blood, when coupled with hypoxemia and hypocapnia from overzealous ventilation, can only exacerbate the cord ischemia caused by surgical traction or hypotension. Other end organs that must be protected from hypotension include the heart and kidneys. The heart is easily monitored by following the ST segment of the V_5 lead of the electrocardiogram. The kidneys are monitored by bladder catheterization and hourly measurement of urine output. Renal perfusion pressure can be assumed to be inadequate if urine output falls to less than 1 mL/kg per hour.

Positioning

Anesthetized patients are extremely vulnerable during positioning for scoliosis surgery because of their inability to feel the extreme discomfort of certain positions that alter the normal mechanics of the body. Vulnerable parts that must be especially protected to avoid injury by pressure or stretching include the peripheral (ulnar) nerves, the male genitalia, the nipples, and the anterior superior iliac spine (to protect the lateral femoral cutaneous nerve of the thigh). Of the peripheral nerves, the brachial plexus is most vulnerable to stretch in the prone position (Martin and Warner, 1997). Stretching of the lower trunks of the brachial plexus is most likely to occur when the head is turned to the contralateral side, the ipsilateral shoulder is abducted, and the ipsilateral elbow is bent. Although efforts to prevent neuropathies are frequently debated, there is little hard evidence to support specific management recommendations.

The patient's eyes are vulnerable to corneal abrasion, optic vein engorgement, and retinal ischemia. Postoperative visual loss is a devastating and poorly understood injury. Over the past decade, speculation has grown that the frequency of perioperative blindness has been increasing among patients undergoing major spine surgery. Roth and colleagues found a much higher incidence of blindness (1 in 600) among patients undergoing complex spinal surgery (Roth et al., 1996, 1997; Roth and Barach, 2001). However, a report from the Mayo Clinic did not support this finding (Nuttall et al., 2001). In an effort to help analyze the risk factors involved, the American Society of Anesthesiologists has established an anonymous postoperative visual loss registry (www.asaclosedclaims.org).

Ischemic optic neuropathy, which affects the anterior or posterior portions of the optic nerve, is the most common cause of postoperative visual loss. Visual loss may also be caused by retinal arterial occlusion and cortical blindness. Awakening with visual impairment is one of the most frightening and catastrophic postanesthesia complications that a patient may sustain. It is also an enormous medicolegal liability problem. Commonly cited risk factors in patients who undergo scoliosis surgery in the prone position include hypotension, anemia, and external compression of the eye. Unfortunately, blindness has

occurred even when these risk factors were not present (Lee and Lam, 2001; Roth and Barach, 2001).

Decreased perfusion pressure in the retina or optic nerve may be caused by decreased MAP or increased pressure in the venous drainage of the retina or optic nerve. Prolonged decreases in blood pressure, especially in patients with disturbed autoregulation, may be deleterious. Increased venous pressure (i.e., with internal jugular vein compression or ligation, prolonged head-down position, or large quantities of fluid infusion) also decreases perfusion. With prone positioning, increases in intraocular pressure might be potentiated by these factors. The combination of decreased blood pressure and increased venous pressure seems to pose the greatest risk.

The prone position increases intraabdominal pressure, which impairs ventilation by decreasing chest compliance and by limiting chest expansion. It also engorges epidural veins, which increases intraoperative bleeding and potentially increases the risk for postoperative epidural hematoma formation. Increased intraabdominal pressure leads to compression of the inferior vena cava, which impedes venous return to the heart, thereby decreasing cardiac output and engorging epidural veins. In an effort to facilitate venous return and avoid increased intraabdominal pressure, specially designed frames have been developed that allow the abdomen to hang free and facilitate respiratory movement (Relton and Hall, 1967).

Turning the anesthetized patient from the supine to the prone position requires careful orchestration by the entire surgical and anesthesia team. Cervical spine injury, dislodgment of intravascular and urinary catheters, accidental extubation or dislodgment of the endotracheal tube, inability to ventilate once prone, and dramatic changes in cardiac output can easily occur. During the turn, monitoring, except with an esophageal stethoscope, is difficult. Once the patient is turned, immediate restoration of pulse oximetry monitoring and auscultation of both lung fields is imperative. Adequate pressure-point padding (e.g., elbows, breasts, scrotum, feet) must be ensured to avoid peripheral nerve compression (i.e., ulnar nerve) and soft tissue damage.

The surgical plan and preference determine the patient's position and the device used to stabilize the patient's head. A pin-type or horseshoe-shaped holder may be employed and requires careful application and padding to avoid catastrophic oculo-facial injuries. Alternatively, the head may be rested on a securely arranged stack of pillows to avoid exaggerated neck flexion or rotation, or ear trauma.

Anesthesia Techniques

Given the potential complications of neurologic injury and profound hemorrhage associated with spinal surgery, the anesthesia technique used should have minimal effects on neurophysiologic monitoring, allow for a wake-up test, and provide hemodynamic stability to minimize complications. The combination of remifentanyl with either desflurane or propofol allows SSEP and MEP monitoring and a rapid wake-up response if necessary.

Patients with preexisting neurologic deficits such as cerebral palsy, paralytic scoliosis, and congenital scoliosis have variable SSEP waveforms of weak amplitude. The use of a ketamine or an etomidate infusion in these patients can augment

the amplitude of the evoked responses and increase the reliability of SSEP monitoring (Banoub et al., 2003; Lotto et al., 2004).

Postoperative Management

Although pulmonary failure and the need for postoperative ventilation are the primary problems of scoliosis surgery, other common postoperative concerns include ongoing blood loss, disseminated intravascular coagulation, hypovolemia, and development of syndrome of inappropriate secretion of antidiuretic hormone, paralytic ileus, and pain. The most important initial decision at the conclusion of surgery is whether to extubate the trachea. This decision is based in large part on the patient's preoperative pulmonary function and on the intraoperative course. Scoliosis surgery produces an immediate and transient decrease in pulmonary function of up to 60% of baseline values. The nadir of pulmonary function occurs on the third postoperative day, and it remains at approximately half of baseline values through the first postoperative week. These changes can resolve within 6 months of the procedure (Yuan et al., 1976). Patients with preoperative FVC levels of less than 50% of predicted and patients with nonidiopathic scoliosis should be extubated in the pediatric intensive care unit after cognitive faculties and respiratory muscle strength have returned to baseline. After spinal fusion, 18 children with severe restrictive lung disease (FVC < 45%) required a mean of 9 days of postoperative ventilation (Wazeka et al., 1976). Other common pulmonary complications in the postoperative period include atelectasis, pneumothorax, and pleural effusions.

Syndrome of inappropriate secretion of antidiuretic hormone is common and manifests as hyponatremia, hyposmolality, decreased urine output, and increased urine osmolality. The increased plasma volume reduces the hemoglobin concentration and can be identified by following the red blood cell's mean corpuscular volume. As the level of antidiuretic hormone increases, plasma water increases, resulting in free water entry into red blood cells. The mean corpuscular volume increases, and the hemoglobin and mean corpuscular hemoglobin content decrease. The mean corpuscular volume should not change in the face of postoperative blood loss (Mason et al., 1989).

Because the surgery is so extensive, pain is an expected complication in all scoliosis patients. Furthermore, if remifentanyl was used intraoperatively without loading the patient with a longer-acting opioid, an exaggerated pain response is to be expected on awaking. Remifentanyl produces opioid-induced hyperalgesia, a paradoxical process by which opioid administration, even for short periods of time, increases the sensitivity to pain and worsens pain when the opioid is discontinued (Crawford et al., 2006). Postoperative pain can be treated with IV opioid therapy (i.e., patient-controlled analgesia [PCA]), regional anesthesia techniques, or both (Tobias, 2004). To use PCA, patients are started on a basal infusion of morphine (0.02 mg/kg per hour) or hydromorphone (0.004 mg/kg per hour) combined with a low-dosage naloxone infusion (0.25 mcg/kg per hour) (Maxwell and Yaster, 2003). The patient or nurse can trigger the PCA machine's bolus button, which provides an additional dose of morphine (0.02 mg/kg) or hydromorphone (0.004 mg/kg) (Monitto et al., 1998). Many centers are using neuraxial techniques for postoperative analgesia (Tobias, 2004).

Typically, a single epidural catheter is inserted by the surgeon at the T8 or T9 level before wound closure. Alternatively, two catheters are placed at the top and bottom of the wound by the surgeon. These catheters are intermittently or continuously infused with opioids (i.e., morphine, hydromorphone, or fentanyl), local anesthetics (i.e., 0.625% to 1.25% bupivacaine solutions), or both.

Nonsteroidal antiinflammatory drugs (NSAIDs) such as ketorolac have a morphine-sparing effect and result in fewer opioid-induced side effects such as somnolence, constipation, and pruritus (Reuben et al., 1997, 1998). The use of ketorolac does not increase bleeding, the need for transfusions, or reoperation (Reuben et al., 1997; Vitale et al., 2003). Nevertheless, for reasons that are discussed later, the use of ketorolac in scoliosis patients should be avoided, because NSAIDs significantly inhibited spinal fusion in human and laboratory studies (Glassman et al., 1998; Martin et al., 1999). NSAIDs such as ketorolac are thought to have deleterious effects on bone healing and fracture repair, although the actual clinical effects appear to be controversial at this point. In some studies, chronic NSAID use for more than 3 months was associated with lower fusion and success rates (Deguchi et al., 1998; Harder and An, 2003).

NSAIDs are thought to principally affect the bone morphogenetic proteins (BMPs) (Harder and An, 2003), which are a class of osteoinductive proteins that play an important role in bone growth and are essential for the growth and development of skeletal tissue and for bone regeneration during fracture repair (Kanakaris and Giannoudis, 2008; Dean et al., 2009). Martin and colleagues (1999), using a rabbit model of spinal fusion, investigated the effects of ketorolac on graft healing. Compared with a saline control group, less than half of the rabbits receiving ketorolac had a stable bone graft. However, the coadministration of a recombinant BMP with ketorolac to a third group of rabbits resulted in a 100% successful fusion rate. The investigators concluded that the effects of the NSAID could be completely reversed by the administration of a BMP (Martin et al., 1999). Clinical trials using recombinant BMPs to improve graft healing are in only the preliminary stage (Khan et al., 2002; Sandhu and Khan, 2003). Initial efforts to evaluate the effects of cyclooxygenase-2 (COX-2)-specific inhibitors of bone healing have produced similar results (Gilron et al., 2003). The healing of stabilized tibial fractures in COX-2-deficient mice was significantly delayed, as was intramembranous calvarial bone formation. These bone-healing deficiencies were reversed by the administration of prostaglandin E₂ and BMP-2 (Zhang et al., 2002; Clark et al., 2009). In some studies, COX-2 inhibition seemed to have less severe effects on bone healing than nonspecific COX-1 and COX-2 NSAIDs (Gerstenfeld et al., 2003).

Clinically, because of limited data, the effects of NSAIDs on bone healing remain controversial (Vuolteenaho et al., 2008). In a retrospective analysis of more than 300 patients undergoing spinal fusion who received a COX-2 inhibitor (ketorolac) or no NSAIDs for the first 5 postoperative days, patients who received ketorolac had a threefold increase in nonunion rate compared with COX-2 recipients or controls (Maxy and Glassman, 2001; Gajraj, 2003). On the other hand, in a retrospective study of 405 patients undergoing spinal fusion, no difference was noted in fusion rates between those who received ketorolac for the first 48 hours postoperatively and those who did not (Pradhan et al., 1976).

JOINT DISORDERS

Arthrogryposis Multiplex Congenita

Arthrogryposis multiplex congenita (AMC) consists of a heterogeneous group of disorders characterized by nonprogressive congenital joint contractures. Fetal akinesia results in the birth of a baby with multiple curved, rigid joints. The incidence is 1 in 3000 live births. Because of their extensive contractures, tense skin, and minimal muscle mass and subcutaneous tissue, these children have been described as looking like thin wooden dolls. Arthrogryposis is a clinical finding that is characteristic of a vast number of disorders (Bamshad et al., 2009). In the past, an in utero, self-limited anterior horn cell disease was proposed (Bonilla-Felix, 2004). AMC is now recognized as resulting from fetal neurogenic, myogenic, or connective tissue abnormalities, as well as maternal disorders such as maternal myasthenia gravis. The child's neurologic examination is fundamental to determining the etiology of AMC. The AMC of children with normal neurologic examinations results from amyoplasia, a distal arthrogryposis, a generalized connective tissue disorder, or fetal crowding. Children with amyoplasia frequently have mid-facial hemangiomas, and 10% have gastroschisis or intestinal atresia. The distal arthrogryposes are a group of 10 autosomal dominant disorders with mutations in the genes that encode proteins of the contractile apparatus of fast-twitch myofibers (Sung et al., 1993). Children with these disorders have characteristic congenital contractures of two or more different body areas. The AMC of children with abnormal neurologic examinations is the result of developmental central nervous system abnormalities, spinal muscular atrophies, peripheral neuropathies, and myopathies (Takano et al., 2001). Mutations in the genes that encode for the neuromuscular junction's acetylcholine receptor proteins appear as AMC (Burke et al., 2003). AMC has also been associated with spinal cord dysplasia, lung hypoplasia, renal tubular dysfunction, and micrognathia (Narkis et al., 2007a, 2007b).

Most children with AMC have quadrilateral limb involvement. Joint involvement is symmetric, increases distally, and results in severe contractures and joint rigidity. The most common orthopedic deformities include talipes equinovarus, dislocated hip, dislocated patella, and scoliosis. Intelligence is usually normal. Surgical management is directed at correcting all lower extremity deformities that delay ambulation, and surgery is ideally performed before the patient is 2 years old. Upper extremity surgery is designed to improve hand function.

The anesthesia management of children with AMC is complicated by associated congenital abnormalities, an abnormal upper airway, and positioning difficulties (Martin and Tobias, 2006). Arthrogryposis is associated with congenital heart disease, pulmonary hypertension, cor pulmonale, and urogenital anomalies. The distal arthrogryposis disorders can be associated with Freeman-Sheldon syndrome, as well as the presence of trismus, cleft palate, or pulmonary hypertension (Laishley and Roy, 1986; Stevenson et al., 2006; Toydemir et al., 2006; Toydemir and Bamshad, 2009). Decreased pulmonary reserve that results from pulmonary hypoplasia and scoliotic restrictive lung disease may potentiate hypoxemia and may necessitate postoperative ventilatory support.

Patients with arthrogryposis have micrognathia, a high arched palate, and a short and rigid neck, making tracheal intubation difficult and at times impossible (Szmuk et al., 2001).

Direct laryngoscopy and intubation become more difficult as the patient ages, because craniofacial involvement often progresses with growth. Alternative strategies to direct laryngoscopy and tracheal intubation, such as the use of the laryngeal mask airway with or without the use of a tube exchanger, or fiberoptics, have been employed successfully in this disorder (Szmuk et al., 2001). The extensive contractures, tense skin, and minimal muscle mass and subcutaneous tissue pose challenges for intraoperative positioning and IV access.

Children with arthrogryposis may have altered responses to neuromuscular relaxants and are akin to other patients with anterior horn cell diseases. Although hyperkalemic responses to succinylcholine have not been reported, prudence mandates avoiding the routine use of depolarizing muscle relaxants.

Children with Freeman-Sheldon syndrome, in particular, are prone to hyperthermia and muscular rigidity responses to inhaled anesthetics and a neuroleptic malignant syndrome response to metoclopramide (Madi-Jebara et al., 2007). Although the response to nondepolarizing relaxants has been reported to be extremely variable, the use of short-acting nondepolarizing agents in association with careful monitoring of neuromuscular function has been successful in these patients.

The association of intraoperative hyperthermic crises with AMC has been sporadically reported. Hopkins and colleagues, in reporting three cases of hyperpyrexia, reviewed the literature of nine additional cases (Hopkins et al., 1991). In nine cases, hyperthermia, tachycardia, and hypercarbia were observed intraoperatively. Six episodes were assumed to be malignant hyperthermia, and dantrolene therapy was immediately instituted. Two cases responded rapidly to aggressive cooling. One patient received a nontriggering anesthetic. The halothane contracture test was not performed in any of these reported cases. In two large series of children with AMC who were anesthetized with triggering agents, no confirmed cases of malignant hyperthermia were reported (Baines et al., 1986). In light of the absence of laboratory confirmation, the occurrence of a hyperthermic crisis without exposure to triggering agents, and a large number of affected patients without hyperthermic response, Hopkins and colleagues (1991) concluded that these hypermetabolic responses are distinct from malignant hyperthermia. Patients with AMC are not considered to be at an increased risk for malignant hyperthermia (Laishley and Roy, 1986; Benca and Hogan, 2009).

Juvenile Idiopathic Arthritis (Formerly Juvenile Rheumatoid Arthritis)

Juvenile idiopathic arthritis (JIA) is the most common autoimmune disease of childhood, affecting 20 to 150 per 100,000 children (Helmick et al., 2008). It is defined as the presence of joint pain, stiffness, and swelling that persists for longer than 6 weeks, first occurring when the patient is younger than 16 years. The estimated incidence is 14 cases per 100,000 children per year. The International League of Associations for Rheumatology reclassified this disease as juvenile idiopathic arthritis to distinguish it from adult-onset rheumatoid arthritis (Weiss and Ilowite, 2005; Hayward and Wallace, 2009).

JIA is divided into three subsets based on the symptoms at onset. *Oligoarticular arthritis*, representing approximately 50% of all JIA cases, is common in girls, with the peak age of onset at 2 years. During the first 6 months of the disease, fewer than

five joints are affected—typically the knees and less commonly the ankles and wrists. Approximately 75% of these patients have a positive antinuclear antibody (ANA) titer. Uveitis occurs in 15% to 45% of children with oligoarticular JIA. Oligoarticular arthritis is rarely destructive. *Polyarticular JIA*, representing 20% to 40% of JIA cases, is also more common in girls, with a peak age of onset of 3 years. In this variant, five or more joints are affected—commonly the small joints of the hand. Only 40% of these patients have a positive ANA titer, and 10% have positive test results for rheumatoid factor. Polyarticular JIA has associated subcutaneous nodules and erosions. The arthritis is destructive in 15% of patients. Moderate systemic manifestations of anemia and growth retardation are seen. *Systemic JIA*, also known as *Still disease*, manifests with fever, macular rash, leukocytosis, lymphadenopathy, and hepatomegaly. Symmetric polyarthritis is seen in these children. Boys and girls are affected equally, and they can present for treatment at any age. The cervical spine, jaw, hands, hips, and shoulders can be involved. Only 10% of these children have positive ANA results. The arthritis can be destructive in 25% of cases. Patients with systemic JIA can have pericarditis (30%), pleuritis, uveitis, splenomegaly, and abdominal pain. Although spontaneous disease remission can occur in patients with JIA, the therapeutic goals are to control pain, preserve joint range of motion, minimize systemic complications, and optimize growth and development.

Patients with juvenile ankylosing spondylitis and arthritis associated with inflammatory bowel disease are included in the enthesitis-related arthritis (ERA) subtype. ERA has a prevalence of 12 to 33 per 100,000 and is most common in boys older than 8 years. It has a strong genetic predisposition, as evidenced by a positive family history and the high frequency of the presence of HLA-B27 in affected patients. The hallmarks of the disease are pain, stiffness, and eventual loss of mobility of the back. ERA should be suspected in any child with chronic arthritis of the axial and peripheral skeleton, enthesitis (inflammation at points where tendons insert to bone), and rheumatoid factor and ANA seronegativity.

Therapy

Physical and occupational therapies are important adjuncts to medication in the management of JIA, because they help to maintain and improve range of motion, muscle strength, and skills for activities of daily living. Splints may be used to prevent contractures and to help in the work of improving range of motion. Arthroplasty may be needed for patients with severe deformities. Medications used to achieve these goals include NSAIDs, glucocorticoids, and disease-modifying antirheumatic drugs (methotrexate, sulfasalazine, leflunomide, cyclophosphamide, gold). Finally, biological agents, including tumor necrosis factor inhibitors (etanercept, infliximab, adalimumab, the interleukin-1 inhibitor anakinra, and the B-cell depleter rituximab), have all been added to the treatment armamentarium with great success (Hashkes and Laxer, 2005, 2006; Weiss and Ilowite, 2005).

Common surgical procedures include various joint arthroplasties and synovectomies, correction of uveitis, scoliosis surgery, limb-length discrepancy surgery, and limb and mandibular osteotomies.

Anesthesia considerations in the child with JIA are principally focused on airway management. JIA involvement of the mandibular head and the temporomandibular joint (TMJ),

which limits mouth opening, occurs in over 60% of children (Pedersen et al., 2001; Sidiropoulou-Chatzigianni et al., 2008). As a result of TMJ disease, the mandible's growth is stunted, producing micrognathia in as many as 30% of children with JIA (Arabshahi and Cron, 2006). Magnetic resonance imaging (MRI) and ultrasound are useful imaging modalities to detect TMJ disease. Cervical spine disease is commonly seen in the systemic and the polyarticular forms of JIA, sometimes resulting in spinal fusion, which reduces cervical mobility (Fig. 26-5). Cervical stiffness is reported in 46% to 60% of patients. Radiographic changes are usually seen in the late stages of the disease and only in children with severe involvement. As a component of atlantoaxial rotatory subluxation or as a solitary manifestation, torticollis can develop, further increasing the degree of difficulty in airway management in these patients (Subach et al., 1998). Cricoarytenoiditis, an unusual manifestation of systemic JIA, can result in airway obstruction and severe distortion of the glottic anatomy (Jacobs and Hui, 1977; Vetter, 1994). Children with JIA should undergo a complete preoperative evaluation of the TMJ and cervical spine to assess for evidence of limited range of motion. The assessment should include dynamic radiographs.

Marfan Syndrome

Marfan syndrome (MFS) is an autosomal dominant connective tissue disorder caused by mutations of the gene *FBNI* on chromosome 15q21, which is responsible for the production of fibrillin-1, a complex glycoprotein that is a major constituent of various connective tissue types (Dietz et al., 2005; Judge and

Dietz, 2005). Mouse models of MFS have revealed that fibrillin-1 mutations perturb the signaling of local transforming growth factor- β (TGF β), in addition to impairing tissue integrity. This discovery has led to the identification of a new disorder (Loeys-Dietz syndrome), which has significantly worse cardiovascular consequences than MFS, and which has led to new avenues of therapeutic intervention (Dietz et al., 2005; Judge and Dietz, 2005; Ramirez and Dietz, 2007). Cardiovascular (mitral valve prolapse), ocular, craniofacial, and musculoskeletal systems are frequently affected in these patients. The cardiovascular complications of MFS and Loeys-Dietz syndrome, specifically aortic root disease (dilation, aneurysm), aneurysms and dissections throughout the arterial tree, and generalized arterial tortuosity, are the major causes of morbidity and premature death of these patients (Dietz et al., 2005; Judge and Dietz, 2005; Ramirez and Dietz, 2007). The clinical features of the musculoskeletal abnormalities of MFS include scoliosis, joint hypermobility, and craniofacial abnormalities. The prevalence of MFS is 2 to 3 cases per 10,000 individuals; about 25% of patients have no family history.

Aortic size appears to correlate with central pulse pressure, and historically, children with MFS were maintained on β -blockade to slow aortic root growth. Recent literature is in conflict as to the efficacy of this approach. Ladouceur and colleagues (2007) found that children treated with β -blockade had decreased aortic root growth; however, Selamet Tierney and colleagues (2007) found that the rate of aortic root dilation was no different between treated and untreated children. A promising new approach to slow the progression of aortic root dilation uses the angiotensin II-receptor blocker losartan, an antihypertensive medication known to inhibit TGF β signaling (Brooke et al., 2008). The long-term survival of patients with MFS and ascending aortas greater than 50 mm is increased with long-term medical therapy in combination with prophylactic cardiac surgery.

In addition to the cardiovascular anomalies, patients with MFS have a high incidence of pectus deformities and spontaneous pneumothoraces. The inward depression of the sternum that results from excessive growth of costochondral cartilages, in combination with severe scoliosis, produces a precarious physiologic state in which respiratory compromise can result from lung compression, or cardiovascular collapse can occur from impeded venous return, distortion of the great vessels, or diminished coronary perfusion. Operative alteration of the complex three-dimensional geometry of a patient with MFS can result in sudden cardiovascular collapse.

MFS affects the spine in several ways. The prevalence of scoliosis in MFS is greater than 50%; only 10% to 20% of these patients require any treatment. The scoliosis of MFS progresses at a faster rate than in the general population. Sagittal plane spinal deformities are also common in MFS; 40% of patients with MFS have a kyphosis greater than 50 degrees (Demetracopoulos and Sponseller, 2007). These patients are at risk for atlantoaxial translocation with neck flexion and extension (Hobbs et al., 1997). Patients undergoing seemingly routine, uneventful direct laryngoscopy and endotracheal intubation can develop atlantoaxial rotatory subluxation, manifested as unresolved torticollis and neck pain in the postoperative period. These events are thought to result from abnormal bone morphology, the abnormal shape of the atlantoaxial facet, or the laxity of ligaments (Herzka et al., 2000). In a series of 100 patients with MFS, greater than 50% had evidence of increased atlantoaxial

■ **FIGURE 26-5.** Radiograph of the cervical spine of a patient with active juvenile rheumatoid arthritis, showing fusion of the neural arch between joints C2 and C3, narrowing and erosion of the remaining neural arch joints, obliteration of the apophyseal space, and loss of the normal lordosis. (From Miller ML, Cassidy JT: *Juvenile rheumatoid arthritis*. In Kliegman RM, Behrman RE, Jenson HB, et al, editors: *Nelson textbook of pediatrics*, ed 18, Philadelphia, 2007, Saunders, p 1004.)

translation. The preadolescent population had a greater range of motion than did the adolescent or adult groups (Hobbs et al., 1997). Atlantoaxial subluxation has been reported as a cause of sudden death in patients with MFS (MacKenzie and Rankin, 2003). MFS is also associated with dural ectasia, a widening of the dural sac and nerve roots in the caudal portion of the spine. The MRIs of children with MFS suggest dural ectasia in 40% of cases. Dural ectasia can manifest as headache, proximal leg pain, leg weakness and numbness, and abdominal, genital, and rectal pain. Bony erosion can lead to myelomeningocele formation (MacKenzie and Rankin, 2003). As demonstrated in [Figure 26-6](#), the presence of a dural ectatic segment (dilation of the dural sac) could have dramatic implications for neuraxial regional anesthetics, and MRI of the lumbosacral spine should be obtained preoperatively when this technique is contemplated in patients with MFS.

Anesthetic management of patients with MFS starts with a preoperative cardiovascular and cervical spine evaluation. Patients who are destined to undergo prone procedures should have the effects of sternal compression evaluated preoperatively by echocardiography. The anesthesiologist should consult with the patient's cardiologist to determine whether the dosages of β -blockade are appropriate. To minimize the risk for aortic dissection or rupture, the anesthesia technique should aim to decrease myocardial contractility and avoid sudden increases in blood pressure. In the setting of mitral valve prolapse, hypovolemia and tachycardia should be avoided. Nasotracheal fiberoptic intubation may be useful in patients with underlying disease and in those with atlantoaxial instability. The differential diagnosis of sudden intraoperative cardiovascular collapse in these patients with MFS should be expanded to include both a tension pneumothorax and a thoracic distortion that results in cardiac failure.

■ **FIGURE 26-6.** T1- and T2-weighted sagittal MR images of the lumbar spine of a 29-year-old man with Marfan syndrome reveal enlargement of the thecal sac (*yellow arrow*) with mild scalloping of the lumbar vertebral bodies and marked focal thinning of the sacrum (*white arrow*). An enlarged flow void anterior to the spine (*red arrow*) is related to dilation of the descending aorta. (From Sánchez I, Concepción L, Cortés JJ, et al: *Dural ectasia in Marfan syndrome*, *Neurology* 71:1378, 2008.)

SYNDROMES OF DISPROPORTIONATE SHORT STATURE: DWARFISM

Children with dwarfism are unified solely by their phenotype of disproportionate short stature and associated limb deformities. More than 35,000 dwarfs are estimated to live in the United States, and the individual osteochondrodysplasias and mucopolysaccharidoses that produce this phenotype number well over 350 (Berkowitz et al., 1990). Achondroplasia is the most common form of dwarfism, with an incidence of 1 in 30,000 live births. It affects more than 250,000 individuals worldwide (Shirley and Ain, 2009). More than 95% of patients have the same point mutation in the *FGFR3* gene, on chromosome 4p16. *FGFR3* codes for fibroblast growth factor receptors, which normally function as an inhibitor to linear bone growth; achondroplastic mutations exaggerate this normal physiologic function (Horton et al., 2007). The mucopolysaccharidosis (MPS) syndromes (i.e., Hurler's syndrome [MPS I-H], Hunter's syndrome [MPS II], Morquio's syndrome [MPS IV], and Scheie's syndrome [MPS V]) are few in number but pose significant anesthesia challenges. Limb-lengthening techniques, cervical decompression, joint replacement, limb realignment, and bone marrow transplantation for patients with mucopolysaccharidoses are but a few of the procedures that are increasingly being performed on these patients. The number of diseases that constitute the dwarfing syndrome is enormous, and the limited anecdotal anesthesia experience for many of these precludes an encyclopedic review of all of the syndromes. Nevertheless, the common pathologic conditions to a large number of the dwarfing syndromes listed in [Box 26-3](#) should be evaluated in the preoperative preparation of an affected patient.

Airway Abnormalities

The anesthesia management of dwarfs is frequently complicated by anatomic abnormalities of the upper airway and by difficulty in visualization of the larynx during direct laryngoscopy. Inability to intubate is the major cause of morbidity and mortality when anesthetizing dwarfs (Berkowitz et al., 1990). Upper airway obstruction is frequently a result of thickened pharyngeal and laryngeal structures, narrowed nasal passages, micrognathia, copious secretions, pharyngeal hypoplasia, and tracheal narrowing. It is seen most frequently in patients with mucopolysaccharidoses, diastrophic dysplasia, camptomelic dysplasia, severe diastrophic dysplasia, and Russell-Silver syndrome. Some patients demonstrate upper airway obstruction even in the awake state. Airway patency can be severely affected by positional changes alone. Some patients with achondroplasia, Morquio's syndrome, and metatropic dysplasia maintain a patent airway with the neck extended but completely obstruct when the neck is flexed. Sedation and general anesthesia often result in complete upper airway obstruction. Direct laryngoscopy and tracheal intubation are extremely difficult to perform in many dwarfs. Children with mucopolysaccharidoses have been described as presenting the worst airway problem in pediatric anesthesia; 54% of patients with MPS I are difficult intubations, and 23% are intubation "failures" (Martins et al., 2009). Endotracheal intubation is often hampered by inadequate laryngeal exposure from a shortened neck and protruding tongue, infiltration of the glottic and epiglottic structures with abnormal mucopolysaccharide, enlarged tonsils and adenoids,

Box 26-3 Systemic Manifestations of the Dwarfing Syndromes

Upper airway abnormalities: mucopolysaccharidosis (MPS), achondroplasia

- Macroglossia
- Micrognathia (mesomelic dysplasia, diastrophic dysplasia, Russell-Silver dwarf)
- Small oral opening
- Temporomandibular joint immobility
- Tonsillar and adenoidal hypertrophy
- Narrow nasopharynx
- Laryngomalacia

Difficult laryngoscopy: MPS (“most difficult intubations bar none”)

- Abnormal, unrecognizable glottic structures
- Short neck, cervical scoliosis (Morquio’s syndrome, metatropic dysplasia, diastrophic dysplasia, spondyloepiphyseal dysplasia)
- Copious secretions

Upper airway obstruction: MPS

- Abnormal neck position
- Abnormal upper airway
- Laryngomalacia
- Copious secretions

Pulmonary dysfunction: MPS, achondroplasia, asphyxiating thoracic dystrophy (Jeune’s syndrome)

- Restrictive lung disease
- Thoracic dystrophy
- Scoliosis
- Pulmonary hypertension
- Obstructive sleep apnea

Cardiovascular dysfunction: osteogenesis imperfecta (OI), MPS, asphyxiating thoracic dystrophy, achondroplasia

- Congenital heart disease
- Acquired valvular disease
- Cor pulmonale
- Restrictive lung disease
- Obstructive sleep apnea

Neurologic complications: achondroplasia, OI

- Atlantooccipital instability, odontoid hypoplasia
- Cervicomedullary compression
- Intracranial hypertension
- Deafness

Hematologic dysfunction: OI

- Platelet aggregation disorder

Other: OI

- Propensity for bony fractures
- Hypermetabolism

and subglottic, tracheal, and bronchial narrowing. In contrast, the patient with achondroplasia, who may also have narrowed nasal passages and pharyngeal hypoplasia because of cranial base angulation and midface hypoplasia, rarely develops peri-induction airway obstruction and can be easily managed with a face mask (Monedero et al., 1997).

Anesthesia Management

Preoperative sedative drugs should be avoided in patients prone to upper airway obstruction. Before induction, IV access is obtained, and an antisialagogue is administered. If the potential for severe upper airway obstruction and difficult intubation is anticipated, the equipment and personnel required to establish an emergency

airway should be present before the induction of anesthesia (see Chapter 13, Induction, Maintenance, and Recovery, and Chapter 12, Airway Management). Spontaneous ventilation is mandatory. Often, the only way to identify the glottis is by observation of the air bubbles during spontaneous ventilation. An inhalational induction with high concentrations of oxygen and sevoflurane or a continuous IV infusion of propofol or ketamine are equally effective approaches in this situation. After an adequate anesthesia plane is achieved, endotracheal intubation can be accomplished by direct laryngoscopy or by fiberoptic-guided bronchoscopy. Alternatives include insertion of the lightwand and fiberoptic intubation by means of a laryngeal mask airway. Neuromuscular relaxants are avoided until the airway is secured. Rarely, a tracheostomy performed while the patient is awake may be the safest approach. The examiner must avoid neck manipulation, particularly neck flexion during laryngoscopy, in patients with atlantoaxial instability or foramen magnum stenosis.

Pulmonary Dysfunction

The pulmonary dysfunction common to children with a dwarfing syndrome is multifactorial in origin. Restrictive lung disease is a consequence of thoracic cage dystrophy (e.g., Jeune’s syndrome) or scoliosis, and it results in reduced lung volumes, ventilation/perfusion mismatching, progressive hypoxemia, and hypercarbia. Obstructive or central sleep apnea causes pulmonary hypertension, behavioral disorders, substantial morbidity, and sudden death (Sisk et al., 1999). Structural abnormalities, particularly in patients with MPS, may cause intrathoracic obstruction. Children with MPS frequently suffer from chronic sinus infections that result from mucosal alterations and an increased viscosity of their secretions, a combination that produces a milieu of chronic airway inflammation (Martins et al., 2009). The preoperative assessment of these patients must include an evaluation of pulmonary function and a sleep study. The finding of central apnea necessitates a neuroradiologic evaluation of the cervical spine and foramen magnum. The presence and severity of pulmonary hypertension can be determined by an electrocardiography and echocardiography.

Anesthesia Management

The degree of pulmonary dysfunction discovered during preoperative evaluation has profound implications on intraoperative and postoperative management. Severe obstructive sleep apnea may preclude an inhalational induction of anesthesia or the use of premedication. Significant restrictive lung diseases with attendant ventilation/perfusion mismatch, proclivity to atelectasis, and development of an increased Pao_2 - Pao_2 gradient may necessitate placement of an indwelling arterial catheter to ensure adequate gas exchange throughout the perioperative period. The severity of restrictive lung disease dictates the necessity for continued intubation and ventilation postoperatively.

Cardiac Dysfunction

Children with dwarfing syndromes have a variety of causes for cardiac dysfunction. A high incidence of coexisting structural heart disease, such as atrial septal defects, occurs in a number

of the dysplasias. Acquired valvular heart disease is a common complicating feature of children with MPS and is occasionally found in osteogenesis imperfecta. Ischemic heart disease may result from infiltrative mucopolysaccharides or from the consequences of cor pulmonale and longstanding pulmonary hypertension. Cardiomyopathy is a severe problem for children with MPS (Mohan et al., 2002; Rigante and Segni, 2002). Physical examination, chest radiography, electrocardiography, and especially echocardiography are useful in diagnosing the extent of cardiovascular involvement. The most reliable indicators of pulmonary hypertension are the presence of tricuspid regurgitation and prolongation of the right systolic time interval. The electrocardiogram should be reviewed for evidence of myocardial ischemia, particularly in patients with Hurler's syndrome or Hunter's syndrome.

Anesthesia Management

The anesthesia management of a patient with dwarfism, impaired myocardial dysfunction, and pulmonary hypertension must be meticulously planned and executed. Invasive monitoring of arterial, central venous, and, in severe cases, pulmonary artery pressures is frequently necessary. The use of intraoperative transesophageal echocardiography may be warranted in patients with severe valvular dysfunction or those who have evidence of ischemic heart disease. Modest hypoxemia and hypovolemia can exacerbate preexisting pulmonary hypertension and borderline right ventricular function, and must be avoided. The need to maintain an adequate anesthesia depth, crucial in avoiding intraoperative pulmonary hypertensive crises, must be balanced by the limitations imposed by compromised ventricular function. Attention must also be directed to the effects of changes in heart rate, blood pressure, filling pressures, and systemic vascular resistance on myocardial function. In light of these challenges, an opioid-based anesthetic in combination with adrenergic-modulating agents may provide the most stable intraoperative milieu for this subset of patients. The use of opioids in patients at risk for postoperative airway obstruction may result in postoperative intubation and mechanical ventilation.

Neurologic Dysfunction

Cervicomedullary compression and hydrocephalus are the main neurologic concerns in patients with dwarfism. The causes of cervical cord compression include atlantooccipital instability, odontoid process hypoplasia, foramen magnum stenosis, abnormal meningeal glycosaminoglycan deposition, and, infrequently, cervical scoliosis (Kachur and Del, 2000). Foramen magnum stenosis is a frequent complication of achondroplasia. Physical findings or a history consistent with upper motor neuron weakness (e.g., progressive weakness, hyperreflexia, abnormal plantar response), sleep apnea, cyanosis, or respiratory distress is suggestive of cervicomedullary compression. Flexion and extension neck films should be obtained to determine the degree of cervical spine instability in affected patients. Achondroplasia and MPS are associated with increased intracranial pressure; hydrocephalus arises from the impaired absorption of cerebrospinal fluid by the arachnoid granulations (Sheridan and Johnston, 1994).

Anesthesia Management

Improper positioning of the head, neck, and shoulders during the induction of anesthesia, laryngoscopy, and surgery may lead to catastrophic intraoperative cord ischemia. Patients with Morquio's syndrome, diastrophic dysplasia, or achondroplasia are at greatest risk. The maintenance of neck stabilization during intubation or fiberoptic intubation may be advisable. Cervical stabilizing devices such as a halo cast or a Milwaukee brace may be applied before anesthesia to avoid cervical subluxation and dislocation. Unfortunately, these devices may make direct laryngoscopy impossible. Succinylcholine should be avoided when there is evidence of pyramidal tract signs, muscle wasting, or paresis. Autonomic hyperreflexia may be a problem in patients with cervical cord compression or myelopathy.

The coexistence of intracranial hypertension and a difficult airway is particularly challenging to the anesthesiologist. The conventional approaches of inhalational or intravenous induction may have salutary effects on one element of management but catastrophic consequences on another. These conflicting requirements must be balanced on a case-by-case basis. One approach is to use an IV infusion of propofol to place a laryngeal mask airway, through which a fiberoptic bronchoscope is passed. Once identification of the glottic structures is ensured, an intubating dose of propofol is administered to blunt the intracranial pressure response to endotracheal intubation.

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta (OI) is another of the dwarfing syndromes that involves unique problems. It is a heritable disorder of collagen production with varying degrees of severity. Its cardinal manifestation is bone fragility, and it frequently appears in childhood with multiple fractures after little or no trauma. Ninety percent of individuals with OI have mutations of the pro- α 1 or pro- α 2 chains of type I collagen (*COL1A1* or *COL1A2*) genes. A number of those without collagen mutations have mutations involving the enzyme complex responsible for posttranslational hydroxylation of the position 3 proline residue of *COL1A1*. Two of the genes encoding proteins involved in that enzyme complex, *LEPRE1* and cartilage-associated protein, when mutated, have been shown to cause autosomal-recessive osteogenesis imperfecta, which has a moderate to severe clinical phenotype, often indistinguishable from OI types II or III (Basel and Steiner, 2009; Shapiro and Sponseller, 2009). The pathogenetic molecular mechanism of these deletions dictates the severity of the clinical features. Chain exclusion, in which the abnormal chain is not incorporated into the collagen triple helix, produces a milder phenotype. Chain inclusion, in which the abnormal chain is incorporated into the collagen triple helix, results in a defective helix and a more severe phenotype (Basel and Steiner, 2009). The effects of OI manifest as abnormalities of bone, teeth, sclera, and ligaments. The four clinical subtypes are listed in [Table 26-7](#) (Cohen, 2002).

The hallmarks of this disease are bony fragility and multiple fractures after even innocuous trauma. Scoliosis and kyphosis are common, producing significant restrictive lung disease and pulmonary hypertension, especially in OI type III. A majority of patients with OI develop valvular regurgitant lesions. Medical management includes the use of bisphosphonates, which are anti-bone-resorptive drugs (Phillipi et al., 2008; Castillo and

TABLE 26-7. Types of Osteogenesis Imperfecta

Type	Features
I	Mildest form Mild bone fragility; bimodal fracture curve (first peak: between 1 year and puberty; second, smaller peak: postmenopausally in women and after 70 years in men); normal stature; blue sclerae; deafness in some cases, most commonly occurring in second decade; dominant inheritance
II	Most severe form: perinatal lethal form Half do not survive day 1, and 90% are dead by 1 week; extreme short stature; short, bowed long bones, particularly lower limbs; ribs have beaded appearance from recurrent fractures; respiratory insufficiency; absence of calvarial mineralization; dominant mutation
III	Progressively deforming type Many fractures; thin ribs with discrete fractures; curvature of spine that may be severe enough to reduce pulmonary reserve; severe short stature; deafness; dentinogenesis imperfecta; dominant mutation; rare recessives unlinked to type I collagen genes
IV	Mild-to-moderate bone fragility; short stature; deafness in some cases; dentinogenesis imperfecta; dominant inheritance

Samson-Fang, 2009). Some data suggest their efficacy in reducing fracture frequency, increasing bone density, promoting remodeling of previously crush-fractured vertebrae, reducing chronic pain, and improving mobility in children and infants with osteogenesis imperfecta (Cheung and Glorieux, 2008; Phillipi et al., 2008; Castillo and Samson-Fang, 2009).

Anesthesia Management

The mainstay of OI management is orthopedic surgery and rehabilitative physiotherapy (Cheung and Glorieux, 2008; Basel and Steiner, 2009). The hallmark of anesthesia management is to handle these patients very gently. Indeed, fractures may occur from simple procedures such as applying a tourniquet or measuring blood pressure or while positioning the patient on the operating room table. Airway management may cause fractures, and the physician must pay particular attention to the teeth, mandible, and cervical spine. Occasionally, visualization of the airway is difficult, and the use of a laryngeal mask airway, as in other patients with difficult airways, may be very helpful (Kostopanagiotou et al., 2000; Asai and Shingu, 2001). Patients with OI have a hypermetabolic state and become hyperthermic during anesthesia (Benca and Hogan, 2009). This condition is not malignant hyperthermia, even though a few case reports of true malignant hyperthermia have been reported in these patients (Rampton et al., 1984; Porsborg et al., 1996). Many have recommended the use of a total IV anesthesia technique (Karabiyik et al., 2002). The routine pediatric anesthesia practice of preventing intraoperative hypothermia, such as using warming blankets and heated, humidified gasses, should be tempered, and antimuscarinics such as atropine and glycopyrrolate should be used judiciously. Some patients with OI bruise easily as a result of a presumed platelet abnormality. Bleeding

and hemorrhage are rare, but approximately 30% of these patients have abnormal bleeding times, capillary fragility, and reduced levels of factor VIII.

OSTEOPETROSIS

Osteopetrosis (i.e., marble bone disease) is an inherited disease with diminished bone resorption resulting from osteoclastic abnormalities, whose clinical hallmark is hard and brittle bones that fracture very easily (Balemans et al., 2005; Del et al., 2008). The metabolic disorders in this group are genetically heterogeneous. Autosomal-dominant osteopetrosis is the result of either abnormal osteoclast resorption or abnormal low-density lipoprotein receptor–related proteins (Balemans et al., 2005; Del et al., 2008). Clinically, osteopetrosis appears in three forms: infantile autosomal recessive (“malignant”), intermediate autosomal recessive, and autosomal dominant. Children with the severe form of osteopetrosis have insufficient bone marrow to support normal hematopoiesis; thrombocytopenia, anemia, and infectious complications are life threatening in the first decade of life. Patients with all forms of osteopetrosis are at risk for pathologic fractures (Tolar et al., 2004). Stem-cell transplantation is the only curative treatment for malignant osteopetrosis (Driessen et al., 2003). Patients with osteopetrosis frequently require anesthetics for bone marrow examinations and for treatment of their pathologic fractures.

Airway and cervical spine issues dominate the perioperative concerns of those caring for a child with osteopetrosis. Burt and coworkers (1999), in a series of 65 anesthetics for children with osteopetrosis, reported that the rate of airway management difficulties was much higher for this group of children than for the other children anesthetized at their institution. Mandibular abnormalities and TMJ immobility contributed to the difficulty of orotracheal intubation, and abnormalities of the nasal turbinates made nasotracheal intubation difficult. Cervicomedullary stenosis limited optimal head positioning, and concurrent thrombocytopenia exacerbated airway instrumentation and limited the options of a regional anesthetic. Afflicted children are also at risk for spontaneous cervical fractures. Children with the malignant infantile osteopetrosis variant have obstructive sleep apnea and nocturnal hypoxemia (Kasow et al., 2008). No particular anesthesia technique was deemed superior, but there was an emphasis on meticulous preoperative airway preparation with the ready availability of the resources for emergency airway management. Placement of intraosseous needles for emergency vascular access is difficult and nearly impossible in patients with this disease.

CEREBRAL PALSY

Cerebral palsy (CP) is a static encephalopathy defined as a non-progressive disorder of posture and movement that manifests as poor muscle control, weakness, and increased muscle tone (Rosenbaum, 2007). Epilepsy and abnormalities of speech, vision, and intellect that result from a defect or lesion of the developing brain are often associated. It is the most common childhood motor disability, occurring in 2 of 1000 live births (Paneth et al., 2006). The CP phenotype results from multiple etiologies. In premature infants, periventricular leukomalacia is commonly associated with the development of CP. In term

TABLE 26-8. The Four Classification Systems of Cerebral Palsy

Physiology	Topography	Etiology	Functional Capacity
Spastic	Monoplegia	Prenatal	Class I—No
Athetoid	Paraplegia	(e.g., infection,	limitation of
Rigid	Hemiplegia	metabolic,	activity
Ataxic	Triplegia	anoxic, toxic,	Class II—Slight

Unclassified	hemiplegia	Postnatal	to great limitation
		(e.g., toxins,	Class IV—No useful
		trauma,	physical activity
		infection)	

infants, early antenatal insults are attributed to be the cause of CNS injury and can manifest as events at the time of delivery. The most common etiologic factors are prematurity and birth weight greater or less than ideal weight for gestational age (Pharoah et al., 1996; Paneth et al., 2006; Rosenbaum, 2007).

CP can be classified by a description of the motor handicap in terms of physiology (major motor abnormality), topography (extremity involved), etiology, and functional capacity (Table 26-8). Although the CNS lesion is static, the degree of impairment can change with time. CP is commonly associated with a spectrum of developmental disabilities, including mental retardation, epilepsy, and visual, hearing, speech, cognitive, and behavioral abnormalities. The motor handicap may be the least of the child's problems. The necessity to treat each patient's problems uniquely and to avoid generalization cannot be overemphasized. Some children with CP may be of normal intelligence but limited in their ability to communicate. Others with marked developmental delay may be difficult to separate from their parents because of natural fear and an inability to reason in a way expected of children with normal intelligence (see Chapter 9, Preoperative Preparation).

Patients with CP often require multiple surgical procedures. Orthopedic operations to improve function of the extremities are common, and some patients require surgical correction of progressive spinal deformities. Common procedures include surgical soft tissue procedures that reduce muscle spasm around the hip girdle, including an adductor tenotomy or psoas transfer and release.

Several drugs are commonly used in treating spasticity, athetosis, dystonia, and seizures in patients with CP, and many of these drugs have significant anesthesia implications. Drugs used to treat spasticity include dantrolene, benzodiazepines, and baclofen. Incapacitating athetosis is treated with levodopa; dystonia, with carbamazepine and trihexyphenidyl. Seizures are commonly treated with phenobarbital, phenytoin, clonazepam, carbamazepine, and sodium valproate. The muscle spasticity of CP is thought to be caused by inadequate release of the inhibitor γ -aminobenzoic acid (GABA) in the dorsal horn of the spinal cord, resulting in a relative excess of excitatory glutamate on the alpha motor neurons, which produces simultaneous contraction of agonist and antagonist muscle groups. The symptoms of spastic diplegia can be treated surgically with rhizotomy, a procedure in which the roots of the spinal nerves are divided (Albright, 1992). Spasticity can also be treated medically by administering a continuous intrathecal infusion of baclofen or

by local intramuscular injection of botulinum toxin (Albright, 1996a). Baclofen is a GABA agonist that binds to the GABA(B) receptor located in the dorsal horn of the spinal cord, where the primary sensory fibers end, producing presynaptic inhibition of monosynaptic and polysynaptic reflexes. Continuous intrathecal baclofen infusions are used to manage intractable and generalized spasticity while minimizing side effects (Albright, 1996b; Verrotti et al., 2006). Most patients will have improved range of motion, decreased painful muscle spasms, and improvements in independent function.

Intramuscular botulinum toxin A (BTX-A) is also used to relieve dynamic deformities that result from muscle spasticity. After injection, BTX-A is taken up in presynaptic terminals, inhibiting acetylcholine release and functionally denervating muscle fibers within 2 to 3 cm of the injection site. Focal controlled muscle weakness is produced, which reduces spasticity for up to 6 months (Bjornson et al., 2007). Tight heel cords may be treated conservatively with serial casting, with botulinum injection, or surgically with an Achilles tenotomy. The child's particular spasticity and resulting joint contractures require vigilant positioning and padding in the operating room to avoid neurovascular compromise and skin ulcerations.

Preoperative concerns for children with CP focus on their pulmonary, gastrointestinal, and neurologic problems. This population is prone to aspiration pneumonia from gastroesophageal reflux and nasopharyngeal aspiration, as demonstrated by the finding that 75% of children with gastroesophageal reflux and delayed gastric emptying are neurologically impaired (Gisel et al., 2003; Ceriati et al., 2006). Many have chronic lung disease with a reactive component, and they suffer from frequent respiratory infections. Obstructive sleep apnea, seen in 20% to 50% of this patient population, has many causes, including bulbar dysfunction, neurogenic laryngomalacia, and decreased pharyngeal tone (Schwengel et al., 2009). Children with developmental disabilities are more than three times more likely to develop sedation-related hypoxia (Kannikeswaran et al., 2009).

Airway management can be complicated by restricted TMJ range of motion and by poor and malpositioned dentition. Patients with CP commonly have gastroesophageal reflux disease, dysfunctional swallowing, and severe food refusal, all contributing to suboptimal nutritional status that portends increased perioperative complications. Children with severe CP have a significant narrowing of their palates, placing them at increased risk for airway obstruction. Children with CP have a higher incidence of latex allergy than the general population. Thirty percent of children with CP require antiepileptic medications (Singhi et al., 2003).

Perioperative seizure management in the patient with CP is the same as for any patient with a seizure disorder. Most anesthesia agents are anticonvulsants, and they can be used safely in patients with underlying seizure disorders. A few anesthesia agents, such as enflurane, etomidate, ketamine, methohexital, EMLA (i.e., eutectic mixture of local anesthetics, 2.5% lidocaine and 2.5% prilocaine), and normeperidine (an active metabolite of meperidine) are proconvulsants and should be avoided if alternatives are available. Most of these proconvulsant anesthesia agents actually raise the seizure threshold in normal patients and are proconvulsant only in patients with underlying seizure disorders. Patients should take their chronic anticonvulsants on the day of surgery. Virtually all anticonvulsants have a long half-life of elimination (24 to 36 hours), and if blood anticonvulsant levels are within the therapeutic range, a 24-hour period

can elapse without the patient having to take the anticonvulsant and without increasing the risk for a seizure.

In most orthopedic surgical procedures performed in patients with CP, almost any anesthesia technique and combination of drugs can be used. Potent inhaled anesthetics, muscle relaxants (including succinylcholine), hypnotics, sedatives, opioids, and local anesthetics have been used safely. Children with CP appear to have a lower MAC than unaffected children (Frei et al., 1997). Succinylcholine does not cause hyperkalemia, and it can be safely administered to patients with CP. They have a slightly increased sensitivity to succinylcholine compared with normal children (Dierdorf et al., 1985; Theroux et al., 1994). Resistance to nondepolarizing muscle relaxants and rapid recovery from neuromuscular blockade have been reported in this patient population, which may be explained by the increase in extrajunctional acetylcholine receptors (Theroux et al., 2002). Propofol requirements are significantly lower in noncommunicative CP children than in their unaffected peers (Saricaoglu et al., 2005).

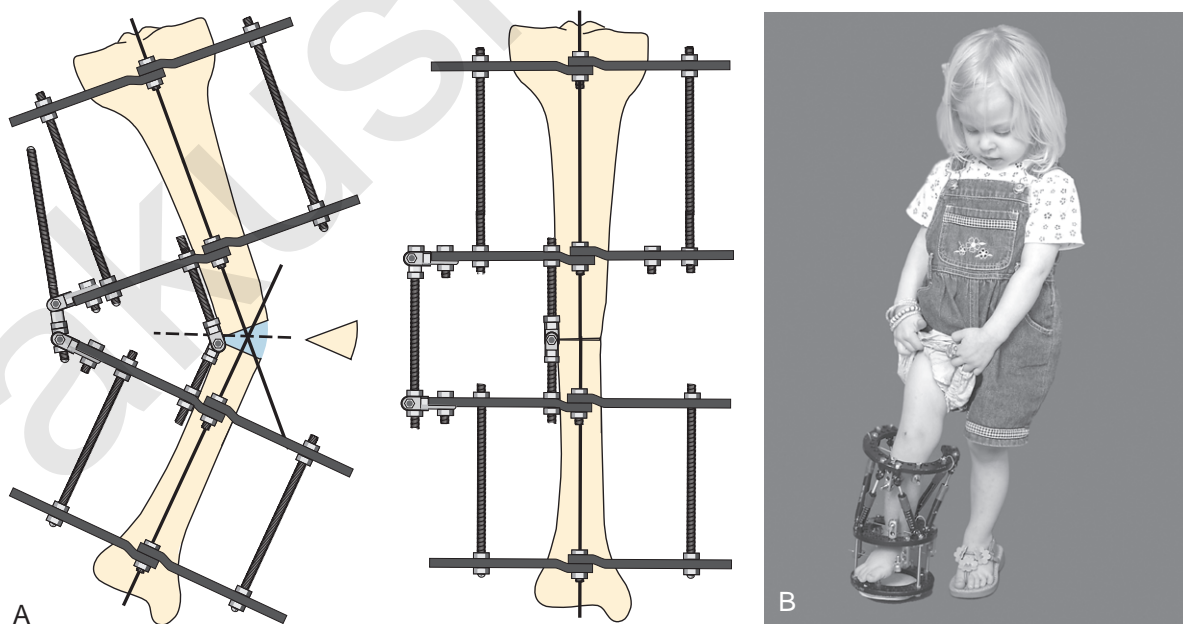

Postoperative pain management is important in the care of patients with CP. The surgical procedures, particularly those for relieving spasticity, are extremely painful. The child severely affected with CP may be unable to communicate his or her pain, and health care providers are often unable to accurately assess the severity of postoperative pain. Parents and other routine caregivers are invaluable in assessing the pain of these patients. The Non-Communicating Children's Pain Checklist–Postoperative Version has been validated for children with intellectual disabilities (Breau et al., 2002, 2003). Postoperative pain is treated with continuous epidural (caudal or lumbar) infusions. Lidocaine (1.5 to 2.0 mg/kg per hour) plus fentanyl (0.5 mcg/kg per hour), chloroprocaine (3 mg/kg per hour) plus fentanyl (0.5 mcg/kg per hour), and bupivacaine (0.625 to 1 mg/mL, 0.2 to 0.4 mg/kg per hour) with or without fentanyl (0.5 mcg/kg per hour) or hydromorphone

(2 to 4 mcg/kg per hour) have all been used. Muscle spasms are virtually universal and are treated prophylactically with IV diazepam. The addition of clonidine to the postoperative epidural infusion at a dosage of 0.08 to 0.12 mcg/kg per hour is also effective at relieving muscle spasm. The management of posterior rhizotomy requires special attention. Often used in severe spasticity, this surgical procedure requires stimulation of the dorsal roots intraoperatively and observation of muscle response (see Chapter 22, Anesthesia for Neurosurgery) (Farmer and Sabbagh, 2007).

ILIZAROV METHOD

Professor G. A. Ilizarov introduced the concept of distraction osteogenesis in the 1950s (Herbert et al., 1995). Working as a general practitioner in Siberia, he found himself treating many patients with chronic osteomyelitis associated with bone loss and many veterans of World War II who had developed fracture nonunions. Using materials from the metal factories at which many of his patients were employed, he fashioned external fixators and transosseous wires to induce the formation of new bone between freshly cut osseous surfaces that are gradually pulled apart. Using this technique, he was able to salvage limbs that otherwise would have been amputated. For many years, he worked in isolation, with his techniques remaining unknown in most of the world (Fig. 26-7).

Over the past 20 years, this method has undergone significant refinements, and it is now employed in the treatment of congenital limb and other skeletal deformities, acquired short limbs, and angular deformities, and in the reconstruction of large bony defects that result from trauma, tumor excision, infection, and fracture nonunions (Herbert et al., 1995). Distraction osteogenesis has also been used to treat the numerous syndromes associated with micrognathia and retrognathia,

■ **FIGURE 26-7.** **A**, Wedge osteotomy (*right*) after application of an Ilizarov apparatus to correct a rotational deformity. With the external fixator in place (*left*), the rotational deformity has been corrected, and the bone is ready for lengthening by slow adjustment of the diaphyseal rings. **B**, Children with external fixators are encouraged to resume as much normal function as possible.

such as the Pierre Robin syndrome, Treacher Collins syndrome, Nager's syndrome, velocardiofacial syndrome, and Pfeiffer's syndrome, all of which can result in airway obstruction (McCarthy et al., 2001; Sidman et al., 2001).

The success of the Ilizarov technique of distraction osteogenesis depends on adherence to the principles of tension-stress phenomena. These include a low-energy osteotomy to preserve periosteal blood supply; a slow, incremental distraction rate to preserve soft tissue blood supply; and maintenance of full function of the extremity. Bone healing is promoted by the biological stress of walking on or flexing a broken limb, causing a trampoline-like effect of pulling and contracting that stimulates bone growth and healing. Using a corticotomy that preserves blood flow to the periosteum and the medullary canal, a gap between healthy, vascular-sufficient bone is created. Wires are inserted into the bone above and below the osteotomy and are attached under tension to an external fixator at 90-degree angles to the plane of the deformity. After an initial latency period, the osteotomy is gradually distracted at a rate of 1 mm/day in four incremental steps. The external fixator serves as the distracting device and provides optimal mechanical stability so that weight bearing and range of motion on the operative limb are possible on the second hospital day. The early functional use of the affected limb stimulates callus formation and osteoblastic activity (Birch and Samchukov, 2004).

Anesthesia Considerations

Because the Ilizarov procedure is applied to children with a wide spectrum of diseases, including those with complex congenital musculoskeletal anomalies, the anesthesia implications of their coexisting diseases often take precedence over those of the operative procedure. These operative procedures are often long and complex but are associated with few hemodynamic perturbations and only modest blood loss. The perioperative complications of the Ilizarov procedure that are affected by anesthesia management include nerve injury and the need for intact motor function and optimal analgesia in the postoperative period. Nerve injury can occur during pin placement and during the distraction process. To recognize inadvertent surgical trauma to nerves in the operative field, neuromuscular relaxation is avoided so that muscle contractions can be recognized. Postoperative surgical pain can be intense in the first 48 hours, and these patients are encouraged to begin physical therapy on the first postoperative day, with an emphasis on passive range of motion and weight bearing (Paley, 1990).

Children undergoing an Ilizarov procedure are often anesthetized with a general anesthetic supplemented with an epidural or peripheral nerve catheter. In most cases, endotracheal intubation is accomplished with short-acting neuromuscular blockade or with deep inhalational or IV anesthesia. Children with concurrent airway or cervical spine anomalies are intubated with a fiberoptic bronchoscope or with a laryngeal mask airway-guided approach during spontaneous breathing. After the induction of general anesthesia, an epidural or peripheral nerve catheter is placed. If an epidural is used, a continuous epidural infusion of 0.8 to 1 mg/mL of bupivacaine with 1 mcg/mL of fentanyl can be started in the operating room at an infusion rate of 1 mL/kg per hour. Anesthesia is maintained with small amounts of opioids and a low concentration of inhaled anesthesia agents. The epidural infusion of bupivacaine and fentanyl is continued for the first 24 to 36 hours postoperatively

and augmented with acetaminophen (see Chapter 16, Regional Anesthesia). In patients who do not have a neuraxial or peripheral nerve catheter in place, IV PCA can be used.

TOURNIQUETS

Pneumatic tourniquets are commonly used to provide a dry operative field and limit intraoperative blood loss during extremity surgery (Kam et al., 2001). Modern pneumatic tourniquets consist of three basic components: a cuff that is similar to a blood pressure cuff and is wrapped around a patient's limb and then inflated, a compressed gas source, and a mechanism with a pressure gauge that is designed to maintain pressure in the cuff at a set value. After elevation and application of an Esmarch's bandage to exsanguinate the limb, the tourniquet is applied over smooth padding and inflated. Older methods inflate the tourniquet to a pressure based on the patient's systolic pressure. Recent practice is to determine the limb occlusion pressure and add a margin of 75 mm Hg for lower extremity surgery and 50 mm Hg for upper extremity procedures. Limb occlusion pressure, first suggested by Cushing, is the minimum pressure necessary to occlude arterial blood flow, as determined automatically or via palpation or pulse oximeter. To prevent accidental injury, the cuff should have a width that is greater than one half of the limb's diameter and an accurate pressure gauge, and the cuff should be inflated to the lowest possible inflation pressure recommended. The duration of inflation should also be carefully monitored (Tuncali et al., 2006; Reilly et al., 2009).

The length of time that the tourniquet can remain safely inflated is controversial. The most common recommendation, 2 hours, is based on the finding that cellular ischemic changes such as mitochondrial swelling, myelin degeneration, glycogen storage depletion, and Z-line lysis are reversible if the tourniquet is inflated for no more than 1 to 2 hours (Patterson and Klenerman, 1979). The deleterious effects of tourniquet inflation include pain while the tourniquet is inflated ("tourniquet pain"), metabolic and hemodynamic changes that occur during tourniquet inflation and deflation, and damage to blood vessels and muscle if the tourniquet is inflated for excessive periods. The use of pneumatic tourniquets has been associated with perioperative neuropathy (Welch et al., 2009).

In awake patients undergoing extremity surgery under regional anesthesia blockade, tourniquet pain is described as a dull, ill-defined ache that occurs approximately 45 to 60 minutes after a tourniquet is inflated. Over time, this pain becomes unbearable, but it subsides immediately after tourniquet deflation. This pain occurs despite adequate regional anesthesia for the surgical procedure itself. The cause of tourniquet pain remains uncertain, and early intervention is imperative. IV opioids have limited efficacy, and induction of general anesthesia or deflation of the cuff is the only effective solution to this problem. Prophylaxis may be possible. The addition of opioids to local anesthesia solutions at the time of neural blockade appears to decrease the incidence of tourniquet pain in patients undergoing a regional anesthesia.

The hemodynamic consequences of tourniquet application include increases in blood and central venous pressures. Kaufman and Walts (1982) reported an overall 30% increase in blood pressure during tourniquet inflation. The blood pressure response is more exaggerated in patients under general

anesthesia than in those undergoing regional blockade (Valli et al., 1987). Tourniquet-induced hypertension can be prevented by the preoperative administration of 0.25 mg/kg of ketamine (Satsumae et al., 2001). Limb exsanguination and tourniquet inflation can redistribute 15% of the total blood volume to the general circulation rapidly. Central venous pressure increases of up to 14 mm Hg have been reported in adults with the application of bilateral tourniquets. The clinical significance of central venous pressure reduction that accompanies tourniquet deflation primarily depends on the presence of preexisting cardiac dysfunction.

The metabolic changes that accompany tourniquet use include an increase in core temperature during tourniquet inflation and the development of transient metabolic acidemia and hypercarbia after tourniquet release. The increased output of CO₂ and lactic acid from the ischemic limb causes a transient decrease in arterial pH, with a maximum decrease within 4 minutes, returning to baseline values within 10 to 30 minutes. The sudden release of CO₂ into the circulation when lower limb tourniquets are released can markedly increase intracranial pressure in patients with head trauma. Normocapnia maintained by hyperventilation after tourniquet deflation can prevent increased cerebral blood flow velocity and intracranial pressure.

Tourniquet-induced hyperthermia, usually 1° to 2° C, occurs within 90 minutes of tourniquet inflation and appears to be the result of decreased cutaneous heat loss from skin distal to the tourniquet. The effect is more profound if bilateral tourniquets are used (Estebe et al., 1996). The combination of metabolic acidosis and hypercarbia that occurs after tourniquet release is the result of reperfusion and the washing out and reentry into the central circulation of lactic acid, potassium, and other toxic substances that accumulated in tissues during tourniquet-induced limb ischemia. Accompanying hemodynamic effects include hypertension and hypotension, tachycardia, bradycardia, and, rarely, ventricular dysrhythmias. These effects are self-limited and usually resolve over a few minutes. Other than increasing minute ventilation in patients who are being mechanically ventilated, most pediatric patients rarely or never require specific therapy for tourniquet deflation.

CLUBFOOT

Clubfoot (talipes equinovarus) is a relatively common congenital deformity that occurs in 1 of 1000 live births (Alvarez et al., 2008; Dobbs and Gurnett, 2009). Most clubfoot deformities are bilateral and can occur in otherwise normal children who have no syndrome, cytogenetic abnormality, or extrinsic cause for the deformity (Drvaric et al., 1989; Cummings et al., 2002). Clubfoot is also commonly seen in patients with neuropathies and myopathies such as myelodysplasia, CP, arthrogryposis, spinal muscular atrophy, and muscular dystrophy (Drvaric et al., 1989; Cummings et al., 2002). Clubfoot has degrees of severity, and the treatment is individualized in each patient. In some patients, manipulation and casting can restore the bony architecture. In others, surgery is required. When to perform surgery is controversial. Some surgeons prefer to operate on neonates; others operate when the affected child is 3 months, 6 months, or older than 1 year.

The patient is positioned prone (for Cincinnati and two-incision techniques) or supine (for Turco incision), and the procedure is performed with a tourniquet. The surgery involves

soft tissue release, including posterior, medial, plantar, and lateral releases; tendon transfer and lengthening; and pin fixation (Drvaric et al., 1989; Cummings et al., 2002). At the completion of surgery, the foot and the calf to the middle thigh are well padded and casted. Postoperatively, patients experience intense pain. Virtually any general anesthesia technique can and has been used for this surgery. Because postoperative pain is such an important aspect of the care of these patients, a combined regional (epidural or sciatic nerve block) and general anesthesia technique is commonly used. The epidural catheter is used intraoperatively and postoperatively.

The percutaneous Ponseti approach to the clubfoot involves weekly stretching of the deformity, followed by application of a long leg cast. By 4 to 5 weeks, all components of the deformity are corrected, with the exception of the equinus. The equinus is addressed with a percutaneous Achilles tenotomy, followed by a final long leg cast (Herzenberg et al., 2002; Janicki et al., 2009).

DEVELOPMENTAL DYSPLASIA OF THE HIP

Developmental dysplasia of the hip (i.e., congenital hip dislocation) is a spectrum of abnormalities of the developing hip joint that ranges from shallowness of the acetabulum to capsular laxity and instability to frank dislocation (Eastwood, 2003; Scherl, 2004). Developmental dysplasia of the hip is relatively common, occurring in 1.5 to 20 of 1000 live births (Swaroop and Mubarak, 2009). Previously known as congenital hip dislocation, it is now understood to be a condition that is not purely congenital but one that develops over time. It is common in children born by breech delivery. Screening in the newborn period consists of looking for asymmetries in skin folds, range of abduction, and height of the knees, as well as using provocative testing. The latter, known as the Ortolani test, elicits a click or clunk as the femoral head is moved in and out of the acetabulum. In the absence of other developmental disabilities, developmental dysplasia of the hip does not cause significant functional disability even if the diagnosis is missed or delayed; however, if untreated, it can lead to degenerative hip arthritis. Ultrasound and MRI are useful for detecting hip dysplasia within the first weeks of life and valuable in following the course of treatment (Harding et al., 1997; Dwek, 2009).

Treatment is designed to relocate and stabilize the femoral head in the acetabulum. Bracing with the Pavlik harness (which prevents extension and adduction of the hip joint while allowing movement in the safe zone) and body casting are used for the first 6 months to 1 year of life. Virtually any general anesthesia technique, including caudal epidural blockade, can and has been used for casting and surgery (Castillo-Zamora et al., 2005).

SLIPPED CAPITAL FEMORAL EPIPHYSIS

Slipped capital femoral epiphysis (SCFE) is a displacement of the femoral head in relation to the femoral neck through the growth plate during a period of rapid growth in adolescence (Aronsson et al., 2006). SCFE is common in obese teenagers and manifests with pain localized to the groin, the knee, or the distal thigh (Kocher et al., 2004). On physical examination, these children limp, and diagnosis is made by obtaining

anteroposterior and frog-leg lateral radiographs of the pelvis. In 20% of patients, SCFE is bilateral on presentation, although only one side may be symptomatic.

Surgical management consists of placing one or two screws across the growth plate of the affected hip to prevent further slippage (Kocher et al., 2004; Aronsson et al., 2006). The pinning is done in situ, meaning that no attempt is made to reduce the epiphysis back to its original position; such maneuvers damage the blood supply to the femoral head and lead to avascular necrosis (Boero et al., 2003). Virtually any general anesthesia technique can and has been used for this surgery. Many of these patients have full stomachs when they present emergently; therefore, patients are at risk for pulmonary aspiration of gastric contents, necessitating a rapid-sequence induction of general anesthesia.

FRACTURES

Children with fractures are among the patients most commonly seen by orthopedic surgeons. Most fractures are simple and treated without an anesthesiologist present. However, major blunt trauma often involves fractures of the long bones in children. These patients should be carefully examined for evidence of trauma that involves other organ systems, particularly the cervical spine. In very young infants, fractures are rare; when they are present, child abuse must be considered in the differential diagnosis.

The method by which to anesthetize a patient with a fracture depends on the urgency of the procedure, the risk for vomiting and aspiration, the child's maturity, and the wishes of the parents and surgeon. Regional or general anesthesia is possible. Regional anesthesia may make it impossible to evaluate motor function even if dilute concentrations of local anesthetics are used. With general anesthesia, full-stomach precautions should be taken to minimize the risks of vomiting and pulmonary aspiration of gastric contents; thus, rapid-sequence induction and airway protection with an endotracheal tube are in order. A complete discussion on how to perform blocks of the upper and lower extremity, and how to manage peripheral nerve catheters, can be found in Chapter 16, Regional Anesthesia.

FAT EMBOLISM SYNDROME

Fat embolism develops in nearly all patients with bone fractures, or during orthopedic procedures, but is usually asymptomatic (Akhtar, 2009). Fat embolism syndrome (FES) is a collection of respiratory, hematologic, neurologic, and cutaneous symptoms and signs that are associated with trauma and other disparate surgical and medical conditions such as sickle cell acute chest syndrome and acute pancreatitis (Georgopoulos and Bouras, 2003). The incidence of the clinical syndrome is low (<1% in retrospective reviews), and embolization of marrow fat appears to be an almost inevitable consequence of closed long-bone fractures (Mellor and Soni, 2001; Parisi et al., 2002). Multiple fractures increase the incidence of FES to 30%. FES is characterized by the triad of hypoxemia, neurologic abnormalities, and a petechial rash (Box 26-4). The challenge to the pediatric anesthesiologist is to recognize the intraoperative manifestations of FES in a multiple-trauma patient or in a patient with an isolated long-bone fracture.

Box 26-4 Diagnostic Criteria in Fat Embolism Syndrome

MAJOR CRITERIA

Pulmonary insufficiency

- $P_{aO_2} < 60$ mm Hg

Neurologic dysfunction

- Confusion
- Disorientation
- Lethargy
- Focal deficits
- Seizures
- Coma

Petechiae

MINOR CRITERIA

Fever

Thrombocytopenia

Anemia

Tachycardia

Elevated erythrocyte sedimentation rate

Retinal changes

Pathophysiology

The pathophysiologic mechanisms that produce the FES remain controversial. In the most accepted mechanical hypothesis, bone injury disrupts the medullary canal, the adipose tissue, and the bone's vasculature; a hematoma forms at the site of this injury. When the intramedullary pressure exceeds venous pressure, fat globules are forced into the circulation (Arai et al., 2007). Chylomicrons are destabilized by the effects of fat intravasation and form very large, circulating fat globules. Fat can be detected in pulmonary arterial samples in up to 70% of patients with long-bone or pelvic fractures, especially if the pulmonary artery catheter is wedged (Byrick et al., 1989). The embolic particles can then obstruct right ventricular outflow or, in the setting of a patent foramen ovale, the systemic circulation. The biochemical hypothesis attributes the manifestations of the FES to the toxic effects of free fatty acids on the pulmonary microcirculation. In the pulmonary vascular bed, these fat particles are hydrolyzed to free fatty acids, which produce pulmonary vasculitis and hemorrhagic pneumonitis—a combination physiologically indistinguishable from acute respiratory distress syndrome. Surfactant activity is compromised, functional residual capacity is decreased, and endothelial integrity is violated, producing a large PA_{O_2} - P_{aO_2} gradient and increased pulmonary vascular resistance. Fat particles and free fatty acids can enter the systemic circulation through pulmonary arteriovenous shunts to generate the central, renal, and cutaneous manifestations of this syndrome. As compared with air, the volume of fat associated with cardiopulmonary failure is 20-fold less (Husebye et al., 2006).

FES can be demonstrated in 90% of patients with long-bone fractures, but symptomatic FES occurs in only 10% to 22% of patients with long-bone or pelvic fractures. Classically, it develops 24 to 72 hours after an injury and is characterized by acute respiratory insufficiency with diffuse pulmonary infiltrates, global neurologic dysfunction, and petechiae. The pulmonary compromise is usually followed by the neurologic changes. If a petechial rash develops, it occurs 48 to 72 hours after the onset of FES. This complete presentation is seen in less than 10% of

cases. Respiratory insufficiency may be the only manifestation of this syndrome, and it may occur in only one third of patients. This unexplained hypoxia is how FES manifests during general anesthesia (van Besouw and Hinds, 1989). Few patients with FES have a fulminant course, in which severe pulmonary hypertension and progressive right heart failure develop within hours of the injury. Vasopressor infusions and cardiopulmonary bypass support may be necessary to treat these sequelae.

The diagnosis of FES is a clinical one, and it may be difficult to establish (Georgopoulos and Bouros, 2003). Supportive laboratory tests include an inexplicable drop in Pao₂, hematocrit, platelet counts, and fibrinogen levels. The characteristic radiograph of bilateral fluffy pulmonary infiltrates may not be apparent for 24 to 48 hours after the onset of FES. Fat is seen in the urine in 50% of patients within 3 days. The usefulness of serum and urinary measurements of fat and lipase activity is limited by their poor sensitivity and specificity and by a lack of availability. Identification of fat droplet cells in bronchoalveolar lavage is the only rapid and specific method of identifying the development of this syndrome (Mimoz et al., 1995). The retinal changes of bilateral cotton-wool spots and intraretinal hemorrhages are seen in 60% of patients with FES.

In the operating room, the time of highest risk for the development of FES occurs when transferring a patient with a fracture from the stretcher to the operating room table. Fulminant FES can manifest within 30 minutes of this transfer, and it is recognized by inexplicable progressive oxygen desaturation and increasing peak inspiratory pressures. A high index of suspicion is necessary to make the diagnosis. Other manifestations of FES during anesthesia include sudden hypotension, tachycardia, bradycardia, dysrhythmia, decreased lung compliance, pulmonary edema, and severe unexplained surgical bleeding or oozing from multiple sites that results from disseminated intravascular coagulation.

End-tidal CO₂ monitoring does not seem to be as sensitive to fat emboli as it is in other embolic states. Although end-tidal CO₂ does change with a massive fat embolism, monitoring it has not been as effective as echocardiography in detecting smaller emboli. Transesophageal echocardiography can detect fat emboli during surgical manipulation of the operative bone, and it can demonstrate the regional wall motion abnormalities and right ventricular dilation that are harbingers of the FES physiologic perturbations (Capan and Miller, 2001).

After FES develops, treatment is nonspecific and supportive. It consists of early resuscitation and stabilization, administration of 100% oxygen, application of positive end-expiratory pressure, and the use of inverse-ratio ventilation. Bronchoscopy and bronchoalveolar lavage are useful in establishing a diagnosis and in removing the intraluminal debris and hemorrhagic exudate that accompany a fulminant presentation. An adequate intravascular volume must be maintained, and inotropic infusions and red blood cell transfusions are often required. Historically, advocated therapies have included IV alcohol, heparin, low-molecular-weight dextrans, and steroids. Limited data support the efficacy of any of these therapies once FES has begun. Early administration of methylprednisolone may decrease the incidence of FES (Lindeque et al., 1987). A 10% mortality rate has been reported for all patients; among children, the mortality rate is 33%.

SUMMARY

The orthopedic patient presents multiple challenges to the anesthesiologist. In many instances, the perioperative anesthesia plan for pediatric orthopedic patients depends more on the child's age and on the site and emergent nature of surgery than on the underlying disease or the specifics of the surgical procedure. In other cases, the underlying medical condition, associated anomalies, pathophysiology, and surgical procedure dictate the anesthesia plan. The anesthesia plan must address these issues and the recurring themes of positioning, airway management, blood loss and fluid replacement, conservation of body temperature, and postoperative pain management. In the future, the continued technological, physiologic, and pharmacologic advances in our specialty will allow longer, more extensive, and more innovative operations on younger and sicker patients than was possible in the past.

A. ARTIFICIAL ORGANS AND ASSIST DEVICES

It is now conceivable that there is not any part of the human body that could not, or should not, be replaced by man-made devices in the twenty-first century. Artificial organs have come a long way since their genesis, when the first man-made kidney was invented over 60 years ago. When the father of artificial organs, Willem Kolff, first dreamed of the purification of blood with an artificial kidney, he met with stiff resistance from some of his hospital superiors. "The Chief Resident got very mad," reportedly; "... such a thing you don't do," he later recalled. However, his persistence paid off, and now some 60 years later over 20 million lives have been saved, all attributed to his first invention.

Later, work on an artificial heart caused even more public ripples, especially when the first patient, Barney Clark, died 112 days after receiving one of the devices in 1982. An even more controversial type of transplant that created significant moral and ethical dilemma was the xenotransplant, in which two baboons were sacrificed and only their livers used for replacement organs. These procedures, along with many others in the past 5 decades, have changed the approach to organ replacement therapy. Even extracorporeal assist devices are being replaced with smaller, continuous, portable implanted devices.

Patients who undergo organ transplants require exposure to potentially toxic pharmaceuticals to suppress their immune systems; otherwise their bodies might reject the organs they receive. However, tissue engineering could make organ transplants a thing of the past. By using a patient's cells to grow new types of tissue in the lab, researchers are finding new ways to custom-engineer new body parts by using a patient's own stem cells.

Bioartificial Kidney

Renal tubular cells perform an enormous number of vital, irreplaceable functions even with the use of dialysis machines. For instance, the kidney functions as an endocrine and exocrine

organ and thus provides vital functions for the human body. Apart from their homeostatic and excretory functions, kidneys also have an endocrine function and therefore are considered endocrine organs. The kidneys secrete active Vitamin D by converting the circulating 25-hydroxycholecalciferol into 1,25-dihydroxycholecalciferol. It also produces the hormone erythropoietin, which is the primary stimulant for red blood cell formation by the bone marrow.

The kidney also manufactures and releases renin into the blood stream, which by acting on the renin-angiotensin system has a regulatory role on vascular contractility and eventually systemic vascular resistance and hence blood pressure, and ultimately influencing cardiovascular function. Lastly but equally important, the kidneys manufacture and secrete prostaglandins as part of their multiple endocrine function. Humes and colleagues have successfully developed a renal assist device (RAD) by seeding human renal proximal tubular cells from cadaveric kidneys (deemed unacceptable for kidney transplantation) into a hollow-fiber, high-flux, polysulfone dialyzer. The normal adult kidney contains approximately one million nephrons. The isolated renal tubular cells line the inner surface of the hollow fibers. This bioartificial kidney is composed of this RAD in combination with a conventional continuous venovenous hemofiltration system. The hemofilter of the system acts as the glomerulus. The ultrafiltrate from the hemofilter is pumped into the lumen of the RAD cartridge and bathes the proximal tubular cells, which perform their metabolic functions. Blood exiting the hemofilter is pumped into the exterior or "dialysate side" of the RAD. Fluid and solutes reabsorbed by the proximal tubular cells of the RAD into the dialysate are mixed with the blood and returned to the patient. The remaining fluid exiting from the RAD is discarded as the urine. Animal studies with the RAD demonstrated increased ammonia secretion, glutathione metabolism, and 1,25-dihydroxycholecalciferol production, and lower plasma-circulating proinflammatory cytokine secretion. Clinically, there appeared to be better cardiovascular

performance and longer survival times. Clinical trials to date with this bioartificial kidney in humans demonstrated increased diuresis from the native kidneys and decreased vasopressor requirement. Further studies of this promising therapy are needed to demonstrate its potential efficacy.

Bioartificial Liver Assist Devices

Acute liver failure (ALF) occurs in approximately 2000 patients per year in the United States. Definitive therapy is orthotopic liver transplantation (OLT). However, liver transplantation is hindered by the increasing shortage of organ donors. Mortality is high in ALF (50% to 80%). For over five decades liver assist therapies and devices have been explored as alternative therapy for ALF, yet to date there is still no definitive effective device. Unlike all the other major organ systems that currently have effective assist devices, there are no such devices for the patient with liver failure. Hence death is inevitable unless spontaneous reversal or transplantation occurs.

The liver performs multiple metabolic functions ranging from protein synthesis inclusive of nearly all the coagulation factors, glycolysis, and gluconeogenesis, and including metabolism of amino acids, lipids, acids, and urea; the detoxification of drugs; and the metabolism of byproducts of multiple cellular processes. More precisely the liver has more than 500 different metabolic functions, and these are difficult to replace by one or a few functional units. This fact has promoted much research into the use of living liver tissue for performing various hepatic functions. The liver also acts in the regulation of the immune system and the metabolism of many hormones in addition to regulating the synthesis of thrombopoietin, thereby influencing the control of platelet production.

In a manner similar to the RAD, bioartificial liver (BAL) support systems often use cultured hepatocytes layered on a bioartificial matrix with an extracorporeal device connected to the patient's circulation, similar to the methodology used in hemodialysis. These devices all attempt to perform, to some extent, the liver's multiple complex endocrine, exocrine, and hematological functions. Currently there are several systems being developed that include the Extracorporeal Liver Assist Device (Vital Therapies, San Diego, California), HepatAssist (Circe Biomedical, Lexington, Massachusetts), Modular Extracorporeal Liver Support system (Charite, Berlin, Germany), and the Amsterdam Medical Center Bioartificial Liver (University of Amsterdam, Netherlands). The HepatAssist and the Amsterdam device use porcine hepatocytes, whereas the Extracorporeal Liver Assist Device and the Modular Extracorporeal Liver Support device use a human cell line.

Although BAL systems have not yet been shown to consistently improve the survival of patients, further development and experimentation is under way. A particularly exciting notion is that of a double-compartment cell-culture apparatus with renal proximal tubular cells on one side of a synthetic microporous membrane and a cell line of hepatic origin at the opposite end. In-vitro studies show that this novel membrane appeared to be capable of selective transport of certain solutes such as ammonium, glucose, and lactate, as well as lidocaine metabolism, suggesting some form of useful interaction between renal and hepatic cells. This type of double-compartment cell-culture apparatus may represent a

novel form of BAL capable of biotransport in addition to biosynthetic and metabolic activities. One of the most impressive artificial liver assist devices was that developed in 1987 by Matsumura et al., who reported the first clinical use of a suspension-cultured hepatocyte system using a hemodialysis chamber in which about 100 g of cryopreserved rabbit hepatocytes (1×10^6 cells) were seeded. The patient with hepatic failure was treated with sequences of repetitive dialysis using the isolated hepatocyte, which eventually resulted in a 68% decrease in total serum bilirubin and improved mental status. However, to date no additional clinical trials of this system have been reported by either the initial research team or other groups. The BAL therapy can function as a bridge to transplantation or liver regeneration. The ultimate goal of these devices is to prevent the eventual complication of ALF, which is hepatic encephalopathy, cerebral edema with uncal herniation that results in death.

Nonbiologic Liver Support

The pathophysiology of ALF results in a number of lower- and middle-molecular-weight toxic substances that are no longer cleared by the dysfunctional hepatocytes, and it results in reduced production of hepatotrophic proteins and other molecules essential for cellular homeostasis. Many attempts have been made to develop nonbiologic liver support therapies based on detoxification of the patient's blood. In the 1950s, hemodialysis was introduced in an attempt to remove toxins; however, no improved survival was appreciated. Hemofiltration alone, however, showed limited benefit.

With the introduction of hemoperfusion and plasma perfusion, a more aggressive approach was also undertaken for the removal of protein-bound substances. Various types of resins have also been used and were particularly effective in the removal of lipophilic substances. Additionally, activated charcoal as an adsorbent of possible toxins has also been used. However, the varied combination of filters and methodologies with charcoal and cation-exchange resins did not improve ultimate survival, although there were invariable reports of clinical improvement as well as survival.

The most promising nonbiologic support therapies to date combine detoxification of water-soluble and protein-bound toxins in a dialysis system, such as the Molecular Adsorbents Recirculating System (MARS), the albumin dialysis system. Unfortunately MARS treatment to date has not demonstrated significant improved survival in controlled trials of all subgroups of patients, except a few with hepatorenal syndrome. MARS uses a system that integrates charcoal hemoperfusion in parallel with a system for removal of albumin bound-molecules perfused across an albumin-exchange chamber. However, the imprecise removal of compounds by these systems and their lack of capacity to synthesize liver-specific proteins and other hepatotrophic factors probably accounts for their limited effect. As with all biologic support devices, however, a significant number of patients have also received transplants, hence limiting the understanding of the true efficacy of these systems. The ability to proceed with a true randomized double-blind controlled prospective study in this population of patients raises a significant number of ethical questions.

All things considered, the concept of BAL support has proven to be successful in experimental animal studies. In addition, clinical application of BAL devices has proven safe by the

current methodology of practice. Clinical evaluation of BAL treatment is rather mired by the variation in the patient groups studied. Additionally, the fact that most patients undergo subsequent OLT prevents any clear understanding whether or not these systems significantly improve morbidity and mortality. However, neurologic and biochemical parameters appeared to improve after treatment with different BAL systems. To ultimately determine the effect of BAL treatment on survival, controlled randomized clinical trials in an appropriate animal model or large patient groups will be required to yield statistically significant outcomes. However, as previously mentioned, a multicenter human clinical trial raises several ethical and moral dilemmas, given that there is an approved effective treatment for the disease entity to be investigated, that being liver transplantation. In parallel, BAL research has focused on the replacement of hepatocytes of animal origin by hepatocytes of human origin, either primary hepatocytes or immortalized cell lines, to overcome possible immunologic reactions, xenozoonosis, and the transmission of porcine endogenous retroviruses (PERVs).

The ultimate quest for the BAL device is filled with enormous difficulty, and possibly better understanding of what substances released by the liver triggers hepatic coma, edema, and brain death will first need to be isolated as a goal to better direct research. Unlocking this key may result in a BAL directed at removing such a substance and could mandate an even greater volume of hepatocytes in the cellular matrices.

Biohybrid Lung

Extracorporeal membrane oxygenation (ECMO) has been the mainstay of therapy for patients who have acute lung injury with severe impairment of oxygenation. It is essentially a heart-lung bypass machine that can be used to support certain critically ill neonates and was once used primarily to care for those with severe complications of persistent pulmonary hypertension, meconium aspiration, congenital diaphragmatic hernia, and sepsis. Since that time, the use of ECMO has decreased, largely because of newer medical advances that have improved the course of these neonates. For some time ECMO was seen as a final therapeutic option for acute lung injury. However, the recent Conventional Ventilatory Support vs. ECMO for Severe Adult Respiratory Failure (CESAR) trial reinstated interest in this support device. Another support device that looms on the horizon is the biohybrid lung.

A membrane oxygenator that incorporates endothelial cells to allow continuous blood flow without the need for or potential risks of anticoagulation therapy will enter animal testing within a few years. This biohybrid oxygenator has the potential to provide functionality and durability unachievable with its fully synthetic predecessors. Another project explores incorporating endothelial cells and microfabrication technology as used in the semiconductor industry to develop artificial alveolar-capillary modules, which may become the building blocks of biohybrid artificial lungs. A related project is focused on developing biologic cellular membranes consisting of tissue cultures between pulmonary epithelial and endothelial cells that may result in a robust biologic membrane with mechanical and gas transfer properties capable of augmenting or replacing pulmonary structures.

Researchers are striving to improve the overall efficiency and the biocompatibility of artificial lung devices. Current

research is focused on the potential to encourage endothelial cell adhesion and growth on commercial and modified microspore polypropylene hollow fibers as a step toward the creation of an artificial lung that is capable of extended patient support. Such research aims to tackle fundamental design issues associated with the artificial lung device, including simultaneous flow, diffusion, and chemical interaction or reaction phenomena.

Through the application of basic tools of chemical-engineering transport phenomena to analyze and understand biotransport processes, researchers are striving towards the concept of the next generation artificial lung. The goal of the program is to manufacture an artificial lung device that retains the ability to support patients with both acute lung disease and/or a failing chronic condition and that may be incorporated into small implantable devices for temporary support, as well as into wearable devices for longer-term support.

The device's novel design incorporates insertion of a central venous catheter into the right atrium or infrahepatic vena cava in order to achieve temporary respiratory support for patients with acute lung failure, pulmonary hypertension, or diseases resulting in chronic hypoxemia. This represents an entirely unique and new way of "breathing" that reduces the demands and strain placed on the lungs, creating a relief period that improves the ability of the injured lungs to recuperate.

B. MANAGEMENT PROTOCOL FOR PATIENTS WITH FULMINANT HEPATIC FAILURE

All the patients with diagnosis of fulminant hepatic failure (FHF) are admitted to the intensive care unit (ICU), and intensivists, the anesthesiologist, surgeons, and the hepatologist are informed.

Patients in stages 1 and 2 of hepatic coma are observed closely.

For patients progressing to stage 3 or 4 of coma, the following steps need to be done in an expeditious manner, because these patients manifest a precipitous clinical decline once they reach late stage 2 or 3. Thus much of the diagnostics and therapy need to be started immediately.

Diagnostics

The main early concern in these patients is the development of intracranial hypertension (ICH) and cerebral swelling. Cerebral herniation is the cause of 80% of mortality in FHF.

Pulmonary Artery

A pulmonary artery catheter and invasive arterial catheters are inserted.

Jugular Venous Bulb Catheter

A jugular venous bulb catheter (preferably on right side) is inserted. The jugular venous bulb catheter position is confirmed with a lateral neck x-ray. The catheter should travel superior in front of the cervical vertebral bodies and terminate at the skull base. Arterial and jugular venous bulb oxygen content is measured. The normal brain arteriovenous (AV) oxygen

content difference is 5 to 6 mL/100 mL. A narrowed AV difference is suggestive of cerebral hyperemia, and a widened AV difference is suggestive of cerebral ischemia.

Caution: Malposition of the jugular bulb catheter or overvigorous blood aspiration may entail extracranial blood that has a higher O₂ saturation and oxygen content. This results in a false low cerebral AV oxygen content difference.

CO₂ reactivity is assessed by AV_{O₂} measurements at two different levels of partial pressure of CO₂ (Pco₂); i.e., 35 and 25. Normalization of the AV difference from a low (narrow) value suggests that hyperventilation may be effective (at least early on) to decrease cerebral hyperemia. Alternatively elevation (widening) of the AV difference (higher than six with induced hypocarbia) is suggestive of cerebral ischemia, and thus the Pco₂ needs to be increased.

Transcranial Doppler

This noninvasive device measures blood flow velocity of the middle cerebral artery (MCA). This device correlates well with more direct measures of flow, such as xenon flow imaging, and AV oxygen content trends. Normal systolic velocity is <100 cm/sec.

CO₂ reactivity can also be assessed by transcranial Doppler. Attenuation of the diastolic flow signal may be a sign of ICH and diminished effective cerebral perfusion.

Xenon Flow Imaging

Computed tomography (CT)-xenon cerebral flow studies can be performed in the radiology suite or at the patient's bedside. In awake subjects at Pco₂ of 40 mmHg, normal averaged Cerebral blood flow (CBF) ranges from 45 to 50 mL/100 g per minute (gray matter 70 to 100 mL and white matter 20 to 100 mL). CBF should be Pco₂-responsive; i.e., it is diminished with hypocarbia with roughly a 3% decrease in flow per mmHg reduction in Pco₂. Loss of CO₂ reactivity is indicative of vasoparalysis.

Continuous Electroencephalograph Monitoring

There is a significant incidence of seizures in these patients because of their underlying metabolic abnormalities. Often these seizures are only electrical. Continuous monitoring is the best method to detect akinetic seizures over a protracted time period.

Intracranial Pressure Monitor

Approximately 50% to 80% of patients reaching stage 3 to 4 of encephalopathy have elevated intracranial pressure (ICP; >20 torr). ICP monitoring is the most accurate and feasible way to monitor such patients, because it provides "second-to-second" feedback for therapeutic measures aimed at controlling elevated ICP. It also provides the clinician with the ability to calculate the cerebral perfusion pressure (CPP; ICP – mean arterial pressure [MAP] = CPP) that needs to be maintained at less than 50 torr. Clearly these patients present a major risk for insertion of an ICP catheter because of their underlying coagulopathy.

The coagulopathy has to be corrected with the use of thromboplastography (TEG) and/or an internal normalized ratio (INR). This can be done with serial boluses of fresh frozen plasma (FFP) or a plasma infusion and platelet transfusions to get the platelet count close to 100,000. Some patients have

thrombocytopenia as a result of uremia or disseminated intravascular coagulation (DIC). This can be treated with cryoprecipitate and desmopressin (DDAVP).

The ICP probe is placed by an experienced neurosurgeon.

An Aesculap epidural monitor system can also be used for ICP monitoring. Its advantages include a less invasive approach, because the dura does not have to be entered and the monitor is self-calibrating. In general, the epidural system is the preferred modality, based on its lower risk and easier maintenance of monitoring.

Transjugular Liver Biopsy

Because of the patient's underlying severe coagulopathy, a transjugular approach is used for biopsy.

Computed Tomography Scanning

A CT of the head to exclude hemorrhage is obtained if the patient is stable for transport. Early signs of intracranial edema (e.g., obscuring of the gray-white margins and shrinking basilar cisterns) are helpful if present but often are not present even when the ICP is elevated. CT scans of the abdomen are obtained to rule out significant pancreatitis, estimate liver volume, and look for signs of chronicity.

Doppler Ultrasound

Doppler ultrasound of the right upper quadrant is used to evaluate for vessel patency and liver homogeneity.

Therapeutics

Most therapy is aimed at minimizing intracranial hemorrhage (ICH). Even if an ICP is not yet in place, a deteriorating mental status in a patient with ALF should be considered to represent possible ICH until it has been proven otherwise. Some other signs of increased ICP may include posturing, rapid shifts in the pupil diameter or pupillary asymmetry, bradyarrhythmias, and hypertension (often a late sign). The following therapies should be considered:

- The head of the bed should be elevated to 30 degrees.
- Minimize elevations of blood pressure caused by agitation, tactile stimuli, suctioning.
- Introduce early airway protection and mechanical ventilation.
- Propofol sedation is the best agent because of its short half-life and titratability
- Hyperventilation is best guided by AV_{O₂} content difference, transcranial Doppler, and ICP.
- Hypothermia may be induced by cooling the patient with an external cooling blanket to 33 to 34° F. Avoid shivering and cardiac depression.
- Mannitol may be given 0.25 to 0.50 g/kg boluses. In patients with renal failure, hyperosmolality (Serum Osm >320) can contribute to rebound ICH. Monitor the serum osmolality every 6 hours.
- For a barbiturate coma it is advised to use short-acting (pentobarbital) or ultrashort-acting agents (thiopental) guided by continuous EEG monitoring to achieve 5- to 10-second EEG burst suppression). The main limiting side effects are

cardiac depression and hypotension. Pentobarbital dosing is usually begun with a bolus of 3 to 5 mg/kg followed by a continuous infusion of 0.2 to 1 mg/kg per hour and titrated based on the EEG, ICP, and hemodynamic status.

- CPP must be maintained at greater than 50 mmHg.
- FHF patients poorly tolerate hemodialysis because of hemodynamic and fluid shifts that may aggravate cerebral edema and cerebral perfusion. **Continuous Veno-Venous Hemodialysis (CVVHD)** is used even in hemodynamically stable patients. Often these patients are fluid overloaded because of a high requirement for blood products; if central venous pressure (CVP) is too elevated, CPP can be compromised. Thus CVVHD is employed early in this population.
- The benefit of **plasmapheresis** has only been anecdotal and has not been supported by any randomized prospective trials. However, plasma exchange may normalize the coagulation parameters and remove some of the unidentified toxins present in the plasma. Patients on CVVHD must be discontinued while on plasmapheresis.
- Anecdotal reports of temporary improvement in both systemic and cerebral parameters have been reported results of **therapeutic hepatectomy**, the removal of the necrosing liver, and the creation of a temporary portacaval shunt.

Sequence and Timing of Observations

The following variables are monitored continuously but recorded every hour:

- Systemic MAP
- CVP
- Pulmonary artery pressure (PAP)
- Core body temperature (°C)

The following variables are monitored and recorded every 4 hours:

- Hepatic coma grade
- Glasgow coma scale
- Arterial blood gas tension and oxygen content, acid-base, and electrolytes (Na, K)
- Hemoglobin and hematocrit (arterial and jugular)
- Blood glucose
- Jugular venous blood gas tension and oxygen content
- Arterial jugular oxygen content difference (AVDO₂)

The following variable is monitored and recorded every 12 hours:

- TEG to determine coagulation status.

The following variables are monitored and recorded every 24 hours:

- CBF by xenon-133 clearance method
- CBF velocity by transcranial Doppler
- Cardiac hemodynamic profile (MAP, PAP, CVP, cardiac index [CI], systemic vascular resistance index [SVRI])
- Liver function test (serum glutamic-oxaloacetic transaminase [SGOT], γ -guanosine triphosphate [gGTP], serum glutamic-pyruvic transaminase [SGPT], alkaline phosphatase, serum bilirubin)
- Serum NH₃ level
- Barbiturate and phenytoin serum level when indicated
- Drug level if there is a history of drug overdose

Initial Management of the Patient in ICU before Transport to CT Scanner

- MAP 80 to 110 mmHg
- CVP 5 to 12 mmHg
- Arterial O₂ saturation >96%
- Pao₂ >80 mmHg
- Blood glucose 80 to 150 mg%
- Hematocrit 30
- AVDO₂ 4 to 8 vol%
- Coagulation
- Reaction time <12 minutes
- Maximum amplitude >40 mm

Management of the Patient after Insertion of ICP Monitor

- MAP 80 to 110 mmHg
- CPP >60 mmHg
- CVP 5 to 12 mmHg
- Pao₂ >80 mmHg
- Arterial O₂ saturation >96%
- Base deficit <-7
- pH 7.3 to 7.5
- Hematocrit >30+2
- Blood glucose 80 to 150 mg%
- Serum osmolality <320
- Serum sodium 140 + 5
- Coagulation
- Reaction time <12 min
- Maximum amplitude >40 mm
- Afebrile
- If the patient is in renal failure, start systemic continuous ultrafiltration dialysis

Cerebral Hemodynamic Parameters: Treatment Plan Criteria and Actions

1. ICP <20 mmHg
AVDO₂ 4.5 to 9 vol%
Low CBF
No cerebral swelling
Action: continue to monitor
2. ICP <20 mmHg
AVDO₂ <5 vol%
Normal or high CBF
No cerebral swelling
Action: mild hyperventilation
3. ICP 20 to 30 mmHg
AVDO₂ <5 vol%
Low, normal, or high CBF
No cerebral swelling
Actions: moderate hyperventilation, head raised 20 degrees, mild hyperthermia
4. ICP 30 to 40 mmHg
AVDO₂ >5 vol%
Low CBF
No cerebral swelling
Actions: head raised 30 degrees, mild hypothermia
5. ICP 30 to 40 mmHg
AVDO₂ >5 vol%

Normal or high CBF

Cerebral swelling

Actions: head raised 30 degrees, mild hypothermia, intravenous (IV) furosemide (80 mg), mannitol (0.5 to 1 g/kg IV)

6. ICP >40 mmHg

AVDo₂ <5 vol%

Low, normal, or high CBF

Cerebral swelling

Actions: hyperventilation, head raised 30 degrees, mild hypothermia, furosemide (80 mg IV), mannitol (0.5 to 1 g/kg IV), barbiturate (pentobarbital load 3 to 5 mg/kg, continuous infusion 0.2 to 1 mg/kg per hour titrated to ICP and cardiovascular effect).

Before initiation of barbiturate, increase the dose of vasopressor (adrenaline, noradrenaline infusion) to maintain MAP >80 mmHg and CPP >60 mmHg.

Criteria for Liver Transplantation

1. There is an ICP >35 mmHg and refractory to therapy or episodes of high ICP >40 mmHg without stimulation.
2. The liver biopsy shows >70% hepatocyte damage or progressive increase in hepatocyte damage on repeat liver biopsy
3. To maintain arterial oxygen tension (PaO₂) >80 mmHg, >7.5 cm H₂O positive end-expiratory pressure (PEEP) and/or fraction of inspired oxygen (FiO₂) >50% are required.
4. Epinephrine infusion (>0.1 mcg/kg per minute) is required to maintain MAP >80 mmHg.

Criteria for Continuation of Medical Therapy

1. ICP is decreasing without episodes of high ICP (>40 mmHg).
2. Liver biopsy shows <30% hepatocyte damage without progressive increase in damage shown by repeat liver biopsy.
3. Liver enzymes and prothrombin time (PT) are improving.

Maintenance of Mean Arterial Pressure

To maintain MAP between 80 to 110 mmHg, CVP of 8 to 12, and CPP >60 mmHg, the initial vasopressor for hypotension is dopamine (2 to 10 mcg/kg per minute). If more than 10 mcg/kg per minute is required, then epinephrine infusion is initiated and titrated as needed.

Base Deficit

Base deficit will be corrected by using tris(hydroxymethyl) aminomethane (THAM) infusion. This will prevent rise in CO₂, osmolality, and serum sodium. THAM also increases the pH of extracellular fluid in the brain that may be necessary for the effectiveness of prolonged hyperventilation.

Pharmacologic Support

Common medications that all or some patients require include the following:

- H2 block or pantoprazole (gastritis prophylaxis)
- Lactulose (oral or enema—accompanying ileus may make oral route difficult)

- Neomycin
- N-acetylcysteine, preferably via IV every 4 hours. Data has suggested its use in non-Tylenol injury and for periods exceeding the usual 17 doses.
- IV acyclovir may be considered for patients who might have herpes simplex virus (HSV) hepatitis.
- Piperacillin/tazobactam (Zosyn) and fluconazole for prophylaxis during candidate period
- Vitamin K
- Dextrose-based IV fluids
- Vasopressors (usually norepinephrine)
- Hydrocortisone (determined based on random cortisol levels)

Other Diagnostics

Standard

- Values for electrolytes, ionized calcium, lactate, ammonia, amylase, lipase, SGOT, SGPT, γ -glutamyltransferase (GGT), bilirubin, complete blood count (CBC) plus differential, hematocrit, platelets, PT, (partial thromboplastin time (PTT), DIC panel, arterial blood gasses (ABG), and lactate
- Random cortisol level
- Hepatitis—A, B, C, D, E serology
- Human immunodeficiency virus (HIV)-1 antibody
- Autoimmune panel (e.g., antinuclear antibody [ANA], anti-mitochondrial antibody [AMA], anti-deoxyribonucleic acid [anti-DNA], anti-smooth muscle, antimicrosomal)
- Serum ceruloplasmin, serum copper, urine copper collection (if appropriate)
- Blood type and cross match
- Tissue typing
- Routine blood cultures
- Viral blood cultures
- Urine/blood toxicity screens
- Acetaminophen level
- Urine pregnancy screen
- Creatine phosphokinase (CPK)
- Troponin level
- TEG

Prognostic Tests

- α -Fetoprotein level (higher levels are more favorable)
- Factor V level <30% predicted
- Factor VIII/factor V ratio
- Arterial ketone body ratio

C. CHILDREN'S HOSPITAL OF PITTSBURGH OF UPMC LIVER TRANSPLANTATION PROTOCOL

Personnel

A fellow, senior anesthesia resident or senior nurse anesthetist should be the assigned along with an attending anesthesiologist.

Premedication

If clinically indicated, patients should receive oral, IV, or intranasal midazolam. Avoid intramuscular injections.

Monitors

In addition to the usual standard monitors, an arterial catheter should be placed in the radial or axillary artery (24, 22, or 20 gauge, sized for the patient's age). The aorta will invariably be crossed clamped, and hence femoral arterial monitoring may be interrupted. Pulse oximeters should be placed on the upper extremity for the same reason. In the event upper extremity arterial access is difficult or unavailable, the femoral artery should be catheterized (18 to 22 gauge) and an upper extremity noninvasive blood pressure (NIBP) should be used if the aorta is cross clamped for the hepatic artery reconstruction (20 to 30 minutes).

Venous Access

A right internal jugular (RIJ) double- or triple-lumen central venous catheter should be placed (sized appropriately for the patient's age) unless venovenous bypass is planned (this procedure is limited to patients weighing more than 20 kg); in such instances, use the LIJ for central line placement. Two large-bore (sized appropriately for the patient's age) peripheral IV catheters or canulae for large-volume resuscitation are necessary. The following list shows catheters that are preferable according to a patient's weight:

- 5 to 10 kg: 22-, 20-, or 18-gauge angiocatheter
- 11 to 20 kg: 20-, 18-, or 16-gauge angiocatheter
- 21 kg and over: 16- or 14-gauge angiocatheter and 7F rapid infusion catheter (RIC)

For all patients over 40 kg, ensure placement of at least one 7F RIC (possibly 2) or the equivalent with a 14-gauge angiocatheter. IV cannulae are best placed in the upper extremities, because the vena cava may be crossed clamped transiently during the procedure. If venovenous bypass (VVBP) is to be used, placement of a RIJ bypass cannula may be optimal.

Induction and Maintenance of Anesthesia

Patients without serious cardiac disease or multisystem organ failure will tolerate routine induction of anesthesia followed by endotracheal intubation; otherwise a rapid-sequence induction is recommended. A rapid-sequence IV induction (where indicated) after appropriate preoxygenation should include the following:

Atropine (0.01 to 0.02 mg/kg)

Sedative hypnotic agents:

- Propofol: 2 to 5 mg/kg
- Etomidate: 0.2 to 0.3 mg/kg
- Ketamine: 1 to 2 mg/kg

Muscle relaxants:

- Rocuronium: 1 to 1.5 mg/kg
- Succinylcholine: 1 to 2 mg/kg

Airway:

A *cuffed* endotracheal tube appropriate for age and size.

Medications on Back Table

An appropriately sized syringe of the following medications should be readily available:

- Propofol: 2 syringes (10 mg/mL)
- Fentanyl: 1 to 5 mL (50 mcg/mL)
- Cisatracurium: 2 to 5 mL (2 mg/mL)
- Rocuronium: 1 to 5 mL (10 mg/mL)
- Succinylcholine: 1 to 5 mL (20 mg/mL)
- Atropine: 2 to 5 mL (0.4 mg/mL)
- Glycopyrrolate: 1 to 2 mL (0.2 mg/mL)
- Calcium chloride (or gluconate): 10 mL (10 mg/mL)
- Epinephrine: 1 mcg/mL (10 mL) (only for patients <10 kg)
- Epinephrine: 10 mcg/mL (10 mL)
- Epinephrine: 100 mcg/mL (10 mL)
- NaHCO₃: (10 to 50 mL)
- THAM: 1 500-mL bottle (1 mL of NaHCO₃ is equal to approximately 3 mL THAM)

Positioning

- The patient is positioned supine on the operating table, with the arms abducted (<90 degrees) and elbows flexed. Use arm boards if necessary.
- It is essential to keep the patient covered, warm, and dry. Avoid stretch injury of the brachial plexus or pressure necrosis of the occiput, ears, heels, sacrum, or elbows.
- Place infants and smaller children on a Bair Hugger warming blanket.
- For older children, place a Bair Hugger warming blanket on the upper (at the nipple line) and lower extremities.
- Cover the head with a plastic wrap in all cases.
- Heat the operating room to 80° to 85° C for at least 15 to 30 minutes before entering.
- Heat all humidified gases and IV fluids if possible.

Additional Adjunct Monitoring

- Rectal, esophageal, or urinary temperature probe
- Esophageal stethoscope
- Indwelling urinary catheter
- Peripheral nerve stimulator only if essential to assess muscular paralysis
- Pulse oximeter on the index finger of the nondominant hand
- Electrocardiograph (ECG) leads placed laterally on the arms and leg (Avoid placing leads posteriorly, because compression necrosis may occur with the leads.)

Ventilation

- Pressure-controlled ventilation is preferable. Adjust as necessary to maintain optimal tidal volume. Peak airway pressure should be less than 20 cmH₂O.
- Tidal volume and respiratory rate should be adjusted to maintain a normal end-tidal CO₂ and arterial CO₂ level of 35 to 40 mmHg.
- Air-oxygen is used with an inspiratory oxygen concentration sufficient (40% to 60%) to maintain adequate oxygenation saturation of 96% to 100%.

- PEEP of 5 cm H₂O is routinely added, because progressive atelectasis is common.
- Do not use nitrous oxide after induction.

General Anesthesia Maintenance

Maintain General Anesthesia

- Isoflurane is the agent of choice. Isoflurane at less than minimum alveolar concentration (sub-MAC) maintains the relation of hepatic oxygen supply to hepatic oxygen consumption better than thiopental, halothane, or sevoflurane.
- Fentanyl, 5 to 10 mcg/kg, as needed and depending on the physiologic status may be used.
- As a muscle relaxant, cisatracurium, 0.1 to 0.2 mg/kg loading dose, if the preferable drug, because metabolites of steroid-based agents may accumulate. 0.03 mg/kg maintenance is recommended for muscle relaxation. There may be varying degrees of renal dysfunction in patients with end-stage liver disease (ESLD).
- Avoid a total IV anesthesia (TIVA), as it is difficult to predict the degree of blood loss during an OLT. Use of a TIVA may result in the patient not being sufficiently anesthetized, because the amount of blood loss may result in significant drug loss down a concentration gradient insufficient to maintain anesthesia.

Fluids and Electrolytes

Arterial blood gas, i-STAT electrolyte monitoring, and hemoglobin/hematocrit levels

Monitor the following conditions every hour (or more frequently in the case of massive hemorrhage and exsanguination).

- 0.9% NaCl for blood-infusion line
- Plasma-Lyte for maintenance IV fluids
- IV infusion for RIJ line (dextrose 5% [D5W], 0.2% NaCl at 1 to 2 mL/kg per hour to maintain glucose at 80 to 120 mg/dL (remember to discontinue) after graft reperfusion if methylprednisolone is administered and the glucose is elevated.
- Ionized hypocalcaemia is a consequence of citrate intoxication; treat with CaCl or gluconate, 10 mg/kg if the Ca²⁺ < 0.9 mg/dL.
- Hyponatremia may be evident at the time of induction; use Plasma-Lyte as well as 0.45% NaCl and avoid 0.9% NaCl. The current formulation of Plasma-Lyte does not contain calcium. Avoid correcting hyponatremia rapidly, because doing so may precipitate central pontine myelinolysis (CPM).
- A serum Na⁺ greater than 145 or less than 130 mEq at the time of induction places the patient at increased risk of CPM. Therefore avoid NaHCO₃ for treatment of acidosis. It is preferential to use THAM. Additionally, use Plasma-Lyte and 0.45% NaCl for fluid replacement. Avoid albumin because of its sodium content of 145 mEq.
- In the case of hyperkalemia, treat potassium levels greater than 5 mEq/dL with an insulin and glucose infusion and/or HCO₃ (1 mEq/kg) + CaCl (10 mg/kg); wash all red cells if possible.

- Ionized hypocalcemia (Ca²⁺ < 0.9 mg/dL) should be treated with CaCl, 10 mg/kg.
- Acidosis should be treated with NaHCO₃ or THAM.

Base deficit greater than or equal to -5 mEq/dL (i.e., -5, -6, -7,...)

- The dose equivalent of THAM to HCO₃ is 3 mL THAM = 1 mL HCO₃.
- Always use Thamasol when the Na⁺ is greater than 145 mEq/L or less than 130 mEq/L.
- The formula to calculate the bicarbonate replacement is as follows:

$$\text{Weight (kg)} \times \text{Base deficit (BD)} \times 0.25 = \text{mEq HCO}_3 \text{ required.}$$

Coagulation

CBC + platelets, PT, activated PTT, fibrinogen, fibrin split product and lactate values should be sent at the following five time points below and more frequently if indicated.

1. Base line values after induction
2. 60 Minutes after skin incision
3. II + 30 Minutes (30 minutes into stage II—after ligation of hepatic artery and portal vein)
4. III + 30 Minutes (30 minutes after reperfusion)
5. III + 90 Minutes (hepatic artery and portal vein reperfused and biliary reconstruction started)

Approximately 80% of patients develop postreperfusion syndrome (PRS), of which only 20% need to be treated). Coagulation abnormalities should be treated based on TEG findings and clinical evidence of bleeding along with consultation with the lead surgeon.

- To achieve adequate coagulation, approximately 25% activity of all the clotting factors is needed. Hence for a 10-kg child with a blood volume of 800 mL, only 200 mL of FFP plus cryoprecipitate is needed to achieve adequate clot formation.
- A platelet count of less than 50,000 should be treated with 1 Unit/10 kg.

TEGs should be performed at these intervals:

1. Base line after induction
2. 60 Minutes after skin incision
3. II + 30 Minutes (30 minutes after hepatic artery and portal vein crossed clamped)
4. III - 5 Minutes (5 minutes before reperfusion)—optional if time allows
5. III + 5 Minutes (5 minutes after reperfusion)—three channels: natural, aminocaproic acid, and protamine.
6. III + 30 minutes (30 minutes after reperfusion)
7. End of postbiliary reconstruction

Fibrinolysis is noted in 80% of patients postreperfusion, but only a few need to be treated. Review the TEGs before treatment, as there are concerns for hepatic artery thrombosis (HAT; ≈20% of the pediatric population). Fibrinolysis is best treated with sigma aminocaproic acid, 10 to 20 mg/kg. Additionally, platelets and cryoprecipitate should be administered depending on TEG findings. All products should be administered in consultation with the surgical colleague to determine whether there is a significant prothrombotic risk.

Blood Transfusion

The primary goal is to minimize the risks of bleeding and hepatic artery thrombosis.

- Avoid overtransfusion.
- At all cost maintain the hematocrit at 26% to 28%.

Clinical Pearls

Hematocrit

1. Part packed RBCs + 2 Parts liquid = Hematocrit \approx 28%
Hence,

100 mL Packed RBCs + 200 mL Crystalloid

or

100 mL Packed RBCs + 100 mL Crystalloid + 100 mL FFP

Either of these mixtures will generally result in a solution with a hematocrit of 28% to 30%. It is preferable to use such a mixture for blood replacement if the results of the hourly blood gas monitoring indicate the need.

Postreperfusion syndrome

Dopamine and epinephrine infusions should be available for all cases. Hypotension upon reperfusion is not uncommon, and if it persists after the first 60 to 90 seconds, it should be treated with a bolus of epinephrine; usually 0.5 to 1 μ mcg/kg is more than enough. Hypotension that requires additional vasopressor 5 minutes after reperfusion should be treated with an infusion of dopamine. If there is a poor response to dopamine then epinephrine should be used. Additional measures to optimize the patient's condition before reperfusion are herein suggested:

- Increase oxygen to 1 Fio₂ about 2 to 5 minutes before reperfusion.
- Double the minute ventilation; acids will be released from the ischemic liver.
- Turn off the isoflurane (temporarily) and give supplemental IV agents 2 to 5 minutes before reperfusion, preferably additional midazolam and fentanyl.

If there is hyperkalemia that has not been adequately corrected (potassium level is greater than 5 mEq/dL), then consider pretreatment with epinephrine 0.5 to 1 mcg/kg before the upper caval anastomosis is unclamped, to prevent the “cardioplegic effect” of the perfusate released from the liver. Coordinate the timing with the surgeon.

- Dopamine, 5 to 25 μ cg/kg per minute, is the first choice for PRS hypotension.
- Epinephrine, 0.01 to 0.2 μ mcg/kg per minute is the second choice for PRS hypotension.
- Vasopressin, 0.01 to 0.04 Units/min; discuss its use with the surgeons before its administration. Its use is inconsequential during stages 1 and 2 (and possibly beneficial by reducing blood loss), but it may affect hepatic blood flow with the transplanted liver during stage 3.

- Correct acidosis and any electrolyte abnormalities before reperfusion (HCO₃ less than or more negative than -5 or an ionized Ca²⁺ of less than 0.90 mg/dL before reperfusion).
- Replace magnesium (Mg²⁺), because it too is chelated.

Pharmaceuticals: Drug Administration

Antibiotics

- Piperacillin and tazobactam (Zosyn), 75 mg/kg at induction and then every 6 hours

Patients Who Are Allergic to Penicillin

- Aztreonam (Azactam), 30 mg/kg at induction and every 6 hours
- Vancomycin, 10 mg/kg at induction and every 8 hours

Recommended Infusion Rates for Additional Drugs that May Be Infused

- Heparin, 5 Units/kg per hour
- Dextran, 2.5 to 5 mL/hr
- Alprostadil (Prostin VR), 0.003 mcg/kg per minute
- Caspofungin, if indicated for antifungal prophylaxis; preferable to amphotericin B liposomal complex (AmBisome):
 - Ages 2 to 11 years: 70 mg/m² (body surface area [BSA] calculation needed) as a loading dose followed by 50 mg/m² for maintenance daily.
 - Older than 12 years: 70 mg as a loading dose followed by 50 mg for maintenance daily.
 - Amphotericin B liposomal complex (AmBisome), if requested: 3 mg/kg.
- Metronidazole, 10 mg/kg every 8 hours
- Hydrocortisone, 2 mg/kg as a bolus if requested

Immunosuppression

Liver, multivisceral, and small-bowel patients

- Thymoglobulin, 5 mg/kg given over 12 hours, starting with induction of anesthesia. Pretreat all patients with methylprednisolone, 2 mg/kg, and diphenhydramine, 1 mg/kg.

Small bowel patients

- Alemtuzumab (Campath), 0.4 mg/kg given over 8 hours. Pretreat all patients with methylprednisolone, 2 mg/kg, and diphenhydramine, 1 mg/kg.
- 10 mg/kg methylprednisolone bolus before reperfusion

D. XENOTRANSPLANTATION

Xenotransplantation is by no means a new concept in medicine. The term *xenotransplantation* is defined as “the transplantation of living organs, cells or tissue from one species to another.” Combining parts of different species dates back to Greek lore from over 3000 years ago in the forms of the centaur

(half man and half horse) and the Chimera (a mixture of goat, lion, and serpent). In terms of medical procedures, the earliest example of combining human and animal parts was in 1682, when a Russian physician repaired a man's skull using the bone of a dog. After the turn of the twentieth century, doctors began grafting tissues from animals to humans, a prime example of this being in 1905, when a French surgeon used slices of rabbit kidney to treat a child suffering from kidney failure. As exploration into xenotransplantation continued with other animals such as pigs, goats, lambs, and monkeys, doctors began to notice that these transplants would fail in relatively short amounts of time, lasting for only weeks at best. It wasn't until the 1940s, when the cause for these transplantation failures, and thus the most significant setback within xenotransplantation, was identified as a crucial connection between the immune system and the rejection of a transplanted organ.

Although experimental xenotransplantation has existed since the early part of the past century, the potential use of xenografts has remained highly controversial. The first human xenotransplantations were performed during the 1960s and 1970s. In 1963 a baboon kidney was transplanted into a woman with end-stage renal failure. The baboon kidney functioned for 3 days, at which time the woman developed severe gastrointestinal hemorrhage, hypotension, and xenograft failure. The xenograft was removed, but the woman continued to bleed and died on the fifteenth day. Subsequently several other attempts were made with the use of primate organs, such as hearts, kidneys and livers, all with the same results; graft failures with high associated mortality rates in the recipients.

With approximately 120,000 individuals on the waiting list for organ transplants and nearly 5000 yearly deaths for those awaiting an organ transplant, all alternatives have been explored for resolution of this burgeoning health care dilemma. Organ shortage continues despite the fact that transplantation centers have liberalized their acceptance criteria for suitable deceased donor livers, advanced living related organ donation, and exploited the use of immunosuppressive agents and newer regimens that have resulted in improved graft and patient survival. These advances, in the past three decades particularly, have led to an increased demand for organs, creating a wide gap between organ availability and supply. Because the number of transplants performed worldwide is limited by this dramatic donor shortage, alternative sources need to be explored. A wider availability of organs would allow an expansion rather than a contraction of the indication for transplantation and at the same time a relaxation of the patient-selection criteria. Hence the continued interest in xenotransplantation, which has exploded in the last decade.

The first cardiac xenotransplantation, performed by Hardy et al. in 1964, also represented the first attempt at cardiac transplantation in humans, predating Barnard's report by nearly 4 years. Since 1964, when Hardy and colleagues at the University of Mississippi performed the world's first heart xenotransplant using a chimpanzee as a donor, there have been eight documented attempts at clinical heart xenotransplantation. Five of these donors were nonhuman primates (two baboons and three chimpanzees), and three were domesticated farm animals (one sheep and two pigs) (Hardy et al., 1964; Cooley et al., 1968; Marion, 1969; Ross, 1969; Barnard et al., 1977). However, by the time the first human neonatal cardiac xenotransplantation was performed by Bailey in 1984 (the so-called "Baby Fae" case), there had been only limited experimental experience with

prolonged graft survival in the newborn xenotransplant recipient. "Baby Fae," was a newborn infant with hypoplastic left heart syndrome and became the longest survivor with a heart xenotransplant (Cooper et al., 2000). This recipient heart of an ABO-blood group-mismatched baboon functioned for 20 days (Bailey et al., 1986). Studies presented by Bailey and coworkers shortly before the Baby Fae case described a mean survival time of 72 days in newborn lamb-to-goat xenotransplants, with one survivor living to 165 days. (Bailey et al., 1985). More recently, Czaplicki and coworkers in 1992 described a case in which they attempted the xenotransplantation of a pig heart into a human recipient with Marfan syndrome (Czaplicki et al., 1992).

In 1992, Makowka and colleagues in Los Angeles transplanted a pig liver into a 26-year-old woman dying of ALF from autoimmune hepatitis and FHF. Subsequently, also in the early 1990s, two baboon-to-human liver xenotransplantations were performed in Pittsburgh (Marino et al., 1994). These experiences demonstrated that humans might live with a baboon liver. However, chimpanzees are most likely the perfect donor for human transplantation, biologically speaking, primarily because of the very small genetic differences between this species and humans, or rather the enormous amount of genetic homology shared between the two; approximately 98% of the DNAs of both species appears to be identical.

The endangered status of the chimpanzee, however, prevents their widespread use for clinical purposes. In the United States fewer than 100 chimpanzees may be used for biomedical research annually, and it is estimated that possibly only 70 additional chimpanzees per year would be available worldwide as potential organ donors. Therefore their use (as well as the use of other great apes such as the gorilla) would further jeopardize these species and would raise insurmountable ethical concerns without solving or greatly impacting the organ shortage problem.

Therefore a universal feature of xenotransplantation remains the short graft-survival times of all the aforementioned trials. The fact that these efforts in xenotransplantation have been ongoing for almost 40 years and there are no reports of 1 year of xenograft-survival conveys the additional fact that there are no near-term prospects of introducing clinical xenotransplantation, even with the release of the governmental restrictions on the use of stem cells.

Before the concept of xenotransplantation advances to a clinical reality, at least four practical challenges must be overcome. First and foremost, however, it is of paramount importance to understand that there are three main rejection mechanisms preventing the clinical application of a pig-to-human xenotransplantation procedure; namely hyper-acute rejection (HAR), AHXR (AHXR) and cellular xenograft rejection (CXR).

1. The first challenge consists of comprehension of the immunologic barriers. This knowledge will help researchers formulate and devise methodologies to control the immune response to the most important of these antigens, the galactose- α -1,3-galactose antigen. Tolerance to several immunodominant pig proteins may confer protection of the entire graft from immune injury by converting pathogenic responses directed at those targets to dominant protective effects.
2. The second issue is the need for the development of more effective, less toxic approaches to control immune responses to xenoantigens. More selective immunomodulatory or immunosuppressive approaches to inhibit

adaptive T-cell and B-cell immune responses to xenoantigens could widen the therapeutic index for the xenografts and hence facilitate cross-species tolerance.

3. Third, there is the need to define and control pathogenic cell–cell interactions unique to the pig-to-primate combination. Improved understanding of various idiosyncratic cross-species interactions should remove technical barriers to transfer of living cells from pig to humans and nonhuman primates.
4. The fourth issue is related to the potential risk of the introduction of novel and life-threatening infectious organisms into the human recipient (and possibly into the human population at large) via the xenotransplant, often referred to as *xenozoonosis*. An important concern is that a latent pig virus or another infectious agent could infect an immunosuppressed organ xenograft recipient and cause disease. Some experts consider it likely that infection of a xenograft recipient with a porcine organism will occur. If this infection is then transmitted among humans by close contact or other means—and particularly if the infection did not cause overt symptoms—it could spread undetected into the community. It is encouraging that, to date, infection with porcine endogenous retrovirus (PERV) has not been detected in humans or other primates exposed to living pig cells and tissues, even with potent immunosuppressants. Infection of human cells by PERVs does not occur readily under most experimental conditions. Thus the risk of significant recipient disease or contagion appears to be small and may be acceptable when weighed against the potential benefits of expanded access to lifesaving transplants to both transplant candidates and society at large. Importantly, systematic, life-long recipient surveillance and archiving of donor and recipient specimens are prudent approaches to limit societal risk by early detection of known or unknown organisms in case a suspicious syndrome in xenograft recipients or their close contacts justifies epidemiologic investigation. Xenotransplantation also raises issues and concerns in several different fields, most notably theology, anthropology, psychology, ethics and law (both local and international) (Caplan, 1985; Reemtsma, 1985).

Survival of primates with life-supporting cardiac, renal, and islet xenografts from pigs for 1, 3, and 8.5 months, respectively, suggests that physiologic, biochemical, or neurohumoral incompatibilities are unlikely to pose a significant problem for porcine xenograft recipients once immunologic barriers are overcome.

Recent work in the area of stem cell research has provided tantalizing evidence supporting the possibility of one day generating bioengineered organs. A major undertaking of this emerging field will be to develop the ability to define and control the cell differentiation processes involved in organ specificity. The limited regenerative capacity of adult tissues represents major obstacles to being able to duplicate the intricate cell-to-cell and cell-to-extracellular matrices involved in the normal function of differentiated cells. To be assured of an easier path in gaining public acceptance of xenotransplantation, emphasis has been placed on using “purpose-bred” animals that have already become well established species for human consumption, such as porcine and bovine. The renewed interest is attributable in part to the emerging new fields of gene therapy and bioengineering. Recent results have demonstrated progress in

developing these species of transgenic animal models. However, whereas in the past, nonhuman primates have been preferred as a source of organs for humans, the transplant community and regulatory agencies (e.g., the United States Food and Drug Administration [U.S. FDA]) in the countries dealing with this issue currently are more auspiciously dedicated to using pigs.

When the most important pig-cell surface antigen for the human immune system (the pig carbohydrate galactose- α -1,3-galactose antigen) was identified and recognized by researchers in the past decade by “knock-out” of the α -1,3-galactosyltransferase gene (“Gal knock-out” or GalT-KO), a quantum leap forward was achieved in overcoming a major immunologic barrier of organ rejection; hence the development of possible appropriate specific cellular immunomodulation agents. This identification has been associated with the longest survivals yet achieved in nonhuman primates with use of this type of genetically engineered pig; that is pigs that no longer express this antigenic cell surface marker. There is observational evidence that traditional immune rejection mechanisms damage the graft. T-cell or antibody-based immune responses targeted against pig molecules other than GalT-KO may mediate the delayed xenograft rejection and thrombotic microangiopathy observed in long-surviving xenografts and humans. It seems likely that one or more of these incompatible molecular interactions contributes to clot formation within the graft's vessels, even under circumstances in which evidence for immune injury is weak. GalT-KO pigs that express human complement, coagulation pathway regulatory proteins, or both are currently undergoing preclinical evaluation based on evidence that both of these mechanisms are involved in pig-organ xenograft injury. If organ xenograft injury is effectively controlled by the expression of human coagulation or complementary regulatory proteins, these modifications may yield a pivotal advance toward clinical application. Alternatively, molecular incompatibilities between pig and human proteins may contribute to physiologically important nonimmune volatility in coagulation and vascular biology.

Currently the PERVs are seen as conferring the most significant risk of xenozoonosis. The capacity of PERVs for vertical transmission, whereby its genome is incorporated into that of its new host, is considered one of the greatest risks to humanity. Such a replication-competent virus not only has a potential for infecting totally unrelated species, but for silently infecting humans decades later that has been demonstrated. Its infectious capacity, whereby it intercalates into its host DNA, could potentially result in novel and yet unheard-of neoplasms. Because the types of pigs used for xenotransplantation containing 50 or more PERVs incorporated into the porcine DNAs are cloned and sequenced, it will be extremely difficult to determine their infectious potential (Rogel-Gilliard et al., 1999).

To date none of the cohort of patients who have either received xenografts or undergone extracorporeal perfusion of their blood with porcine organs have demonstrated evidence of PERV infection. This has been confirmed by the lack of seroconversion with evident PERV-antibodies (using serologic assays or polymerase chain reaction viral genomic primers) and by the absence of PERV DNA detectable in peripheral blood monocytes (Paradis et al., 1999). These results need, however to be viewed with caution, because it is possible that PERVs themselves may result in immune dysfunction (Tackle et al., 2000). The hope of breeding PERV-free animals seems, however, to be a realistic prospect for the not-too-distant future (Stoye, 1997).

Since 2000, the use of genetic engineering has resulted in a marked improvement of the survival time of pig organs that have been transplanted into a nonhuman primate model (Cozzi et al. 1995). Nevertheless, substantial immunologic barriers still exist. Although the use of genetic engineering has resulted in significant improvement in survival time for a pig organ in a nonhuman primate, these survival times do not yet approach that of human organ allotransplantation. The ultimate goal here is obviously to obtain immunologic tolerance of the graft by the recipient organism and hence enhanced graft and patient survival.

Successful xenotransplantation may also require the induction of T-cell tolerance with the use of deliberate mixed hemopoietic chimerism using donor and recipient bone marrow, an approach that has been used successfully in baboons to transiently suppress anti-Gal responses in marrow transplant (Ohdan et al., 1999). Human-to-baboon bone marrow transplantation has already been performed (after conditioning the donor marrow with nonlethal irradiation). However, it remains to be seen if partial or complete chimerism will be achieved and change the image of animal organs enough to create immunologically viable “allografts” with in-situ surveillance by the human immune system.

As noted previously, an unquestionable universal result of xenotransplantation remains the ephemeral graft survival of less than 1 year from all reports, with an intense determination and effort for the past 4 decades, confirms the fact that there are no near-term prospects of replacing solid organ and bone marrow transplantation with xenotransplantation.

E. Tissue Engineering

Tissue engineering represents a newer interdisciplinary field that necessitates combining the principles of engineering with those of the biologic sciences to develop composites that would substitute for physiologic tissues and organs. Several different approaches are being used for the development of biohybrids. A simple approach consists of encapsulating purified cell populations isolated from complex tissues or established cell lines.

Another recent and more complex approach entails the actual attempt to develop a three-dimensional composite tissue or scaffold matrix of a functional organ. With these approaches, isolated cells are adhered to polymer scaffolds that have been constructed to mimic the desired organ. In the case of a composite scaffold of tissues, the ultimate goal is to develop constructs that contain all of the heterogeneous cell types required for appropriate organ function. It is preferable and ideal to derive autologous sources of the requisite cells to avoid the immunologic rejection that is unavoidable when allogeneic or xenogenic tissue sources are used. Deriving an adequate supply of autologous cells represents a major hurdle for bioengineering, because in most cases only a small number of viable tissue specific cells can easily be procured.

Therefore the viability of tissue engineering is contingent upon the acquisition of a population of isolated autologous cells, and in all probability will need to be expanded ex-vivo in cell culture to generate substantial numbers to craft a viable organ. Highly differentiated cell types, such as those required for organ specificity are notoriously difficult to stimulate through the mitotic cycle and are known to turn over very rarely in vivo. One evident challenging example is islet cells that can now be easily isolated from the intact pancreas yet cannot be replicated in in-vitro cell

culture (unlike hepatocytes), a principal obstacle in producing an artificial pancreas with at least endocrine functionality.

The expertise required in the development of biohybrids can be categorized into two general areas:

- The first can be categorized as “material sciences” for lack of a better terminology. Evidently, any synthetic materials used in the genesis of biohybrids mandates materials that are biocompatible and devoid of immunogenicity. Other material concerns that need to be addressed include biodegradability and permeability with functional aspects such as elasticity, compressibility, and tensile strength or wall stress. Likewise, there are numerous issues pertaining to any specialized application, such as the requirement of nonthrombogenicity of any and all vascularized surface.
- Cell biology represents the second general specialty in tissue engineering. Expertise is required for the isolation of a relatively small population of cells from a complex of organ tissue, such as the isolation of islets of Langerhans from an intact pancreas, where these insulin-producing cells constitute approximately 2% of the pancreatic mass.

Once the desired cell populations are isolated, a major goal will be to develop technology to expand the cell lines in vitro without losing differentiating organ specificity. A growing area of research now involves isolating stem cells that can be stimulated to differentiate, while avoiding the simultaneous expression of antigenic immune cell surface markers to prevent the need for concomitant immunosuppression when using allogeneic stem cells.

Specific issues must be solved, such as the need to support angiogenesis to adequately maintain complex three-dimensional constructs. Physical requirements could include the need to maintain the developing constructs with pulsatile perfusion to develop “normal” endothelial integrity and blood vessel wall strength.

The reality of attempting to develop bioengineered organs is the inherent complexity of tissues and organs. The development of biohybrids must take into consideration the functional complexity of organs in terms of the requisite cell-to-cell and cell-to-extracellular matrices and cell-to-physiologic system communication. More importantly, it may be naive to view the possibility of a biohybrid being able to replace the physiologic role of an organ by simply incorporating a single cell type isolated from the original organ, such as fibroblasts replacing the many functions attributed to skin or islets replacing all the endocrine functions of the pancreas. A more realistic view may need to take into consideration the construction of biohybrids containing all the heterogeneous cell types necessary to provide equivalent function.

Stem Cells and Cloning

In 1998 with the creation of human embryonic stem cells derived from discarded human embryos a gargantuan political, ethical, moral, religious, and societal conundrum was created. In addition to the ethical dilemma surrounding the use of embryonic stem cells, their clinical application is also limited because they represent an allogenic resource and thus have the potential to evoke an immune response. Newer stem cell technologies (such as cloning, or somatic cell nuclear transfer, and reprogramming), however, provide a promise to overcome this limitation.

Two types of nuclear cloning, reproductive cloning and therapeutic cloning, have been described, and a better understanding of the differences between the two types may help to alleviate some of the controversy that surrounds these technologies. Banned in most countries for human applications, reproductive cloning is used to generate an embryo that has the identical genetic material as its cell source. This embryo can then be implanted into the uterus of a female to give rise to an infant that is a clone of the donor.

On the other hand, therapeutic cloning is used to generate early stage embryos that are explanted in culture to produce embryonic stem cell lines whose genetic material is identical to that of its source. These autologous stem cells have the potential to become almost any type of cell in the adult body, and thus would be useful in tissue and organ replacement applications. Therefore therapeutic cloning, which has also been called *somatic cell nuclear transfer*, may provide an alternative source of transplantable cells. Although promising, somatic nuclear cell transfer technology has certain limitations that require further improvements before therapeutic cloning can be applied widely in replacement therapy. Currently, the efficiency of the overall cloning process is low. To improve cloning efficiency, major improvements are required in the multiple complex steps of nuclear transfer, such as enucleation and reconstruction, activation of oocytes, and cell-cycle synchronization between the donor cells and recipient oocytes.

Recently, exciting reports of the successful transformation of adult cells into pluripotent stem cells through a type of genetic “reprogramming” have been successful. Reprogramming is a technique that involves undifferentiation of adult somatic cells to produce patient-specific pluripotent stem cells, without the use of embryos. Cells generated by reprogramming would be genetically identical to the somatic cells (and thus the patient who donated these cells) and would not be rejected. Yamanaka was the first to discover that mouse embryonic fibroblasts and adult mouse fibroblasts could be reprogrammed into an induced pluripotent state. The resultant state of the transformed cells possessed the immortal growth characteristics of self-renewing embryonic stem cells and generated embryoid bodies in vitro. Since then major advancements have resulted in the ability to reprogram human cells.

Another alternate source of stem cells is the amniotic fluid and placenta. Amniotic fluid and the placenta are known to contain multiple partially differentiated cell types derived from the developing fetus. Unlike human embryonic stem cells, the cells derived from the aforementioned areas do not appear to form tumors in vivo. Clonal human lines verified by retroviral marking can be induced to differentiate into cell types representing each embryonic germ layer, including cells of adipogenic, osteogenic, myogenic, endothelial, neuronal, and hepatic lineages. In this respect, they meet a commonly accepted criterion for pluripotent stem cells without implying that they can generate every adult tissue.

The cells could be obtained either from amniocentesis or chorionic villus sampling in the developing fetus or from the placenta at the time of birth. The cells could be preserved for self-use and used without rejection, or they could be banked. A bank of 100,000 specimens could potentially supply 99% of the United States population with a perfect genetic match for transplantation. Such a bank may be easier to create than with other cell sources, because there are approximately 4.5 million births per year in the United States.

Finally, it may be possible to employ adult stem cells in the regenerative process. Adult stem cells, particularly hematopoietic stem cells, are the best understood cellular population in stem cell biology. Adult stem cell research remains an area of intense study, because their potential for therapy may be applicable to a myriad of degenerative disorders. Since 2000, adult stem cell populations have been found in many adult tissues other than the bone marrow and the gastrointestinal tract, including the brain, liver, muscle, and skin. Many other types of adult stem cells have been identified in organs all over the body and are thought to serve as the primary repair entities for each respective organ. The discovery of such tissue-specific progenitor cells has unlocked several new areas for research. Research into adult stem cells, however, has progressively slowed and even crawled to a halt, primarily because investigators have had extreme difficulty in maintaining adult nonmesenchymal stem cells in tissue culture, in addition to the obvious political opposition.

Biomaterials

In cell-based tissue engineering, an additional area of investigation, the expanded cells are seeded onto a scaffold synthesized with the appropriate biomaterial. In tissue engineering, biomaterials replicate the biologic and mechanical function of the native extracellular matrix (ECM) found in tissues in the body by serving as an artificial ECM. Biomaterials provide a three-dimensional space for the cells to form into new tissues with appropriate structure and functionality and can also allow for the delivery of cells and appropriate bioactive factors (e.g., cell-adhesion peptides and growth factors) to the desired sites. As the majority of mammalian cell types are anchorage-dependent and will die if no cell-adhesion substrate is available, biomaterials provide a cell-adhesion substrate that can deliver cells to specific sites in the body with high loading efficiency. Biomaterials can also provide mechanical support against in vivo forces such that the predefined three-dimensional structure is maintained during tissue development. Furthermore, bioactive signals, such as cell-adhesion peptides and growth factors, can be loaded along with cells to help regulate cellular function.

There are three classes of biomaterials that have been used for engineering tissues and organs:

- Naturally derived materials, such as collagen and alginate
- Acellular tissue matrices, such as bladder submucosa and small-intestinal submucosa (SIS)
- Synthetic polymers, such as polyglycolic acid (PGA), polylactic acid (PLA), and polylactic-co-glycolic acid (PLGA)

Naturally derived materials and acellular tissue matrices have the potential advantage of biologic recognition, but synthetic polymers can be produced reproducibly on a large scale with controlled precision, tensile strength, reliable degradation rate and a flexible microstructure.

Collagen is the most abundant and ubiquitous structural protein in the body, and it can be readily extracted and purified from both animal and human tissues. Moreover, collagen has minimal inflammatory and antigenic properties and has been approved for multiple medical applications by the U.S. FDA. Alginate, a polysaccharide that has been isolated from seaweed, is injectable and has gelatinous properties. A biodegradable form of Alginate has been synthesized, and now PGA,

PLA, and PLGA are widely used in regenerative medicine. These polymers have gained FDA approval for human use in a variety of applications, including sutures. The degradation products of PGA, PLA, and PLGA are nontoxic, natural metabolites that are eventually eliminated from the body in the form of CO₂ and water. Because these polymers are thermoplastics of sorts, they can easily be formed through various techniques into a three-dimensional scaffold with a desired microstructure, gross shape, and dimension. One disadvantage of the synthetic polymers is lack of biologic recognition. As an approach toward incorporating cell recognition domains into these materials, copolymers with amino acids have been synthesized.

Nanotechnology, defined as the science of material features between 10⁻⁹ and 10⁻⁷ meter in size, and has only now begun to make a leap into the clinical arena. This technology, which exploits the ability to use small molecules that have distinct microproperties, has been used to fabricate clever biomaterials to facilitate regenerative medicine. The manufacturing of these biomaterials can also lead to enhanced cell alignment and tissue formation. Regenerative medicine efforts are currently underway experimentally for virtually every type of tissue and organ within the human body. Because regenerative medicine incorporates the fields of tissue engineering, cell biology, nuclear transfer, and materials science, personnel who have mastered the techniques of cell harvest, culture, expansion, transplantation, as well

as polymer design, are essential for the successful application of these technologies to extend human life. Various tissues are at different stages of development, with some already being used clinically, a few in preclinical trials, and some in the discovery stage. Recent progress suggests that engineered tissues may have an expanded clinical applicability in the future and may represent a viable therapeutic option for those who would benefit from the life-extending benefits of tissue replacement or repair.

Anesthetics and anesthesiology are central to all these new approaches in facilitating organ and tissue replacement in the human body. As the science and molecular effects of anesthetics on the immune system become unraveled, it is evident that the choice of agents and techniques for organ and tissue replacement will need to evolve. Fluorinated inhalation anesthetics will need to be carefully evaluated with respect to their use with the synthetic polymers such as PGA, PLA, and PLGA. Potential interaction with these newer plastics could result in tissue breakdown or even the production of unexpected antigenicity. Moreover, the approach to cellular transplantation may require alternative techniques that will involve other specialties such as radiologists in order to facilitate less invasive methodologies to facilitate the transplant procedure.

These images are of the liver from a 12-year-old child with FHF. His native liver at the time of transplantation demonstrates a very small necrotic and atretic liver.

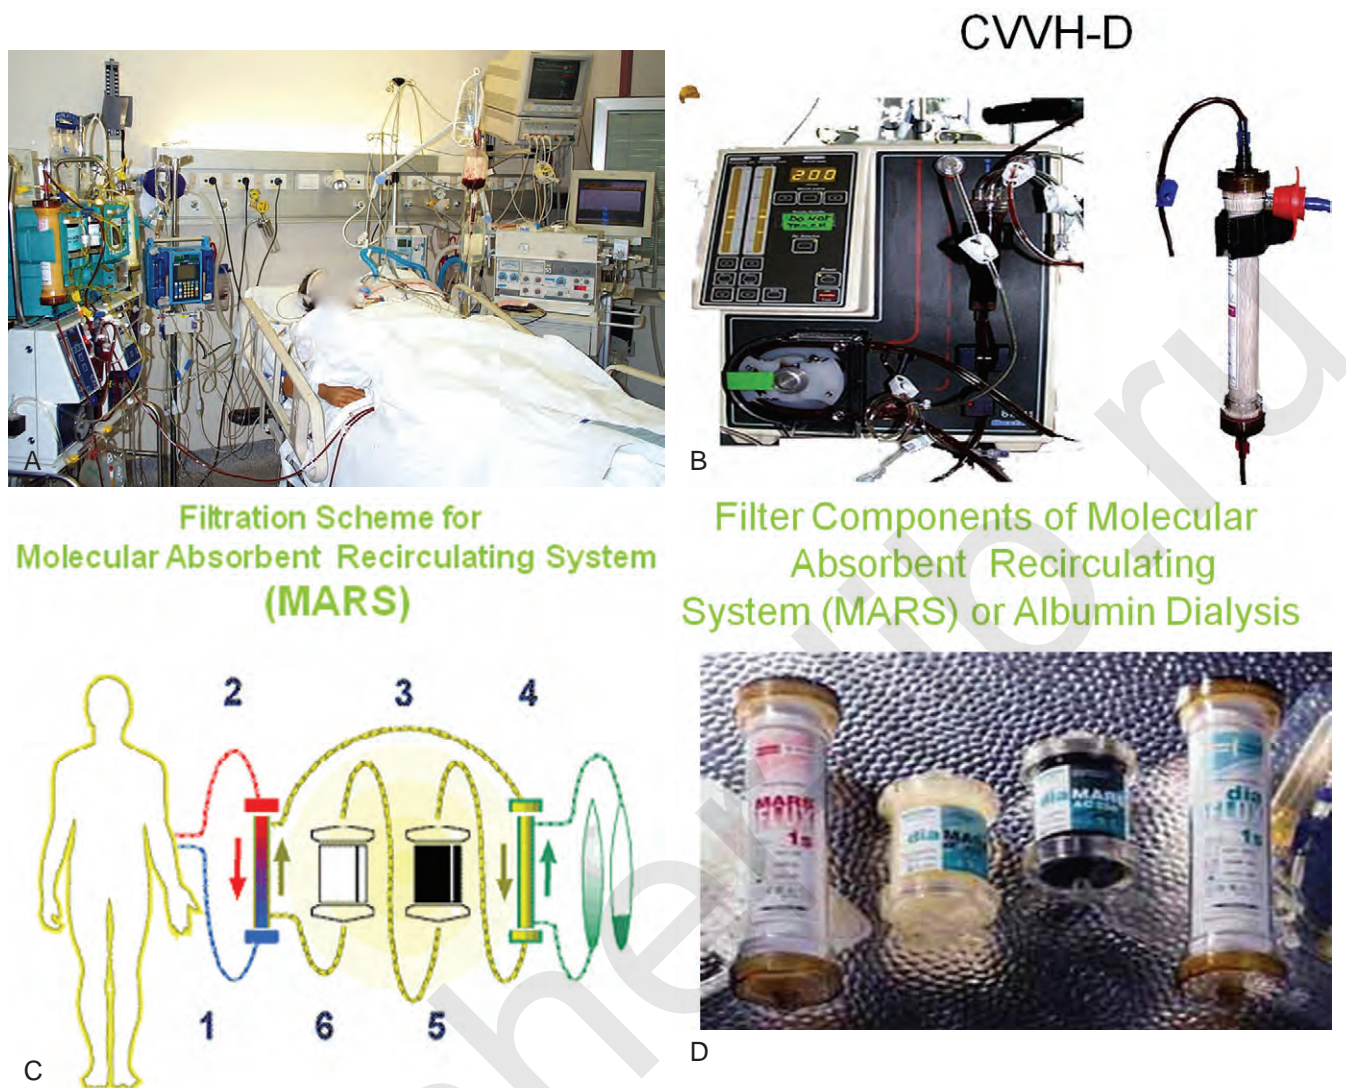

■ **FIGURE W26-1.** These are two of the sequential slices across the liver. **A** illustrates intravascular thromboses of both the hepatic arteries and the portal veins. **B**, Note the arborization of clots in the portal venous system as well as a small clot in the left hepatic artery. Additionally there are periportal thrombi and hemorrhage extending beyond the confines of the vascular endothelium and into the hepatic parenchyma as a result of portal hypertension and cellular necrosis.

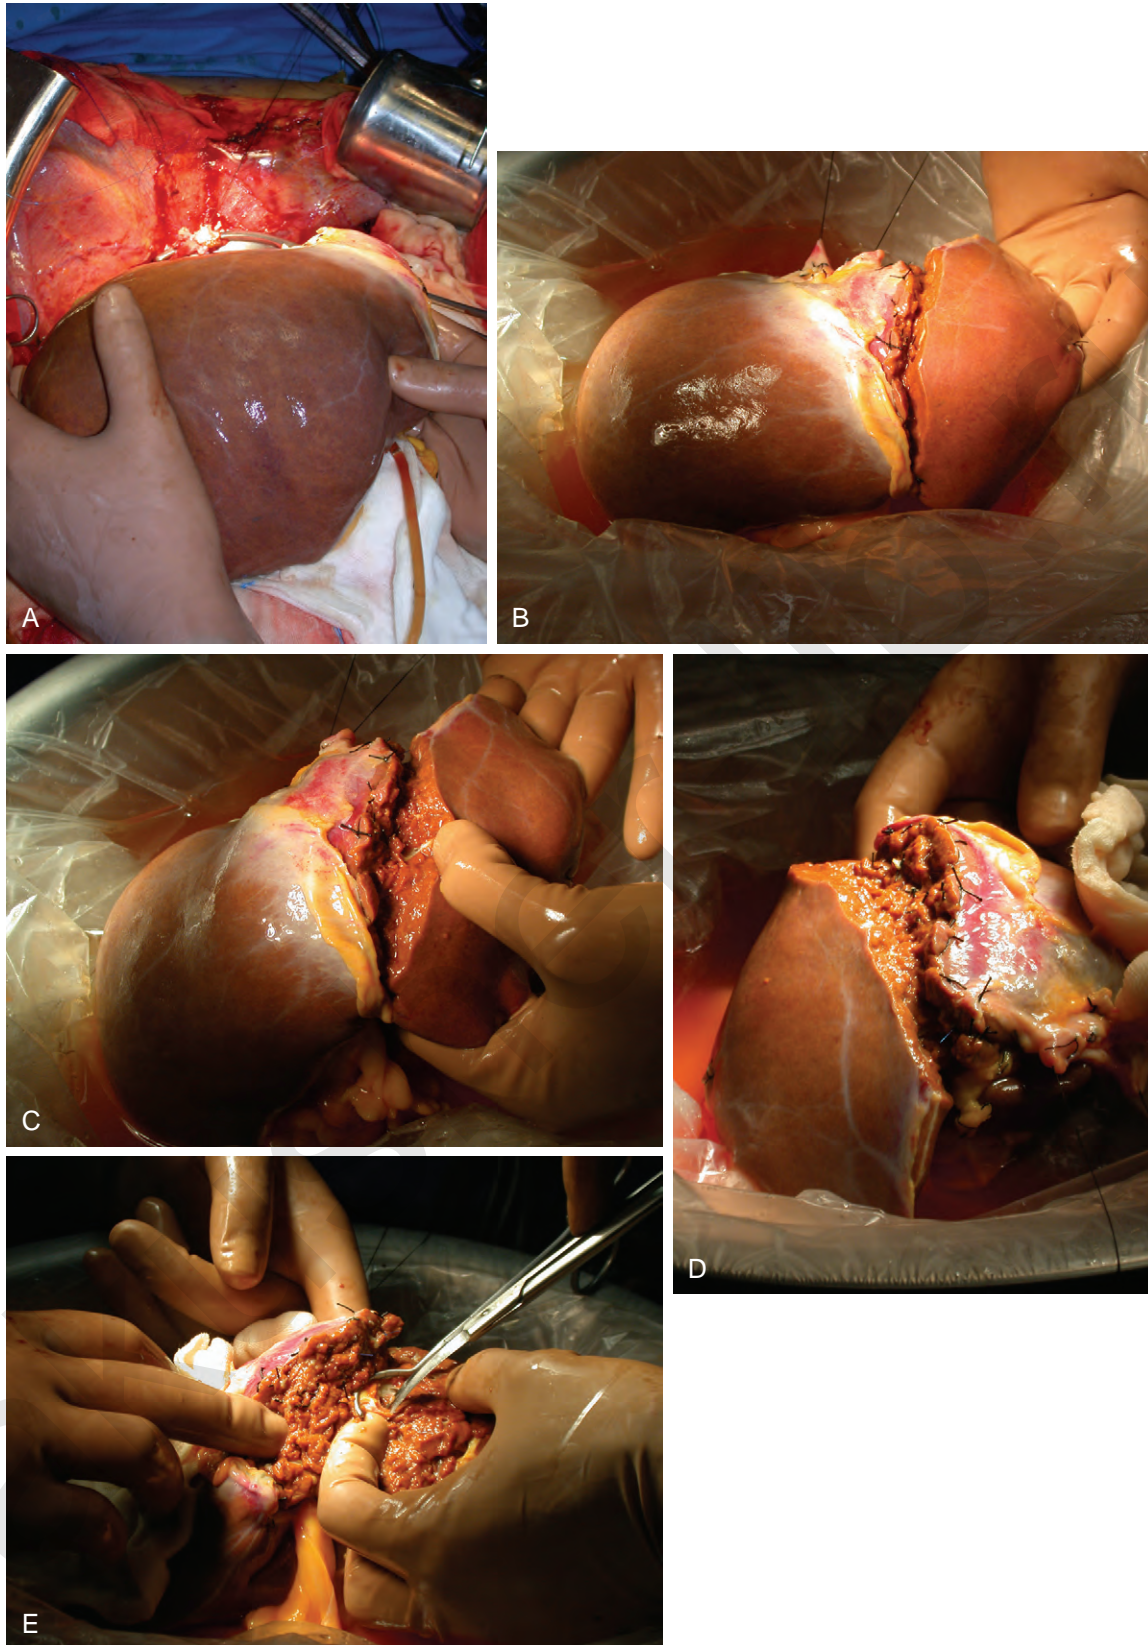

■ **FIGURE W26-2.** Hepatic anatomy. **A** is an anatomic demonstration of the vasculature as well as the biliary drainage system of the liver. **B** demonstrates the vascular segments of the liver. **A**, This image by Cameron demonstrates the anatomically correct position of the right and left hepatic arterial and portal venous systems. The liver is the largest organ in the body, weighing approximately 1.5 kg. It is wedge-shaped and lies predominantly in the right upper quadrant of the abdominal cavity. The liver is held in this position primarily by attachment of the hepatic veins to the IVC (IVC) and by the peritoneal ligaments. The liver is attached to the anterior abdominal wall and the diaphragm by four distinctive ligaments: (1) the coronary ligament, which connects the posterior surface of the right hepatic lobe to the diaphragm with a superior and an inferior layer between that lies in the bare area of the liver; (2) the right triangular ligament, which is formed by fusion of the superior and inferior layers of the coronary ligament; (3) the left triangular ligament, which connects the posterior surface of the left lobe of the liver to the diaphragm; and (4) the sickle-shaped falciform ligament, which extends from the diaphragm and anterior wall above the level of the umbilicus to the surface of the liver, where it divides the left hepatic lobe into the left lateral and left medial segments. The inferior free border of the falciform ligament contains the *ligamentum teres* (obliterated umbilical vein). A plane that extends from the gallbladder fossa to the IVC, at approximately a 75-degree angle with the horizontal plane, is called *Cantlie's line*. This line divides the liver into the right and left lobes (**A**). **B**, Further subdivisions of the liver are based on Couinaud nomenclature. The two lobes are further subdivided into sectors on the basis of the position of the major hepatic vein and their respective portal pedicles. Each plane that divides the liver along the major hepatic vein is called a *fissure*. Though the term *fissure* is used, there is no groove to mark these planes in the intact liver, and thus Couinaud nomenclature refers to fissure as *scissura*. Additionally, the hepatic venous drainage and connection to the vena cava is presented. Note that the left and middle hepatic veins become confluent before their attachment to the cava. The right hepatic vein consistently attaches to the cava independently. The right hepatic vein, larger than the left and middle hepatic veins, has a short extrahepatic course of approximately 1 cm. The left and middle hepatic veins may drain separately into the IVC, but they are usually joined after a short extrahepatic course to form a common venous channel approximately 2 cm in length that traverses to the left part of the anterior surface of the IVC below the diaphragm. There are additional hepatic veins to the three major hepatic veins. Note the hepatic biliary system as it courses with hepatic artery from which it receives 100% of its blood supply. This image demonstrates segments of the liver; these are the functional divisions of the liver (i.e., liver segments according to Couinaud nomenclature).

■ **FIGURE W26-3.** Living related liver resection. These images are sequential images of a left hepatic lobe resection for a living donation. Sequential transection of the liver is demonstrated as the liver is divided into left and right lobes and the vasculature is exposed and resected. **A** indicates the liver marked for resection. Note the falciform ligament to the left of the line of demarcation with the purple pen. **B**, Sequential image of a partially resected liver. Note the clean, well-cauterized margins of the liver that have been sliced with the use of the CUSA Ultrasonic Surgical Aspirator and argon bovie. These images are in distinction to the images shown for the split liver procedure, wherein the liver is resected and the vessels tied and ligated with sutures. Note the left portal vein branch posterior to the left lobe of the liver. **C**, Hepatic vein ligation from the cava and clipping of the left lobe resected with the portal vein and hepatic artery exposed. Note the right biliary duct cannulated to facilitate drainage as well as preservation, for the eventual biliary reconstruction of the right bile duct. **D**, Progression of the hepatic resection is noted with exposure of the hepatic vein posteriorly. **E**, Complete resection of the liver is now noted with the right hepatic lobe intact and the prominent right hepatic vein in place.

■ **FIGURE W26-4.** Molecular Absorbent Recycling System (MARS). MARS is a liver support system developed to support excretory liver function. It incorporates elements from extracorporeal renal replacement techniques such as ultrafiltration, which may include the dialysis component. There are no active biologic components such as hepatocytes. **A** and **B**, MARS requires a standard dialysis machine as depicted herein or a CVVHD (e.g., BM 25; Edwards Life Sciences GmbH, Munich, Germany, also shown) to control the blood and dialysate circuits. An extra device (MARS monitor; Teraklin AG, Rostock, Germany) is necessary to control and monitor the closed-loop albumin circuit. The latter circuit connects the blood and dialysate circuits. This method uses an albumin-enriched dialysate to facilitate the removal of albumin-bound toxins. It contains three different fluid compartments (“circuits”); i.e., the blood circuit; an albumin circuit; and an open-loop, single-pass dialysate circuit. The blood circuit uses a venovenous access (double-lumen catheter) and is driven by the blood roller pump of the dialysis machine and the CVVH monitor. The blood flow rate is 150 to 250 mL/min, depending on the hemodynamic status of the patient. Blood is passed through a non-albumin-permeable, high-flux dialysis membrane (MARS Flux; Teraklin AG, Rostock, Germany) (see [Figures W26-1](#) and [W26-2](#)). **C** and **D**, The albumin circuit, containing 20% human serum albumin (has), is driven by a roller pump of the MARS monitor at 150 mL/min. The dialysate HSA is passed through the dialysate compartment of the blood dialyzer (MARS Flux) and subsequently regenerated by dialysis against a bicarbonate-buffered dialysate (dialysate circuit) and followed by passage through two sequential columns; the first contains uncoated charcoal, and the second contains an anion exchanger resin. Heparin is used as an anticoagulant. The activated clotting time is maintained between 160 and 190 seconds throughout the treatment.

■ **FIGURE W26-5.** Split liver procedure. These images illustrate a split liver procedure. The liver (**A**) is divided ex-vivo sequentially into left and right lobes (**B** and **C**). The organ is maintained cold, in an ice bath, along with preservation solution infused. Note that as the hepatic lobes are divided, surgical with ties/sutures that are used to meticulously ligate the vasculature and biliary system (**D**). The vena cava is left intact with the right lobe. The left hepatic vein is preserved for eventual anastomosis to the vena cava for the left lobe (**E**).

■ **FIGURE W26-6.** Vena caval anastomosis (vascular invagination). These images illustrate the suprahepatic vena caval anastomosis in a classic standard orthotopic liver transplantation operation with a direct cava-to-cava anastomosis, as compared with the piggyback procedure often used in the pediatric patient who may receive a split liver or living-donor liver organ. **A**, In this procedure, the lateral margins of the vena cava are approximated and are usually of similar diameter and size. Two sutures are placed at 180 degrees, at opposite sides of the vessel. The two sutures are unusual, because each end of these sutures has a needle attached to it. This is preferable in order to allow the surgeons to suture the (posterior) back wall of the cava in a continuous fashion so that there is no disruption of the sutures, thus allowing for a single site where the sutures are finally tied and ligated. Note that the back (posterior) wall of the vena cava is sutured first, working towards the anterior caval wall (**B**). Most importantly, these images demonstrate the technique of invagination of one vessel sutured inside the other as the vena cava is reconstructed. This technique of vascular invagination minimizes and prevents any potential vascular leaks.

Anesthesia for ophthalmologic procedures in children requires an understanding of several physiologic and pharmacologic concepts that are unique to this population. The majority of ophthalmic procedures are brief and noninvasive, but the spectrum extends to more invasive procedures in patients with significant comorbid disease. Caring for otherwise healthy children undergoing nasolacrimal duct probing or strabismus surgery may be relatively straightforward, but the pediatric anesthesiologist is also required to care for vulnerable infants born prematurely or with congenital disorders and associated pathology of the eye. In 2005 there were 2.2 million procedures performed on patients younger than 15 years of age; 12,000 of these were operations on the eye (Defrances and Hall, 2007). Most of these procedures are performed in the ambulatory setting. In an analysis of ophthalmic procedures performed in surgery centers, the reasons for cancellation of surgery within 24 hours were explored. The pediatric group (0 to 9 years of age) had the highest rate of cancellation when compared with those in other age groups. The majority of cancellations, however, were because of unpreventable causes such as patient illness (Henderson et al., 2005). The information contained in this chapter will give anesthesiologists the information needed to plan for and safely perform anesthesia for ophthalmic procedures.

Anesthesiologists with a particular interest in ophthalmologic anesthesia can find valuable resources through the Ophthalmic Anesthesia Society (<http://www.eyeanesthesia.org>) and the British Ophthalmic Anaesthesia Society (<http://www.boas.org>). A glossary of terms is given in **Box 27-1**.

ANATOMY AND PHYSIOLOGY

Knowledge of the anatomy and physiology of the eye is paramount to understanding the array of ophthalmic procedures performed, the influence that anesthesia may have on normal and abnormal ocular physiology, and the systemic effects that surgical manipulation of the eye may have on the patient (McGoldrick, 1992a).

Anatomy Overview

The eye is an extension of the central nervous system (the diencephalon) that rests in the orbit, is cushioned by fat, and is supported by ligaments and fascial structure.

The orbit is formed by a complex arrangement of seven cranial bones: frontal, zygomatic, sphenoid, maxilla, palatine, lacrimal, and ethmoid (**Fig. 27-1**). The optic foramen transmits the

Box 27-1 Glossary of Ophthalmologic Terms

- Blepharospasm:** Tonic spasm of the orbicularis oculi muscle, producing more or less complete closure of the eyelids
- Buphthalmos:** Enlargement and distention of the fibrous coats of the eye
- Cyclocryotherapy:** Freezing of the ciliary body, performed for the treatment of glaucoma
- Epiphora:** Abnormal overflow of tears, also known as illacrimation
- Episcleritis:** Inflammation of tissues overlying the sclera, also inflammation of the outermost layers of the sclera
- Gonioscopy:** Examination of the angle of the anterior chamber of the eye
- Goniotomy:** Operation for glaucoma characterized by an open angle and normal depth of the anterior chamber; consists of the opening of Schlemm's canal under direct vision secured by a contact glass
- Tonometry:** Measurement of tension or pressure commonly assessed by the applanation
- Tonometer:** Instrument that measures intraocular pressure by determination of the force necessary to flatten a corneal surface of constant size
- Trabeculectomy:** Creation of a fistula between the anterior chamber of the eye and the subconjunctival space by surgical removal of a portion of the trabecular meshwork

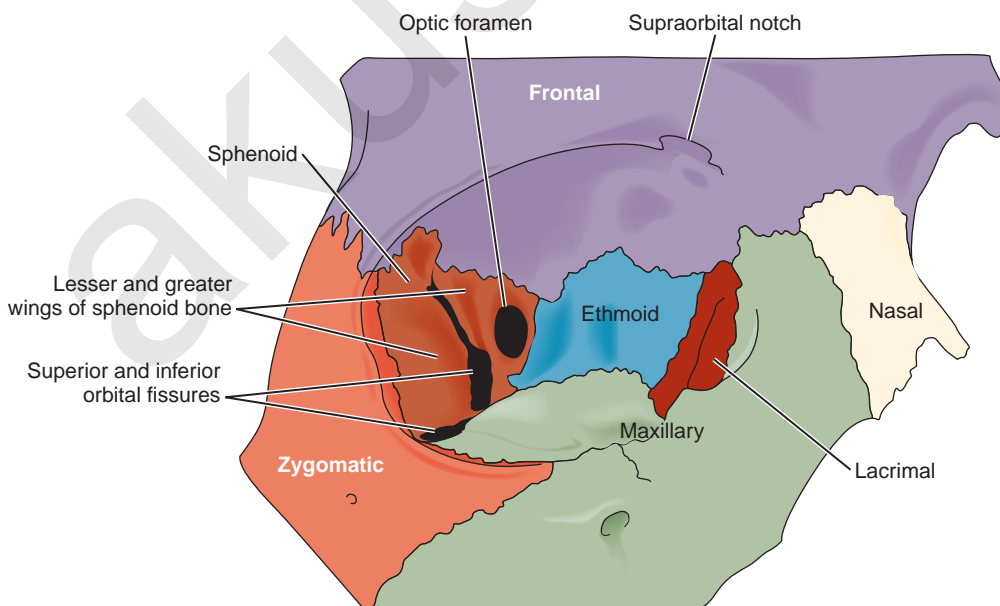

From *Dorland's illustrated medical dictionary*, Philadelphia, 2000, Saunders.

optic nerve, the ophthalmic artery and vein, and the sympathetic contributions from the carotid plexus. The superior orbital fissure transmits branches from four other cranial nerves (oculomotor, trigeminal, trochlear, and abducens) and the superior and inferior ophthalmic veins. The infraorbital fissure (representing the weakest aspect of the orbit) transmits the infraorbital and zygomatic nerves. The infraorbital foramen (located below the orbital rim) transmits the infraorbital nerve, artery, and vein.

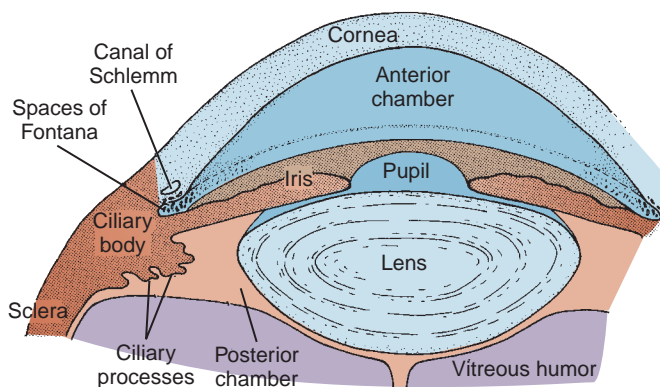

The globe is composed of three contiguous layers: the sclera, uveal tract, and retina. The sclera is the dense outer covering that provides the fibrous structure necessary for maintaining the shape of the globe. The anterior portion of the sclera (the cornea) is transparent and avascular, permitting transmission of light to the retina. The highly vascular uveal tract is composed of the iris, ciliary body, and choroid, enveloping the posterior aspect of the globe. The iris divides the anterior segment of the eye into the anterior and posterior chambers. The ciliary body is the site of aqueous humor production and contains the ciliary muscles that are responsible for accommodation of the lens. The choroid is the highly vascular layer of the globe that provides blood supply to the retina. The retina is a delicate membrane composed of 10 distinct layers that are involved in the conversion of light to neural impulses. The axons of the retinal ganglion nerves converge at the optic disc and pierce the sclera to form the optic nerve.

The aqueous humor occupies the anterior and posterior chambers of the eye and is responsible for providing nutrients to the avascular lens and the endothelial aspect of the cornea (Fig. 27-2). The volume of aqueous humor (0.3 mL in the adult) is primarily responsible for intraocular pressure (IOP) regulation. The vitreous humor, created embryologically between 1 and 4 months' gestation, is a hydrophilic gel that accounts for 80% of the volume of the globe. The vitreous humor is 99% water, although in the presence of hyaluronic acid (a mucopolysaccharide), its viscosity is twice that of water. The volume of the vitreous humor is more constant than that of the aqueous humor, although it may be slightly influenced by hydration status and osmotically active medications.

The optic nerve (cranial nerve II) is the nerve of vision and may be thought of as a diverticulum of the forebrain. The oculomotor nerve (cranial nerve III) provides motor innervation to four of the six extraocular muscles and the levator palpebrae superioris, as well as parasympathetic innervation to the pupillary sphincter (miosis) and ciliary muscles (accommodation). The two other extraocular muscles are innervated by the trochlear and abducens nerves. The ophthalmic division of the

■ **FIGURE 27-1.** Skeletal anatomy of the orbit.

■ **FIGURE 27-2.** Anatomy of the anterior eye. (From McGoldrick KE: *Anesthesia for ophthalmic surgery*. In Motoyama ES, Davis PJ, editors: *Smith's anesthesia for infants and children*, ed 6, Philadelphia, 1996, Mosby.)

trigeminal nerve (cranial nerve V) transmits all of the nonvisual sensory innervation from the eye and orbit and provides sympathetic innervation to the pupillary dilators (mydriasis). The temporal and zygomatic branches of the facial nerve (cranial nerve VII) innervate the orbicularis oculi (Ellis and Feldman, 1997).

Blood is supplied to the eye and orbit through branches of the internal and external carotid arteries. The first branch of the intracranial carotid artery, the ophthalmic artery, divides into the central retinal artery, as well as the long and short posterior ciliary arteries, to nourish the retina. The long and short posterior ciliary arteries converge to supply the choriocapillaris, the capillary layer within the choroid that supplies 60% to 80% of the oxygen to the retina. The anterior portion of the optic nerve is perfused by the posterior ciliary arteries. It is this network of arteries that is subject to significant individual variation, predisposing some patients to anterior ischemic optic neuropathy after periods of hypotension. The posterior optic nerve is perfused by pial vessels branching from the ophthalmic artery. Superior and inferior ophthalmic veins drain the orbit, and the central retinal vein provides ocular drainage. All venous drainage is subsequently transmitted to the cavernous sinus (Williams, 2002).

Physiology Overview

The physiology of the eye is quite complex, but an understanding of the physiologic and pharmacologic control of IOP is of primary importance to the anesthesiologist. The ability to avoid deviations in IOP is key to providing satisfactory anesthesia for all intraocular procedures and in caring for the patient with glaucoma and traumatic injury to the globe.

Normal IOP varies between 10 and 20 mm Hg and may differ by as much as 5 mm Hg between the two eyes. Normal pressures are somewhat lower in the newborn (average, 9.5 mm Hg) but approximate adult pressures by 5 years of age (Pensiero et al., 1992). A pressure above 25 mm Hg at any age is considered abnormal (Johnson and Forrest, 1994). Transient changes in IOP are well tolerated in the intact eye, although chronic elevations may be detrimental to normal retinal perfusion and vision.

Three primary determinants of IOP are external pressure, venous congestion, and changes in intraocular volume. The volume and exertional pressure of the aqueous humor are carefully regulated in the normal eye to maintain normal IOP. As mentioned previously, the volume of the vitreous humor is usually constant.

The aqueous humor is formed primarily by the ciliary bodies, where secretion is facilitated by the carbonic anhydrase and cytochrome oxidase systems. The feedback control of aqueous humor formation is poorly understood, although production of aqueous humor is known to be augmented by sympathetic stimulation and suppressed by parasympathetic control. Variations in the osmotic pressure of the aqueous humor and plasma influence aqueous humor formation, as illustrated by the following equation:

$$IOP = k[(OP_{aq} - OP_{pl}) + P_c]$$

where k is the coefficient of outflow, OP_{aq} and OP_{pl} are the osmotic pressures of the aqueous humor and plasma, respectively, and P_c is the capillary perfusion pressure. The benefit of hypertonic solutions in lowering IOP is realized through an understanding of this equation.

Most of the aqueous humor produced in the posterior chamber flows through the pupil into the anterior chamber, exiting the eye through Schlemm's canal (a thin vein that extends circumferentially around the eye) and into the orbital venous system.

Fluctuations in aqueous humor outflow also dramatically alter IOP. The prime factor determining outflow of aqueous humor is the diameter of Fontana's spaces, as illustrated by the following equation based on the Hagen-Poiseuille Law:

$$A = \frac{r^4(Pi_{op} - P_v)}{8\eta l}$$

where A is the volume of aqueous humor outflow per unit of time, r is the radius of Fontana's spaces, Pi_{op} is IOP, P_v is venous pressure, η is viscosity, and l is length of Fontana's spaces.

With mydriasis, Fontana's spaces narrow, resistance to outflow is increased, and IOP rises. Mydriasis is a threat in both closed-angle and open-angle glaucoma.* Hence, a miotic agent such as pilocarpine hydrochloride is often efficacious when applied conjunctivally before surgery in patients with glaucoma.

Stimulation of α_1 -sympathetic receptors leads to mydriasis, a decrease in aqueous outflow, and an increase in IOP. Most of the agents used to produce mydriasis also modestly increase IOP. β -stimulation has no effect on pupillary diameter, but paradoxically, both β -agonists and β -antagonists may decrease IOP. Cholinergic stimulation or parasympathetic stimulation produces miosis and a decrease in IOP such that glaucoma patients are commonly treated with miotic agents.

The arterial circulation of the eye is autoregulated. Only marked deviations in systemic arterial pressures affect IOP. Elevated venous pressures, on the other hand, can dramatically increase IOP, primarily by augmenting the choroidal blood volume and tension of the orbit. Coughing, vomiting, and Valsalva maneuvers may increase IOP to 40 mm Hg or more. Respiratory acidosis increases IOP, whereas metabolic acidosis has the opposite effect. Conversely, respiratory alkalosis decreases IOP, whereas metabolic alkalosis increases IOP (Calobrisi and

*Open-angle glaucoma, also known as chronic simple glaucoma, is a condition of elevated IOP in an eye with an anatomically open anterior chamber angle. The trabecular meshwork is thought to be sclerosed, resulting in inefficient aqueous filtration and drainage. Closed-angle glaucoma is a mechanical closing of the pathway for aqueous egress for the eye. The iris may move into direct contact with the posterior surface of the cornea, impeding the aqueous outflow path, or the crystalline lens may swell, resulting in papillary blocking. In the latter case, the lens blocks the route for aqueous humor to travel from the posterior to the anterior chamber.

Lebowitz, 1990). Hypoxia is capable of increasing IOP by dilating intraocular vessels, whereas hyperoxia appears to decrease IOP (Johnson and Forrest, 1994).

Three ophthalmic reflexes that should be recognized by the anesthesiologist caring for the ophthalmic patient include the oculocardiac reflex (OCR), the oculorespiratory reflex (ORR), and the oculoemetic reflex (OER). All three reflexes are elicited by pressure or torsion on the extraocular muscles transmitting afferent impulses through the ophthalmic division of the trigeminal nerve.

The OCR, through its vagal efferent pathway, may manifest as sinus bradycardia, ectopy, and sinus arrest. Death secondary to the OCR in otherwise healthy children has been described (Lang and Van der Wal, 1994; Smith, 1994). A more thorough description of this reflex, prophylaxis, and therapy are provided later in the discussion on intraoperative complications.

The ORR has also been recognized for nearly 100 years but is less often appreciated with the use of controlled ventilation. Through a postulated connection between the trigeminal nerve, the pneumotaxic center of the pons, and the medullary respiratory centers, pressure on the extraocular muscles may result in tachypnea or respiratory arrest (Johnson and Forrest, 1994). This reflex is not inhibited by the use of atropine or glycopyrrolate. A review of the ORR and its potential for causing hypercapnia and hypoxia (potentially aggravating the OCR) has heightened awareness of the reflex and led some investigators to recommend controlled ventilation during strabismus surgery (Blanc et al., 1988).

The OER is admittedly more theoretic than the other two reflexes but would explain the high incidence of nausea and emesis after strabismus surgery. An association between the OCR and the OER has been demonstrated such that patients who exhibit

the OCR intraoperatively are 2.6 times more likely to experience postoperative vomiting than those without OCR manifestations (Allen et al., 1998). Anticholinergic therapy does not decrease the incidence of postoperative nausea and vomiting (PONV). Appropriate prophylaxis and treatment of PONV have been studied extensively and are thoroughly reviewed later in this chapter.

GENERAL CONSIDERATIONS IN CARING FOR THE OPHTHALMOLOGIC PATIENT

The anesthesiologist caring for the ophthalmologic patient should be familiar with the disorders and syndromes commonly associated with ocular pathology, the effects of ophthalmic medications used preoperatively and intraoperatively, and the ocular effects of the anesthetic agents to be used during the perioperative period.

Associated Congenital and Metabolic Conditions

Ophthalmologic disorders may be inherited as isolated defects in autosomal recessive, autosomal dominant, and X-linked recessive fashion. An additional large number of metabolic defects, congenital syndromes, and chromosomal abnormalities are also associated with ocular pathology. The anesthesiologist caring for the ophthalmologic patient must be aware of these associations. An overview of the commonly encountered syndromes and disorders along with their ocular manifestations and potential anesthetic implications is provided in [Table 27-1](#) (McGoldrick, 1992d; Butera et al., 2000; Baum and O'Flaherty, 2006).

TABLE 27-1. Congenital Syndromes and Chromosomal Abnormalities with Associated Ocular Manifestations

Disorder or Syndrome	Ocular Manifestations	Anesthetic Implications
Acute intermittent porphyria	Cataracts, retinal degeneration, optic atrophy	Various medications, including barbiturates and etomidate, may trigger attacks.
Apert's syndrome	Glaucoma, cataracts, strabismus, hypertelorism, proptosis	Possibly difficult intubation, possible choanal stenosis, cervical spine fusion, CHD (10% incidence)
Cri du chat syndrome	Strabismus	Micrognathia and possibly difficult intubation, hypotonia, prone to hypothermia, CHD (33% incidence)
Crouzon's disease	Glaucoma, cataracts, strabismus, hypertelorism, proptosis	Possibly difficult intubation, possible elevated intracranial pressure
Cystinosis	Corneal clouding, retinal degeneration	Chronic renal failure, possible diabetes mellitus, esophageal varices, recurrent epistaxis, hyperthermia
Down syndrome	Cataracts, strabismus	Trisomy 21, airway obstruction, atlantoaxial instability, CHD (50% incidence), may be more sensitive to atropine
Ehlers-Danlos syndrome	Retinal detachment, blue sclera, ectopia lentis, keratoconus	Laryngeal trauma possible with intubation, careful positioning, avoid arterial and central venous lines
Goldenhar's syndrome	Glaucoma, cataracts, strabismus, lacrimal drainage defects	Hemifacial microsomia and possible cervical spine abnormalities, possible difficult mask and intubation, rare CHD, and hydrocephalus
Hallerman-Streiff syndrome	Congenital cataracts, coloboma, microphthalmia, glaucoma	Major craniofacial abnormalities with likely difficult intubation, upper airway obstruction, chronic lung disease
Homocystinuria	Ectopia lentis, pupillary block glaucoma, retinal detachment, central retinal artery occlusion, strabismus optic atrophy,	Marfanoid habitus with kyphoscoliosis and sternal deformity, prone to thromboembolic complications and hypoglycemia
Hunter's syndrome	Retinal degeneration, optic atrophy	Often difficult intubation, copious secretions, macroglossia, stiff temporomandibular joint, limited neck mobility, possible ischemic or valvular heart disease

TABLE 27-1. Congenital Syndromes and Chromosomal Abnormalities with Associated Ocular Manifestations—cont'd

Disorder or Syndrome	Ocular Manifestations	Anesthetic Implications
Hurler's syndrome	Corneal clouding, retinal degeneration, optic atrophy	Often difficult intubation and difficult mask, possible cervical spine instability, possible ischemic or valvular heart disease
Jeune syndrome	Retinal degeneration	Limited thoracic excursion, pulmonary hypoplasia, possible renal and hepatic insufficiency
Lowe's syndrome	Cataracts, glaucoma (hydrophthalmia)	Renal failure, renal tubular acidosis
Marfan syndrome	Ectopia lentis, glaucoma, retinal detachment, cataracts, strabismus	Aortic or pulmonary artery dilation, aortic and mitral valve disease, pectus excavatum, risk for pneumothorax
Moebius sequence	Strabismus, ptosis, congenital nerve VI and VII palsy	Possibly difficult intubation, micrognathia, copious secretions, possible cervical spine anomalies
Myotonia congenita	Cataracts, blepharospasm	Prone to myotonic contractions, sustained contraction with succinylcholine
Myotonic dystrophy	Cataracts, ptosis, strabismus	Prone to myotonic contractions, succinylcholine-associated contractions and hyperkalemia, cardiac conduction abnormalities, sensitive to central nervous system depressants
Rubella syndrome	Cataracts, microphthalmos, glaucoma, optic atrophy	Neonatal pneumonia, anemia, and thrombocytopenia; CHD, hypopituitarism, diabetes mellitus
Sickle cell disease	Retinal detachment, vitreous hemorrhage, retinitis proliferans	Tendency for sickling occurs with high hemoglobin S concentrations, hypoxemia, cold, stasis, dehydration, and infection
Smith-Lemli-Opitz syndrome	Congenital cataracts	Possibly difficult intubation, micrognathia, pulmonary hypoplasia, CHD, gastroesophageal reflux, seizure disorders
Stickler syndrome	Vitreous degeneration, retinal detachments, cataracts, strabismus	Possibly difficult intubation, micrognathia, mitral valve prolapse, marfanoid habitus, scoliosis, kyphosis
Sturge-Weber syndrome	Choroidal hemangioma, glaucoma, ectopia lentis	Angiomas of the airway, CHD and high output failure, seizure disorders, hyperkalemic response to succinylcholine in those with hemiplegia
Treacher Collins syndrome	Lid defects, microphthalmia	Often difficult intubation, mandibular hypoplasia, CHD
Turner's syndrome	Ptosis, strabismus, cataracts, corneal scars, blue sclera	Possibly difficult intubation and intravenous access, CHD
von Hippel-Lindau syndrome	Retinal hemangioma	Possible increased intracranial pressure, possible pheochromocytoma, cerebellar tumors may also produce episodic hypertension
von Recklinghausen's disease	Ptosis, proptosis, optic glioma and meningioma, optic atrophy, glaucoma, Lisch nodules	Possibly difficult mask ventilation and intubation, possible airway tumors, restrictive lung disease, renovascular hypertension, possible pheochromocytoma, sensitive to neuromuscular blockers
Zellweger syndrome	Glaucoma, cataracts, optic atrophy, optic nerve hypoplasia	Micrognathia, possible CHD, renal and adrenal insufficiency

CHD, Congenital heart disease.

Ophthalmologic Medications and Their Systemic Effects

There are a variety of medications used by pediatric ophthalmologists in the outpatient and perioperative settings that may have important anesthetic ramifications. As with all medications, the ophthalmic agents have both desirable and undesirable effects that may be more pronounced and ominous in the pediatric patient by virtue of greater systemic absorption or higher dosing relative to body weight and pharmacologic compartment. The anesthesiologist must be familiar with every medication used in the perioperative period and pay particular attention to the total dose administered and potential for deleterious effects. An overview of the ophthalmic medications is provided (Table 27-2).

Topical ophthalmologic agents have greater use than systemic agents in the pediatric and adult populations, primarily because most of the side effects that would be consequential to systemic administration are diminished. Nevertheless, the

excess from ocular application invariably enters the lacrimal system, reaching the nasopharyngeal mucosa where systemic absorption is greatly enhanced compared with that at the conjunctival sac. Whereas a single drop from a commercial eye dropper may have a volume ranging between 50 and 75 μL , maximal ocular bioavailability is reached by instillation of only 20 μL (McGoldrick, 1992b). It has been recommended that digital pressure over the lacrimal duct for 5 minutes after instillation may reduce systemic absorption by 67% (Zimmerman et al., 1984). Keeping the eye gently closed for 5 minutes may afford similar benefit, yet both techniques are understandably difficult in the conscious and fretful child.

Cycloplegic and Mydriatic Agents

Those agents used most commonly in the perioperative setting include cycloplegic and mydriatic agents. The agents are necessary for performing certain procedures, cycloplegic refraction,

TABLE 27-2. Commonly Used Ophthalmic Medications

Type	Medication	Concentration	Pertinent Systemic and Ocular Effects
Cycloplegic	Cyclopentolate	0.5%, 1%, 2%	Muscarinic antagonist; side effects include gastrointestinal disturbance, atropine-like toxicity, and inhibition of plasma cholinesterase (in vitro).
	Tropicamide	0.5%, 1%	Muscarinic antagonist; side effects are minimal.
	Atropine	1%	Muscarinic antagonist with the most potent ocular effects and a duration of action of longer than 1 week; side effects are numerous.
	Homatropine	2%, 5%	Muscarinic antagonist with a shorter onset and duration of action than atropine; side effects are numerous.
	Scopolamine	0.25%	Muscarinic antagonist that is not commonly used for diagnostic cycloplegia and mydriasis and for the treatment of iridocyclitis; side effects include an increase in intraocular pressure such that IV or IM scopolamine as a premedication should not be used in the patient with glaucoma.
Mydriatic	Phenylephrine	2.5%, 10%	α -Agonist used for maximal mydriasis and vasoconstriction without cycloplegia; potential side effects include hypertension, tachycardia or reflex bradycardia, pulmonary edema, cardiac arrhythmia, cardiac arrest, and subarachnoid hemorrhage.
	Hydroxyamphetamine	1%	Sympathomimetic used in combination with tropicamide primarily for differentiating preganglionic and postganglionic lesions producing Horner's syndrome.
Miotic	Acetylcholine	1%	Cholinergic agonist used intraocularly to produce complete miosis after cataract surgery, keratoplasty, other anterior segment surgery; side effects include bradycardia, hypotension, and bronchospasm.
Glaucoma Agent	Pilocarpine	1% to 8%	Cholinomimetic or parasympathomimetic agent used to produce miosis and a decrease in intraocular pressure for chronic and acute angle-closure glaucoma; side effects include gastrointestinal disturbance, diaphoresis, and brow pain.
	Echothiophate iodide	0.125%	Long-acting anticholinesterase agent used to produce miosis for open-angle glaucoma; side effects include bradycardia, hypotension, nausea, vomiting, diarrhea, weakness, and inhibition of plasma cholinesterase for up to 6 weeks after discontinuation.
	Timolol, levobunolol	0.25%, 0.5%	Nonselective β -antagonists that reduce intraocular pressure by decreasing aqueous humor production and possibly outflow; side effects include bronchospasm, bradycardia, hypotension, and apnea in neonates.
	Betaxolol	0.5%	Selective β_1 -antagonist; side effects are possible but less commonly observed in contrast to the nonselective β -antagonists.
	Apraclonidine	0.5%, 1%	Selective α_2 agonist incapable of crossing the blood-brain barrier and used to reduce aqueous secretion; side effects are minimal.
	Brimonidine	0.15%, 0.2%	Selective β_2 -agonist capable of crossing the blood-brain barrier; side effects include apnea, bradycardia, hypotension, hypothermia, and somnolence with an incidence as high as 83%.
	Latanoprost, bimatoprost, travoprost	Varies	Prostaglandin F ₂ analogues that increase aqueous humor outflow and decrease intraocular pressure in open-angle glaucoma; side effects are minimal and usually limited to ocular side effects.
	Acetazolamide	Varies	Systemic competitive inhibitor of carbonic anhydrase that reduces formation of aqueous humor; side effects include acidosis, hypokalemia, hyponatremia, and allergic reactions.
	Dorzolamide, brinzolamide	Varies	Topical carbonic anhydrase inhibitors that reduce the production of aqueous humor; side effects are uncommon.
	Mannitol	25%	Inert sugar that increases plasma osmotic pressure and decreases the volume of aqueous humor; side effects include transient hypervolemia followed by hypovolemia and potential for hypotension.

Continued

TABLE 27-2. Commonly Used Ophthalmic Medications—cont'd

Type	Medication	Concentration	Pertinent Systemic and Ocular Effects
Miscellaneous			
	Proparacaine, tetracaine	0.5%	Ester local anesthetics commonly used intraoperatively and during examination; side effects are minimal and usually limited to burning and possible epithelial damage.
	Cocaine	4%, 10%	Ester local anesthetic with vasoconstrictive properties; side effects include tachycardia, hypertension, dysrhythmias, hyperthermia, and seizures.
	Naphazoline	0.01%, 0.1%	α -Agonist used primarily for intraoperative vasoconstriction.
	Fluorescein	NA	Intravascular dye used to evaluate the integrity of retinal vasculature; side effects include hypertension, nausea, and vomiting.
	Sulfur hexafluoride	NA	Intraocular gas known to persist for up to 4 weeks after injection.
	Perfluoropropane, carbon octofluorine	NA	Intraocular gases known to persist for up to 6 weeks after injection.
	Botulinum toxin	NA	Neurotoxin produced by <i>Clostridium botulinum</i> , which inhibits release of acetylcholine used for treatment of strabismus and blepharospasm.

and funduscopy. The cycloplegic agents act via parasympatholytic action to block the muscarinic receptors of the ciliary body, paralyze the ciliary muscles, and inhibit accommodation. Outside of the perioperative period, the cycloplegic agents are also used to decrease the discomfort of ciliary body spasm common to a variety of inflammatory conditions.

Cyclopentolate, a commonly used cycloplegic agent, has a peak effect within 20 to 45 minutes and residual effects that persist for as long as 36 hours (Cooper et al., 2000). Mild gastrointestinal discomfort and feeding intolerance are the most commonly encountered side effects, although more severe atropine-like toxicity with symptoms ranging from vomiting, ileus, hyperthermia, delirium, and grand mal seizures (Kennerdell and Wucher, 1972; Bauer et al., 1973) has also been reported.

Tropicamide is a belladonna alkaloid that is also used as a topical cycloplegic agent. Maximal cycloplegic effect takes place within 20 to 40 minutes, and residual effects may persist for 6 hours. Because tropicamide is less reliable than cyclopentolate, it is most often used in combination with cyclopentolate or phenylephrine.

Atropine and homatropine are extremely potent anti-accommodative agents that are rarely used for pediatric patients in the perioperative setting. These agents are more commonly used for intraocular inflammation and amblyopia therapy; they may also be used for prolonged mydriasis after cataract extraction to prevent the formation of synechiae. Common side effects include thirst, tachycardia, and hyperthermia, although more severe symptoms may result after overzealous administration (McGoldrick, 1992b).

Mydriasis is usually produced as a secondary effect of the cycloplegic agents (by paralyzing the constrictors of the iris), yet additional mydriatic agents are often used to maximize peripheral and anterior retinal visualization. The mydriatic agents are sympathomimetic agents that mimic the effects of endogenous epinephrine and norepinephrine.

Ophthalmic phenylephrine (available in 2.5% and 10% concentrations) is commonly used for mydriasis and vasoconstriction during various procedures. Maximal effects are usually observed within 15 minutes, and residual effects may persist for 4 hours after administration. The generally accepted dosing limit for pediatric patients is one drop of the 2.5% solution in each eye per hour (Borromeo-McGrail et al., 1973). One drop (50 μ L) of the 2.5% solution contains approximately 1.25 mg of phenylephrine. The potential for severe hypertension, pulmonary edema, cardiac arrhythmia, cardiac arrest, and subarachnoid hemorrhage with topical phenylephrine is well appreciated by surgeons and anesthesiologists alike. With careful application of the 2.5% solution, systemic effects are typically mild, well tolerated, and generally observed within 1 to 20 minutes after application (Fraunfelder et al., 2002). Although one study demonstrated no significant difference in the mydriatic effects of cyclopentolate vs. phenylephrine (both administered in combination with tropicamide), many ophthalmologists still rely on the medication either primarily or when additional dilation is needed after the administration of other preparations (Rosales et al., 1981).

Glaucoma Pharmacologic Therapy

Unlike the management of adult glaucoma, the primary treatment for pediatric glaucoma is surgical. Medical therapy may occasionally be instituted perioperatively in an effort to minimize IOP. There are an expansive number of medications and combination products available, but none is formally approved for pediatric use. Convenient classifications for the glaucoma medications include the direct- and indirect-acting parasympathomimetics, sympathomimetics, β -antagonists, selective α_2 -agonists, carbonic anhydrase inhibitors, prostaglandin analogues, and hypertonic solutions.

Pilocarpine is a parasympathomimetic agent that produces miosis and a fall in IOP that is thought to result from an increase

in aqueous humor outflow. It is rarely used for temporary treatment before surgery in children but should be discontinued on the evening before surgery for adequate assessment of pressure (Khaw et al., 2000). At recommended dosages, side effects are thought to be rare but may include gastrointestinal disturbances and diaphoresis. More severe cardiovascular effects (e.g., hypotension, bradycardia, and atrioventricular block) are occasionally observed in the geriatric patient (Everitt and Avorn, 1990).

The long-acting anticholinesterase drugs (echothiophate iodide and demecarium bromide) are uncommonly used in the pediatric patient. They are occasionally used in the adult refractory to other glaucoma therapy. These agents are of particular interest to the anesthesiologist because of their ability to profoundly inhibit the metabolism of succinylcholine, mivacurium, and the ester anesthetics for up to 6 weeks after discontinuation of therapy.

Topical epinephrine and its prodrug, dipivefrin, are sympathomimetic agents historically used in the treatment of glaucoma. Topical epinephrine is occasionally used by ophthalmologists in the intraoperative setting and is known to potentiate dysrhythmias in the myocardium sensitized by the volatile agents. Of all the potent inhalation agents, halothane clearly has the greatest dysrhythmogenic potential, although one study has demonstrated that the pediatric heart may be more resistant to the interactions between halothane and exogenous epinephrine (Karl et al., 1983; Ueda et al., 1983). At equipotent concentrations, isoflurane has three times less dysrhythmogenic potential than halothane (Marshall and Longnecker, 2001). Desflurane and sevoflurane are thought to be similar to isoflurane in this regard (Moore et al., 1993; Navarro et al., 1994).

The β -blocking agents timolol, levobunolol, and betaxolol act by decreasing the production of aqueous humor and are occasionally used postoperatively in children. The agents should not be used in the neonatal and infant populations in light of several reports of apnea with the use of timolol (Olson et al., 1979; Bailey, 1984). In older children and adults, the use of betaxolol, which is selective for the β_1 -receptors, is associated with fewer complications involving the pulmonary system, although dyspnea and bronchospasm have been reported (Everitt and Avorn, 1990). Lethargy, bradycardia, and heart block are possible with all of the topical β -blocking agents (Gross and Pineyro, 1997).

Apraclonidine and brimonidine are topical α_2 -agonists that decrease sympathetic tone and subsequently reduce aqueous humor production. Brimonidine, unlike apraclonidine, is capable of crossing the blood-brain barrier and should be used with great caution in young children. Bradycardia, hypotension, hypothermia, hypotonia, and apnea have all been reported with the use of brimonidine (Enyedi and Freedman, 2001).

Newer topical agents, including the prostaglandin analogues (latanoprost, bimatoprost, and travoprost) and the topical carbonic anhydrase inhibitors (dorzolamide and brinzolamide), are generally very safe in the pediatric population but are believed to be less effective than they are in adults (Beck, 2001). The topical carbonic anhydrase inhibitors, like systemic acetazolamide, are sulfonamide derivatives that should be avoided in the patient with sulfa sensitivity.

Miscellaneous Ophthalmologic Agents

Topical anesthetics, including cocaine, tetracaine, and proparacaine, are occasionally used by ophthalmologists in the perioperative setting. Cocaine is rarely used, but it is unique among

the local anesthetics because of its vasoconstrictive properties. The potential for serious cardiovascular and central nervous system effects should be recognized by both the surgeon and anesthesiologist. The accepted maximum dose is 3 mg/kg, 1.5 mg/kg in the presence of volatile anesthetics. One drop of the 4% formulation contains approximately 1.5 mg of cocaine (McGoldrick, 1992b). The drug should not be used in patients with cardiovascular disease or in the presence of additional adrenergic-modifying medications such as monoamine oxidase inhibitors or tricyclic antidepressants.

Intraocular gases, including sulfur hexafluoride, perfluoropropane, and carbon octofluorine, are poorly diffusible inert gases that may be injected during certain vitreoretinal procedures. When nitrous oxide is present during injection, the nitrous oxide equilibrates with these new gas spaces to increase the volume and pressure of the intraocular injection, potentially compromising retinal perfusion. Animal studies, case reports, and mathematic models have demonstrated the necessity of discontinuing nitrous oxide no less than 15 minutes before intraocular gas injection and avoiding subsequent use of nitrous oxide for at least 4 weeks after the use of sulfur hexafluoride and 6 weeks after the use of perfluoropropane or carbon octofluorine (Wolf et al., 1983; McGoldrick, 1992b; Seaberg et al., 2002).

Effects of Various Anesthetic Agents on Intraocular Pressure

It is important to understand the ocular effects of the various anesthetic agents. An anesthetic plan should be chosen that provides optimal surgical conditions for intraocular procedures and minimizes risk of morbidity in those patients with preexisting intraocular hypertension and traumatic injury to the globe.

The central nervous system depressants (benzodiazepines, barbiturates, and opioids) commonly used by the anesthesiologist decrease IOP in both normal and glaucomatous eyes. The agents commonly used for preoperative anxiety in the pediatric population are associated with minor decreases in IOP that should not affect diagnostic measurements and likewise should not be relied on to attenuate the increase in IOP attributable to the use of succinylcholine and laryngoscopy. Effects specific to the use of oral or rectal midazolam in the pediatric population have not been delineated, although two studies of the use of intravenous (IV) midazolam in adults demonstrate minimal effects on IOP (Virkkila et al., 1992; Carter et al., 1999).

With the possible exception of ketamine, all of the IV induction agents are associated with a significant decrease in IOP. Thiopental and propofol reduced IOP by 40% and 53%, respectively, in one study, although both agents are unable to completely attenuate increases that are secondary to succinylcholine and laryngoscopy (Mirakhor and Shepherd, 1985; Mirakhor et al., 1987). Etomidate diminished IOP more profoundly than thiopental in one adult study (Calla et al., 1987). Etomidate-related myoclonus could be hazardous to the patient with traumatic injury and bothersome to the ophthalmologist. Early studies of the effects of ketamine uniformly demonstrated an increase in IOP, but subsequent studies in adults and children have demonstrated either insignificant changes or minor decreases in IOP (Peuler et al., 1975; Ausinsch et al., 1976). There is no clear consensus regarding the effects of ketamine

on IOP, although its association with blepharospasm and nystagmus makes other induction agents more useful for ophthalmologic surgery.

All of the volatile anesthetics are associated with a dose-dependent decrease in IOP. Various postulated mechanisms include a reduction in aqueous humor production with a concomitant increase in outflow, relaxation of the supporting musculature, and depression of the central nervous system control center for IOP (McGoldrick, 1992c). As was previously demonstrated with halothane, reliable measurements of IOP may be made for approximately 10 minutes after mask induction with sevoflurane (Watcha et al., 1990; Yoshitake et al., 1993).

The deleterious effects of succinylcholine on IOP and the various methods of attenuating these effects have been evaluated by numerous investigators for several decades. The augmentation of IOP is thought to be mediated not only by tonic contractions of the extraocular muscles but also by dilation of the choroidal vasculature and relaxation of the orbital smooth muscle (Calobrisi and Lebowitz, 1990). In a study of patients undergoing elective enucleation, it was noted that the change in IOP after succinylcholine administration was the same in the normal eye as in the eye where the extraocular muscles were detached; therefore, it does not appear that extraocular muscle contraction significantly contributes to the increase in IOP after succinylcholine administration (Kelly et al., 1993). In adult patients with normal IOP, succinylcholine at doses between 1.5 and 2 mg/kg increased pressures by no more than 9 mm Hg, with peak effects demonstrated within 3 minutes after administration (Pandey et al., 1972). In patients who were not intubated, IOP was restored to baseline within 6 minutes, although other studies have demonstrated mild elevations that may persist for 30 minutes after succinylcholine administration. Whereas these effects of succinylcholine are significant in comparison with the effects of the nondepolarizing agents, they are clearly insignificant in comparison with the increase in IOP that is possible with laryngoscopy, coughing, and retching.

Numerous methods of blunting the rise in IOP secondary to succinylcholine and laryngoscopy have been evaluated, although none has demonstrated consistent or reliable efficacy. The results of early studies of pretreating patients with small doses of the nondepolarizing agents were promising but later refuted (Miller et al., 1968; Meyers et al., 1978). In two adult studies, the use of alfentanil was demonstrated to significantly attenuate the response to succinylcholine and intubation (Polarz et al., 1992; Eti et al., 2000). Another study comparing the effects of fentanyl and alfentanil demonstrated that although both agents were effective in attenuating the response to succinylcholine, fentanyl did not significantly attenuate the increase in IOP secondary to laryngoscopy (Sweeney et al., 1989). Early studies concerning the benefit of lidocaine before succinylcholine were discouraging, but lidocaine had favorable effects on IOP during laryngoscopy and intubation in subsequent investigations (Smith et al., 1979; Mahajan et al., 1987; Warner et al., 1989). The opioids and lidocaine may also facilitate gentle extubations after intraocular procedures and in patients with elevated IOP.

More contemporary methods of controlling IOP with the use of succinylcholine and laryngoscopy have been promising. Premedication with sublingual nifedipine and oral clonidine has demonstrated efficacy in the elderly population (Ghignone et al., 1988; Indu et al., 1989; Polarz et al., 1993). Intramuscular (IM) dexmedetomidine also effectively reduced IOP during regional

anesthetic procedures in adults (Virkkila et al., 1994). None of these methods has been evaluated in the pediatric population.

More information regarding airway management and the effects on IOP are discussed in Chapter 30, Anesthesia for the Pediatric Trauma Patient. In addition, Vachon and others (2003) review the use of succinylcholine and the open globe.

GENERAL ANESTHETIC CONSIDERATIONS

Premedication

The value of premedication is well appreciated by all physicians providing anesthetic care to children. Premedication is useful to ease separation from parents and to provide for a smooth induction. Children between the ages of 1 and 6 years commonly benefit from premedication. Older children, especially those subject to repeated procedures, may also benefit from premedication or having a parent present during induction of anesthesia (Kain et al., 2006). Parental presence has also been shown to enhance the effects of oral midazolam on induction and emergence behavior (Arai et al., 2007). Oral midazolam (0.25 to 0.5 mg/kg) is commonly used and is generally effective within 10 to 20 minutes after administration (Coté et al., 2002). Nasal midazolam (0.2 mg/kg) may be useful in the patient refusing oral administration, but the acidity of the formulation is associated with a 71% incidence of burning and crying on administration (Karl et al., 1993). Oral clonidine (2 to 4 mcg/kg) also provides adequate anxiolysis within 30 minutes and has been demonstrated to decrease the incidence of PONV after strabismus surgery in two investigations (Mikawa et al., 1995; Handa and Fujii, 2001). In one study, oral clonidine was more effective than oral midazolam in multiple aspects of premedication, including acceptance by patients, more effective sedation, and better recovery from anesthesia (Almenrader et al., 2007). Neither midazolam nor clonidine consistently decreases the incidence of emergence delirium (Fazi et al., 2001; Valley et al., 2003). At recommended doses, neither of the agents should prolong the time required for discharge from the postoperative recovery unit.

General Anesthesia

General anesthesia for ophthalmologic procedures in children is similar to that provided for other brief surgical procedures. Many ophthalmologic procedures may be performed on an out-patient basis when the age of the patient does not mandate postoperative monitoring. Mask induction with nitrous oxide and sevoflurane is common for young patients who do not require rapid-sequence induction. Clear communication with the ophthalmologist can delineate which procedure may be performed with mask anesthesia or requires the use of a laryngeal mask airway or endotracheal tube. Consideration should be given to the proposed duration of the procedure and the possibility that access to the airway may be difficult.

Anesthesia can be maintained with any of the volatile agents, but the incidence of emergence delirium may be higher with the newer, less-soluble agents (Welborn et al., 1996; Lapin et al., 1999). Nitrous oxide is avoided if inert gas is to be injected into the eye. Nitrous oxide has been associated with an increased incidence of PONV in some adult studies, although similar effects

cannot be demonstrated in the pediatric population (Hartung, 1996; Tramer et al., 1996, 1997). One study demonstrated no correlation between the use of nitrous oxide and the incidence of PONV in pediatric patients with strabismus (Kuhn et al., 1999). Maintenance with propofol may also be used, but three studies have demonstrated a higher incidence of dysrhythmias attributable to the OCR with propofol anesthesia (Watcha et al., 1991; Larsson et al., 1992; Tramer et al., 1998). Neuromuscular blockade is often indicated for intraocular procedures to ensure that the field remains motionless and that coughing or bucking does not result in damage to the eye and untoward increases in IOP.

A smooth emergence from anesthesia is desired after ophthalmologic procedures. This may be facilitated by deep extubation in the lateral position. Any of the inhaled agents may be safely used for deep extubation, although slightly more airway complications may occur with the use of desflurane (Valley et al., 2003). Small doses of IV lidocaine (0.5 to 1 mg/kg) may be administered before extubation if the depth of anesthesia is unclear.

Local and Regional Anesthesia

The primary methods of administering local anesthetics for ocular procedures include topical application, infiltration, and regional blockade. Conjunctival injection is often used to provide anesthesia for the treatment of retinopathy of prematurity (ROP). Topical application or infiltration may be useful in the cooperative older child to perform otherwise uncomfortable examinations and simple procedures such as foreign body removal and laceration repair. Regional techniques, including retrobulbar, peribulbar, and sub-Tenon's blocks, are useful in adults as the primary anesthetic for a variety of ophthalmologic procedures, but they are less likely to be used as the sole anesthetic in children younger than 18 years of age (Johnson and Forrest, 1994). The benefits of regional techniques as adjuncts to general anesthesia in children are controversial.

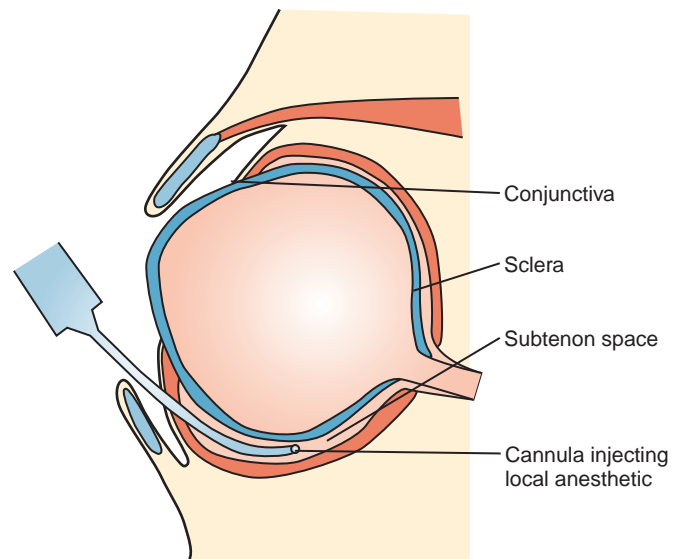

The retrobulbar or intraconal block was first described in 1884. The block involves injection of local anesthetic into the posterior cone of the extraocular muscles and is effective in producing anesthesia and akinesia by blocking the ciliary ganglion and the oculomotor and abducens nerves. Hyaluronidase is a commonly used adjuvant that decreases the time for onset. The retrobulbar technique is not often used in the pediatric population. Complications of the retrobulbar block include stimulation of the OCR, retrobulbar hemorrhage, penetration of the optic nerve, intravascular injection, and brainstem anesthesia (McGoldrick, 1992e). One study evaluating the efficacy of retrobulbar blocks in combination with general anesthesia for pediatric strabismus surgery demonstrated no significant benefit, although the sample size was relatively small (Ates et al., 1998). An additional study of 45 patients showed a significant decrease in incidence and severity of OCR with retrobulbar block, and a decrease in PONV with retrobulbar block or topical local anesthesia (Gupta et al., 2007).

The peribulbar or periconal block has been used increasingly since it was first described in 1986. Because the cone of the extraocular muscles is not entered, the potential for intraocular and intradural injection is minimized, and the risk of retrobulbar hemorrhage and direct nerve injury is virtually eliminated (McGoldrick, 1992e). Disadvantages of the peribulbar block

include a slightly higher failure rate (10% incidence) and an increased forward pressure on the globe secondary to the larger volumes of local anesthetic required (Zahl, 1992). Two pediatric studies that compared peribulbar blocks with IV meperidine for vitreoretinal and strabismus surgery demonstrated superior analgesia and significantly less PONV for up to 24 hours after surgery (Deb et al., 2001; Subramaniam et al., 2003). Parental satisfaction was also greater for those patients receiving adjunctive regional blocks.

The sub-Tenon's block was first reported in adults in 1992 as a blunt-needle alternative to the sharp needle peribulbar or retrobulbar blocks (Stevens, 1992). Tenon's capsule is a fascial sheath that envelops the eyeball and separates it from the orbital fat. The inner surface is separated from the outer surface of the sclera by a potential space called the episcleral or sub-Tenon's space (Fig. 27-3). Typically, a blunt, curved cannula is inserted in the inferonasal quadrant under the Tenon's capsule and 3 to 5 mL of local anesthesia are deposited in adults. In pediatric patients the volume is considerably less. The advantages include relatively painless insertion of the block and the ability to use a blunt needle with less opportunity to inject into unwanted areas of the eye. This block is associated with a higher incidence of chemosis and subconjunctival hemorrhage (Guise, 2003).

The sub-Tenon's block in conjunction with general anesthesia has been reported to decrease PONV, improve postoperative pain control, and reduce intraoperative analgesia requirements in patients having strabismus surgery (Steib et al., 2005). Ghai et al. (2009) in a prospective, randomized, blinded study of pediatric cataract patients compared sub-Tenon's block (0.06 to 0.08 mL/kg 2% lidocaine with 0.5% bupivacaine [50:50 mixture]) to IV fentanyl (1 mcg/kg) and found significantly less pain and lower incidence of oculocardiac reflex. There was no statistically significant reduction in PONV, but parent satisfaction scores were higher with the sub-Tenon's block. Additionally, it has been proposed as a technique in conjunction with sedation to perform laser surgery for ROP in neonates at the bedside (Parulekar et al., 2008).

■ **FIGURE 27-3.** Anatomy of the sub-Tenon's space (From Ghai B et al.: *Subtenon block compared to intravenous fentanyl for perioperative analgesia in pediatric cataract surgery*, *Anesth Analg* 108:1132, 2009.)

Although pediatric ophthalmologic patients are not often candidates for a pure regional anesthetic, its use in combination with general anesthesia will likely increase as benefits are measured. Although it is unlikely that most pediatric anesthesiologists will perform such procedures, a general understanding of the techniques and potential complications is important when caring for these children.

INTRAOPERATIVE AND POSTOPERATIVE COMPLICATIONS

Oculocardiac Reflex

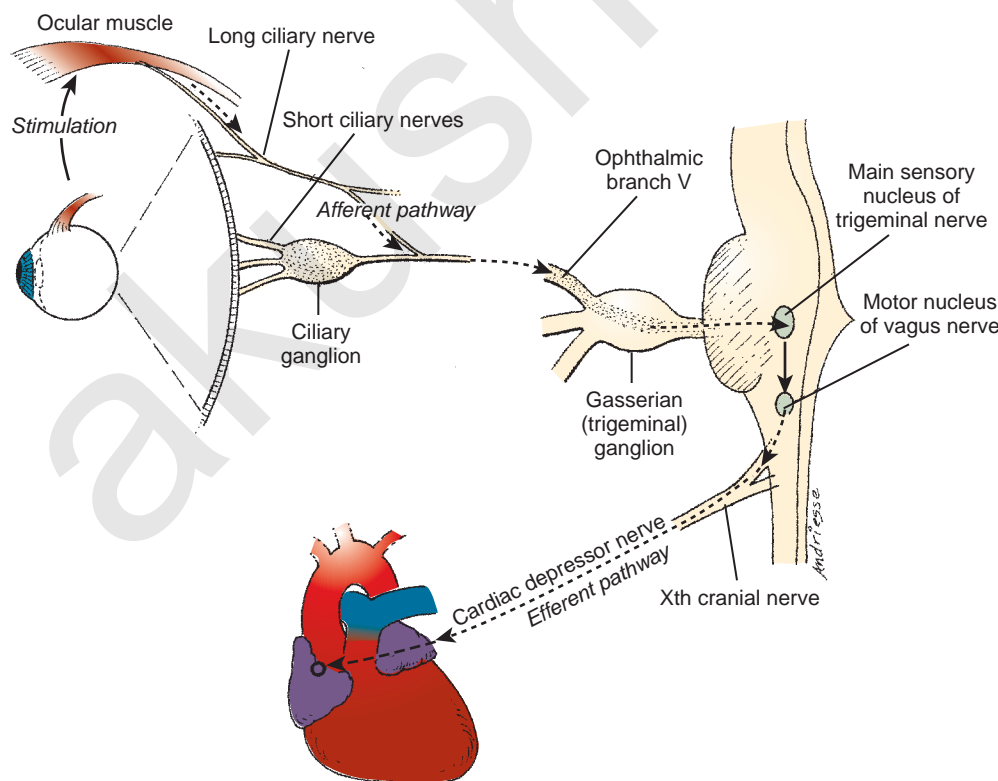

The OCR was first described by two independent observers in 1908. The OCR is reported to occur at an incidence as high as 70% to 79% during pediatric ophthalmologic surgery (particularly strabismus surgery) without the use of prophylaxis (Ruta et al., 1996; Allen et al., 1998). The reflex is most often elicited by traction on the extraocular muscles but is also elicited by pressure on the eye and after intraorbital or retrobulbar injections. The reflex has been observed in the child who is congenitally anophthalmic and in the patient with an empty orbit after enucleation (Kerr and Vance, 1983; Ward and Bass, 2001). The anesthesiologist should be aware of the OCR and its potential consequences.

The OCR is mediated by the afferent ophthalmic division of the trigeminal nerve and the efferent vagal nerve (Fig. 27-4). The most common manifestation of the reflex is sinus bradycardia, but more ominous manifestations, including atrioventricular block, ventricular bigeminy, ventricular tachycardia, and asystole, have been described. Most studies define significant

OCR-related bradycardia as a 10% to 20% decrease in the resting heart rate that is sustained for 5 seconds or longer. With sustained traction on one of the extraocular muscles, a counterregulatory adrenergic phase and restoration of heart rate occurs, which may be followed by a further increase in heart rate once traction is released (Braun et al., 1993). Most often, the initial bradycardia is associated with a variable degree of hypotension, although bradycardic hypertensive responses are also possible (Hahnenkamp et al., 2000).

When the reflex occurs intraoperatively, release of the stimulus is usually effective in ablating dysrhythmias within 10 to 20 seconds. If bradycardia persists or is worrisome, the patient may be given atropine (10 to 20 mcg/kg, IV) or glycopyrrolate (10 mcg/kg, IV). The initial effects of atropine should be evident within 20 seconds, and the maximal response is observed after 80 seconds (Braun et al., 1993). In the event that IV access is not available or is unreliable, one study has determined that intraglossal administration is superior to the IM route and in fact may be superior to IV administration (Arnold et al., 2002). It is generally safe to proceed with surgery once normal sinus rhythm at a rate within 10% of baseline is restored.

The value of prophylaxis has been debated for many years. There clearly is no method of completely eliminating the occurrence of the OCR. The consensus is that most pediatric patients (but not adults) undergoing strabismus surgery should be treated with IV atropine at a dose of 20 mcg/kg before manipulation (Steward, 1983). IV glycopyrrolate at a dose of 10 mcg/kg also has demonstrated efficacy with slightly less pronounced tachycardia. One randomized study of 120 children demonstrated a reduction in the incidence of OCR to 5% with glycopyrrolate and 2% with atropine given immediately after induction (Chisakuta and Mirakhur, 1995). Preoperative treatment by

■ **FIGURE 27-4.** Anatomy and physiology of the oculocardiac reflex. (From Vassallo SA, Ferrari LR: *Anesthesia for ophthalmology*. In Coté CJ et al., editors: *A practice of anesthesia for infants and children*, ed 2, Philadelphia, 1993, Saunders.)

oral or IM routes is generally not warranted and is probably less effective (Mirakhur et al., 1982; Mirakhur, 1991). Opponents to prophylaxis with atropine maintain that possible dysrhythmias secondary to atropine itself (e.g., ventricular tachycardia, ventricular fibrillation, and left bundle branch block) may be more ominous and difficult to treat than the dysrhythmias associated with the OCR (Massumi et al., 1972; McGoldrick, 1992f). These effects are much more common in the adult patient. In otherwise healthy children, the tachycardic effects of atropine or glycopyrrolate should be safe and well tolerated.

Retrolbulbar blocks are effective in preventing the OCR (Taylor et al., 1963; Braun et al., 1993; Deb et al., 2001); regional blocks are not commonly used during pediatric procedures and have triggered the reflex during placement. Topical lidocaine, applied directly to the medial rectus at 1 mg/kg, decreased the incidence of the OCR to 19% (vs. 79% in the control population); this technique has not been investigated since the initial study of 36 pediatric patients (Ruta et al., 1996).

The reflex may occur during regional and general anesthesia, and the depth of anesthesia has been thought to be irrelevant. However, there is one study using bispectral index (BIS) to estimate the depth of anesthesia that suggests a BIS of 40 to 50 seems to adequately prevent the OCR, compared with a BIS greater than 60 (Yi and Jee, 2008). Hypercarbia and hypoxemia, which may be more likely in the spontaneously breathing patient, are associated with a greater incidence of the bradycardic response. At least six studies have demonstrated that the choice of maintenance agents may influence the incidence or severity of the OCR. In one study of 39 pediatric patients who were mechanically ventilated through laryngeal mask airways, propofol anesthesia was associated with the greatest decrease in heart rate during a standardized traction of an extraocular muscle. Ketamine was associated with the least decrease in heart rate, whereas halothane and sevoflurane were associated with intermediate effects (Hahnenkamp et al., 2000). In another study of spontaneously breathing normocarbic patients who were not pretreated with atropine, sevoflurane was associated with a 38% incidence of OCR, whereas halothane was associated with an incidence of 79% (Allison et al., 2000). There is no discernible difference between the OCR provoked with desflurane vs. sevoflurane (Oh et al., 2007). Remifentanyl appears to have an effect on the incidence of OCR. During strabismus surgery on children between 1 and 9 years of age without anticholinergic prophylaxis, those with maintenance of anesthesia using remifentanyl had twice the incidence of OCR compared with those in the group receiving sevoflurane (Chung et al., 2008).

Postoperative Pain

Many of the common ophthalmologic procedures have minimal postoperative analgesic requirements. Examinations under anesthesia, nasolacrimal duct probing, and cataract extraction are associated with negligible postoperative discomfort. The various procedures performed for glaucoma and strabismus are associated with moderate postoperative pain. The requirements for analgesia should be reviewed with the surgeon, the patient, and the family during the formulation and general discussion of the anesthetic plan.

For patients requiring minimal analgesia, rectal acetaminophen (30 to 40 mg/kg) may be administered after induction and followed with subsequent doses (20 mg/kg) at 6-hour intervals

(Birmingham et al., 2001). Up to 120 minutes may be required to achieve peak serum levels. IV ketorolac (0.5 mg/kg) yields consistent analgesia for those procedures resulting in moderate postoperative pain (Dsida et al., 2002). Two studies of ketorolac administered for strabismus surgery have demonstrated analgesia equivalent to that provided by fentanyl (1 mcg/kg) or morphine (0.1 mg/kg) with a substantial reduction in PONV (Munro et al., 1994; Mendel et al., 1995). Another more recent study investigated the effect of topical tetracaine on postoperative pain control and emergence delirium. Although they were unable to make conclusions about emergence agitation, they did demonstrate that tetracaine drops improved pain control in the early postoperative period (Anninger et al., 2007).

Opioid analgesics should not be withheld from patients requiring more intensive analgesia. More painful procedures include cryotherapy (for various disorders), ablation, and enucleation for patients with retinoblastoma. Nausea, vomiting, and respiratory depression can complicate postoperative recovery, but the opioid agents provide greater facility for titration, may minimize coughing and bucking at extubation, and attenuate the incidence of emergence delirium.

Postoperative Nausea and Vomiting

Nausea and vomiting after ophthalmologic procedures are so common that they often serve as a model for the evaluation of various prophylactic techniques. Because nausea is subjective and difficult to measure in children, most studies look only at postoperative vomiting (POV). Several large scale studies report POV in children to occur at an incidence ranging from 13% to 42% after general anesthesia for all procedures (Rose and Watcha, 1999). The incidence of POV in untreated children after strabismus surgery ranges from 40% to 88% (Lerman, 1995). Older children and those receiving opioid analgesics are at greater risk. Whereas prophylaxis vs. symptomatic treatment is debated for low-risk procedures in children, it is generally accepted that prophylaxis should be provided for children undergoing strabismus surgery and all intraocular procedures regardless of demographics and the anesthetic technique employed. Retching and vomiting may be particularly detrimental after surgical or traumatic trespass of the globe. A summary of prophylactic measures is provided in [Box 27-2](#).

One simple measure that does not involve the administration of any drug prophylaxis is the use of IV fluid therapy. In a

Box 27-2 Prophylaxis for Postoperative Nausea and Vomiting

DEMONSTRATED BENEFIT

- Avoiding opioid analgesics
- Avoiding nitrous oxide (controversial)
- Dexamethasone 0.15-1 mg/kg, IV
- Ondansetron 50-200 mcg/kg, IV
- Other 5-HT₃-receptor antagonists (if available)
- Adequate IV hydration
- Withholding oral intake postoperatively

NO DEMONSTRATED BENEFIT

- Anticholinergic therapy

comparison of pediatric patients undergoing strabismus surgery, the amount of fluid resuscitation was shown to make a difference in the incidence of PONV. POV was reported in 54% of the control group, who received 10 mL/kg per hour of lactated Ringer's solution, vs. only 22% of the "superhydration group," who received 30 mL/kg per hour of lactated Ringer's solution (Goodarzi et al., 2005).

The efficacy of droperidol, a butyrophenone, has been demonstrated in numerous studies over the past 20 years. Low doses (20 mcg/kg) given after induction are as effective as higher doses (75 mcg/kg) and are less likely to prolong recovery time (Brown, et al., 1991). Lower doses (15 mcg/kg) in combination with ondansetron (100 mcg/kg, IV) are more effective than either drug given individually (Shende et al., 2001). The Food and Drug Administration (FDA) issued a black box warning in 2001 regarding the potential for fatal dysrhythmias associated with prolonged QTc intervals in rare instances when patients were given droperidol (Gan et al., 2002). No significant complications have been reported in children with the use of low-dose droperidol. However, considering a recent study showing doses of 25 mcg/kg of droperidol and 150 mcg/kg of ondansetron administered at induction of anesthesia to be equally effective in reducing the incidence and severity of POV, the pediatric anesthesiologist may find it easier to use alternative drugs than to comply with the rigorous monitoring recommendations made by the FDA (Bharti and Shende, 2003).

Ondansetron is a serotonin 5-HT₃-receptor antagonist commonly used for prophylaxis and rescue therapy at doses ranging from 50 to 200 mcg/kg, IV. The half-life in children is slightly shorter than it is in adults (2.5 vs. 3.8 hours), and side effects are unusual in all populations (Culy et al., 2001). Administration either before or after surgical manipulation is acceptable with equivalent benefit (Madan et al., 2000). It has been demonstrated that doses of 75 mcg/kg are as effective as higher doses in the immediate postoperative period (Sadhasivam et al., 2000). Two studies have demonstrated that higher doses (150 to 200 mcg/kg) are required for significant benefit carried through the initial 24-hour postoperative period (Rose et al., 1994; Bowhay et al., 2001).

Other 5-HT₃-receptor antagonists have been developed since 1991, primarily in an effort to provide a longer duration of action. Granisetron (20 to 40 mcg/kg, IV or orally [PO]) and dolasetron (12.5 mg or 350 mcg/kg, IV) have demonstrated efficacy in the pediatric strabismus population (Munro et al., 1999; Wagner et al., 2003). Tropisetron (200 mcg/kg up to 2 mg) has also been used in pediatric patients. As costs fall on these newer agents, their use may become more common.

Studies of dexamethasone as an antiemetic have been favorable, primarily in light of the agent's low risk, low cost, long duration of action (up to 48 hours), and potential for augmenting postoperative analgesia (Splinter and Rhine, 1998). Many studies demonstrate its efficacy both alone and in conjunction with other antiemetics. In a dose response study, 250 mcg/kg, IV was found to be as effective as higher doses (Madan et al., 2005). The greatest reduction in POV after surgery for strabismus was reported in a study using low-dose dexamethasone (150 mcg/kg, maximum 8 mg) in combination with ondansetron (50 mcg/kg) after induction (Splinter, 2001). These results were upheld in a more recent study using 0.15 mg/kg of ondansetron and 0.2 mg/kg dexamethasone, resulting in only a 10% incidence of POV (Bhardwaj et al., 2004). One study comparing high-dose dexamethasone at 1 mg/kg (maximum of

25 mg) to ondansetron at 100 mcg/kg (maximum 4 mg) demonstrated a similar incidence of PONV during the initial 6 hours but significantly less during the subsequent 18 postoperative hours in those treated with dexamethasone (Subramaniam et al., 2001). The severity of POV and the number of patients requiring rescue medication were also significantly less in the dexamethasone group. Facial flushing is possible after dexamethasone, but there is no evidence in the literature for more detrimental side effects (e.g., hyperglycemia, delayed wound healing, or adrenal suppression) after single dose therapy (Subramaniam et al., 2001; Madan 2005).

Metoclopramide is a dopaminergic antagonist that provides central antiemetic action as well as increased gastric emptying and increased tone at the lower esophageal sphincter. There is inconsistent support in the literature for the use of metoclopramide for POV prophylaxis. Two randomized studies have demonstrated moderate benefit with metoclopramide at a dose of 250 mcg/kg given after induction, although two more recent studies failed to demonstrate any significant benefit (Broadman et al., 1990; Lin et al., 1992; Shende and Haldar, 1998; Kathirvel et al., 1999). A recent consensus panel failed to find evidence to recommend metoclopramide as a routine antiemetic (Gan, 2007).

Four early studies comparing propofol with halothane demonstrated a significant attenuation of POV after strabismus surgery when propofol was used (Watcha et al., 1991; Larsson et al., 1992; Reimer et al., 1993; Weir et al., 1993). The benefit was demonstrated primarily during the immediate postoperative period. A more recent study comparing propofol with isoflurane failed to demonstrate any significant benefit with propofol (Hamunen et al., 1997).

Other modalities of prophylaxis for POV will continue to emerge in response to an appropriate focus on cost effectiveness and patient and parental satisfaction. It is left to each clinician to determine what risk is tolerable and which patient population may derive the greatest benefit from therapy.

SPECIFIC PATHOLOGY AND SURGICAL AND ANESTHETIC MANAGEMENT

Examination under Anesthesia

Although some centers perform simple examinations and minor procedures for young children under procedural sedation, many ophthalmologists prefer general anesthesia to perform more thorough and accurate examinations. Common evaluations include tonometry, funduscopy, and the assessment of visual evoked potentials. Most examinations take no more than 5 to 10 minutes, but a sufficient depth of anesthesia must be provided. Premedication and anxiolysis are most beneficial to children who require a series of examinations over time.

For healthy children, mask induction and maintenance of spontaneous ventilation provide adequate conditions for the ophthalmologist and affording accurate control of anesthetic depth and a smooth emergence from anesthesia. Accurate measurements of IOP can be made for the initial 10 minutes after induction and maintenance with both sevoflurane and halothane (Watcha et al., 1990; Yoshitake et al., 1993). More lengthy examinations, including photographic retinal mapping and assessment of visual evoked potentials, may be performed

with either propofol sedation or spontaneous ventilation with inhaled anesthetic agents and a laryngeal mask airway.

Retinopathy of Prematurity

ROP is a multifactorial disease initiated by delayed retinal vascular growth after premature birth (phase 1) followed by abnormal retinal vessel growth (phase 2). The infant with ROP may require anesthetic care for procedures both related and unrelated to ocular pathology. ROP is of particular interest to the pediatric anesthesiologist, because the routine management of the infant at risk may alter the development or progression of the disease itself.

Conditions associated with ROP include low birth weight, prematurity, oxygen exposure, mechanical ventilation, blood transfusions, intraventricular hemorrhage, sepsis, and vitamin E deficiency. ROP occurs in approximately 70% of infants who weigh less than 1000 g at birth. Fortunately, 80% to 90% of these infants have spontaneous regression of their retinal changes (Simons and Flynn, 1999; Moore, 2000). The greatest risk of oxidative damage to the developing retina appears to be in the first few weeks of life (Gaynon, 2006). It is clear that supplemental oxygen and relative hyperoxia are not the only factors responsible for development of the disease. Nevertheless, the immature retina is indisputably more susceptible to damage from the higher ex utero concentrations of oxygen and subsequent elevated levels of vascular endothelial growth factor (VEGF).

The immature retina responds to elevated oxygen tension (or another insult) by arrest of normal vasculogenesis and later by neovascularization and fibrous-tissue formation in the retina and vitreous humor. Retinal tears and detachment may occur secondary to contraction of the vitreous humor. Vasculogenesis takes place between 16 and 44 weeks' postconception. In the normal developing retina, there is no clear border dividing the vascular and avascular tissue. This border becomes more prominent in those patients with ROP and forms the basis for staging the disease. The International Classification of Retinopathy of Prematurity (ICROP) was established in 1984 to uniformly describe the anatomic zone involved and the severity or stage of disease (Committee for the Classification of Retinopathy of Prematurity, 1984). This was revisited in 2005 with some modifications, including a description of a more virulent form of retinopathy in the tiniest babies (International Committee for the Classification of Retinopathy of Prematurity, 2005). Definitions for the various stages are provided in [Box 27-3](#) and can be seen [Figure 27-5](#). Threshold ROP, defined by specific ICROP criteria, is the stage of progression that is amenable to treatment.

Investigations have demonstrated the benefit of extremely limited oxygen supplementation in premature infants without ROP and the potential benefit of more liberal oxygen therapy in older infants with established prethreshold disease (Sinha and Tin, 2003). At one institution, rigorous guidelines restricting the use of oxygen greatly diminished the occurrence of advanced ROP and abolished the need for laser therapy over a 5-year period (Chow et al., 2003). The STOP-ROP multicenter controlled trial revealed that patients with established prethreshold disease are not harmed by oxygen supplementation and that a subset of these patients may benefit from higher arterial saturations (STOP-ROP Multicenter Study Group, 2000).

Box 27-3 International Classification of Retinopathy of Prematurity Stages

- Stage 1:** Fine demarcation line is visible between vascular and avascular regions.
- Stage 2:** Broad ridge divides the vascular and avascular regions.
- Stage 3:** Neovascularization is noted at the ridge, on the posterior surface and anteriorly toward the vitreous cavity.
- Stage 4:** Subtotal retinal detachment has occurred.
- Stage 5:** Total retinal detachment in an open or closed funnel configuration has occurred.

From Committee for the Classification of Retinopathy of Prematurity: An international classification of retinopathy of prematurity, *Pediatrics*, 74:127, 1984.

It is prudent to the anesthesiologist to limit oxygen supplementation in those infants without a diagnosis of ROP during the period of retinal vascularization. Older infants (older than 44 weeks' postconceptional age) and those with established prethreshold disease are probably less vulnerable to higher oxygen tensions commonly provided during transports and general anesthesia. Anesthesia provided for nonophthalmologic procedures was once believed to increase the risk of ROP, but controlling for other risk factors has revealed that such a population is at no greater risk (Flynn, 1984).

Infants with threshold ROP are treated by cryotherapy or laser photocoagulation, depending on specific clinical findings. Cryotherapy involves placement of a probe chilled with nitrous oxide on the outer surface of the globe. Cryonecrosis of the underlying retinal tissues results in a decrease in the incidence of retinal detachment. Laser procedures (diode and argon lasers) are the preferred modality of therapy and are easier for the infant and the therapist than the cryotherapy technique. In many hospitals, these procedures are performed at the bedside in the neonatal intensive care unit. Both procedures may be performed with atropine, analgesics including opioids and ketamine, and local anesthesia that includes the sub-Tenon's block (Lyon et al., 2008). Infants who are not intubated for the procedure may experience respiratory or hemodynamic instability, leading some neonatologists to electively intubate these infants for the procedure (Sullivan TJ et al., 1995). Cardiorespiratory disturbances may occur in 5% to 9% of all cases (Brown et al., 1990; Haigh et al., 1997). Some ophthalmologists prefer the benefits of general anesthesia in an operating-room setting. In a recent survey of pediatric ophthalmologists, 50% preferred general anesthesia with a controlled airway, whereas the rest used IV or oral sedation with local anesthesia (Chen et al., 2007). Variation in practice is because of the ophthalmologists' beliefs and experiences, and also because of resource allocation, such as the availability of pediatric anesthesia. Once ROP progresses to stage 4 or 5, scleral buckle or vitrectomy are performed to attempt to prevent blindness. These surgeries are almost always performed with general endotracheal anesthesia.

Strabismus

Strabismus has a prevalence of 3% to 5% in the pediatric population (Vivian, 2000). The disorder is most often idiopathic but may be associated with poor vision, cataracts, trauma, neuromuscular

■ **FIGURE 27-5.** Retinopathy of prematurity. **A**, Stage 1: Demarcation line—a line that is seen at the edge of vessels (*black arrows*), dividing the vascular from the avascular retina. Retinal blood vessels fail to reach the retinal periphery and they multiply abnormally where they end. **B**, Stage 2: Ridge (*R*) of scar tissue and new vessels in place of the demarcation line. The white line now has width and height and occupies some volume. Small tufts of new vessels (“popcorn vessels”) may appear posterior to the ridge (*white arrowhead*). **C**, Stage 3: Increased size of the vascular ridge (*between white arrowheads*), with growth of fibrovascular tissue on the ridge and extending out into the vitreous. Fibrous scar tissue is beginning to form in this stage, with attachments between the vitreous gel and the ridge. **D**, Stage 4a: Partial retinal detachment; detachment does not include the macula, and the vision may be good. In Stage 4B (not shown) the macula is detached, and visual potential is markedly decreased. **E**, Stage 5: Complete retinal detachment. (Courtesy of Dr. Richard Hertle, The Children’s Hospital of Pittsburgh.)

disorders, or one of several congenital syndromes (see [Table 27-1](#)). Surgical correction involves isolation of one or more of the extraocular muscles with subsequent recession (transection and reinsertion) or resection (shortening) of the muscle. Contemporary techniques involving botulinum toxin injection and postoperative adjustable sutures are not commonly used in the pediatric population. Amblyopia develops in approximately 50% of all patients with congenital esotropia and should be treated with occlusion therapy before surgical correction for strabismus (Guthrie and Wright, 2001).

General anesthesia may be provided by a flexible laryngeal mask airway, although endotracheal intubation with controlled ventilation may lessen the risk of hypercarbia and hypoxemia, which are known to increase the incidence and severity of the OCR (Blanc et al., 1988). Many ophthalmologists request the use of paralytic agents for performance of the forced duction test to more clearly differentiate paretic and restrictive disorders before surgical correction. This possibility should be discussed with the surgeon before formulating the anesthetic plan. Prolonged contractions of the extraocular muscles associated with the use of succinylcholine interfere with interpretation of the forced duction test for at least 15 minutes after administration (France et al., 1980). Its use is relatively contraindicated.

Masseter muscle rigidity after succinylcholine administration is four times more common in children anesthetized for strabismus surgery than in the general pediatric surgical population (Carroll, 1987). Because of the association of masseter muscle rigidity with malignant hyperthermia and an increased incidence of malignant hyperthermia in patients undergoing strabismus surgery, these patients are thought to be at a greater risk for the development of malignant hyperthermia (Strazis and Fox, 1993) (see Chapter 37, Malignant Hyperthermia).

Prophylaxis for both the OCR and PONV are critical for the patient undergoing strabismus repair. Postoperative pain is generally mild and of conjunctival origin. Acetaminophen, IV ketorolac, or both are usually effective. Topical analgesics (ketorolac, diclofenac, and benoxinate [oxybuprocaine]) have been evaluated in the strabismus population, and clear advantages over systemic agents and uniform efficacy have not been demonstrated (Morton et al., 1997; Bridge et al., 2000).

Lacrimal Apparatus Dysfunction

Congenital nasolacrimal duct obstruction is present in 60% to 70% of all infants at birth; spontaneous resolution is observed in 96% of these children by 1 year of age (Freitag and Woog, 2000). Congenital obstructions are most often isolated findings, but they may be associated with a variety of syndromes and craniofacial defects ([Table 27-1](#)). Acquired nasolacrimal duct obstruction is uncommonly encountered in the pediatric population but may be secondary to trauma, granulomatous disease, and systemic neoplasms (leukemia and lymphoma). The anatomy of the nasolacrimal duct system is illustrated in [Figure 27-6](#).

The initial surgical management of congenital obstruction usually requires only simple probing to establish patency. A small Bowman probe is inserted through one or both of the puncta, through the lacrimal sac, and subsequently into the nasolacrimal duct to pierce the valve of Hasner beneath the inferior turbinate (Freitag and Woog, 2000). The procedure is often atraumatic, requires no more than 5 to 10 minutes, and has been performed successfully in the office setting in children younger than 6 months of age. Usually the procedure is performed with general mask anesthesia. As with similar noninvasive procedures, IV access is not absolutely required for patients who are

■ **FIGURE 27-6.** Anatomy of the lacrimal duct apparatus. (From Nowinski TS: *Anatomy and physiology of the lacrimal system*. In Bosniak S, editor: *Principles and practice of ophthalmic plastic and reconstructive surgery*, vol 2, Philadelphia, 1996, Saunders.)

easily ventilated with a mask. Patients with significant comorbidities may be more safely cared for with IV access (Eippert et al., 1998). Although transient bacteremia has been demonstrated after nasolacrimal duct probing, the benefit of antibiotics to prevent endocarditis is questionable (Wilson et al., 2007).

The lacrimal system may be irrigated with saline or fluorescein after the procedure to demonstrate patency. Preventing excessive pooling, possible laryngospasm, and aspiration may require only head-down positioning and careful suctioning through the ipsilateral naris or oropharynx. Some anesthesiologists believe that patients are better managed with intubation to provide optimal protection of the airway (Johnson and Forrest, 1994). Analgesic requirements after nasolacrimal probing and irrigation are negligible.

Secondary surgical management of nasolacrimal obstruction may include infraction of the inferior turbinate, placement of silicone tubing that remains in place for 3 to 12 months, and dacryocystorhinostomy (Freitag and Woog, 2000). Dacryocystorhinostomy is a procedure used to bypass the nasolacrimal duct by creating an anastomosis between the lacrimal sac and the nasal mucosa beneath the middle turbinate. A small incision is made just medial to the medial canthus and overlying the lacrimal sac. These more complex procedures may require up to 2 hours to perform and may be complicated by appreciable blood loss. They require general anesthesia with endotracheal intubation. Topical vasoconstrictors may be used to minimize bleeding at the highly vascular nasal mucosa, and pharyngeal packing is usually beneficial. Acetaminophen, ketorolac, or small doses of opioids should provide adequate postoperative analgesia.

Cataracts

The prevalence of pediatric cataracts is between 1.2 and 6:10,000 live births. Bilateral cataracts are most commonly associated with systemic disease (see Table 27-1), whereas unilateral cataracts are more often idiopathic (Russell-Eggitt, 2000; Fallaha and Lambert, 2001). Surgery for bilateral congenital cataracts must be performed within the first several weeks of life to allow for normal retinal development. Unilateral congenital disease requires surgical attention within the first 4 months of life to prohibit the development of irreversible amblyopia.

Lens extraction is performed after maximal mydriasis with one or more of the topical agents. Ultrasonic phacoemulsification (commonly used in adults) is not often used in the pediatric population because of the pliable nature of the immature lens. Vitrectomy instrumentation is the preferred method of extraction in young children; the entire procedure is typically performed with only one intraocular instrument. Capsular opacification occurs often in children, and a capsulectomy is usually performed at the time of primary surgery. Intraocular lens implants are commonly provided to children older than 6 months with unilateral disease and children older than 1 year with bilateral disease (Fallaha and Lambert, 2001).

Anesthesia for lens extraction should provide complete akinesia and meticulous control of IOP. Because most of these patients are infants, controlled ventilation with muscle relaxants provides optimal operating conditions. The anesthesiologist should be aware of associated systemic disease and the potential systemic effects of the topical preparations used by

the ophthalmologist. Rarely (1:200,000), maximal pupillary dilation requires an infusion of epinephrine delivered and then continuously aspirated from the anterior chamber. Attention to the electrocardiogram tracing permits detection of systemic absorption, which fortunately is uncommon (McGoldrick, 1992b). Analgesic requirements are usually minimal and under normal circumstances may be met with acetaminophen.

Postoperative apnea has been reported in the otherwise healthy full-term infant after cataract surgery (Tetzlaff et al., 1988). Speculation has associated ocular pathology or procedures with postoperative apnea in the otherwise healthy infant, but this association has yet to be clearly described.

Surgical postoperative complications include the formation of secondary membranes, glaucoma, and endophthalmitis (Fallaha and Lambert, 2001). Endophthalmitis may be avoided by treating nasolacrimal duct obstruction before cataract surgery and postponing cataract surgery in children with evidence of upper respiratory tract infection.

Glaucoma

Pediatric glaucomas are a diverse group of disorders with a prevalence of 1:10,000 live births (Khaw et al., 2000). Pediatric glaucoma is most often a congenital abnormality inherited in an autosomal recessive pattern that is slightly more prevalent in males (McGoldrick, 1992f). Only 10% of pediatric glaucoma diagnoses are associated with systemic disease, congenital disorders, or other ocular abnormalities. The diagnosis may be suspected in the patient who has buphthalmia, epiphora, photophobia, or corneal clouding (Khaw et al., 2000). The definitive diagnosis is made only by tonometry, corneal examination, funduscopy, and gonioscopy (examination of the iridocorneal angle).

Open-angle glaucoma is diagnosed when a normal trabecular meshwork is visible via gonioscopy. Closed-angle glaucoma is diagnosed when the iridocorneal angle is obstructed by the iris. Infantile glaucoma develops before the age of 3 years and is a primary disorder in approximately 50% of all cases. Juvenile glaucoma refers to disease that develops after the age of 3 years and is most often secondary to or associated with other ocular or systemic disorders.

Surgical management varies between patients and is dependent on the measurements and observations made under general anesthesia. Corrective procedures include goniotomy, trabeculotomy, trabeculectomy, and cyclocryotherapy (Beck, 2001). Goniotomy is a relatively brief procedure, whereas the other surgical techniques may require longer periods of general anesthesia. Patients often require repeated evaluations, because surgical correction is typically incremental and performed in carefully monitored stages.

The anesthetic management is quite similar for all procedures. A careful review of the past medical history, comorbid conditions, and concurrent pharmacologic therapy is crucial (see Tables 27-1 and 27-2). Premedication with atropine or glycopyrrolate is acceptable, but the use of scopolamine is generally contraindicated in the patient with glaucoma. Mask inductions are acceptable and followed by gentle laryngoscopy and placement of an oral Ring-Adair-Elwyn (RAE) endotracheal tube. Stable IOP and complete akinesia must be maintained throughout the surgical procedure. Neostigmine with glycopyrrolate or atropine may be safely administered for reversal of

neuromuscular blockade; both agents have only minimal ocular effects at the routinely recommended doses. Unlike many other ocular procedures, surgery for glaucoma (particularly cyclocryotherapy) may be associated with moderate to severe postoperative pain. Opioids, in conjunction with prophylaxis for PONV, should be incorporated into the anesthetic plan.

Retinoblastoma

Retinoblastoma is the most common intraocular malignancy in the pediatric population with a prevalence of 1:20,000 live births. Fifty percent of all cases are secondary to mutations of the retinoblastoma gene, although only 25% of patients with the heritable form of the disease have a positive family history (Moore, 2000). The diagnosis is generally made by 3 years of age. Children with a positive family history have a 5% risk for developing retinoblastoma; these patients require regular examinations until the age of 5 years.

Therapy for retinoblastoma varies according to the severity of disease and has evolved dramatically since the 1970s. Treatment modalities may include combinations of enucleation, external beam radiation, localized radiotherapy, laser ablation, thermotherapy, cryotherapy, and chemotherapy (Uusitalo and Wheeler, 1999). Enucleation of the affected eye (or the more involved eye in bilateral disease) followed by external beam radiation was the cornerstone of treatment in the 1990s, leading to survival of over 90%. However, the risk of second cancers in the field of radiation began to appear with the risk increasing by 10% per decade of life. Through chemoreduction and focal ablation methods, many children with retinoblastoma are spared enucleation and serial external beam radiotherapy (Shields and Shields, 1999). Candidates for external beam radiotherapy include patients with bilateral disease that requires enucleation of the more involved eye and patients with diffuse vitreous and subretinal seeding.

Anesthetic requirements for enucleation are similar to those for other moderately complex ophthalmic procedures. The incidence of OCR-mediated dysrhythmias is high, and appropriate prophylaxis with atropine or glycopyrrolate is warranted. Contemporary surgical techniques effectively minimize blood loss such that the need for transfusion is uncommon. Postoperative pain is often significant.

External beam radiotherapy may require as many as 24 radiation sessions and anesthetics over the course of 4 to 6 weeks. Each session is of a few minutes' duration, but the session requires the patient to remain motionless. Various anesthetic methods have been used, including rectal or IM methohexital, IV or IM ketamine, and brief inhalation anesthetics by insufflation methods, laryngeal mask airway, and endotracheal intubation (McGoldrick, 1992f). When a central venous catheter has been placed for adjuvant chemotherapy, a single bolus of propofol is probably the most effective method of providing the required 2 to 3 minutes of anesthesia with minimal recovery requirements.

Vitreoretinal Disorders

Retinal tears and detachment in the pediatric population are most often secondary to ROP but may also result from trauma and vitreous degeneration common to certain syndromes (see

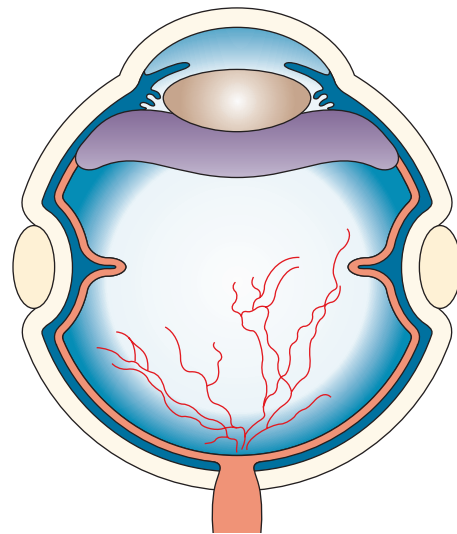

Table 27-1). Small tears may be amenable to laser therapy or cryopexy, but more significant tears and detachment often require complex surgical management and up to 3 hours of general anesthesia. Surgical options include scleral buckling (in combination with cryopexy), closed vitrectomy, and open-sky vitrectomy (Hunter et al., 2000).

The scleral buckle procedure involves the attachment of a tiny sponge or silicone band that constricts the sclera and holds the retina in position (Fig. 27-7). The scleral buckle remains permanently attached to the eye and may restrict normal growth of the child's eye if tension is not released with subsequent surgery. Vitrectomy may be considered in the presence of a failed scleral buckle, for high retinal detachment, and for media opacification. The closed vitrectomy is slightly more difficult in the pediatric population and involves lensectomy for segmentation and removal of the vitreous by microvitrectomy blades and vitrectomy instruments. The open-sky technique involves complete removal of the cornea, lensectomy, and en bloc removal of the fibrous mass filling the funnel of the detached retina (Hunter et al., 2000).

Anesthetic considerations for such procedures include prophylaxis for the OCR (the extraocular muscles are often bridled to permit optimal positioning), complete neuromuscular blockade, and the potential need to lower IOP with agents such as mannitol and acetazolamide. Silicone oil or one of the long-acting inert gases may be injected into the vitreous chamber at the conclusion of the procedure in an effort to improve surgical success (see Table 27-2). Should reoperation be necessary within a month of injection of an inert gas, nitrous oxide may be contraindicated because of its potential to expand the gaseous space.

Traumatic Injury and Ruptured Globe

The optimal management for the patient with ocular injury has been widely debated for many years, although many contemporary pundits consider the controversy mundane. Ophthalmic

■ **FIGURE 27-7.** Scleral buckle. (From Sears J, Capone A: *Retinopathy of prematurity*. In Yanoff M, Duker JS, editors: *Ophthalmology*, Philadelphia, 1999, Mosby.)

injuries are most often superficial, but a disproportionate number of serious penetrating injuries occur in children (Johnson and Forrest, 1994). It is often difficult to differentiate the emergent case (penetrating injury) from the nonemergent (nonpenetrating injury) case in children without examination under general anesthesia.

The pressure in the ruptured globe becomes atmospheric, and any external pressure or increase in internal pressure may lead to prolapse of the intraocular contents and a diminished possibility for recovery of vision. The possibility of salvaging the eye after penetrating injury requires surgical intervention within several hours of the injury. Traditional periods of fasting are not acceptable.

The importance of maintaining a quiet environment in the preoperative period cannot be overemphasized. Crying and thrashing can have devastating effects on IOP. Forceful eyelid closure may increase IOP by as much as 70 mm Hg (McGoldrick, 1993). Venous cannulation can be facilitated by pentobarbital, oral or rectal midazolam, and transdermal anesthetics. Access subsequently permits the administration of additional anxiolytics, analgesics, and prophylaxis for aspiration. Once sedation is adequate, the injured eye should be patched to provide comfort and minimize ocular movement.

When IV access is available, the anesthesiologists must consider the risks and benefits of succinylcholine (Vachon et al., 2003). Current consensus remains in favor of succinylcholine for rapid provision of optimal intubating conditions and reliable attenuation of coughing and bucking immediately after the endotracheal tube is secured. It is widely accepted that succinylcholine increases IOP despite various methods of blunting the response, but it is also clear that the succinylcholine-induced rise in IOP is inconsequential in relation to the possible rise with laryngoscopy and intubation (Cunningham and Barry, 1986). Support for the use of succinylcholine is derived from feline models of both anterior and posterior segment trauma and retrospective chart reviews and testimonials from the Wills Eye Hospital and the Massachusetts Eye and Ear Infirmary (Libonati et al., 1985; Donlon, 1986; Moreno et al., 1991).

Some anesthesiologists use nondepolarizing neuromuscular blockers for modified rapid sequence inductions in patients with penetrating ocular injuries. The nondepolarizing agents provide either no effect on or a slight decrease in IOP. Three described methods for accelerating the onset of the older

nondepolarizing agents are divided doses of pancuronium, high-dose vecuronium, and synergism with d-tubocurarine and pancuronium (Mehta et al., 1985; Abbott and Samuel, 1987; Abdulla, 1993). Most anesthesiologists concede that none of these techniques provides the speed and reliability of succinylcholine. Rocuronium (1.2 mg/kg) has been demonstrated to have no effect on IOP and may provide intubating conditions comparable to succinylcholine within 60 seconds (Mazurek et al., 1998; Mitra et al., 2001; Perry et al., 2003). For patients with comorbid conditions that mandate avoidance of succinylcholine, rocuronium is probably the most effective alternative.

Although isolated ocular injuries are more common in children, the anesthesiologist should be aware of other injuries that may compromise the patient's condition. Liberal doses of either propofol or thiopental, adjuvant agents, and neuromuscular monitoring are paramount before attempted laryngoscopy and placement of the endotracheal tube. A gastric tube should be placed to evacuate the contents of the stomach only after the airway is protected and paralysis is complete. Complex surgical repairs may not be performed during the initial presentation, and surgical time may vary from 1 hour to several hours. Complete paralysis and attention to IOP are mandatory throughout the procedure. Deep extubation is an option for patients not considered at risk for aspiration.

SUMMARY

The pediatric population provides the anesthesiologist with a wide variety of ophthalmologic pathology. The anesthetic challenges are considerable. An understanding of the pertinent physiologic and pharmacologic principles, as well as an appreciation of the continued advancement in surgical therapy, affords optimal patient management and favorable outcomes.

Since the inception of the United Network of Organ Sharing (UNOS) in 1987, nearly half a million solid organ transplants have been performed in the United States. Of these, 375,000 have been from deceased donors, or donation after cardiac death (DCD), and 103,000 have been from living donors (UNOS 4-2010) (Tables 28-1 and 28-2). The total number of pediatric transplants has reached nearly 37,000, and the total number of living donors is 9200 for all pediatric patients. In 2009, the yearly totals for pediatric organ transplants increased significantly for the first time in 6 years, to a total of 2019, from a low of 1964 transplants in both of the years 2005 and 2008. Unfortunately, the yearly total of pediatric living donors decreased from a decade high of 560 in 2001, to 387 in

2009. The incidence of end-stage organ disease increases with age, and children still account for only a small fraction (7.60%) of the total number of transplant recipients.

In 1973, the U.S. Congress recognized organ donation as a legal voluntary gift by adopting the Uniform Anatomical Gift Act. In addition, the Omnibus Budget Reconciliation Act (implemented in October 1987) stipulates that hospitals will not receive reimbursement from Medicare or Medicaid unless written protocols for the identification of potential organ donors are established. Physicians are now routinely expected to approach families of brain-dead patients and request organ donation. UNOS established uniform policies and standards, with a guarantee of equitable access of member institutions to

all available donor organs. UNOS revised and reviewed a number of their inclusion criteria for both donors and recipients in November 2009.

With the new changes, Organ Procurement Organization (OPO) members must submit data to the Organ Procurement and Transplantation Network (OPTN) under the directorship of the U.S. Department of Health and Human Services through the use of standardized forms and electronic databases. There are 11 OPTNs in the United States and Puerto Rico (Fig. 28-1). In addition to providing data on all deceased donors, living donors, potential transplant recipients, and actual transplant recipients, all OPOs must also submit of the total number of reported deaths by donor hospital.

As of January 2010, there are 486 transplant centers or hospitals in the United States that operate one or more organ transplant programs. These centers house 1136 types of solid organ transplantation programs, managed by the 11 OPTNs (UNOS-OPTN, April 2010), as reported by the Health Resources and Services Administration of Health and Human Services. Data extracted from the UNOS database suggest that there are currently over 100,000 candidates awaiting transplantation. Table 28-3 demonstrates the numbers of pediatric and adult candidates awaiting organ transplantation by organ type. Pediatric patients outnumber these adults only in the category of intestinal transplantation.

■ **FIGURE 28-1.** A map of the 11 organ procurement and transplantation networks in the United States in 2010. (From the United Network for Organ Sharing (UNOS) and Organ Procurement and Transplantation Network (OPTN) data, 2010. Available at <http://optn.transplant.hrsa.gov/data>.)

From the United Network for Organ Sharing (UNOS) and Organ Procurement and Transplantation Network (OPTN) data, 2010. Available at <http://optn.transplant.hrsa.gov/data>.

The number of pediatric candidates awaiting organ transplantation pales in comparison with the total number of available organs. In fact, for the past 5 years, the total number of patients awaiting transplantation (~100,000) is one fifth of the total number of patients transplanted since 1985 (~500,000). Although organ transplantation procedures are relatively infrequent compared with the over 50 million surgical procedures performed per year in the United States, perioperative care for these patients has become highly specialized. Maintenance of physiologic homeostasis during the removal of a failed native organ and the subsequent allograft reperfusion period are challenging for both anesthesiologists and surgeons. This chapter focuses on the current body of knowledge for each type of major solid organ transplantation, with a specific focus on special considerations for the management of children. In addition, cellular transplantation, stem-cell transplantation, immunosuppression, complications, graft-versus-host disease, and posttransplant lymphoproliferative disease will be addressed. Information on artificial assist devices being used in the treatment of end-organ failure or as a bridge to

transplantation, and information on xenotransplantation. See related video online at www.expertconsult.com.

DETERMINATION OF BRAIN DEATH IN CHILDREN

The medical and legal aspects of determining brain death have evolved over the past 3 decades. The need for special criteria for determination of brain death in infants and children was clear as early as 1967 when the first successful heart transplantation took place. The organ came from a brain-dead, beating-heart donor, and the first U.S. committee met to form a consensus opinion.

The pediatric central nervous system (CNS) may be more resilient to certain forms of injury, a fact that should be considered when interpreting diagnostic evidence and confirming brain death in infants and children. Brain death is defined as the absence of cortical and cerebral function without preservation of brainstem function. When measured in this setting, cerebral blood flow (CBF) is absent. Publication of brain death criteria specifically addressing findings in infants and children has clarified most of the ambiguities created by age-related neurologic differences. The Task Force for the Uniform Determination of Brain Death in Children was assembled in 1987 (Report of Special Task Force, Pediatrics, 1988). **Box 28-1** summarizes the currently accepted guidelines for determination of brain death in neonates, infants, and children.

Box 28-1 Guidelines for Brain Death in Children

1. Diagnosis of irreversible coma
 - a. Exclude all potentially reversible causes of coma: drug intoxication (barbiturates, sedatives, hypnotics, and alcohol).
2. Physical examination
 - a. Coma
 - b. Apnea (determined by standardized testing)
 - c. Absence of brainstem function (no cough, gag, sucking reflexes; no oculocephalic or cold caloric-induced eye movement)
 - d. Normothermia
 - e. Normotension
 - f. Flaccid tone, absence of spontaneous movement
 - g. Atropine resistance (failure to increase the heart rate by more than 5 beats/min after atropine sulfate is given intravenously at a dosage of 40 mcg/kg)*
3. Consistent physical examination during period of observation, as follows:
 - a. For ages 7 days to 2 months: two examinations and isoelectric electroencephalograms (EEGs) 48 hours apart
 - b. For ages 2 months to 1 year: two examinations and isoelectric EEGs 24 hours apart, or one examination and isoelectric EEG, plus radionuclide angiogram showing absence of cerebral blood flow
 - c. For ages greater than 1 year: two examinations 12 to 24 hours apart, EEGs, and isotope angiography.

*From Hosenpud JD, Novick RJ, Breen TJ, et al: The Registry of the International Society for Heart and Lung Transplantation: eleventh official report—1994, *J Heart Lung Transplant* 13:561–570, 1994.

If hypoxic encephalopathy is present, observation for 24 hours is recommended. This time may be reduced if an electroencephalogram shows electrocortical silence, or if a radionuclide study is negative for CBF. In patients with electrocortical silence, metabolic coma must be excluded. Detailed reviews of these guidelines and their applications have been published (Ashwal and Schneider, 1991; Ashwal, 1993; Koszer and Moshe, 2010). Prospective donors must fully meet the age-appropriate criteria and be declared legally brain dead before attempting to obtain consent for organ donation from their family. A physician must record the official time of death in the chart before transferring the donor to the operating room for the organ procurement procedure. Although the donor is officially dead, the care of an anesthesiologist is needed during these procedures to continue efforts to maintain cardiac output, at least until the viscera have been flushed with the cold preservative solution. At this point, ventilation can be discontinued and the responsibility of the anesthesiologist is concluded.

One area that remains particularly controversial is the appropriateness of organ donation from anencephalic newborns. This developmental anomaly results in absence of the cerebral cortex and upper brainstem, so these infants possess no potential for normal neurologic development. Despite the uniformly fatal outcome in these cases, such infants never meet the usual criteria for brain death (Baird and Sadovnick, 1984).

DONOR STRATEGIES

Successful donor-directed strategies for the 21st century focus on increasing the size of the donor pool through expansion of acceptable donor criteria, adoption of comprehensive donation

management guidelines, and innovative surgical techniques that allow organ sharing. Here, the term *pediatric organ donors* refers to critically ill children, from the newborn to the 17-year-old, with cessation of neurologic function. Unique challenges may limit the number of deceased pediatric donor organs available for transplantation, including size and weight constraints, as well as the lack of expertise required for declaration of brain death and management of the pediatric donor at some institutions. Thus, organ availability for transplantation (kidney, liver, lung, small bowel, and pancreas) is becoming increasingly dependent on living donors, on split-liver transplantation, and on asystolic, non-heart-beating (DCD) donors.

Organ donation in the pediatric population has decreased by almost 25% in the past 15 years, from 1201 in 1995, to 919 in 2009, with a low in 2008 of 879, the lowest number of pediatric donors since the inception of UNOS data collection (Table 28-4). Additionally, living donation has also decreased significantly in the past 5 years, a result of the ethics controversy and the complications that are now apparent with respect to living donation. The distribution of pediatric donor ages has remained consistent, with close to 60% being between the ages of 11 and 17 (Table 28-5). Although the number of adult donors is significantly greater than the number of pediatric donors, the percentage of recovered organs in the pediatric age range is generally greater than the percent of adult transplanted organs. For deceased kidney donors, 94.7% of the pediatric kidneys recovered were transplanted compared with 91.6% of the kidneys recovered from donors aged 18 to 49 years. There was a similar trend for pancreas donors (81.4% versus 72.2%), liver donors (96.0% versus 91.4%), and intestine donors (94.7% versus 85.7%). For heart and lung donors, the percentage of recovered organs transplanted was high, and it was similar for both

From the United Network for Organ Sharing (UNOS) and Organ Procurement and Transplantation Network (OPTN) data, 2010. Available at <http://optn.transplant.hrsa.gov/data>.

pediatric donors and adult donors aged 18 to 49 years (98.9% versus 99.0% for heart and 98.1% versus 96.4% for lung) (OPTN/SRTR, 2010).

Over the past decade, the number of pediatric DCD donors increased from six (less than 1%) in 1997, to 77 (8%) in 2006. Although the percentages of DCD donors currently are similar in the adult and pediatric populations, there is probably an unmet potential of DCD donors in the pediatric population.

Recovery of organs from deceased donors requires continuing care of the patient's preexisting condition, with a shift in primary emphasis from minimizing neurologic injury and preserving life to protection of specific organs. Principles of pediatric donor care are comparable with those of adults, but meticulous adjustments are necessary because of the special physiologic needs of children. The leading causes of death in children are asphyxia and trauma, so a history of cardiac resuscitation, hypotension, and hypoxemia is frequent in this donor population (Fischer-Froehlich et al., 2002).

Pediatric donation management goals and dosing guidelines are available for reference from NATCO (Nakagawa, 2008b), the UNOS Critical Pathway for the Pediatric Organ Donor (www.unos.org), and the Canadian Council for Donation and Transplantation (www.ccdt.ca) (Shemie et al., 2006). In 2001, a Consensus Conference made specific recommendations for management of cardiac donors (Zaroff et al., 2002). See also Kutsogiannis (2006), Braunfeld (2004), Wood et al. (2004), and Ullah et al. (2006).

Ultimately, the management of the pediatric organ donation is dictated by regional standards of care and the physicians caring for the child. The primary responsibilities of the pediatric intensive care specialist and anesthesiologist are to anticipate the normal physiologic sequelae of brain death (Table 28-6), and to direct therapy toward normalizing gross alterations in physiologic and biochemical parameters.

Organs from deceased donors may be injured or damaged from many things: the preexisting comorbid factors; hemodynamic instability (autonomic surge, hypotension, cardiac ischemia, metabolic acidosis, and use of vasopressors); endocrine, metabolic and electrolyte imbalances; hypoxemia (acute respiratory distress syndrome [ARDS]); coagulopathy; thrombocytopenia; renal failure; endotoxin release; and immune activation inherent in the brain death process (Jawan et al., 2002; Zaroff et al., 2002). The presence of brain death-related complications has been reported to have no effect on the number of

organs donated if an aggressive donation management protocol is instituted (DuBose and Salim, 2008).

Organ Retrieval

Organ procurement is usually completed in 4 hours or less, depending on the operating team's experience, the number of organs intended for retrieval, and the presence of variations in the vascular anatomy. In the face of worsening hypoxemia, coagulopathy, or refractory hypotension, the organ recovery surgery should be expedited to prevent warm ischemic injury to transplantable organs. The specific organs to be retrieved determine the type of fluid management, the ideal central venous pressure (CVP), the fraction of inspired oxygen (F_{iO_2}), and the choice of inotropic or vasopressor support and maximum allowable dosages. Management decisions depend on the organs being considered; for example, hemodynamic goals preferred by abdominal transplant surgeons occasionally differ from those of cardiothoracic transplant surgeons. Pediatric donation management goals are summarized in (Table 28-7) (Nakagawa, 2008b).

Preoperative donor evaluation includes the determination of hemodynamic stability and vasopressor support, electrolytes and therapy for diabetes insipidus, pulmonary status, renal function and urine output, coagulopathy, and the degree of hypothermia. Routine anesthesia monitoring is supplemented with the placement of an intraarterial catheter in an upper extremity to facilitate sampling and monitoring of the arterial blood pressure. Measuring CVP is especially important if the heart and lungs are being considered for donation. Arterial blood gases, hematocrit, electrolytes, blood glucose, and osmolality are usually assessed every hour, or more frequently as needed.

Strict asepsis is observed, prophylactic antibiotics are administered, and the donor is positioned and prepared surgically. If the corneas are to be harvested, the eyelids are taped shut and covered with cold saline compresses or ice packs for corneal protection. After 300 U/kg of heparin is administered and cardioplegia is achieved, the liver, intestines, pancreas, and kidneys are flushed with cold preservation solution, and sequential removal of organs can proceed. The spleen and omental lymph nodes are removed for tissue typing, and the aorta, inferior vena cava, and common carotid and iliac vessels are taken for vascular grafts. Anesthesia support of the organ donor is necessary

TABLE 28-6. Normal Physiologic Sequelae of Brain Death

Sequela	Cause	Management
Hypotension	Neurogenic shock, hypovolemia, hypothermia, electrolyte disorders, endocrine abnormalities, myocardial dysfunction	Mean arterial pressure > 60 mm Hg CVP 4 to 12 mm Hg PCWP 8 to 12 mm Hg SVR 800 to 1200 dyne/sec per cm ⁵ Cardiac index > 2.4 L/min per m ² Inotropic support in order of preference (in mcg/kg per min): Dopamine <10 Dobutamine <10 Epinephrine <0.1 Norepinephrine and renal-dose dopamine
Endocrine abnormalities	Disruption of the hypothalamic pituitary axis, resulting in adrenal insufficiency, hypothyroidism, or diabetes insipidus	Volume replacement; correct electrolytes; inotropic support Steroids: methylprednisolone (15 mg/kg) T ₃ : 4-mcg bolus and 3 mcg/hr infusion Arginine vasopressin: 1-U bolus, then continuous infusion at 0.5 to 4 U/hr, titrated to a systemic vascular resistance of 800 to 1200 dyne/sec per cm ⁵ Insulin: 1 U/hr minimum. Titrate to maintain blood sugar 120 to 180 mg/dL
Hypothermia	Loss of hypothalamic, neural, or endocrine regulation; resuscitation with cold fluids or blood products	Early aggressive warming to maintain temperature at >36° C At <30° C, may be unresponsive to ACLS, drug therapy, defibrillation, or pacing
Anemia	Hemorrhage, hemodilution	Transfuse, hemoglobin 7-10 g/dL
Coagulopathies	DIC, fibrinolysis, dilutional, hypothermia	Factor replacement, transfusion rewarming, early organ retrieval

*For children, normal systolic blood pressure = 80 + 2 × age in years.

until the proximal aorta is surgically occluded and in situ flushing of organs has begun. Subsequently, the ventilator should be disconnected and monitoring discontinued, as electrocardiographic (ECG) activity may persist for up to 70 minutes after cardiac arrest (Oaknine, 1975; Logigian and Ropper, 1985).

To avoid reflex muscular contractions and facilitate surgical exposure, a long-acting muscle relaxant is administered intravenously. Complex movements of the limbs and trunk

can be confused with reflex movements of cerebral origin and may create tremendous anxiety for the operating room personnel because, although the declaration of brain death requires the loss of cerebral and brainstem reflexes, spinal reflexes may remain intact.

In addition to spinal reflexes, a reflex pressor response to nociceptive stimuli is sometimes observed. This vasopressor response may lead to excessive operative blood loss and damage

to the renal grafts. Management requires a reduction in preload or afterload, or both, while minimizing any possible adverse drug toxicity, especially to the liver and kidneys. Thus, antihypertensive agents such as nitroglycerin or nitroprusside may be required if the volatile anesthetic, preferably isoflurane, is not successful in ablating this response.

Because brain death results in the loss of central mechanisms that control the endocrine and autonomic nervous systems, cardiac death usually occurs within 48 to 72 hours despite maximal physiologic support. Up to 25% of potential brain-dead organ donors are lost each year in North America because of cardiovascular collapse (Jenkins et al., 1999). Hypotension and hemodynamic instability secondary to neurogenic shock, dysrhythmias, and hypovolemia, all resulting from the absence of brainstem function, should be anticipated and treated in all donors.

Intravascular Fluid Management

Brainstem injury produces a sequence of hemodynamic events, beginning with an increase in parasympathetic tone and evolving to a massive autonomic surge with hypertension (systolic blood pressure > 200 mm Hg) and tachycardia (>140 beats/min) (Audibert et al., 2006). The pathophysiology of neurocardiogenic injury involves an initial neural phase (catecholamine surge and mixed venous oxygen saturation [MVo₂] supply-demand imbalance) within hours, followed by a humoral phase and release of inflammatory cytokines. Depletion of thyroid hormones and cortisol, and decreased coronary perfusion pressure may also impair myocardial function. Coronary vasoconstriction, subendocardial ischemia, focal myocardial necrosis, and endothelial injury are factors that contribute to accelerated cardiac allograft vasculopathy in the recipient (Segel et al., 2002; Szabo et al., 2002; Mehra et al., 2004). Systolic and diastolic dysfunction has been reported in 10% to 28% of pediatric donors and 71% of adult donors. It is reversible in the majority of cases (Banki and Zaroff, 2003). Despite normal or increased perfusion pressure, the resulting vasoconstriction may cause tissue ischemia that disrupts the production of ATP, generates oxygen free radicals, increases cytosolic calcium concentration, and activates various enzymatic cascades such as endonucleases and nitric oxide syntheses (Kunzendorf et al., 2002). A subsequent hypotensive phase caused by loss of autonomic regulation of the peripheral vasculature and unopposed vasodilation may further reduce oxygen supply to the tissues. Hypovolemia is seen with diuresis and fluid restriction during brain resuscitation, inadequate volume replacement after trauma, and diuresis resulting from diabetes insipidus or hyperglycemia.

Brain death is a dynamic inflammatory process. The activation of inflammatory mediators leads to a nonspecific immune response, which may be associated with accelerated acute graft rejection and poor long-term outcomes (Kunzendorf et al., 2002). In addition, a significant factor in organ injury after storage and cold ischemia is caused by reperfusion, initiated by leukocyte adhesion to endothelial cells and the production of oxygen-derived free radicals and peroxides.

Fluid replacement therapy with colloid or crystalloid solutions and cytomegalovirus (CMV)-negative blood products directed at restoring and maintaining the intravascular volume is the first step in resuscitation of the hemodynamically unstable donor. Use of lactated Ringer's solution, normal saline, Plasmalyte, or 5% albumin, is recommended, starting with a 20-mL/kg intravenous (IV) bolus and followed by hemodynamic

reassessment of the donor and two additional boluses as needed. The lowest acceptable systolic blood pressure can be calculated by multiplying the patient's age in years by 2, and adding 70. Hypotonic and dextrose-containing crystalloid solutions should never be used for fluid resuscitation. Hetastarch (Hespan) or other artificial plasma expanders should be avoided for fluid resuscitation because of their inherent risk for coagulopathy and renal impairment. Volume loading with crystalloid- or colloid-containing solutions usually depends on institutional preference and the sensitivity of the liver and lungs to low osmotic pressure-mediated tissue edema. When only the kidneys are to be procured, the donor can be maximally volume loaded. For lung or heart-lung retrieval, fluid restriction (CVP ≤ 6 mm Hg) is preferred. Infusion of colloids is recommended, with limited use of crystalloid and early initiation of inotropic support to maintain a mean arterial pressure of 60 mm Hg or greater.

If the initial two-dimensional echocardiographic evaluation reveals that the left ventricular ejection fraction is less than 45%, management with invasive monitoring, fluids, inotropes, vasopressors, hormonal, replacement therapy (with hydrocortisone, levothyroxine, or triiodothyronine), and treatment of diabetes insipidus (with desmopressin [DDAVP] or vasopressin infusion) is strongly recommended (Table 28-8).

Hourly maintenance fluids are calculated according to the 4-2-1 rule; that is, for the first 10 kg, use 4 mL/kg; for the second 10 kg, use 2 mL/kg; when the weight is greater than 20 kg, use the weight in kilograms plus 40. Guidelines for transfusion therapy are listed in Table 28-9. Packed red blood cells (RBCs) are transfused to maintain the hemoglobin at 10 g/dL for unstable donors, with the lowest acceptable being 70 g/L. Platelets, International Normalized Ratio (INR), and partial thromboplastin time (PTT) have no predefined targets, with transfusion indicated in cases of clinically evident bleeding or coagulopathy. The recommended hemodynamic endpoints are mean arterial pressure (MAP), 60 mm Hg or greater; CVP and pulmonary capillary wedge pressure (PCWP), 12 mm Hg or less; systemic vascular resistance (SVR), 800 to 1200; cardiac index, 2.5 or

greater; left ventricular stroke work index, 15 or greater; and dopamine dosage, 12 mcg/kg per minute or less (UNOS Critical Pathway for the Pediatric Organ Donor).

Cardiovascular Management

Hypotension in the potential organ donor most commonly results from hypovolemia (absolute or effective with a reduction in venous return), cardiac dysfunction, or arterial vasodilation from neurogenic shock (Table 28-10). The goals of hemodynamic support are to correct hypovolemia, to adjust vasoconstrictors and vasodilators to maintain a normal afterload, and to optimize cardiac output and maintain perfusion pressure gradients without relying on high dosages of β -agonists or other inotropes. Proposed adverse biochemical, histopathologic, and functional effects of catecholamine infusions on the myocardium include high-energy substrate depletion, intramyocardial noradrenaline depletion, and myocardial β -adrenoceptor down-regulation (Sakagoshi et al., 1992; Pinelli et al., 1995; Zaroff et al., 2002). With persistent hypotension despite volume replacement, vasopressor therapy should be initiated.

Dopamine up to 10 mcg/kg per minute is the drug of choice because the glomerular filtration rate (GFR) is increased as well as cardiac output while dilating the renal, mesenteric, and coronary vasculature. Inotropic agents should be titrated to maintain a normal blood pressure for the patient's age (normal systolic blood pressure mm Hg = $80 + 2 \times$ age in years). Blood pressure alone does not indicate adequate tissue perfusion. Therefore, serum biomarkers such as base deficit and lactate should be followed as inotropic support is titrated (Table 28-11).

Echocardiography should be performed early, followed by insertion of a pulmonary artery catheter, especially if the ejection fraction is less than 40% or the donor requires high-dosage inotropes. According to Zaroff (2004), ejection fraction is the most significant predictor of nonuse of potential donor hearts, with an odds ratio of 1.48 per 5% decrease in ejection fraction.

When dopamine is used for inotropic support in infants, dosages significantly higher than those needed in the adult may be

TABLE 28-10. Causes of Hypotension in the Potential Organ Donor

Hypovolemia	Cardiac Dysfunction	Vasodilation
Initial injury	Preexisting disease	Spinal shock
Inadequate resuscitation	Initial injury	Catecholamine depletion
Third spacing	Myocardial contusion	Loss of vasomotor control and autoregulation

TABLE 28-11. Inotropic Infusions

Drug	Dosage
Milrinone (Primacor)	0.25-0.75 mcg/kg per min IV Loading dose: 50 mcg/kg
Dopamine	2-20 mcg/kg per min IV
Dobutamine (Dobutrex)	2-20 mcg/kg per min IV
Epinephrine	0.1-1 mcg/kg per min IV
Norepinephrine (Levophed)	0.05-2 mcg/kg per min IV
Phenylephrine (Neosynephrine)	0.1-0.5 mcg/kg per min IV Bolus: 5-20 mcg/kg
Vasopressin (Pitressin)	0.3-2 mU/kg per min IV Note: Dosage is different for treatment of patients with diabetes insipidus

From Nakagawa TA: Updated pediatric donor management and dosing guidelines. NATCO, Organization for Transplant Professionals, 2008. Available at www.natco1.org/prof_development/index.htm#guidelines; accessed September 2008.

required, presumably because of catecholamine receptor immaturity or deficiency (Kelly et al., 1984). At these higher dosages (15 mcg/kg per minute), no adverse effects on GFR or urine output are apparent (Outwater and Rockoff, 1984). Dopamine at α -agonist dosages has not been shown to influence outcomes

in liver, kidney, or heart in pediatric donors (Finfer et al., 1996). There is evidence that dopamine may reduce allograft rejection, not only through support of blood pressure but possibly also through more complex immunomodulatory effects that inhibit expression of adhesion molecules, which are required for leukocyte migration into the graft to produce acute rejection (Carlos et al., 1997; Schnuelle et al., 1999).

An infusion of an α -adrenoceptor vasoconstrictor, epinephrine or phenylephrine, may be useful to increase peripheral vascular tone, but they have the inherent risk of causing marked peripheral vasoconstriction and/or an increase in pulmonary artery pressure (PAP) or oxygen consumption. Jhanji and colleagues (2009) have shown norepinephrine to be protective of global oxygen consumption, without affecting the splanchnic circulation or producing significant deleterious renal effects. An infusion of vasopressin starting at 0.3 mU/kg per minute and titrated to the desired blood pressure, with a maximal infusion rate of 2 mU/kg per minute, may be efficacious in the setting of hypotension and low SVR, especially in combination with an inotropic infusion such as epinephrine. Vasopressin is not recommended as first-line therapy, as there are limited data available in children. Recent studies, however, suggest it is most efficacious when coupled with corticosteroids (Bücheler et al., 2009). Dobutamine (IV, at 2 to 20 mcg/kg per minute) should be used when cardiac output is decreased because of reduced myocardial contractility and pulmonary hypertension. ECG abnormalities are common during the brain-death process, manifested as marked ST-T wave abnormalities, ischemic changes, inverted T waves, widened QRS complexes, and prolonged QT interval. In addition, atrial and ventricular arrhythmias and varying degrees of conduction abnormalities may occur. These arrhythmias usually result from autonomic instability (catecholamine storm and loss of the vagal motor nucleus) compounded by oxygenation, acid-base, temperature, and electrolyte (e.g., low magnesium and potassium) disturbances or increased intracranial pressure (ICP) (Cushing's reflex) (Powner and Allison, 2006). The difficulty lies in differentiating these transient findings from those of catecholamine-induced myocardial injury or irreversible

ischemia, which can produce global myocardial dysfunction. Bradycardia is not a problem unless it contributes to hypotension. It may be treated with any inotropic agent or temporary transthoracic or venous pacing.

Eventually, the heart stops. Despite all therapeutic efforts, the arrhythmias encountered are usually resistant to therapy (Table 28-12). Bradyarrhythmias leading to asystole rather than ventricular fibrillation (as seen in adults) are the terminal cardiac rhythms in pediatric patients. The propensity for this particular dysrhythmia may be related to the immature autonomic nervous system and small muscle mass in the pediatric donor (Walsh and Krongrad, 1983). In the event of a sudden cardiac arrest during the procurement procedure, cardiopulmonary resuscitation should be started to facilitate organ perfusion, and liver, pancreas, intestines, and kidney procurement should proceed rapidly with cross-clamping of the aorta at the diaphragm and infusion of cold preservation solution into the distal aorta and portal vein.

Pulmonary Management

All potential organ donors require mechanical ventilation, usually for a period of several days. Progressive pulmonary dysfunction may result from pulmonary contusions resulting from trauma, aspiration pneumonitis, fat emboli, and pulmonary edema (cardiogenic and neurogenic). Any of these may result in hypoxia, placing all perfuseable organs at risk for ischemia. In addition, infectious complications, oxygen toxicity, barotrauma or volutrauma, pulmonary embolism, and atelectasis may contribute to an increase in the alveolar-arterial oxygen gradient. High-dosage methylprednisolone administration has been shown to significantly improve oxygenation and increase donor lung recovery (Follette et al., 1998). The beneficial effects of steroids probably result from attenuation of the effects of proinflammatory cytokines released as a consequence of brain death (Glasser et al., 2001). Interleukin (IL)-8 expression and neutrophil infiltration of the donor lungs may result in impairment of graft oxygenation, development of severe early graft dysfunction, and early recipient mortality (Fisher et al., 2001). As the total lung water increases

TABLE 28-12. Antiarrhythmic Agents and Correction of Metabolic Acidosis

Drug	Dosage	Route	Comments
Adenosine (Adenocard IV)	100 mcg/kg	Rapid IV push	Repeat dose: 200 mcg/kg Max. single dose: 12 mg
Amiodarone (Cordarone)	5 mg/kg infused over 5-60 min	IV	Repeat dose: 5 mg/kg Infusion: 5-15 mcg/kg per min Monitor for hypotension
Atropine	0.02 mg/kg	IV	Min. dose: 0.1 mg Max. dose: 0.5-1.0 mg
Lidocaine	1-2 mg/kg	IV	Infusion: 20-50 mcg/kg per min
Magnesium sulfate	30 mg/kg infused over 10 min	IV	Max. dose: 2.5 g Repeat dose: 10 mg/kg
Sodium bicarbonate	1 mEq/kg	IV	May increase plasma osmolarity. Hypernatremia can occur or be aggravated with repeated dosing.
Tromethamine (THAM)	Base deficit \times wt (kg) = mL of 0.3M solution of THAM	IV	Does not increase osmolarity or CO ₂ production. Hypoglycemia can occur. Contraindicated in renal failure; may increase coagulation time.

From Nakagawa TA: Updated pediatric donor management and dosing guidelines. NATCO, Organization for Transplant Professionals, 2008. Available at www.natcol.org/prof_development/index.htm#guidelines; accessed September 2008.

from a combination of pulmonary capillary leakage and disruption of the Starling forces in the lungs, pulmonary compliance decreases, with resultant impedance of alveolar gas exchange. Neurogenic pulmonary edema is best managed with positive end-expiratory pressure (PEEP), diuresis, and small volume fluid resuscitation. Lung-protective strategies include maintenance of an arterial saturation of 95% or a P_{aO_2} greater than 100 mm Hg, with the lowest possible F_{iO_2} setting preferably being no higher than 40%, and with P_{aO_2}/F_{iO_2} greater than 300. Limiting high distention pressures in the lung during volume-controlled modes of ventilation using tidal volumes of 6 to 8 mL/kg, low peak inspiratory pressure (28 to 30 cm H_2O), and avoiding PEEP in excess of 5 cm H_2O is desirable. P_{aCO_2} should be normalized to 35 to 45 mm Hg, and serum pH to 7.35 to 7.45. The maintenance of a mild to moderate alkalemia has been reported by some to reduce the likelihood of ventricular fibrillation (programmed ventilator sigh) (Becker et al., 1981). Pulmonary hygiene, bronchodilators, and lung-expansion techniques every hour or two may help in preventing atelectasis and improve the quality of donor lungs. Recruitment maneuvers for oxygenation impairment include periodic increases in PEEP (up to 15 cm H_2O) and sustained inflations (peak inspiratory pressure at 30 cm H_2O for 30 to 60 seconds).

Endocrine Management

Diabetes insipidus (DI) occurs in the vast majority of brain-dead donors. It is a direct result of hypothalamic-pituitary dysfunction, with a resultant deficiency of antidiuretic hormone from the posterior lobe of the pituitary. Typically, DI is clinically manifested by a massive urine output that bears no relationship to the intravascular fluid volume, with decreasing urine osmolarity (≤ 200 mOsm), rising serum osmolarity (≥ 300 mOsm), and normal sodium excretion. This massive hypotonic diuresis (urine output, >4 mL/kg per hour) then leads to hypovolemia and rising serum sodium (≥ 145 mmol/L), as well as loss of potassium, calcium, magnesium, and phosphate.

Once the diagnosis is confirmed, therapeutic intervention should consist of pharmacologic management to decrease urine output to 3 mL/kg per hour or less. Replacement of urine output with 0.2% one-fourth or 0.45% normal saline should be used in conjunction with desmopressin (intermittent IV DDAVP, 0.25 to 1 mcg every 6 hours) or vasopressin (0.5 to 0.7 mU/kg per minute IV to a maximum dosage of 2.4 U/hour) infusion to maintain serum sodium levels between 130 and 150 mEq/L. DDAVP is an analogue of arginine vasopressin, which is highly selective for the vasopressin V_2 receptor subtype found in the renal collecting duct, and without the vasopressor activity in humans that is mediated by V_1 receptors on vascular smooth muscle. DDAVP has a long half-life of 75 to 120 minutes, so an IV infusion may be discontinued 2 to 3 hours before organ recovery. Several mechanisms regulate the release of arginine vasopressin (AVP). Hypovolemia resulting from hemorrhage or any other cause results in a decrease in atrial pressure. Specialized stretch receptors in the atrial walls and large veins (cardiopulmonary baroreceptors) entering the atria decrease their firing rate when there is a fall in atrial pressure. Afferent nerve fibers from these receptors synapse in the nucleus tractus solitarius of the medulla, which sends fibers to the hypothalamus, a region of the brain that controls AVP release by the pituitary gland. Atrial receptor firing normally inhibits the release of AVP by the posterior pituitary. With hypovolemia or decreased AVP, the decreased firing of atrial stretch receptors leads to an increase

in AVP release. Hypothalamic osmoreceptors sense extracellular osmolarity and stimulate AVP release when osmolarity rises, as occurs with dehydration. Finally, angiotensin II receptors located in a region of the hypothalamus regulate AVP. Therapy should always be guided by serum electrolyte and osmolality measurements made every 2 to 4 hours. Several investigators have demonstrated prolonged hemodynamic stability in donors, with the addition of an infusion of AVP to existing pressor support. Donors without clinically apparent DI may demonstrate a baroreflex-mediated defect of vasopressin secretion and pressor hypersensitivity to exogenous hormones. In these patients, low-dosage vasopressin significantly increases blood pressure (Chen et al., 1999). Absence of AVP may be a predominant contributing factor to the eventual cardiac arrest in all brain-dead patients.

Vasopressin is a potent vasoconstrictor. Its hemodynamic effects are dosage dependent and include generalized systemic vasoconstriction; increased blood pressure; decreased cardiac output; diminished coronary, splanchnic, and renal blood flows; bradycardia; and arrhythmias. These effects may cause irreversible ischemia to donor organs. Therefore, it is desirable to avoid and discontinue its use at least 1 hour before surgery.

Endocrine and Metabolic Functions

Despite disruption of the hypothalamic-pituitary-adrenal axis, hormone production from the anterior lobe of the pituitary gland persists in most brain-dead patients. The prevalence of anterior pituitary dysfunction is estimated at 30% (Schneider et al., 2005), with evidence of at least one abnormal hormonal function in 53% (Dimopoulou et al., 2004). More recently, Nicolas-Robin and colleagues (2010) noted in 31 brain-dead donors older than 18 years that the incidence of adrenal insufficiency was 87% and that the administration of 50 mg of hydrocortisone enhanced cardiovascular stability and decreased the requirement for norepinephrine. The incidences of hormonal reduction are estimated as follows: adrenal, 15%; thyroid, 5% to 15%; growth hormone, 18%; gonadal, 25% to 80%; and vasopressin, 3% to 37%. Endocrine failure is associated with basilar skull fracture, hypothalamic edema, prolonged unresponsiveness, hyponatremia, and hypotension (Powner and Allison, 2006).

Rapid depletion of vasopressin, cortisol, insulin, thyroxine (T_4) and free triiodothyronine (T_3) occurs in experimental animal models of brain death (Novitzky et al., 1984, 2006), but endocrine dysfunction in humans is usually manifested solely as DI (Wijdicks, 2001). Novitzky and others (1987) claim that true hypothyroidism exists, as evidenced by a decrease in free T_3 . They have shown that hormonal replacement therapy (T_3 , cortisol, and insulin with glucose) improves cardiac output and reduces the need for pressor support. Brain death is also associated with global mitochondrial dysfunction with a change to anaerobic metabolism and lactic acidosis. It leads to depletion of myocardial high-energy phosphates and cellular dysfunction. Thus, many organ procurement groups administer thyroid hormones to hemodynamically "rescue" unstable donors who show evidence of anaerobic metabolism or profound hypotension refractory to volume resuscitation and therapy with multiple vasopressors. In a landmark paper published in 1995, Wheeldon and colleagues (1995) showed that by using invasive hemodynamic monitoring and a standard donation management protocol (steroids, insulin, vasopressin, and T_3), the Papworth Hospital Group in Cambridge, United Kingdom, was able to functionally resuscitate 92% of initially unacceptable donors into acceptable donors. Hormonal

replacement therapy (methylprednisolone, T_4) has been shown to decrease the need for inotropic support and improve metabolic stability in critically ill children with cessation of neurologic function and hemodynamic instability (Powner, 2001; Salim et al., 2001; Zuppa et al., 2004). Rosendale and colleagues (2003) compared non-hormone replacement with a three-hormone replacement protocol (methylprednisolone bolus and infusions of vasopressin and T_3 or T_4) in brain-dead donors, with 30-day mortality and early graft dysfunction used as measures of outcome. Multivariate results demonstrated a 46% reduced odds of death within 30 days and a 48% reduced odds of early graft dysfunction in the three-hormone replacement donor group.

An infusion of nitroglycerine or nitroprusside is occasionally recommended to prevent myocardial ischemia and the potential untoward renal effects of diminished renal perfusion with the use of vasopressin. Vasopressin supplementation (2 to 10 mcg/kg per minute continuous infusion) in a porcine model of brain-dead potential organ donors resulted in physiologic levels of the hormone, with normal plasma osmolality and serum sodium levels and decreased urine output, potassium needs, and fluid requirements, without effects on peripheral vascular resistance and without microscopic evidence of organ ischemia (Blaine et al., 1984).

North American Transplant Coordinators Organization (Nakagawa, 2008a) currently recommends that hormonal replacement therapy (T_4 or T_3 , steroids, insulin) be considered early in the course of pediatric donation management to improve donor heart function. Levothyroxine (Synthroid) is administered as a bolus dosage of 1 to 5 mcg/kg followed by an IV infusion of 0.8 to 1.4 mcg/kg per hour, with infants and smaller children requiring a larger bolus and infusion dosage. IV T_4 has the disadvantage of a slower and unpredictable onset of action. Alternatively, T_3 may be replaced as an infusion 0.05 to 0.2 mcg/kg per hour IV. Although T_3 may rescue the donor heart, it may have detrimental effects, including tachycardia, arrhythmia, metabolic acidosis, and profound hypotension. Methylprednisolone (Solu-Medrol), 20 to 30 mg/kg IV bolus, is administered and may be repeated in 8 to 12 hours. An IV insulin infusion (0.05 to 0.1 units/kg per hour) is titrated to control blood glucose levels to 60 to 150 mg/dL, with monitoring for hypoglycemia (Table 28-13).

Electrolyte disturbances are routine, most being iatrogenic, resulting from treatment of the original injury or in response to physiologic perturbations during the brain-death process. Hyponatremia is inevitable as a result of DI, and a variety of strategies are used to treat elevated ICP. The liver is exquisitely sensitive to hyponatremia (>155 mEq/L) with increased levels correlating with primary graft loss after transplantation (Figuera et al., 1996). Serum potassium, magnesium, calcium, and phosphate levels are often depleted and require prompt replacement therapy. Hyperglycemia may be caused by glucose intolerance (steroids) or administration of large amounts of a dextrose-containing solution for fluid resuscitation.

Hypothermia

Although hyperthermia is common in the early phase of the sympathetic storm, the donor rapidly becomes hypothermic as a result of vasodilation and the loss of thermal regulation by the CNS. The patient becomes poikilothermic, with the body temperature determined by the environmental temperature. Although a mild degree of hypothermia may be beneficial to organ protection and preservation, the undesirable consequences of hypothermia, which are clinically significant, include diuresis and hypovolemia, hyperglycemia, coagulopathy, arrhythmias, myocardial depression, pulmonary hypertension, and eventually cardiac arrest (Reuler, 1978). Hypothermia further complicates the process of certification of brain death by causing the pupils to appear fixed and dilated. Active rewarming measures to maintain a core body temperature 36° to 38° C should be initiated early.

Organ Preservation

The field of organ preservation includes *in situ* core cooling, organ preservation fluids, and machine perfusion techniques. Traditionally, optimal organ preservation has been achieved by the combination of maximizing donor hemodynamics, using improved surgical procurement techniques with minimal dissection of vascular structures, cannulating the abdominal aorta

TABLE 28-13. Pharmacologic Agents for Hormonal Resuscitation

Drug	Dosage	Route	Comments
Desmopressin (DDAVP)	0.5 mcg per hr	IV	Half-life, 75-120 min Titrate to decrease urine output to 3-4 mL/kg per hr May be beneficial in patients with an ongoing coagulopathy
Vasopressin (Pitressin)	0.5-1 mU/kg per hr	IV	Half-life, 10-35 min Titrate to decrease urine output to 3-4 mL/kg per hr Hypertension can occur
Levothyroxine (Synthroid)	0.8-1.4 mcg/kg per hr	IV	Bolus dose of 1-5 mcg/kg can be administered. Infants and smaller children require a larger bolus and infusion dosage.
Triiodothyronine (T_3)	0.05-0.2 mcg/kg per hr	IV	—
Methylprednisolone (Solu-Medrol)	20-30 mg/kg	IV	Dose may be repeated in 8-12 hours Fluid retention Glucose intolerance
Insulin	0.05-0.1 U/kg per hr	IV	Titrate to control blood glucose levels to 60-150 mg/dL Monitor for hypoglycemia

for rapid in situ core cooling, removing abdominal organs en bloc with separation of graft components on the back table, employing cold storage techniques with a hyperkalemic hyperosmolar solution at a temperature of 4° C, and treating the donor or recipient (or both) pharmacologically. Most centers use static cold storage to preserve organs, and this is useful for younger donors with good-quality organs (Southard and Belzer, 1995; Marshall, 1997). With the introduction of extended donor criteria, the limitations of cold storage have probably been reached. Kidneys can be preserved for up to 72 hours but seldom do well in the recipient after 36 to 48 hours with cold ischemia. The heart and lungs should be transplanted within 4 to 6 hours, and the pancreas preferably within 6 to 12 hours.

The preservation solution introduced by the University of Wisconsin (UW solution) in 1987 allowed extension of the safe preservation time of the donor livers from 8 to 24 hours (Jamieson et al., 1988) and kidneys for up to 72 hours. Iced storage and core cooling result in a slowing of cellular metabolism and energy consumption; glucose or hydrogen ion buffers prevent cellular acidosis; donor heparinization (30,000 U, or 300 U/kg) prevents microvascular thrombosis and promotes a more even organ flushing and reperfusion. Effective impermeants are saccharides and nonsaccharide anions. Molecular weight determines the effectiveness of saccharides to prevent cell swelling, with larger saccharides being more effective (Sumimoto et al., 1990; Hart et al., 2002). The UW solution, histidine-tryptophan-ketoglutarate (HTK), and Celsior are the primary solutions used currently for organ preservation (Table 28-14).

HTK, originally introduced for cardioplegia in 1980, has gained popularity in clinical transplantation for cold perfusion and organ storage since the U.S. Food and Drug Administration (FDA) approved its use for kidney and liver preservation (Lam et al., 1989). Early experiences with HTK have demonstrated that it compares favorably with the UW solution in kidney and liver organ preservation. Growing clinical experience with living donor liver transplantation has shown comparable clinical performances of UW solution and HTK (Lange et al., 1997; Testa et al., 2003). UW solution and HTK also show clinical equivalence for deceased donor liver transplants, although UW solution remains the gold standard for longer preservation times (Guarrera and Karim, 2008).

The non-heart-beating (DCD) kidney perfusion protocols of Hoffman and D'Alessandro (Wisconsin), Koostra (Maastricht, The Netherlands), and Gage and Light (Washington, DC) have increased the donor pool of organs. The expansion of organ perfusion from kidneys to other solid organs became a reality in 2004, when Guarrera, Arrington, and Kinkhabwala became the world's first team to successfully transplant a machine-perfused liver into a human.

In the early 1970s, hypothermic machine perfusion (HMP) was used by many centers in the United States and Europe to preserve kidneys, allowing transportation to distant transplantation centers. Although modern HMP systems are smaller, lighter, and more sophisticated than the original machine used by Belzer and coworkers, the principles of HMP have not changed. Machine perfusion generates a controlled continuous or pulsatile recirculating flow of preservation solution at 0° to 4° C. This continuous flow allows complete perfusion of the organ, promoting a thorough washout of blood and subsequent tissue equilibration with the preservation solution. Beneficial effects of machine perfusion are a low incidence of delayed graft function, the possibility of real-time organ viability assessment, the ability to provide metabolic support during perfusion, and the potential to add pharmacologic

agents to the perfusate. A meta-analysis reported by Wight and coworkers noted that HMP produced a 20% reduction in delayed graft function compared with cold storage (Guarrera and Karim, 2008). Most experience with HMP involves the kidneys (Henry, 1997), and clinical application of HMP in human liver transplantation has been limited to the recent pioneering work of Guarrera and colleagues (2004).

LIVING RELATED ORGAN DONOR

Over the past several years, a consistently widening gap has become evident between the demand for and supply of transplantable organs. At the end of 2009, there were 1907 pediatric

transplant candidates on the waiting lists for various organs, out of a total of 113,702 candidates of all ages awaiting all organs. Of the pediatric candidates, approximately 50% were from 11 to 17 years old. This reflects a decline in the past 10 years and a decrease in the size of the liver and lung waiting lists, with the majority of children wait-listed for liver and kidney organs. The number of pediatric deceased donors over the past decade has steadily decreased (OPTN/UNOS, January 1988 to June 2010). Compared with adult deceased donors, pediatric deceased donors are more likely to donate a specific organ, as evident in data reported up to 2010: kidneys (92%), livers (87%), lungs (16%), heart (50%), pancreas (40%), and intestine (9%) (OPTN/UNOS, December 2009). With this serious shortage of donor organs of appropriate size and suitability for infants and small children, the waiting times for some organs has increased dramatically. For example, with only 20% of lungs from deceased donors meeting stringent donor criteria, the waiting period varies from 42% of pediatric patients waiting less than 1 year, to 15% listed for 5 or more years. This chronic shortage has prompted the development of programs for living related organ donation. The original concept was developed for renal transplantation in the early 1950s, and, currently in the United States, 25.2% of pediatric transplants are from living donors (OPTN/UNOS, 2009) (Table 28-15). Justification was relatively easy, as healthy relatives could “safely” donate one of their two kidneys without jeopardizing renal function in their remaining solitary kidney, and the results from living related pediatric renal transplantation have, until recently, been superior to deceased donor transplantation, at all ages. Later, techniques were developed to use one or more left-lateral segments of a parent’s liver, which would be suitable for a small child with chronic liver disease (Broelsch et al., 1991; Lang et al., 2004). Lessons learned from split or reduced-size deceased adult livers for implantation into children were used in the development of living related liver transplantation programs, which can accommodate large children and small adults

using the right lobe of the liver. From 1987 to 2009 in the United States, 1264 of the total 3967 pediatric liver transplants were from living donors (see Table 28-15). With similar methods, living donor transplantation has been successfully developed for pancreas, lung (unilateral and bilateral lower lobes), and small bowel transplantation.

Living-related organ donation has, for the most part, been performed from parent to child. The use of children for living kidney donation remains highly controversial, and in general, most transplant programs do not use a donor younger than 18 years except in very limited circumstances, such as identical twins or an emancipated minor for his or her own child (Abecassis et al., 2000). Living-related donor procedures have several advantages, including the fact that they can be electively scheduled when the recipient is in optimal condition. However, with the exception of living related renal transplantation (which has excellent outcomes, with 1-year graft survival in children older than 1 year ranging from 94% to 96%), the long-term functional outcome of living-donor lung, pancreas, and small intestine transplants remains to be established because of the relatively small number of transplants performed. Currently, the risk for mortality and graft loss is *less* for children younger than 2 years if they receive a liver allograft from a living donor compared with a deceased donor (Reding et al., 2003). In addition, many troubling ethical issues arise, such as the risk to the donor and recipient, the validity of informed consent, and concerns about donor privacy and confidentiality. Uncomplicated unilateral nephrectomy has an exceedingly low mortality (less than 0.1%), but the same is *not* true for right lobe liver donors (0.2% to 1%, or 4 to 10 of 2000 cases), left segment/lobe liver donors (0.06% to 0.2%, or 2 to 6 of 3300), and right lobectomy of the lung, less than 5% mortality (Hayashi and Trotter, 2002; Trotter et al., 2002). Additionally, Hashikura and colleagues (2009) reported an 8.4% complication rate in 299 donors undergoing living related liver donation. Postoperative donor

From the United Network for Organ Sharing (UNOS) and Organ Procurement and Transplantation Network (OPTN) data, 2010 (<http://optn.transplant.hrsa.gov/data>). ADT, All donor types; DCD, deceased donor; LD, living donor; Tx, transplant; 1° Tx, primary transplant.

complications included biliary complications (3.0%), reoperation (1.3%), severe aftereffects in two cases (0.06%), and death (apparently related to donor surgery) in one donor (0.03%). The incidences of postoperative complications in left- and right-lobe donors were 8.7% and 9.4%, respectively.

In addition, there have been increasing interest and use of DCD, with the hope of expanding this pool from 200 to 1000 donors per year in the United States. Although pediatric donors constitute approximately 20% of the total DCD donor pool, very few of the kidneys recovered are allocated to pediatric recipients (OPTN/UNOS, 2009). This practice may reflect concerns about long-term graft function, given the limited outcomes data available.

IMMUNOSUPPRESSION

Since the early 1980s, organ transplantation has emerged from an experimental therapy to a highly successful treatment for end-organ failure of multiple causes. The single most important factor in this progression has been the development of effective immunosuppressive regimens. The following discussion focuses on the immunosuppressive agents used, complications, and the emergence of newer agents.

History

The idea of organ transplantation is a century old, and only with the development of immunosuppressive agents has the viability of this field reached its zenith today. Before 1981, patient survival was poor because of inadequate immunosuppressive regimens. Corticosteroids and azathioprine were the mainstays of therapy, with graft survival in the range of only 30% to 50%. The introduction of the calcineurin inhibitors cyclosporine (in 1981) and then tacrolimus revolutionized the field of solid organ transplantation, with 1-year graft and patient survival rates as high as 90%, and greater for some organ systems. The main goal of any effective immunosuppression regimen is the prevention of organ rejection with minimal side effects and complications. Various immunosuppressive agents are used for induction (primary) therapy, maintenance therapy, and treatment of rejection after organ transplantation, but, regardless of the organ system, the applied principles are almost identical. The major agents used by most transplant centers worldwide are the calcineurin inhibitors cyclosporine and tacrolimus. Although steroids were always part of the induction therapy, they are now commonly eliminated.

Immunosuppression Medications

Corticosteroids

Corticosteroids were the initial mainstay of therapy for organ transplantation, but their use is on the decline. They are particularly effective in both the prevention and treatment of acute rejection episodes. Their predominant mechanisms of action include the inhibition of IL-1 and IL-2 production, suppression of helper and suppressor T cells, suppression of cytotoxic T cells, and reduction in the migration and activity of neutrophils (Cohen, 2002). The long-term use of corticosteroids has been

questioned because of their adverse side effects, particularly in the pediatric population. The trend during the past decade and a half is to use fewer steroids for maintenance therapy (Margarit et al., 1989; Ascher, 1995). Many centers do not now use steroids as part of their long-term regimens. The first report of steroid withdrawal after transplantation was published in 1989 (Margarit et al., 1989). Everson and associates (1999) published a literature review, which demonstrated that greater than 50% to 85% of patients can be withdrawn from steroids without changes in acute rejection episodes, patient survival, or graft survival rates (Stegall et al., 1997). This percentile difference depends on the antirejection agent used for maintenance therapy (e.g., tacrolimus versus cyclosporine or serolimus). Steroid withdrawal is preferable, as it is associated with significantly less hypertension, hypercholesterolemia, and diabetes mellitus, and, moreover, it is less likely to result in cushingoid features and delayed development and obesity in the pediatric patient. Despite controversy over their use in maintenance therapy, corticosteroids remain the first-line agents for the treatment of acute rejection. The response rates vary depending on the organ system and whether the patient is maintained on cyclosporine or tacrolimus (U.S. Multicenter FK506 Liver Study Group, 1994).

Azathioprine

Azathioprine, the imidazole derivative of 6-mercaptopurine, was introduced in the late 1950s and early 1960s. Its mechanism of action is the inhibition of differentiation and proliferation of T and B lymphocytes by blocking DNA and RNA synthesis. The effect is a reduction in the numbers of circulating white cells, both lymphocytes and granulocytes. One notable advantage of this agent is its steroid-sparing effect, allowing lower dosages of steroids to be used with equal efficacy and fewer side effects. The use of this agent is limited, however, by side effects, particularly hematologic and gastrointestinal (GI). Its use may result in as many as 50% of patients exhibiting bone marrow suppression and a profound leukopenia or thrombocytopenia (Cattral et al., 2000). Gastrointestinal side effects include pancreatitis, nausea, vomiting, and hepatotoxicity. Patients are at increased risk for opportunistic infections. An increased risk for malignancy, especially lymphoma, however, remains controversial. The primary pathway of metabolism is inactivation by xanthine oxidase, an enzyme blocked by allopurinol. The recommended dosage of azathioprine is 1 to 2 mg/kg per day. Plasma levels are not monitored for this agent.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) (CellCept) is a morpholinoethyl ester of mycophenolate. It is well absorbed orally and hydrolyzed to its active form, mycophenolic acid, which acts by competitively inhibiting inosine monophosphate dehydrogenase and hence blocks de novo synthesis of purines, primarily guanine. Lymphocytes, unlike other rapidly replicating cells, depend entirely on this pathway for purine synthesis. Hence, the primary mechanism of action of MMF is the selective inhibition of lymphocyte proliferation. This drug is one of the newer agents introduced in the past 10 years and has been shown to be more efficacious than azathioprine in combination therapy (Fisher et al., 1998). There is also some experimental evidence to suggest that MMF may reduce the risk for chronic allograft rejection, which has been attributed to its antiproliferative

activity against B lymphocytes and arterial smooth-muscle cells (Azuma et al., 1995; Schmid et al., 1995). The most common side effects are GI, including nausea, abdominal pain, anorexia, gastritis, and diarrhea. Diarrhea affects as many as 30% of patients but usually responds to a decrease in dosage. MMF also causes leukopenia and thus should be avoided in combination with azathioprine. The usual dosage is 1 to 3 g/day orally in two divided doses. Like azathioprine, blood levels are not monitored with this agent. The antivirals acyclovir and ganciclovir increase MMF levels, and antacid decrease the absorption of MMF (Cohen, 2002).

Calcineurin Inhibitors

Calcineurin inhibitors are the primary immunosuppressives agents that have been developed to date; they include tacrolimus and cyclosporine and are effective by their interaction with calcineurin. The most important cytokine in the immunology of transplantation rejection appears to be IL-2. It is produced through a sequence of events, which commence when a recipient antigen-processing cell comes into contact with the donor cells' major histocompatibility (MHC) antigens. The donor MHC fragment is processed and placed on the antigen-processing cell surface. When an appropriate recipient T cell is encountered, the T-cell receptor and the donor MHC bind. This initiates a cascade of intracellular enzymatic reactions via phosphorylation, and calcium stores are released, which then combine with calmodulin. This calcium-calmodulin complex then activates calcineurin. Calcineurin appears to be directly involved in the pathway that induces the production of the IL-2 molecule. Cyclosporine and tacrolimus act primarily by binding calcineurin via the cyclosporine-cyclophilin complex or the tacrolimus-FK binding protein complex, respectively. Binding of calcineurin by either of these complexes inhibits its enzymatic action, preventing the dephosphorylation of nuclear factor of activated T cells. This nuclear factor of activated T cells must be dephosphorylated to enter the nucleus, where it is required for IL-2 gene transcription.

Cyclosporine

Cyclosporine is a neutral lipophilic cyclic endecapeptide extracted from the fungus *Tolypocladium inflatum* in the early 1970s. Cyclosporine is poorly absorbed from the GI tract, and there is considerable variation in its bioavailability, as biliary output is essential for its absorption. Neoral (Novartis Pharmaceutical Corp., East Hanover, NJ), the microemulsion formula of cyclosporine, is much less dependent on bile production and flow than Sandimmune (Novartis Pharmaceuticals Corp.), the standard preparation. Neoral gives a more consistent level of cyclosporine and is associated with less evidence of rejection (Graziadei et al., 1997; Pinson et al., 1998), so it has replaced Sandimmune in most major transplant centers worldwide.

Cyclosporine is metabolized by the cytochrome P450 3A system (Cantarovich et al., 1998). Agents that induce these enzymes increase the metabolism of cyclosporine, resulting in lower blood levels, whereas agents that inhibit P450 activity result in higher circulating cyclosporine levels. In addition, cyclosporine can interfere with the metabolism of other medications. Digoxin, lovastatin, and prednisolone can have significantly decreased clearance with resultant toxicity.

The side effects associated with cyclosporine are numerous. Nephrotoxicity is one of the most significant, and it may involve acute or chronic renal pathologic alterations. The acute nephrotoxicity, which often resolves on reducing or discontinuing the medication, probably results from afferent arteriolar vasoconstriction with resulting decreased GFR. The chronic nephrotoxicity, which does not appear to be reversible, is associated with arteriolar hyalinosis, tubular vacuolization, interstitial nephritis, and cortical atrophy. Neurotoxicity is another common side effect, seen in as many as 50% of patients. This can range from headaches and tremors to seizures and coma. Because of variations in absorption and metabolism, cyclosporine levels tend to fluctuate. Dosages should be determined on the basis of the formulation used (i.e., Neoral versus Sandimmune) and serum or blood levels. Techniques to measure cyclosporine levels include radioimmunoassay and high-pressure liquid chromatography. The levels can be measured in whole blood, serum, or plasma. Most centers use whole blood trough levels by the radioimmunoassay technique. A level of 100 to 200 ng/mL is generally desirable in the first 3 to 6 months after transplantation, depending on the organ transplanted. The level can usually be maintained at lower levels thereafter, depending on the organ transplanted.

Tacrolimus

The calcineurin inhibitor tacrolimus, initially researched and brought to the market under the name FK-506, is a novel immunosuppressant that was isolated from *Streptomyces tsukubaensis* in 1985 (Kino et al., 1987; Starzl et al., 1989). Tacrolimus (FK506, Prograf) shares many similarities with cyclosporine, including its basic mechanism of action and metabolism by cytochrome P450 3A, in addition to its side-effect profiles. However, significant differences between these drugs have been elucidated in the past decade. Tacrolimus is 10 to 100 times more potent than cyclosporine, it possesses hepatotrophic properties, and it does not rely on bile for its absorption. Renal impairment, neurotoxicity, and hypertension occur with similar frequencies in both cyclosporine- and tacrolimus-based regimens. Tacrolimus is associated with more hyperglycemia. Reportedly, as many as 20% of tacrolimus recipients become insulin-dependent diabetics because of the agent's direct effect on pancreatic beta cells and peripheral insulin receptors. Tacrolimus appears to have a higher incidence of posttransplant lymphoproliferative disease. Considering that accelerated atherosclerosis is an important issue after solid organ transplantation, it is important to note that tacrolimus produces less hyperlipidemia and thus a less adverse cardiovascular risk profile than cyclosporine. Statistically significant improvements have been seen in total cholesterol, low-density lipoprotein cholesterol, and triglyceride levels when patients were switched from cyclosporine to tacrolimus (Manzarbeitia et al., 2001). Tacrolimus levels are usually measured in whole blood specimens by enzyme immunoassay techniques. Drug levels of 5 to 15 ng/mL are desirable in the first few months after transplantation, depending on the organ system transplanted.

Efficacy of Cyclosporine and Tacrolimus

After its introduction, cyclosporine became the drug of choice for the prevention of allograft rejection. Tacrolimus, initially reserved for use as rescue therapy in refractory rejection, has

now become a first-line immunosuppressive agent in many centers worldwide. Large multicenter U.S. and European randomized clinical trials have been performed to compare tacrolimus and cyclosporine (Sandimmune) for primary and maintenance immunosuppression (European FK506 Multicenter Liver Study Group, 1994; U.S. Multicenter FK506 Liver Study Group, 1994; Wiesner, 1998). In the European trial, patient and graft survival rates were similar; however, significantly lower rates of acute rejection were seen in the tacrolimus group in some organ systems. More episodes of acute and steroid-resistant rejection were seen in the cyclosporine group. The tacrolimus group had a lower cumulative steroid exposure and fewer requirements for monoclonal antibody therapy (European FK506 Multicenter Liver Study Group). Patients on tacrolimus, however, had significantly more medication-related adverse effects. At the 5-year follow-up, tacrolimus showed less rejection but no overall improvement in patient or graft survival for all solid organ transplants. Many of these large trials used Sandimmune as the cyclosporine preparation, hence confounding some of the data to date. Neoral has been shown to be superior to Sandimmune (Freeman et al., 1995; Mirza et al., 1997). Tacrolimus appears to be superior to cyclosporine for the treatment of periodic rejection. These episodes of acute rejection, even steroid-resistant events, may resolve when patients are switched from cyclosporine- to tacrolimus-based therapy (Jonas et al., 1996; Millis et al., 1996a, 1996b, 1998; Doria et al., 2003; Mazariegos, 2010). Additionally, chronic rejection was responsive in more than half of patients converted from cyclosporine to tacrolimus for some solid organ transplants (Klintmalm et al., 1993). Hence, the choice of calcineurin inhibitor tends to be a matter of institutional preference. Many institutions are now using tacrolimus-based therapy, citing less rejection, less steroid use, reduced metabolic derangements (including reduced rates of hyperlipidemia), diminished neurologic complications, and less OKT3 needed for immunosuppression. However, many centers still advocate the use of cyclosporine (usually Neoral) based on equivalent patient or graft survival rates and a lower incidence of diabetes mellitus and posttransplant lymphoproliferative disease.

Rapamycin

Rapamycin (Sirolimus) is a macrolide antibiotic isolated from the fungus *Streptomyces hygroscopicus*. It effectively inhibits both B- and T-cell activity (Poon et al., 1996; Poston et al., 1999). Rapamycin is structurally similar to tacrolimus. It uses the same intracellular binding protein as tacrolimus but blocks B- and T-cell activation at a later stage than the calcineurin inhibitors. Rapamycin and cyclosporine appear to act synergistically to inhibit lymphocyte proliferation (Kimball et al., 1991). The oral bioavailability of rapamycin is variable. Like the calcineurin inhibitors, it is metabolized by the cytochrome P450 3A system. The efficacy of rapamycin in solid organ transplantation was initially shown in the renal transplant population (Groth et al., 1999; Kahan et al., 1999; McAlister et al., 2000). Small studies in liver transplant patients have shown rapamycin to be an effective agent when combined with a calcineurin inhibitor (Watson et al., 1999; Trotter et al., 2001). Most of these patients could be maintained on steroid-free regimens. Acute rejection episodes were significantly decreased compared with historical controls (30% versus 70%) (Kahan for the Rapamune U.S. Study Group 2000). A primary role of rapamycin is to facilitate a dosage reduction of calcineurin inhibitor in those patients with evidence of

tacrolimus or cyclosporine toxicity (Brattstrom et al., 1998; Groth et al., 1999). The most frequent dosage-related adverse effects include hyperlipidemia, leukopenia, thrombocytopenia, oral ulcerations, and joint pains. Both cholesterol and triglyceride levels can significantly increase and should be monitored while on therapy. Calcineurin inhibitor levels, especially those of cyclosporine, have been shown to significantly increase while on rapamycin therapy and should be closely monitored.

Antilymphocyte and Antithymocyte Globulins

Antilymphocyte globulin (ALG) and antithymocyte globulin (ATG) are produced by extracting immunoglobulins from animals (usually horse or rabbit) that have been immunized with human lymphocytes or thymocytes, respectively. The IV administration of these polyclonal antibodies causes rapid and profound depletion of peripheral lymphocytes. A major limitation of all polyclonal antilymphocyte preparations is batch-to-batch heterogeneity, which results in unpredictable side effects and more importantly, variable efficacy. ALG and ATG are not typically used as first-line agents for immunosuppression. They appear to delay the onset of the first episodes of organ rejection, but the overall rates of rejection are similar to those seen with calcineurin inhibitors (Neuhaus et al., 2000). The focus of this form of therapy is as the primary immunosuppression in patients unable to tolerate calcineurin inhibitors (i.e., because of significant pretransplant renal insufficiency) and in the treatment of steroid-resistant (and possibly OKT3-resistant) rejection. Commonly observed side effects include allergic reactions, serum sickness, fever, and thrombocytopenia, as with OKT3 and other systemically infused immunoglobulins. Cytokine release syndrome (cardiovascular collapse with a hemodynamic profile similar to septic shock, noncardiogenic pulmonary edema, seizures, hyperpyrexia and renal insufficiency) may be seen with the administration of these agents, which is similar to that sometimes seen with OKT3 or any other immunoglobulin. The incidence of lymphoproliferative disease is also increased among patients who have received ALG and ATG.

OKT3

OKT3 (Orthoclone OKT3, muromonab-CD3) is a monoclonal antibody directed against the CD3 complex of the cell membrane of lymphocytes (Fung et al., 1987); it is an antibody specifically directed at the T3 antigen of human T cells—the cells that directly attack the transplanted organ—and it is unlike the polyclonal antibody preparations. IV infusion results in tremendous lymphocyte depletion. Induction with OKT3 has not shown any significant benefit over the calcineurin inhibitors (McDiarmid et al., 1991). Because of its toxicity and the availability of less toxic agents, OKT3 is generally reserved for patients with severe steroid-resistant rejection (Portela et al., 1995; Wall and Adams, 1995). OKT3, ALG, and ATG provide 60% to 90% graft salvage rates for acute rejection in various organ system transplants. The side-effect profile of OKT3 is similar to that of ALG and ATG, including the cytokine release syndrome, infectious complications, and malignancy potential. This protein, like ALG and ATG, should be administered to a patient who is monitored. Lymphocyte and platelet counts must be closely monitored. CMV infection should be anticipated in all patients treated with OKT3 if they have not received CMV prophylaxis.

Interleukin-2 Receptor Antagonists

As discussed earlier, IL-2 is the most noteworthy cytokine known to be involved in the rejection of transplanted solid organs. Although calcineurin inhibitors decrease the amount of IL-2 produced, competitive inhibition by IL-2 receptor antagonists prevents the protein itself from binding to the active lymphocytes. Unlike ALG, ATG, and OKT3, which target the entire lymphocyte population, IL-2 receptor antagonists specifically target the actively dividing cells by binding to the IL-2 receptor's CD25 moiety, which is expressed only in active cells (Langrehr et al., 1998). The two available IL-2 receptor antagonists are basiliximab and daclizumab. Early studies indicated that these agents need to be combined with calcineurin inhibitors to be effective (Vincenti et al., 1998). These agents should probably be used for induction of immunosuppression (Eckhoff et al., 2000) in those patients at high risk for calcineurin inhibitor–related toxicity. Additionally, they appear to be well tolerated without significant adverse effects. Dosages and timing of administration of these agents vary, depending on the organ system to be transplanted. Moreover, it appears that IL-2 receptor antagonists are needed immediately at the time of the transplantation (immediately before or after reperfusion of the transplanted organ), with a second dose at approximately 4 days in the immediate immunosuppressive induction period.

Belatacept

Belatacept is a fusion protein composed of the Fe fragment of a human IgG1 immunoglobulin linked to the extracellular domain of CTLA-4, which is a molecule crucial for T-cell costimulation, selectively blocking the process of T-cell activation. It is intended to provide extended graft survival while limiting the toxicity generated by standard immune suppressing regimens, such as calcineurin inhibitors.

In a phase II multicenter study comparing the safety and efficacy of belatacept and cyclosporine A in 218 patients who had undergone renal transplantation with deceased- or living-donor kidneys, Vincenti and colleagues (2005) noted that at 6 months after transplantation, there were no significant differences in the incidence of clinically suspected, biopsy-proved acute rejection between the two treatment groups. In addition, investigators noted that renal function and chronic allograft nephropathy were significantly better in patients receiving belatacept, and the cardiovascular and metabolic endpoints of hypertension, hyperlipidemia, and posttransplantation diabetes were also better in patients receiving belatacept.

Alemtuzumab (Campath-1H)

The use of alemtuzumab (Campath-1H) in organ transplantation goes back to 1986, when Hale and colleagues (1986) in Europe reported on the preliminary results of a pilot study in renal, liver, and pancreas transplant recipients. Alemtuzumab is a humanized immunoglobulin IgG1 monoclonal antibody directed against CD52, a cell-surface glycoprotein expressed on circulating T and B cells and to a lesser extent on natural killer cells, monocytes, and macrophages. It has been suggested that after binding to its target, alemtuzumab causes cell death through complement-mediated cell lysis and antibody-mediated cellular cytotoxicity (Hale et al., 1986; Nuckel et al., 2005; Weaver and Kirk, 2007). Alemtuzumab was approved by the FDA for the

treatment of lymphoid malignancies in 1999. It has been used off-label in bone marrow transplantation to prevent graft-versus-host disease and to treat various autoimmune diseases such as rheumatoid arthritis, scleroderma, and multiple sclerosis. Because of its rapid and profound lymphocyte-depleting effects, alemtuzumab was initially used off-label as induction therapy in renal transplantation to allow safe avoidance or minimization of steroid or calcineurin-inhibitor therapy. Retrospective analysis of the OPTN/UNOS database revealed that alemtuzumab induction was associated with a lower rate of acute rejection during the first 6 months after transplantation compared with no induction. Other studies have shown that antibody preconditioning with alemtuzumab without maintenance immunosuppression failed to achieve tolerance in clinical transplantation. Campath-1H also has an associated cytokine-release syndrome, which reportedly has been prevented completely by coadministration of solumedrol (2 mg/kg), Benadryl (2 mg/kg), and other antiinflammatory agents. Most patients who are pretreated still become febrile with the induction dose of the medication. The treatment for this hyperpyrexia is discontinuation of the agent. The usual pediatric induction dose is 0.3 to 0.4 mg/kg infused over 8 hours. Opportunistic infections and malignancies are of grave concern with a potent lymphocyte-depleting agent such as this, but an excessive frequency has not been reported.

LIVER TRANSPLANTATION

The first successful pediatric liver transplantation was performed in 1967 (Starzl et al., 1968). Before 1980, with the use of the immunosuppressive agents azathioprine and prednisone, the 5-year survival rate in the pediatric patient after liver transplantation was 20% (Gordon and Bismuth, 1991; Gordon et al., 1991). After the introduction of cyclosporine in 1980, long-term survival after liver transplantation became a reality. For the first time, 5-year patient survival began to exceed that of the life expectancy related to the specific disease process. Graft survival has progressively improved since 1992, with, for example, a 1-year graft survival of 81% in the 6- to 10-year-old recipient, compared with 68% a decade ago (UNOS, 2009). Patient survival for this age group is estimated to be 90.5% at 1 year, 85.9% at 3 years, and 83.8% at 5 years. Patient survival in the first year after transplantation is similar for all age groups except children younger than 1 year, who have the highest annual death rate. For these infant recipients transplanted between 2003 and 2004, there was a marked decline in 1-year death rate, a trend also seen for children ages 1 to 5 years and those ages 11 to 17 years. Improvements in patient and graft survival rates have been attributed to new immunosuppressive regimens consisting of tacrolimus Campath, mycophenolate, and rapamycin, with diminished use of cyclosporine, azathioprine, and corticosteroids and improved access to the donor pool using reduced grafts, living donors, and a new UNOS pediatric end-stage liver disease (PELD) scoring system for estimating medical urgency.

The majority of pediatric liver transplantations are performed in children less than 5 years of age. In children, 28% of grafts have been transplanted in patients less than 1 year of age, 37% in patients 1 to 5 years of age, and 35% in children 6 to 17 years of age. From 1988 to 2010, a total of 11,958 pediatric liver transplantations have been performed in the United States, of which 1264 (approximately 10%) have been living related (UNOS, 2009) (see [Table 28-15](#)).

General Indications and Contraindications

The recognition of orthotopic liver transplantation (OLT) as a viable alternative for pediatric patients with liver failure has increased the number of potential recipients. The indications for OLT can be classified in general as follows:

- End-stage liver disease (ESLD) expected to progress to death
- Secondary disease confined to the liver
- Prevention of the complications of major metabolic disorders
- Nonprogressive liver disease in which mortality is greater than the risk of OLT
- Fulminant hepatic failure

Disease-specific indications for OLT are shown in [Box 28-2](#).

With improvements in surgical and medical expertise, the absolute and relative contraindications to pediatric OLT continue to evolve. There are very few absolute contraindications to OLT: the presence of any active, untreated bacterial, fungal, or viral infection at the time of transplantation; cancer outside the liver or those liver tumors not meeting cure criteria; actively replicating hepatitis B virus infection; acquired immune deficiency syndrome; or surgery that is technically not feasible. The relative contraindications are more variable and tend to be transplantation center-specific. Examples include a child with ESLD and advanced cardiopulmonary disease, epilepsy, or multisystem organ failure states; or human immunodeficiency virus (HIV)-positive serology.

Box 28-2 Disease-Specific Indications for Orthotopic Liver Transplantation

BILIARY ATRESIA

- Biliary hypoplasia
- Alagille's syndrome
- Extrahepatic

METABOLIC DISEASES

- Tyrosinemia
- Glycogen storage disease types I and II
- α_1 -Antitrypsin deficiency
- Wilson's disease
- Primary oxalosis/oxaluria
- Hemochromatosis/hemosiderosis
- Hyperlipidemia II, homozygous
- Cystic fibrosis
- Maple syrup urine disease
- Urea cycle defects

CHOLESTATIC AND NONCHOLESTATIC CIRRHOSIS

MALIGNANT NEOPLASMS AND BENIGN TUMORS

ACUTE HEPATIC NECROSIS

MISCELLANEOUS

- Budd-Chiari syndrome
- Liver disease induced by total parenteral nutrition or hyperalimentation
- Neonatal hepatitis
- Congenital hepatic fibrosis
- Familial cholestasis
- Trauma
- Graft-versus-host disease secondary to transplantation (other than liver)

Pathophysiology of End-Stage Liver Disease

ESLD is an irreversible process that results in diffuse fibrosis and cirrhosis with loss of functional hepatocytes. The clinical manifestations are independent of the etiology but are primarily related to the degree of liver dysfunction. This dysfunction is secondary to structural changes that the liver undergoes after it sustains any type of significant damage. Irrespective of the cause of the hepatic injury, cell necrosis is followed by an attempt at regeneration. If the damage is of a chronic nature, this regeneration leads ultimately to fibrosis, further necrosis, and micronodular or macronodular cirrhosis (or both). Interestingly, the liver is the only solid organ in the body that can fully regenerate after sustaining up to 80% destruction of its functional capacity.

The two main mechanisms through which structural changes lead to hepatic failure are cellular dysfunction and portal hypertension. In cellular dysfunction, liver cell mass decreases as hepatocytes become necrotic. As the liver attempts to regenerate, fibrosis develops, with the eventual disruption of the portal triads. The result is formation of intrahepatic shunts, sinusoidal thickening, and an overall increase in the resistance to blood flow. This constellation of abnormalities results in the development of portal hypertension and varices. Similarly, biliary drainage becomes abnormal, leading to the intracellular accumulation of by-products that are normally secreted (proteins, bile). Together, these changes lead to abnormal hepatocyte energy metabolism, defects in protein and lipid synthesis, and alterations in substrate clearance.

Portal hypertension develops as a result of the increased resistance to blood flow through the disrupted sinusoids. In addition to this increase in resistance, there is an increase in splanchnic arterial blood flow caused by the development of arteriovenous shunts and vasodilation as liver failure progresses. Worsening portal hypertension is manifested by ascites, splenomegaly, and portosystemic shunts (varices, hemorrhoids, telangiectasia). These portosystemic shunts lead to decreased clearance of previously metabolized substrates by the liver. Cellular function is further compromised as oxygen is shunted away, leading to a potentially dysoxic hepatocellular environment. Regardless of the cause of the underlying liver failure, the pathophysiologic derangements are manifested similarly in the cardiovascular, pulmonary, renal, neurologic, and hematologic systems.

Child-Pugh Classification

The Child-Pugh classification is a universal scoring system of the degree of liver failure in patients with cirrhosis. Traditionally, the Child-Pugh class (A, B, or C) has been used as a predictive index for operative mortality rate in adult patients undergoing portosystemic shunting procedures. The estimated 1- and 5-year survival rates are 95% and 75% for patients with Child-Pugh class B, and 85% and 50% for patients with Child-Pugh class C. After the onset of the first major medical complication (ascites, variceal bleeding, jaundice, or encephalopathy), survival rates for these patients are significantly reduced. Variables measured by this system include ascites, encephalopathy, serum albumin, bilirubin, and prothrombin time (PT). Points are then assigned to different degrees of each variable, and the total points are used to assign a grade in the Child-Pugh scoring system ([Table 28-16](#)). Although a liver

TABLE 28-16. Child-Pugh Scoring System* for Cirrhosis

Score (points)	Bilirubin (mg/dL)	Albumin (g/dL)	Prothrombin Time (sec > control)	Hepatic Encephalopathy	Ascites (grade)
1	<2	>3.5	<4	None	None
2	2 to 3	2.8 to 3.5	4 to 6	1 to 2	Mild
3	>3	<2.8	>6	3 to 4	Severe

*Child class A = 5 to 6 points, class B = 7 to 9 points, class C = 10 to 15 points.

biopsy is often helpful in assessing histologic activity and the amount of fibrosis in patients with chronic hepatitis, it is not essential for the determination of the Child-Pugh class. Until February 2002, the Child-Pugh score was used by transplantation centers to group patients into one of four medical urgency categories. Blood type, patient size, medical urgency and waiting time determined liver allocation.

Pediatric End-Stage Liver Disease Scale

The PELD numerical scale is currently used by UNOS for liver allocation for children less than 12 years old. (PELD replaced the previous status 2B and 3 for pediatric patients, but status 1 is not affected by PELD.) PELD is based on bilirubin, INR, albumin, growth failure, and age when the patient is listed for transplantation, and it is used to calculate a numerical value that is an accurate predictor of 3-month mortality, independent of the complications of portal hypertension and the etiology of the liver disease. The MELD (model for end-stage liver disease) scale is a similar numerical scale ranging from 6 (less ill) to 40

(gravely ill) that is used for patients 12 years old and older. The score indicates how urgently the patient needs a transplant in the next 3 months. The number is calculated from three routine laboratory test results: bilirubin, INR, and creatinine. The measures used are as follows:

- Bilirubin, which measures how effectively the liver excretes bile
- INR (prothrombin time), which measures the liver's ability to make blood clotting factors
- Albumin, which measures the liver's ability to maintain nutrition
- Growth failure
- Whether the child is less than 1 year old

Systemic Manifestations of End-Stage Liver Disease

ESLD is associated with unique systemic physiologic alterations (Box 28-3) (Robertson, 1998).

Box 28-3 Cardiovascular, Pulmonary, and Renal Complications of Advanced Cirrhosis

CARDIOVASCULAR

- "Hyperdynamic" circulation
 - Increased cardiac index and stroke volume
 - Decreased systemic vascular resistance
 - Low to normal mean arterial pressure (widened pulse pressure)
 - Increased heart rate
- Central hypovolemia
 - Increased circulating blood volume
 - Decreased effective plasma volume
 - Increased sympathetic tone
- Hyporesponsiveness of the vasculature to pressor therapy
- Flow-dependent oxygen consumption
- Hepatic and splanchnic vasculature
 - Portal hypertension
 - Portosystemic collateral circulation
 - Decreased hepatic blood flow
- Alcoholic cardiomyopathy (reduced left-ventricular ejection fraction)
- Cirrhotic cardiomyopathy (impaired cardiac contractility, defective excitation contraction coupling, impaired systolic and diastolic function, prolonged QTc interval, autonomic dysfunction, impaired β -adrenergic function and postreceptor defect, decreased responsiveness to catecholamines, conduction abnormalities)
- Arrhythmias

PULMONARY

- Arterial hypoxemia ($P_{aO_2} < 70$ mm Hg)
 - Hepatopulmonary syndrome
 - Portopulmonary hypertension
 - Impaired hypoxic pulmonary vasoconstriction
 - Increased pulmonary blood flow
 - V/Q Mismatch
- Parenchymal abnormalities
 - Restrictive ventilatory pattern resulting from ascites limiting diaphragmatic excursion, pleural effusions, or chest wall deformity caused by osteoporosis
 - Obstructive airway disease, emphysema, bronchitis/bronchiectasis
 - Interstitial lung disease (infection, pneumonitis, pulmonary edema)

RENAL

- Renin-angiotensin-aldosterone activation: impaired sodium handling, water excretion, potassium metabolism, and concentrating ability
- Impaired renal acidification
- Prerenal insufficiency (ascites or diuretics)
- Acute renal failure (acute liver failure, biliary obstruction, sepsis)
- Hepatorenal syndrome
- Glomerulopathies

Cardiovascular System

Progressive liver failure is characterized by a hyperdynamic circulation with a left ventricular (LV) ejection fraction of greater than 65%, fixed low total peripheral resistance, and a compensatory rise in cardiac output, impaired circulatory reserve, and diminished response to catecholamine infusions. High-risk patients have cardiomyopathy and dysrhythmias, congestive heart failure from fluid and electrolyte imbalances, and moderate to severe pulmonary hypertension.

Systemic vascular resistance is low because of peripheral vasodilation and shunting (cutaneous, splanchnic, intrapulmonary, portopulmonary, lumbrical, and pleural). This profound vasodilation may result from abnormal levels of vasodilator substances, possibly originating in the splanchnic circulation, which would otherwise be cleared by the liver, or from the lack of a substance produced by the liver. The most likely mediators include nitric oxide, tumor necrosis factor- α , and endothelium-derived relaxing factor. Activation of the renin-angiotensin-aldosterone system causes an increase in extracellular fluid volume through salt and water retention, and release of AVP results in a decrease in free-water excretion. Similarly, the sympathetic nervous system is activated in an attempt to cause peripheral vasoconstriction to maintain an adequate MAP. Mixed venous oxygen saturation (S_{vo_2}) measured in the pulmonary artery outflow tract is markedly elevated (usually $\geq 85\%$). The increase in S_{vo_2} presumably results from poor oxygen extraction capacity and correlates somewhat with cardiac index (Jugan et al., 1992; Steib et al., 1993). Yet there is no evidence of tissue dysoxia or increased serum lactate with the patient at rest.

Respiratory System

Cirrhotic patients are predisposed to arterial hypoxemia from intrapulmonary shunting because of capillary vasodilation, restrictive lung disease caused by ascites or pleural effusions, impaired hypoxic pulmonary vasoconstriction, increased pulmonary blood flow, and a rightward shift in the oxygen-dissociation curve resulting from decreased levels of 2, 3-diphosphoglycerate. Respiratory compromise may also result from the hepatopulmonary syndrome (HPS), portopulmonary hypertension, defects in alveolar oxygen diffusion, or pulmonary manifestations of systemic disease (e.g., cystic fibrosis, autoimmune disease, α_1 -antitrypsin deficiency). These defects are seemingly compensated for by an increase in S_{vo_2} and resting cardiac output (Schott et al., 1999; Teramoto et al., 2000). Arterial hypoxemia usually responds to supplemental oxygen and positive pressure ventilation suggestive of a V/Q mismatch. Depressed airway reflexes, delayed gastric emptying, hiatal hernia, and massive ascites increase the risk for aspiration. Pulmonary edema, atelectasis, and pneumonia are also common findings in patients with ESLD.

The frequency of HPS (chronic liver disease, increased alveolar-arterial gradient while breathing room air, and intrapulmonary vasodilation) is reported to be between 4% and 29% (Naeije, 2003; Mazzeo et al., 2004). Patients with liver disease may develop progressive and refractory hypoxemia when abnormal intrapulmonary vascular dilation causes anatomic shunting and diffusion-perfusion abnormalities (Hoepfer et al., 2004). The prognosis for patients with HPS is poor, and a mortality rate of 41% within 2 to 5 years has been reported (Krowka et al.,

1993). In contrast, up to 20% of cirrhotic patients are at risk of developing portopulmonary hypertension (portal hypertension and increased pulmonary vascular resistance). Severe pulmonary hypertension may cause acute right ventricular failure and sudden cardiac death (Scott et al., 1999). Preoperative therapy with epoprostenol and nitric oxide may improve outcome in this group if right ventricular function is preserved and treatment results in a decrease in pulmonary pressures and vascular remodeling.

Renal System

Renal dysfunction is common in patients with ESLD, and the kidneys are very susceptible to injury and prone to failure. Fluid and electrolyte imbalances are secondary to diuretic therapy, hypoalbuminemia, and portal hypertension causing generalized ascites, progressive edema, hypovolemia, dilutional hyponatremia, and hypokalemic metabolic alkalosis resulting from renin-aldosterone activation. Three main mechanisms, singularly or in combination, contribute to renal insufficiency: prerenal causes, acute tubular necrosis, and hepatorenal syndrome. Renal insufficiency not only complicates the management of liver failure but, more importantly, may increase patient mortality. Thus, it is important to evaluate and treat reversible causes of renal insufficiency (Box 28-4). Renal function is often difficult to assess in these patients because reduced muscle mass and hepatic synthesis of creatine reduces the serum creatinine level. Creatinine clearance will overestimate the GFR.

Prerenal azotemia is most commonly associated with aggressive use of diuretic therapy in the treatment of ascites. With a decreased effective arterial volume, patients are more susceptible to the volume depletion effects of diuretics and

Box 28-4 Strategy for Optimizing Renal Function and Preventing Hepatorenal Syndrome

INITIAL MANAGEMENT

- Homeostatic environment (electrolytes, acid-base status, hematocrit)
- Cardiovascular stability (euvolemia, mean arterial pressure > 60 mm Hg)
- Identify intrinsic renal parenchymal disease
- Treat bacterial infections and complications related to liver disease (i.e., ascites, dilutional hyponatremia, and variceal bleeding)
- Avoidance of nephrotoxic agents (e.g., nonsteroidal antiinflammatory drugs or aminoglycosides)

OPTIMIZE RENAL PERFUSION

- Intravascular volume expansion
- Drug therapy (splanchnic vasoconstriction or renal vasodilators): vasopressin analogues, α -adrenergic agonists, endothelin antagonists, antioxidants

STRATEGIES

- Transjugular intrahepatic portosystemic shunt
- Albumin and antibiotic therapy for spontaneous bacterial peritonitis

Adapted from Gines P, Guevara M, Arroyo V, Rodes J: Hepatorenal syndrome, *Lancet* 362:1819, 2003.

large volume paracentesis without adequate intravascular volume replacement. As with other types of prerenal azotemia, the urine sodium level is low (<10 mEq/L), with a fractional excretion of sodium (FENa) of less than 1%. This type of renal failure is amenable to careful volume replacement.

The kidneys in patients with liver failure are also at increased risk for developing acute tubular necrosis (ATN) as a result of decreased renal perfusion. This decreased perfusion is a consequence of a relative decrease in central blood volume caused by splanchnic pooling, which activates secretion of vasopressin, in combination with other compensatory mechanisms attempting to restore MAP, such as increased sympathetic tone and renin-angiotensin activity. Renal perfusion is further compromised because prostaglandin synthesis is reduced in advanced liver disease. Prostaglandins are potent renal arteriolar vasodilators (Govindarajan et al., 1987; Claria and Arroyo, 2003). Hence, tubular function is much closer to an ischemic threshold in patients with liver failure. This low ischemic threshold renders the kidneys more susceptible to nephrotoxic drugs such as IV contrast dye or aminoglycosides. Additionally, in the patient with tense ascites, renal cortical perfusion may also be diminished as a result of elevated intraabdominal pressure. Urine sodium in this setting is usually greater than 20 mEq/L, with a FENa of greater than 1% (Epstein, 1985). Treatment should be directed at minimizing additional renal injury, optimizing renal perfusion, and maintaining urine output, with some form of dialysis possibly introduced until the ATN resolves. This usually occurs within 10 to 14 days. It is not uncommon, however, for the hepatorenal syndrome to become superimposed once the patient develops ATN.

The most consequential form of renal dysfunction is the hepatorenal syndrome, and it has a very poor prognosis. It is characterized by a rapid deterioration in renal function associated with profound sodium retention and low urinary sodium excretion. It is usually precipitated by a major physiologic event, such as GI hemorrhage, sepsis, or surgery. It is differentiated from prerenal azotemia by the lack of responsiveness to volume expansion. The pathogenesis is severe renal vasoconstriction with absence of renal cortical blood flow. Interestingly, this vasoconstriction is reversible if the kidney is transplanted into a host with normal hepatic function (Koppel et al., 1969). This form of renal failure requires dialysis to sustain life, but it may be reversible with liver transplantation (Iwatsuki et al., 1973).

Hematologic Complications

Anemia, thrombocytopenia, and coagulopathy are the expected findings in the patient with liver failure. Anemia is usually a result of bone marrow suppression, vitamin deficiency, hemorrhage, and diminished erythropoietin production caused by renal insufficiency. Thrombocytopenia (platelet count < 100,000/mm³) is seen in 70% of patients with liver disease (Kang et al., 1985) and is primarily a result of diminished thrombopoietin production and portal hypertension with platelet sequestration in the spleen (Kaushansky, 1995; Martin et al., 1997). However, bone marrow suppression, abnormalities in platelet metabolism or autoimmune causes may also be contributing factors (Peck-Radosavljevic, 2000). Impaired platelet aggregation and clot retraction caused by qualitative platelet defects are also seen in patients with liver disease and renal failure.

The tissue factor pathway of coagulation is classically assessed by measuring PTT and PT. The liver is the main site

TABLE 28-17. Clotting Factors: Activity and Half-Life

Factor	Biological Half-Life	Vitamin K Dependent	Plasma Concentration
Fibrinogen	90 hr	No	300-400 mg/dL
Prothrombin	60 hr	Yes	10-15 mg/dL
Factor V	12-36 hr	No	0.5-1.0 mg/dL
Factor VII	4-6 hr	Yes	0.1 mg/dL
Factor VIII:C	12 hr	No	1-2 mg/dL
Factor IX	20 hr	Yes	4 mcg/mL
Factor X	24 hr	Yes	0.75 mg/dL
Factor XI	40 hr	No	1.2 mg/dL

of synthesis of all coagulation factors except von Willebrand's factor, which is produced primarily in the vascular endothelium. Failure of bile salt secretion results in poor absorption of vitamin K, which is a cofactor necessary for the post-transcriptional γ -carboxylation and activation of factors II, VII, IX, and X (Table 28-17). In cirrhotic patients, the levels of fibrinogen and factor VIII are usually supranormal, and the production of all other clotting factors is diminished. Additionally, approximately 80% of patients with liver failure produce an abnormal fibrinogen molecule (dysfibrinogenemia) (Martinez et al., 1978; Cunningham et al., 2002). Control of coagulation therefore depends on the balance of hepatic synthesis of clotting factors and the clearance of activated clotting factors, plasminogen activators, and fibrinolytic proteins.

Neurologic Complications

Hepatic encephalopathy is a frequent metabolic complication of acute or chronic liver disease. The neuropsychiatric abnormalities are often reversible, with the clinical presentation ranging from subtle personality changes to frank coma. Neuromuscular symptoms include tremor, hyperreflexia, and decerebrate posturing. The three theories regarding the pathogenesis of hepatic encephalopathy are (1) ammonia toxicity with accumulation of toxins in the brain, (2) an alteration in plasma amino acid composition with accumulation of false neurotransmitters, and (3) an increase in neuroinhibitory substances, such as manganese, monoamines, and endogenous opiates. Various studies have supported aspects of each hypothesis, yet none has been conclusively established. In patients who have died in hepatic coma, neuropathologic findings occur in the astrocytes rather than in the neurons. Positron emission tomography studies show

decreased glucose use in the cerebral cortex, which may explain some neuropsychiatric abnormalities (Butterworth, 1996).

Forty percent of ammonia is generated in the intestine from ingested nitrogenous substances, and it is subsequently metabolized in the liver into urea, which is excreted through the kidneys and into the colon. With liver failure and portosystemic shunting, ammonia, which is a known neurotoxin, accumulates and readily diffuses into the brain, where it exerts its neurotoxicity. Arguments against ammonia being the sole factor in the pathogenesis have been based on (1) the lack of a strong correlation between blood ammonia levels and the degree of hepatic encephalopathy, (2) the presence of this condition in the absence of elevated ammonia levels, and (3) the neuroexcitatory effects of low ammonia concentration. Other metabolic by-products, such as mercaptans and short-chain fatty acids, have also been implicated.

With progressive liver failure, the ratio of branched-chain amino acids to aromatic amino acids decreases. These aromatic amino acids cross the blood-brain barrier and may competitively inhibit normal neurotransmitters and favor the generation of false neurotransmitters (e.g., octopamine) that have an inhibitory effect on cerebral function.

Gamma-aminobutyric acid (GABA), a major inhibitory neurotransmitter in the CNS, regulates the chloride channel. It has been suggested that elevated ammonia levels enhance GABAergic neurotransmission and synergistically augment the action of benzodiazepine receptor agonists (Basile and Jones, 1997). This theory is supported by the fact that hepatic encephalopathy can at times be improved by the benzodiazepine receptor-antagonist flumazenil.

Among the multiple precipitating factors of hepatic encephalopathy are azotemia, drugs (sedatives, tranquilizers, analgesics), GI bleeding, excess dietary protein, metabolic alkalosis, infection, and constipation (Abou-Assi et al., 2001). Treatment consists of reducing dietary protein, avoiding sedatives, administering antibiotics such as neomycin or Bactrim, administering lactulose (which converts ammonia to nonabsorbable ammonium and modifies the colonic flora), correction of hypokalemia, discontinuation of diuretics, treating infection, and volume expansion.

Endocrine dysfunction is common in ESLD. Oversecretion of growth hormone and glucagon leads to peripheral and hepatic insulin resistance and impaired glucose metabolism, with lipids as a preferred energy substrate. Hypoglycemia is an ominous sign indicative of depletion of glycogen stores in the liver and survival is limited to days without IV glucose supplementation and transplantation. It is often seen with infections or sepsis.

Pathophysiology of a Few Uncommon Genetic Disorders

Although liver transplantation is performed for a myriad of metabolic disorders, a few conditions merit special mention because of their unique pathophysiology. Two important features are common among them. First, patients have no intrinsic hepatic dysfunction and thus have not developed the portosystemic collaterals that afford the visceral protection from mesenteric venous hypertension during portal vein clamping. These patients also do not have the compensatory increase in hepatic arterial flow seen in patients with parenchymal liver disease and portal hypertension. In addition, these patients are generally

not coagulopathic and it is often necessary to begin anticoagulant therapy after reperfusion so as to prevent thrombotic complications. The second feature is that patients with metabolic disorders cannot become catabolic. Dextrose-containing solutions and careful avoidance of stress are necessary for successful outcomes. Given the known risk for metabolic stroke and coma, allograft selection for these patients is imperative, and any possibility of primary nonfunction should be avoided with careful attention paid to cold and warm ischemic times.

Urea-Cycle Disorders

Urea-cycle disorders are one of the common inborn errors of metabolism that are clinically cured by liver transplantation (Morioka et al., 2005). As the urea cycle is the final pathway for the elimination of nitrogen. Enzymatic defects or errors in the pathway lead to the accumulation of nitrogen as ammonia, alanine, glutamate, and other intermediate metabolites. The urea cycle contains five enzyme systems, and the clinical manifestations depend on the enzyme that is deficient (Fig. 28-2). These enzyme deficiency syndromes are carbamoyl phosphate synthetase I deficiency, ornithine transcarbamylase deficiency (OTCD), argininosuccinate synthetase deficiency (citrullinemia), argininosuccinate lyase deficiency, and *N*-acetylglutamate synthetase deficiency. OTCD is the most common urea-cycle disorder, with a prevalence of 1 in 40,000 live births, and it is inherited as an X-linked, partially dominant chromosomal defect. Ornithine transcarbamylase is a mitochondrial enzyme that catalyzes the conversion of ornithine (the product of carbamoyl phosphate synthetase-catalyzed ammonia and bicarbonate) and carbamylphosphate to citrulline. OTCD thus results in the accumulation of ammonia, carbamylphosphate, and glutamate, with diminished production of citrulline, arginine, and urea. Because of the X-linked, partially dominant inheritance of OTCD, the phenotypical expression of OTCD is varied. In the severe form, which affects homozygous males, hypothermia, lethargy, and vomiting follow a 24- to 72-hour asymptomatic period. Symptoms are progressive and severe and are related to accumulation of glutamine and ammonia and secondary cerebral edema. In heterozygous females, the expression is more varied and can range from neonatal expression to clinically imperceptible disease. Accumulation of ammonia is exacerbated by protein breakdown at times of stress (surgery, sepsis, dehydration, anesthesia) or fasting, and also with the ingestion of high-protein foods or parenteral nutrition. Anesthesia management in these children focuses on avoidance of catabolic states through infusion of physiologic fluids containing at least 10% dextrose. Avoidance of emotional stress is imperative, with liberal use of perioperative benzodiazepines and analgesics. Hypothermia should be prevented with the use of warm room temperatures, irrigation, and warming blankets. Some centers also use continuous intraoperative IV infusions of sodium benzoate (300 to 500 mg/kg per day) for nitrogen binding. OTCD may also be independently associated with a hypercoagulable state, with documented thrombotic complications in four children (Venkateswaran, 2009).

Maple Syrup Urine Disease

Maple syrup urine disease (MSUD) is an inborn error of amino acid metabolism caused by the autosomal recessive-mediated deficiency in branched-chain α -ketoacid dehydrogenase (BCKD)

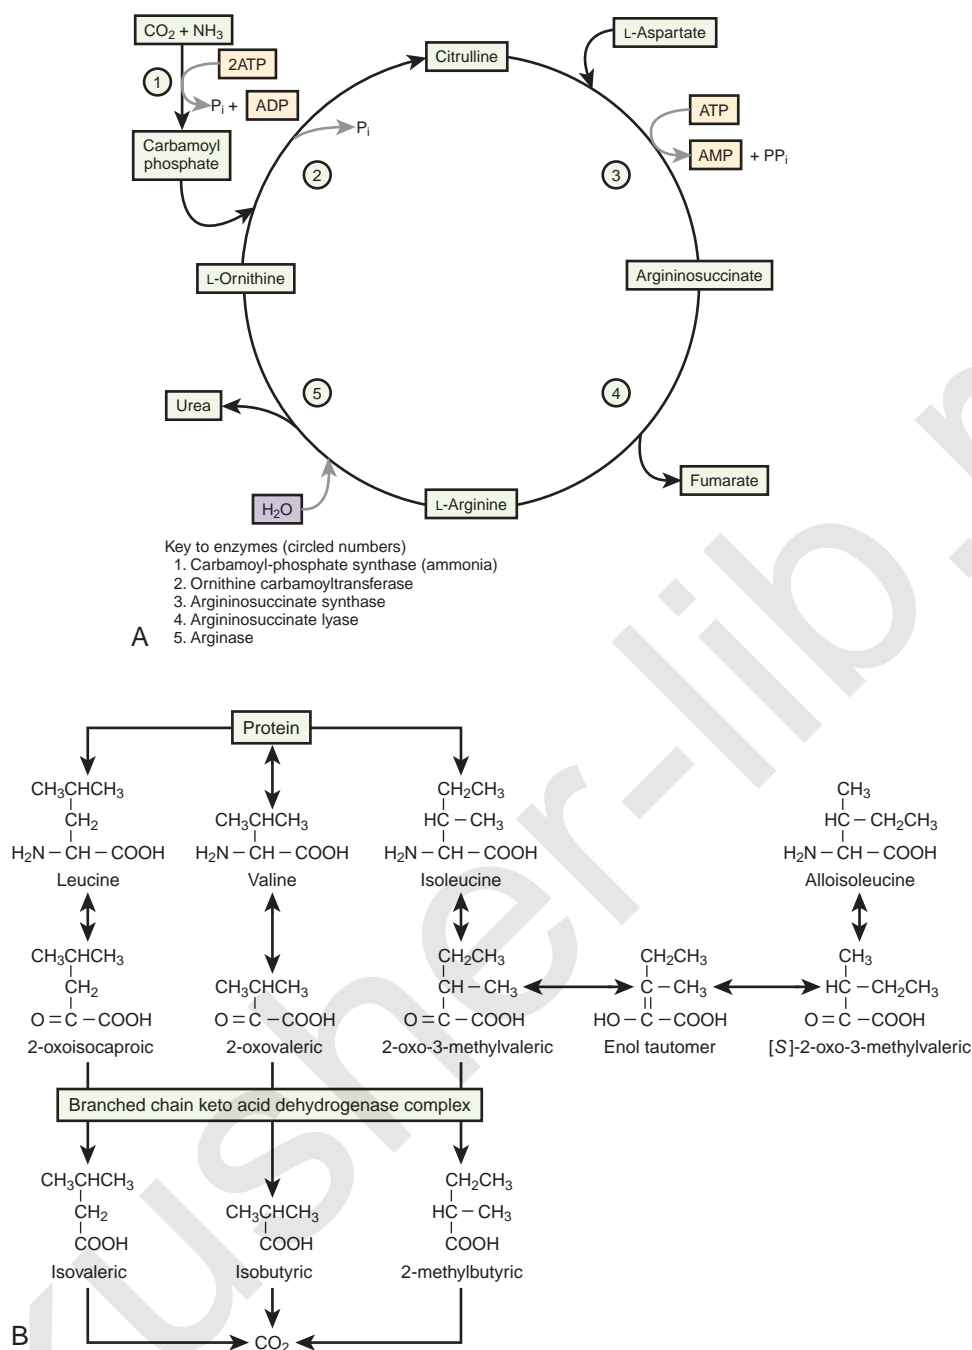

FIGURE 28-2. A, Urea cycle, showing the reactions by which excess nitrogen in the form of ammonia is converted to soluble urea, using L-ornithine as a recyclable carrier. **B**, Pathway of branched-chain amino acid (BCAA) catabolism. Note that the branched-chain organic acids are derived from the BCAAs by deamination, and the site of the defect in maple syrup urine disease (MSUD) is the dehydrogenase complex. The asymmetry of the β -carbon of isoleucine and the reversibility of the keto-enol interconversion give rise to alloisoleucine, which is virtually pathognomonic for MSUD. (From Khanna A, Hart M, Nyhan WL, et al: *Liver transplantation in maple syrup urine disease*, *Liver Transplant* 12:876, 2006.)

activity. BCKD is the second enzyme in the pathway used in the degradation of the branched-chain amino acids leucine, isoleucine, and valine (Morton et al., 2002) (see Fig. 28-2). The pathophysiology of MSUD is primarily explained by the accumulation of leucine in the plasma and in the organs. Similar to the urea-cycle disorders, severe metabolic decompensation is associated with catabolism of tissue proteins at times of starvation and stress. The disease usually manifests within

48 hours of birth with ketonuria, irritability, and dystonia that progresses to seizures and coma by the fourth day of life (Felber et al., 1993). Diagnosis is confirmed by testing for the presence of branched-chain 2-ketoacids in the urine and by quantification of branched-chain amino acids in the plasma. Children are treated with dietary restriction of branched-chain amino acids and avoidance of catabolic states. Despite strict dietary control, severe metabolic crises can still develop suddenly

during intercurrent illnesses and can be associated with life-threatening cerebral edema. In addition to facing the dangers of acute metabolic decompensation, patients with MSUD often suffer from neurocognitive disorders, probably from imbalances of branched-chain amino acids in the brain. Because of their protein-restricted diet, MSUD patients can also develop essential-amino-acid deficiencies, resulting in immunodeficiency, growth failure, and global developmental delays. Patients undergoing liver transplantation for MSUD are carefully selected, and successful outcomes depend on a multidisciplinary approach to their management in the perioperative period (Strauss, 2006). A careful neurologic examination should be documented before sedation to serve as a baseline, and a careful history of past metabolic crises and neurologic deficits should be obtained. Baseline levels of branched-chain amino acids should be recorded, and, if they are excessive, transplantation should be deferred and medical treatment initiated. Like patients with urea-cycle disorders, patients with MSUD cannot be fasted without catabolic consequence. In addition, specialized total parenteral nutrition (TPN) should be used that include concentrated dextrose infusions. MSUD patients should never receive hypotonic infusions, and plasma osmolality should be carefully monitored and kept in the normal range. Perioperative sedation and analgesia should be optimized to avoid catabolism, and physiologic stress should be kept to a minimum (Kahraman, 1996; Fuentes-Garcia, 2009). Leucine levels are generally followed after reperfusion of the liver and daily after the transplantation. Patients are immediately fed an unrestricted diet or are given enteral feedings with standard protein compositions.

Domino Liver Transplantation

Domino liver transplantation is a procedure in which an index patient (e.g., one with MSUD) with a genetic defect receives a hepatic allograft, and that index patient's liver is then carefully resected and removed, maintaining anatomic integrity, and it is then flushed and used as an allograft for a second patient (Khanna, 2006; Wilczek, 2008). The hepatectomy of the index donor must preserve adequate vascular and biliary cuffs for use in implantation into the second recipient. Because of the anatomy of the hepatic veins, this often requires the hepatectomy to be performed in the standard manner, which involves removal of the retrohepatic vena cava together with the hepatectomy specimen. As the index patients do not have portal hypertension or parenchymal liver disease, portal and caval clamping is not well tolerated and venovenous bypass (VVB) is often required in older patients to avoid significant mesenteric venous hypertension, associated visceral edema, and hemodynamic instability.

The index liver can then be transplanted into a patient with ESLD, who must not be a carrier of the genetic defect that results in MSUD. The liver removed from the patient with MSUD can function as a normal liver because the genetic defect, α -ketoacid dehydrogenase deficiency, is not present in any of the recipient's cells or organ systems. Hence, cellular metabolism and degradation of the branched-chain amino acids leucine, isoleucine, and valine occurs without consequence. Thus, in this case, the index liver is not disposed of but used in another recipient without that particular genetic defect, who can now live normally. Domino transplantation is initiated only when there is a donor organ offered for the MSUD index patient.

Alagille's Syndrome

Alagille's syndrome (AS) is an autosomal disorder characterized by bile duct paucity, cholestasis, and progression to cirrhosis, requiring transplantation in 30% of patients. The syndrome is also associated with characteristic facial features, ocular manifestations, vertebral anomalies, and pancreatic insufficiency. Renal disease is another important feature of this syndrome with structural and functional disorders in up to 50% of patients including renal artery stenosis, dysplastic or ectopic kidneys, and tubulointerstitial nephropathy. Idiopathic intracranial hemorrhage occurs in up to 15% of patients and is often fatal. Patients with AS should be screened with magnetic resonance angiography (MRA) of the head prior to transplantation to identify any cerebral vascular malformations. Cardiac anomalies are also a component of AS, with the most common manifestation being central or peripheral pulmonary arterial stenoses. Up to 24% of patients also have associated intracardiac anomalies. Tetralogy of Fallot, aortic coarctation, septal defects, patent ductus arteriosus, pulmonary atresia and pulmonary stenosis have also been reported with AS (Perlmutter and Shepherd, 2002). In patients with right ventricular outflow obstruction, the severity of the outflow gradient is a major factor in the perioperative morbidity and mortality.

Wilson's Disease

Wilson's disease (hepatolenticular degeneration) is an autosomal recessive disorder characterized by progressive or acute liver decompensation in the first 2 decades of life, although its appearance later with neuropsychiatric symptoms is also common. Wilson's disease represents a mutation in the *ATP7B* gene, which causes a progressive accumulation of copper in the liver as a result of impaired copper excretion into the bile. As time passes, the capacity of the liver to accumulate copper is exceeded, and copper is released into the circulation. In addition to liver decompensation, copper accumulation also affects the CNS, with a myriad of neuropsychiatric symptoms. Severe Coombs-negative (non-immune-mediated) intravascular hemolysis is frequent and is the presenting symptom in up to 15% of patients. Arrhythmias, autonomic dysfunction, and LV hypertrophy are seen in up to 25% of patients (Hlubocká et al., 2002).

α_1 -Antitrypsin Deficiency

α_1 -Antitrypsin deficiency (A1AT) is a relatively common autosomal recessive disorder. It is a serine protease inhibitor that inhibits destructive neutrophil proteases, and it limits the destructive effects of neutrophil effectors during times of inflammation. In the homozygous form, there is a 90% reduction in circulating concentrations of A1AT. α_1 -Antitrypsin has a reported incidence of liver involvement in 10% to 20% of patients, primarily those who are PIZZ homozygotic (Psacharopoulos et al., 1983). The incidence of this phenotype is 1 in 7000 in the United States and 1 in 2000 in Scandinavia (Schwarzenberg and Sharp, 1990). Males are affected more frequently than females. Some 10% to 20% of PIZZ individuals develop neonatal cholestasis, and jaundice is often the first sign of this disease. The liver disease associated with A1AT deficiency can become clinically apparent at any time from infancy to late adulthood. Of note for anesthesiologists, patients with

homozygous AIAT deficiency develop progressive emphysematous lung disease; however, these changes are generally not severe until well into adulthood.

Fulminant Hepatic Failure

Fulminant hepatic failure (FHF) is the most severe, life-threatening complication of liver failure. See related video online at www.expertconsult.com. Differentiating acute fulminant liver failure from an acute exacerbation of chronic liver disease has important therapeutic and prognostic implications, as not all patients with acute liver failure are the same. Fulminant hepatic failure is usually defined as rapidly progressive liver failure, with the onset of encephalopathy within 8 weeks of the onset of jaundice in patients without a previous history of liver disease. However, no uniform definition of FHF in children has been established yet. One definition that is widely accepted is the sudden onset of liver failure with altered mental status and coagulopathy in an otherwise healthy child (Nazer and Nazer, 2004). FHF was the primary diagnosis in 15% of pediatric patients transplanted from 1995 to 2000. Viral hepatitis and drug-induced hepatotoxicity are the two most common causes, but in most cases, the etiology is unidentified. For the majority of patients with fulminant failure, survival ultimately depends on medical stabilization and urgent liver transplantation, as mortality rates may reach 80%.

The etiology of FHF is quite varied. In approximately 50% of patients, FHF is caused by acute viral hepatitis (A, B, C, D, E, or non A–E). Hepatitis C virus infection is not a significant cause of FHF in children. Many other viruses are also recognized, including Epstein-Barr virus, CMV, paramyxovirus, varicella-zoster virus, herpesvirus types 1, 2, and 6, parvovirus, and adenovirus. Less common causes include hepatotoxic drugs (acetaminophen, salicylates, chlorinated hydrocarbons, halothane, isoniazid, IV tetracycline, sodium valproate, and methanol), *Amanita* mushroom poisoning, ischemia, vascular obstruction (Budd-Chiari syndrome), massive steatosis (Reye's syndrome), and metabolic causes (Wilson's disease in older children; inborn errors of metabolism and hemochromatosis in neonates).

Jaundice is the most common presenting symptom, with mental changes occurring over the next two weeks in most patients. The condition then progresses to coma in as many as 80% of patients, with the development of ascites, cerebral edema, decortical and decerebrate posturing, severe coagulopathy, GI bleeding, respiratory failure, pulmonary edema, and hemodynamic instability.

Cerebral edema appears to be the major cause of morbidity in patients with FHF and contributes to the high mortality. Early signs and symptoms include increased muscle tone, arterial hypertension, seizures, agitation, and sluggish papillary response to light. Infants may present with poor feeding, irritability, and altered sleep patterns. The mechanism of cerebral edema is unknown, although vasogenic and cytotoxic etiologies have been proposed. Whatever the cause, cerebral edema ultimately leads to intracranial hypertension, impairment of cerebral perfusion, irreversible neurologic brain injury, uncal herniation, and death (Hanid et al., 1979). Encephalopathy may be classified according to the scheme in [Table 28-18](#). This is useful to judge the effects of treatment and assess the progression of the disease process.

TABLE 28-18. Staging (Grading) of Hepatic Encephalopathy

Stage	Mental Status	Tremor (Asterixis)	Electroencephalography
I	Euphoria, altered sleep, slurred speech	Slight	Δ and α irregularities
II	Drowsiness, incontinence	Marked	Slow α and Δ
III	Arousable from sleep, confused	Diminished	τ wave prevalent
IV	Responsive to painful stimuli	Absent	Slow Δ to flat
V	Unresponsive to pain	Absent	Flat

Medical treatment is generally supportive until either recovery with hepatocyte regeneration, liver transplantation (deceased, split, or living related donor), hepatocyte transplantation, or death. See related video online at www.expertconsult.com. Experimental approaches have been attempted using liver-assist devices. Supportive measures are directed at minimizing morbidity and mortality from serious complications. This includes a critical care unit, monitoring, endotracheal intubation for airway protection, infusions of 10% to 20% dextrose to prevent hypoglycemia, replacement of calcium phosphorous and magnesium, antibiotic treatment of infections, maintenance of adequate urine output, avoidance of nephrotoxic drugs with surveillance for renal insufficiency, and H_2 -blockers for stress ulcer prophylaxis. Correction of coagulopathy is with vitamin K and plasmapheresis. In general, platelets and fresh frozen plasma are reserved for patients with active bleeding. Normalization of the patient's PT is often used as a prognostic indicator for recovery of synthetic function. Avoiding volume overload and management of intracranial hypertension are crucial in the management of FHF. Protein intake is restricted. Lactulose enemas and oral neomycin are administered to decrease enteric bacteria that produce ammonia. If a causative agent is identified, specific treatment should be initiated early (e.g., *N*-acetylcysteine for acetaminophen overdose).

Initial management of cerebral edema should begin with a computed tomography (CT) scan of the brain to assess cerebral blood flow with xenon (Aggarwal et al., 1994). If there is evidence of cerebral edema and compromise of cerebral blood flow without CO_2 responsiveness, continuous monitoring of intracranial pressure is vital, especially in stage 3 or 4 encephalopathy. Therapeutic measures to reduce ICP include head-up positioning, ventilatory support with moderate hyperventilation, and mannitol for a documented ICP greater than 30 mm Hg and for progressive edema. It may be efficacious to place a jugular bulb catheter so that adequate assessment of cerebral metabolism is possible (Lassen and Lane, 1961). The important parameters that aid in management are the measured arteriovenous oxygen content difference ($AVDO_2$), glucose, and lactate differences across the brain (Aggarwal et al., 1993, 1994). Mild hypothermia (to 34° C) and barbiturate coma remain controversial topics with respect to the management of hepatic coma. Barbiturate coma should be reserved until all therapeutic interventions have failed to reduce ICP. However, hypothermia

should be initiated early in stage III coma. Continuous EEG monitoring is essential, as the goal is to achieve EEG silence with IV barbiturates.

Serial abdominal CT scans may be useful in assessing the hepatic size and morphology. A transjugular liver biopsy may be necessary but may not provide a definitive diagnosis. Histologic findings are usually of two types: extensive necrosis of the peripheral hepatocytes with little or no regeneration (drugs and viral hepatitis), and microvesicular steatosis and centrilobular necrosis (Reye's syndrome and metabolic disorders). Serum levels of liver enzymes do not correlate with the severity of the disease. Typically, conjugated hyperbilirubinemia is present, with hyponatremia, hyperkalemia, respiratory alkalosis, and metabolic acidosis.

Prognostic criteria include the patient's age, cause of liver disease, onset and degree of encephalopathy relative to the appearance of jaundice, serum bilirubin level, PT and INR, serum creatinine, factor V level, and arterial pH. A sensitive predictor of outcome is the INR value. With an INR of 4 or more, the mortality rate reaches 86%; with an INR of less than 4, it may be as low as 27% (Nazer and Nazer, 2004).

Preoperative Evaluation

Risk assessment of the patient scheduled for OLT is still in its evolutionary stage. The primary focus for the anesthesiologist is to evaluate the *whole* patient for systemic manifestations of ESLD as well as predictable disease-specific extrahepatic manifestations (such as pulmonary involvement with cystic fibrosis).

Cardiovascular Evaluation

Cardiac evaluations of pediatric candidates for OLT should be tailored to the underlying cause of cirrhosis. Inherited metabolic liver disorders rank second behind biliary atresia as an indication for OLT in children, so possible myocardial involvement should be considered in patients with oxalosis, glycogen storage disease types III and IV, Gaucher's disease, Niemann-Pick disease, Wilson's disease, neonatal iron storage disease, and amyloidosis. The physical examination and diagnostic work-up should focus on cardiac auscultation, the presence or absence of cyanosis (arterial oxygen saturation SpO_2 and Pao_2), or clubbing and transthoracic echocardiography. Detection of a cardiac anomaly may then require cardiac catheterization.

Cardiac function in adults with cirrhosis has been extensively investigated, but there is little information available on children. A study of 22 children with cirrhosis compared with a control group of healthy age- and gender-matched children (mean age, 4.1 ± 3.5 years) reported that pediatric OLT candidates have normal LV systolic function unless their heart was primarily involved in the underlying disease. In advanced liver failure, LV systolic function may be impaired. These children also had increased systolic LV posterior wall thickness, which may reflect LV hypertrophy and impaired diastolic function. LV ejection fraction is usually normal or increased at rest in adults with cirrhosis unaccompanied by ascites (Grose et al., 1995; Laffi et al., 1997). The presence of ascites adversely affects cardiac function in adults (Valeriano et al., 2000). In contrast, most

pediatric patients with ascites have normal LV systolic function. Cyanosis is not a reliable sign of hypoxemia in children because of changes caused by crying, anemia, and jaundice. Clubbing in patients with chronic liver disease is a common finding, with a prevalence ranging from 23% to 32% (Ozcay et al., 2002). Given the physiologic stresses inherent in liver transplantation surgery, cardiac problems may emerge perioperatively that contribute to significant morbidity and mortality in patients with cirrhosis and mild or latent cardiomyopathy (Myers and Lee, 2000).

Pulmonary Evaluation

Patients with FHF have varying degrees of pulmonary impairment, including normal Pao_2 and reduced diffusion capacity of the lung for CO (D_Lco), significant arterial hypoxemia, HPS, portopulmonary hypertension, and preexisting lung disease. It is not known whether the high-risk pediatric patient scheduled for liver transplantation surgery can be identified by obtaining values for forced expiratory volume at 1 second (FEV_1), D_Lco , and Pao_2 . Investigative studies include chest radiography, pulmonary function studies, a high-resolution CT lung scan, contrast echocardiography, a technetium-99m radionuclide scan, arterial blood gas measurements, and a multiple inert gas elimination technique (MIGET) study when indicated.

Cirrhosis affects the pulmonary circulation, lung parenchyma, and pleural spaces. Reduced alveolar-capillary diffusion (D_Lco) may be seen in the absence of significant hypoxemia, especially in patients with hepatitis C virus (HCV) cirrhosis. This anatomic derangement of the alveolar-capillary membrane worsens with disease progression, with the measured D_Lco becoming abnormal at less than 80% of predicted value. A reduced diffusion capacity may persist up to 15 months after transplantation (Ewert et al., 1999). Of interest, the Hepatitis C Association supports a no-smoking policy for teens and adults, as smoking has been determined to be an independent risk factor associated with elevated ALT levels among anti-HCV-seropositive patients (Wang et al., 2002; Hezode et al., 2003).

Mild Arterial Hypoxemia. Mild arterial hypoxemia is common in patients with cirrhosis and primarily caused by a decrease in functional residual capacity (FRC) and total lung capacity (ascites, pleural effusions), impaired diffusion capacity, and pulmonary arteriovenous shunting (Liu and Lee, 1999). In advanced liver diseases, ventilation-perfusion (\dot{V}/\dot{Q}) defect is an important cause of hypoxemia. The arterial blood gas analysis with the patient standing and breathing 100% Fio_2 is of particular importance, because severely hypoxemic patients with at least a moderate response to breathing 100% oxygen on standing ($Pao_2 > 150$ mm Hg) are thought to have an adequate pulmonary reserve and may be safely oxygenated intraoperatively (Krowka et al., 1997; Mohamed et al., 2002). Unresponsive patients should be suspected of having a fixed shunt, and transplantation should be delayed pending further evaluation.

Hepatopulmonary Syndrome. Hepatopulmonary syndrome was once considered a contraindication to transplantation, but now it is considered an indication for early liver transplantation, as there is no successful long-term medical treatment. Patients typically present with progressive exertional dyspnea and hypoxemia. HPS is characterized by the triad of chronic liver disease, hypoxemia, and intrapulmonary shunting in the

absence of primary cardiac or pulmonary disease. The incidence in the pediatric patient population is unknown. The pathologic defects causing arterial hypoxemia include intrapulmonary vascular dilation resulting from dilated precapillaries, direct arteriovenous communications, portopulmonary communication, and pleural arteriovenous malformations. This results in decreased oxygen diffusion into the dilated vessels, along with decreased intrapulmonary transit time and decreased hypoxic pulmonary vasoconstriction. This is not a true anatomic shunt, as the patient with the more common type I lesion demonstrates a significant P_{aO_2} response to 100% oxygen. Appropriate preoperative evaluation should include a chest radiograph, an arterial blood gas measurement with the patient breathing room air and then 100% F_{iO_2} , and one of several imaging techniques: perfusion lung scanning, contrast-enhanced (microbubble) transthoracic echocardiography, lung scintiscan, and, rarely, pulmonary angiography (which identifies type I O_2 reactive versus type II O_2 nonreactive lesions). With liver transplantation, HPS is reversible (Liang et al., 2001), but regression of vascular abnormalities in patients with true anatomic shunts and those with marked precapillary dilation and evidence of poor response to supplemental oxygenation is not predictable (Lange and Stoller, 1995). Treatment of HPS type II presents a dilemma, although liver transplantation with concomitant lung transplantation is a possible choice (Yuan et al., 2003).

Portopulmonary Hypertension. Pulmonary arterial hypertension as a consequence of liver dysfunction is termed portopulmonary hypertension (PPH). This is a pulmonary vasoproliferative and vasoconstrictive process leading to pulmonary hypertension (increased peripheral vascular resistance and normal PCWP or LV end-diastolic pressure) and right heart failure frequently not reversible by liver transplantation. This disorder is uncommon (20% of patients with cirrhosis of the liver), and its existence in the pediatric population is not well described. How rapidly PPH can develop varies, as reports indicate anywhere from 3 weeks to 5 years. Remarkably, a review of published PPH cases through 1999 documented that 65% of diagnoses were first recognized during the liver transplantation procedure (Krowka et al., 2004). The clinical presentation is subtle and includes exertional dyspnea, fatigue, ankle edema, chest pain, and syncope. Arterial hypoxemia is reported in 80% of patients with moderate to severe disease, with an increased alveolar-arterial oxygen gradient, reduced diffusion capacity, and accentuated respiratory alkalosis (Kuo et al., 1997; Cotton et al., 2002). Transthoracic contrast-enhanced echocardiography is the screening procedure of choice, with right heart catheterization the gold standard for making the diagnosis and assessing right ventricular function. The best prognosis is in patients with mild symptoms, preserved right heart function, and pulmonary arteries responsive to vasodilator therapy. Treatment options include inhaled nitric oxide, sildenafil (Viagra), calcium channel blockers, anticoagulation, digoxin, diuretics, supplemental oxygen, and IV prostacyclin. The significance of this disease entity is its high perioperative morbidity and mortality in patients undergoing OLT. The available data indicate a perioperative mortality of greater than 70% with a mean pulmonary artery pressure of 45 mm Hg or higher, and up to 100% if the mean pressure is greater than 50 mm Hg at the time of transplan-

tation. The national liver transplantation database reports an overall mortality perioperatively of 36%. The key to survival is preserved right ventricular function. Even after OLT, however, the pulmonary vascular abnormalities may progress unless long-term pulmonary vasodilator therapy is instituted.

Pulmonary involvement in the pediatric patient with α_1 -antitrypsin deficiency or cystic fibrosis is not uncommon. A1AT deficiency is also associated with cirrhosis and primary liver cancer and may be associated with coexisting obstructive lung disease. Therefore, appropriate assessment should be obtained in this particular group of patients with liver failure.

Renal Evaluation

Renal dysfunction in conjunction with worsening hepatic function is common. Acute renal failure requiring hemodialysis is a strong predictor of mortality in these patients. Bartosh and colleagues (1997) reported abnormal renal function in one third of children after liver transplantation, with acute renal failure requiring dialysis (in 6.2%) being a predictor of a high mortality rate (85%). The etiology of renal insufficiency in the patient with ESLD is usually multifactorial. Possible causes include hepatorenal syndrome, disturbances of salt and water clearance, acute tubular necrosis, renal pathology associated with the underlying liver diseases, and diminished intravascular volume causing prerenal azotemia. Exposure to nephrotoxic drugs such as IV contrast dyes, aminoglycosides, or nonsteroidal antiinflammatory agents may also contribute to ATN.

Urine sodium handling is an important variable during evaluations. Both prerenal azotemia and hepatorenal syndrome are characterized by normal urinary sediment, very low urine sodium concentrations (<10 mEq/L), azotemia, and oliguria; it is therefore important to exclude hypovolemia. Specifically, hepatorenal syndrome does not respond to a fluid challenge with diuresis, whereas the expected response in the patient with prerenal azotemia is diuresis and a subsequent decrease in the serum creatinine and urea nitrogen levels. ATN tends to be salt wasting at its initial presentation, with urine sodium concentrations characteristically greater than 20 mEq/L. An important diagnostic test is the FENa, which also aids in the distinction between these two disease processes (FENa \leq 1% for HRS and prerenal azotemia, and greater than 1% for ATN). Obtaining an accurate GFR using creatinine clearance rate values in patients with cirrhosis and ascites may give spurious results, as GFR measurements may range from high values to those diagnostic of end-stage renal disease despite the presence of a normal serum creatinine level (Papadakis and Arieff, 1987).

Renal ultrasonography is a simple (noninvasive), useful adjunct in the evaluation of azotemia. Kidney size and structural abnormalities should be ascertained for evidence of obstructive uropathy. If a renal biopsy demonstrates irreversible renal disease, a combined liver and kidney transplantation should be considered.

Prerenal azotemia caused by hypovolemia usually resolves with judicious volume replacement. ATN is usually self-limited, with resolution in 4 to 6 weeks with appropriate support. However, the hepatorenal syndrome is usually not reversible without liver transplantation (Gonwa et al., 1989).

Surgical Technique

The technique used for liver transplantation in children has evolved over the past two decades and varies greatly between different centers, but the physiologic changes that occur during the procedure can be divided into four distinct stages. Here, we review the operative considerations during each stage, and a little later, the anesthesia management during each stage will be discussed. In general, open communication between the surgical and anesthesia teams is essential to avoid difficulty in the progression between the different stages. See related video online at www.expertconsult.com.

Stage I: Preanhepatic Stage

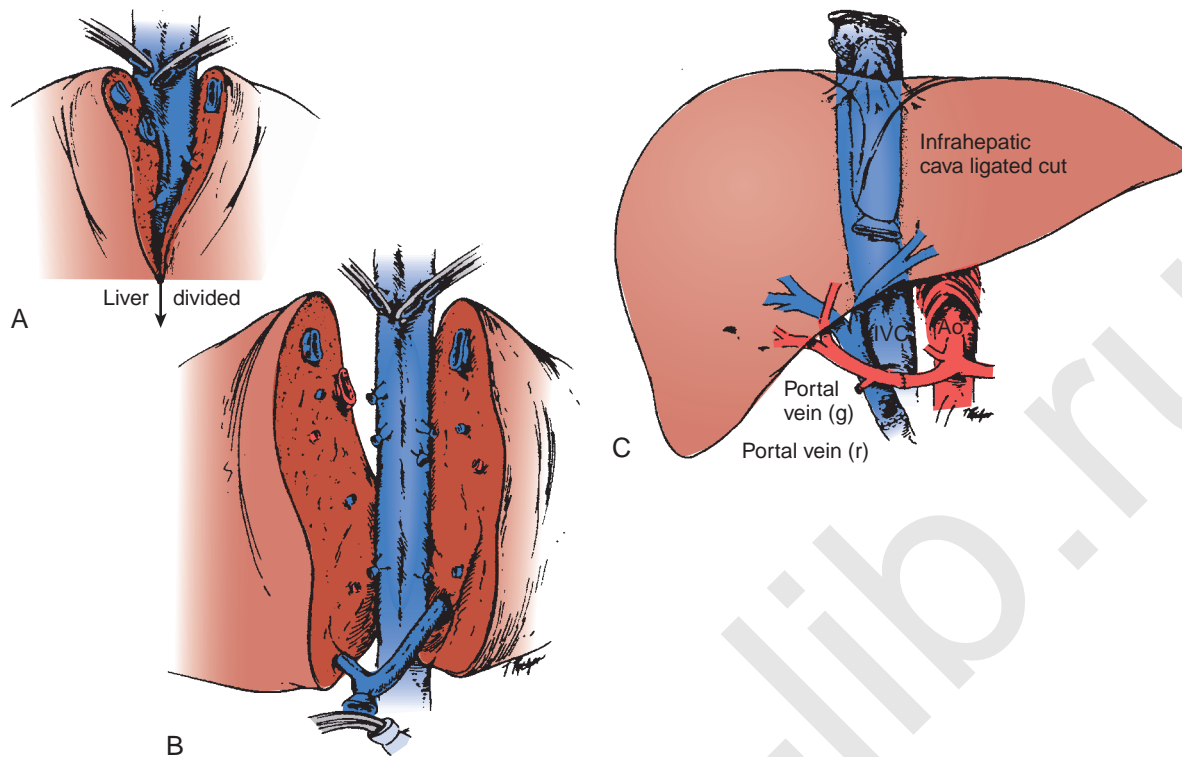

Stage I begins at the time of incision and, from an operative standpoint, is dominated by the careful dissection of the liver from surrounding structures. In reoperative cases, this stage can be of considerable length and can involve a significant amount of blood loss because of the presence of portal hypertension and collateralized mesenteric venous circulation. Meticulous dissection of the hilum is imperative in this stage, as preservation of the vascular inflow to the new liver is crucial to successful transplantation. The adequacy of the flow in the native hepatic artery and portal vein is assessed at this point, and if flow is believed to be inadequate, several techniques can be used either to augment flow in the native vessels or to bypass them altogether. Sufficient portal flow is a requisite to successful reperfusion of the liver. In cases of inadequate portal flow, the vein is dissected to the level of the confluence of the superior mesenteric vein and the splenic vein. Major collaterals shunting blood away from the portal vein are ligated, including the left gastric vein. If flow remains poor, a careful search for collaterals from the splenic vein to the renal vein is undertaken and these are ligated if present. In some cases, the portal vein is relatively atretic in the hilum, but the flow and caliber of the vein dramatically improve at the level of the confluence. In such cases, extension grafts of donor iliac vein can be anastomosed at the level of the confluence. If flows are still inadequate for inflow, the superior mesenteric vein (SMV) should be

carefully dissected below the level of the middle colic vein. This thin-walled vein is often surrounded by multiple collateral vessels, requiring meticulous dissection to avoid significant blood loss. An appropriately oriented vein graft is then anastomosed in an end-to-side manner with the SMV, and this can be tunneled through the transverse mesocolon to the hepatic hilum. The hepatic arterial inflow is then assessed for adequacy. If the native hepatic artery is diminutive, an aortic graft is often used to deliver arterial flow from the infrarenal aorta to the hepatic artery of the donor liver. It can be expected that hemodynamic changes will be encountered during the several minutes of aortic occlusion needed to fashion an end-to-side anastomosis between an appropriate arterial conduit and the native infrarenal aorta.

The second portion of stage I entails the dissection of the inferior vena cava (IVC), culminating in the hepatectomy. This can be performed in two ways. The standard complete hepatectomy (Starzl et al., 1984; Starzl and Iwatsuki, 1987) (Fig. 28-3) is performed with complete excision of the retrohepatic vena cava along with the liver. The alternative approach is the one primarily used for the pediatric patient: the “piggyback” hepatectomy (Tzakis et al., 1989). With the standard technique, during stage I, the infrahepatic cava is circumferentially dissected with careful control of adrenal vasculature, and the suprahepatic cava is prepared for clamping. Similarly, the suprahepatic cava is isolated. The standard procedure requires careful preparation for complete caval occlusion. IV infusions should be limited to the tributaries of the superior vena cava (SVC), as those infused below the diaphragm encounter upstream obstruction once the IVC is clamped. Most children tolerate complete caval occlusion well; however, the surgical team should always perform a brief test clamp before structures are divided to allow proper fluid resuscitation to begin. If hemodynamic stability is not achieved with clamping, the use of VVB to augment preload during caval clamping should be considered (see later). Although the standard hepatectomy generally affords some usefulness in tumor cases and can be done relatively quickly, excision of the native cava requires a separate, lower caval anastomosis to be performed prior to reperfusion, possibly extending the warm ischemic time and adding an additional site of potential complication.

■ **FIGURE 28-3.** Biliary tract reconstruction with choledochojejunostomy, using a Roux-en-Y limb. (From Starzl TE, Iwatsuki S, VanThiel DH, et al: *Evolution of liver transplantation*, *Hepatology* 2:614, 1982.)

■ **FIGURE 28-4.** The native liver is dissected away from the inferior vena cava (IVC), and the vascular pedicle of the hepatic veins is isolated. The native liver, after being devascularized, may then be transected to allow intraparenchymal exposure of the hepatic veins (**A** and **B**). The final appearance of the recipient liver, with the native IVC intact and the confluence of the recipient's hepatic veins at the suprahepatic cava, being anastomosed to the donor's intact IVC (**C**). (From Tzakis A, Todo S, Starzl TE: Orthotopic liver transplantation with preservation of the inferior vena cava, *Ann Surg* 210:649, 1989.)

The piggyback hepatectomy (Tzakis et al., 1989) (Fig. 28-4) involves careful dissection of the liver from the retrohepatic vena cava with preservation of the native vena cava. Briefly, the hepatic veins connecting the posterior liver and the cava are isolated and divided, allowing the liver to be lifted off the vena cava. The main hepatic veins are also circumferentially dissected and readied for clamping. Although the piggyback procedure can take some additional time, avoidance of caval division and the need for one less anastomosis makes it an attractive option in children. Hemodynamic instability is usually insignificant because of the retroperitoneal collateralization of vessels with the azygous system. However significant blood loss can occur with accidental injury to the vena cava, the short hepatic veins, or the main hepatic veins. Although complete caval occlusion is not needed, partial obstruction of the cava generally occurs and can result in some instability (Moreno-Gonzalez et al., 2003).

Stage I is completed with the removal of the native liver. This requires occlusion and division of the portal vein in the hilum (usually at the level of the bifurcation) and subsequent clamping of the hepatic veins in the piggyback technique or the division of the suprahepatic and infrahepatic venae cavae in standard cases. Immediately on ligation of the hepatic artery and removal of the liver, the anhepatic stage begins. In general, there is no value in correcting coagulation defects in this stage, as most of this correction will immediately be subject to extensive fibrinolysis associated with allograft reperfusion. In addition, as inflow structures are occluded at this point, formation of intravascular thrombi is a realistic concern.

Stage II: Anhepatic Stage

Stage II is a crucial time in pediatric transplantation, and errors made during this relatively brief period can significantly alter the patient's course. From a surgical standpoint, the anhepatic stage begins with creation of an upper caval cuff to sew by invagination to the donor suprahepatic cava. This is accomplished by careful occlusion of the cava just above the level of the confluence of the hepatic veins. In the standard operation, the entire suprahepatic cava is clamped and the anastomosis is between the donor and the entire recipient suprahepatic vena cava. In the piggyback method, a clamp is placed just above the level of the hepatic veins, only partially occluding the vena cava. A common cuff of the three ostia of the hepatic veins is then created and prepared for anastomosis with the upper cava of the donor liver. Once the upper caval anastomosis is completed, in standard cases, a separate anastomosis is performed between the infrahepatic cava of the donor liver and the suprarenal vena cava of the recipient. Once the vena cava has been addressed, a vascular anastomosis is fashioned between the portal vein and the mesenteric inflow vessel of the recipient (either the native portal vein or a mesenteric vein graft).

Stage II is completed with the resumption of flow to the hepatic allograft by either the hepatic artery (HA) or the portal vein (PV), or by both vessels. Most often it is with the portal vein only. Anesthesia management in the second stage represents a careful preparation for the instability associated with reperfusion. Concerns about hyperkalemia, acidosis, and hemodynamic lability should all be addressed during the terminal

portion of the second stage. Close communication between the surgical and anesthesia teams accomplishes a smooth transition through graft reperfusion. Stage II is also the proper time to administer immunosuppressive dosages of corticosteroids.

Stage III: Reperfusion Stage

Surgical considerations early after hepatic reperfusion focus on the rapid achievement of necessary surgical hemostasis. The initial attempt at hemostasis should be judicious, as relatively severe coagulopathy is the rule before the allograft function recovers from the stress of ischemia and reperfusion. Careful rotation of the liver should allow a rapid assessment of the caval and portal anastomoses, and, once immediate hemostasis is achieved and the patient is stabilized, attention can be turned to the hepatic arterial anastomosis. Because the vessels used in pediatric liver transplantation are small, this anastomosis is often time consuming and can involve the use of either the native hepatic artery or an aortic graft as inflow. Maintenance of an adequate perfusion pressure and avoidance of procoagulants is imperative to the success of this anastomosis. Some centers also employ low dosages of IV anticoagulants during this stage. Once hepatic arterial inflow is established, it is evaluated with intraoperative Doppler ultrasound.

The second portion of stage III (sometimes referred to as stage IV) involves the establishment of biliary continuity. In adults and larger children, this can be performed with a standard duct-to-duct anastomosis. In smaller children and in patients with diseased native bile ducts, creation of a biliary-enteric anastomosis is required. Although several possibilities exist, this is generally achieved with a Roux-en-Y limb of jejunum, and either the hepatic or the common bile duct of the donor. With the newly implanted denervated liver, optimal hepatic arterial flow is essential as the biliary system now becomes 100% of its blood supply from the HA. Careful surgical technique is imperative in this stage to avoid biliary and enteric leaks, which can lead to significant morbidity and mortality in both the early and late postoperative stages.

The final consideration in stage III involves abdominal closure. Because of the greater donor-to-recipient size ratios in pediatric liver transplantation, accidental creation of an intraabdominal compartment syndrome is possible and must be avoided. In addition to the reperfusion-associated inflammation of the allograft, visceral edema from mesenteric venous clamping and tissue edema often makes closure difficult. Even slight increases in abdominal pressure and associated hemodynamic instability can cause allograft vascular thrombosis in the early postoperative period. Careful attention should be paid to changes in ventilatory compliance, peak airway pressure, and hemodynamics with abdominal closure, and any significant changes should be rapidly communicated to the surgical team. Abdominal closure is often achieved with temporary prosthetic mesh, with gradual closure over several days after careful diuresis and diminished edema. Indeed, temporary closure of skin alone, leaving a large ventral hernia, is often needed. Formal closure of fascia, often requiring component separation and use of prosthetic mesh, is often deferred for several months, even up to 1 year after the transplantation.

Venovenous Bypass

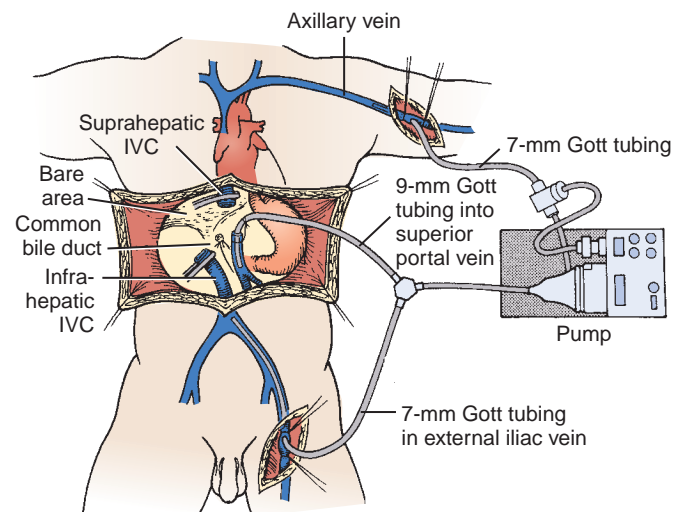

The routine use of VVB during the anhepatic phase of OLT, with or without preservation of the cava, remains controversial. In early

experiments of OLT in a noncirrhotic dog model, it was discovered that clamping of the portal vein or IVC resulted in death of the animal within 30 minutes (Shaw et al., 1985). Although it was later found that most patients can tolerate caval and portal vein clamping remarkably well, Shaw and colleagues (1984) reported a 10% intraoperative mortality due to hemodynamic instability in adults during the anhepatic phase. Therefore, a bypass system was developed consisting of heparin-bonded tubing and a centripetal-vortex pump, allowing cannulation of the femoral and portal veins and diversion of mesenteric and IVC blood to the SVC through the subclavian or axillary veins (Griffith et al., 1985) (Fig. 28-5). There are no published randomized clinical trials of specific outcomes to evaluate its potential benefits.

It is difficult to use VVB in patients weighing less than 40 or 45 pounds (~20 kg) (Shaw et al., 1984, 1985). The prerequisite VVB blood flow is usually 20% to 40% of the cardiac output, or greater than 1 L/min (Griffith et al., 1985). As patients are not heparinized, the extremely low-flow states (<500 to 700 mL/min) that result in children weighing less than 20 kg would predispose to almost certain formation of emboli. Despite these findings, VVB still has some specific value in pediatric liver transplantation—notably in larger children with FHF or in older pediatric recipients who are being used as donors for living-donor domino transplantations.

Anesthesia Management

Anesthesia management can be categorized into four distinct stages corresponding to the four surgical stages previously described. Thus, an understanding of the pathophysiologic changes that occur in each stage of the surgery allows the anesthesiologist to anticipate and appropriately diagnose, manage,

■ **FIGURE 28-5.** This technique was developed to augment cardiac output and diminish vascular congestion during the anhepatic stage of the surgery. Note the placement of the cannulas, joined by a connector, into the portal vein and the femoral veins. Blood drained from the splanchnic and systemic venous systems is then returned to the right heart through the axillary vein with the aid of a pump. (From Kang Y, Gelman S: *Liver transplantation*. In Gelman S, editor: *Anesthesia and organ transplantation*, Philadelphia, 1987, Saunders, pp 139–185.)

and treat the cardiovascular, hematologic, metabolic, and other derangements encountered throughout the surgery (Borland et al., 1985; Carlier et al., 1987; Kang and Gelman, 1987; Lindop and Farman, 1987; Carton et al., 1994a, 1994b). Liver transplantation in the pediatric patient is very similar to that in adults from a technical point of view, but there are distinct differences in transfusion requirements and strategies for minimizing blood loss, perioperative coagulation, hemodynamic consequences of caval clamping and reperfusion of the liver, monitoring, vascular access, incidence of thrombosis of the hepatic artery, retransplantation rate, and postoperative pain relief.

Induction and Maintenance of Anesthesia

Liver transplantation has essentially become a semiurgent or elective procedure. The recipient is premedicated with oral, IV, or intranasal midazolam. In the operating room, standard monitors are placed and the patient is preoxygenated. Patients without serious cardiac disease or multisystem organ failure can tolerate routine induction of anesthesia followed by endotracheal intubation. Rapid-sequence IV induction includes atropine (0.01 to 0.02 mg/kg); a sedative hypnotic agent using thiopental (3 to 5 mg/kg), propofol (2 to 5 mg/kg), etomidate (0.2 to 0.3 mg/kg), or ketamine (1 to 2 mg/kg); and rocuronium (1.0 mg/kg) or succinylcholine (1 to 2 mg/kg). The airway is secured with an oral endotracheal tube (preferably cuffed) with tincture of benzoin and adhesive tape. Placement of an uncuffed tracheal tube of insufficient diameter may result in inadequate alveolar ventilation (especially as chest compliance is reduced during surgery by upper abdominal retraction), tissue edema of the lung parenchyma, surgeons accidentally leaning on the chest wall, and placement of a large liver graft. Additionally, the postoperative risk for silent aspiration must be considered.

Succinylcholine has traditionally been used for intubation in pediatric patients at risk for aspiration. Today, this practice is controversial because of its black-box warning. Because it is difficult to identify which patients are at risk, it is recommended that the use of succinylcholine in children should be reserved for emergency intubation or for when immediate securing of an airway is necessary, as succinylcholine has a faster onset (30 to 60 seconds) than other muscle relaxants. Liver disease, especially if chronic and severe, may be associated with decreased plasma levels of pseudocholinesterases, which will result in prolongation of the duration of action of succinylcholine or drugs requiring ester hydrolysis for degradation (Khoury et al., 1987). However, this effect is of little clinical significance when one considers the duration of perioperative ventilation and the dilutional effect of blood replacement during massive intraoperative bleeding.

Preoperative hyperkalemia may be seen in patients with episodes of acute rejection, sepsis, or poor renal function, or in those taking oral cyclosporine who have chronic rejection or hepatic artery thrombosis. Administration of succinylcholine may increase the serum potassium concentration by 0.5 to 0.7 mmol/L, predisposing the patient with already high serum potassium levels to cardiac arrhythmias and hemodynamic instability. ECG abnormalities and arrhythmias typically do not appear until the serum potassium level is greater than 6.5 mEq/L. Common ECG signs include widened QRS, peaked T-waves, prolonged PR interval, loss of P waves, and atrial systole. ST-segment elevation may mimic acute myocardial infarction. First-degree block may ultimately lead to complete heart

block. Late signs include prolonged QRS complex that can lead to sine wave ventricular arrhythmia, ventricular fibrillation, or asystole. Treatment for succinylcholine-induced hyperkalemia focuses on direct cardiac antagonism, intracellular shift, and removal of potassium from the body. Arrhythmia and hypotension are treated with either calcium gluconate or calcium chloride. Intracellular shifting of potassium can be accomplished by administering sodium bicarbonate, glucose, and insulin and hyperventilation (Paco₂, 25 to 30 mm Hg). Kayexalate, furosemide, peritoneal dialysis, or hemodialysis can decrease the total body potassium level.

Alternatively, using a relatively large dosage of a nondepolarizing muscle relaxant (e.g., rocuronium) permits securing the airway rapidly without placing the patient at risk for hyperkalemia. Cisatracurium is the ideal drug for patients with end-stage liver or kidney disease, as it undergoes spontaneous breakdown at physiologic temperature and pH (Hoffmann elimination), as well as ester hydrolysis. However, the dosage required for a rapid onset of action may result in hypotension. In patients with hepatorenal syndrome, nondepolarizing muscle relaxants should be administered cautiously and titrated to effect. Muscle relaxants requiring significant renal excretion include pancuronium (40%), doxacurium (30%), and pipecuronium (38%). Vecuronium and pancuronium also have 3-hydroxy metabolites, which accumulate in renal failure. The 3-hydroxy metabolite of vecuronium is 50% as potent as the parent compound, and that of pancuronium has two-thirds the potency of the parent compound. Muscle relaxants that are metabolized in the liver include pancuronium, vecuronium, rocuronium, and pipecuronium. Vecuronium and rocuronium also have significant biliary excretion. Pancuronium has an increased volume of distribution, prolonged elimination half-life, and decreased plasma clearance in patients with cirrhosis. Therefore, these patients may need more pancuronium initially to achieve muscle relaxation, and they have a prolonged recovery of blockade between doses (Duvaldestin et al., 1978). In patients with biliary obstruction, the initial dosage of pancuronium required is unchanged, but the duration of action of each dose is similarly prolonged (Duvaldestin et al., 1978). This may be advantageous because the operative procedure is lengthy and ventilation is usually required for at least 24 hours postoperatively.

Following induction, the patient is positioned on the operating table supine with the arms abducted and elbows flexed. It is essential to keep the patient covered, warm, and dry. Strategies include the use of a warming blanket, heated humidified gases, or IV fluid warmers; wrapping the extremities; mylar foil wrapping; and use of a thick cotton mattress pad below with a U-shaped surround Bair Hugger forced-air warming device. Care should be taken to avoid stretch injury of the brachial plexus or pressure necrosis of the occiput, ears, heels, sacrum, or elbows. After the induction of anesthesia, additional monitoring is established, using end-tidal CO₂, rectal and esophageal temperature probes, an esophageal stethoscope, an indwelling urinary catheter, a peripheral nerve stimulator, and systemic arterial and CVP cannulas. Access to arterial pressure monitoring above the diaphragm is ideal because cross-clamping of the abdominal aorta may be necessary during the hepatic arterial anastomosis. A femoral arterial catheter can also be used during surgery if there is concern about the accuracy of the radial arterial blood pressure (Kamath et al., 2001). One or two additional large IV cannulas (preferably 20- or 18-gauge) are then

inserted in the upper extremities, either percutaneously or by surgical cutdown. The use of VVB in larger children may preclude use of the left arm for venous access. If vascular access in the arms is difficult to obtain, the lower extremities may be used, with the understanding that during the anhepatic stage, venous return to the heart depends on collateral flow or VVB. A central venous catheter is placed in the external or internal jugular vein. In smaller children, the surgeon will often insert a Hickman catheter (large-bore, double-lumen central venous line). The use of a sheath-type catheter in larger children allows the rapid infusion of large volumes of blood components and, in rare circumstances, the insertion of a flow-directed, balloon-tipped pulmonary artery catheter. Technical difficulties in placing a pulmonary artery catheter and subsequent displacement or migration by surgical maneuvers generally preclude its routine use in pediatric patients.

The patient is ventilated with a tidal volume and respiratory rate adjusted to maintain a normal end-tidal CO_2 and arterial CO_2 level of 35 to 40 mm Hg. Tidal volume and minute ventilation can be improved by using a pressure-limited mode. Air oxygen is used with an inspiratory oxygen concentration sufficient to maintain adequate oxygenation. A PEEP of 5 cm H_2O is routinely added because progressive atelectasis is common. Nitrous oxide is avoided because of its sympathomimetic effects, its propensity to cause bowel distention (which may make surgical exposure and closure of the abdomen difficult), and its limiting effect on increasing the inspiratory concentration of oxygen.

During anesthesia, all factors inducing arterial hypotension should be avoided. General anesthesia and surgery decrease hepatic blood flow and jeopardize oxygen supply to the liver. Intraoperative reductions in the arterial blood pressure and cardiac output decrease portal blood flow. Contributing factors include anesthesia drugs (inhalational anesthetics, vasodilators, β -blockers, α -1-agonists, histamine receptor-2 (H_2) blockers, and vasopressin), hypovolemia, ventilatory mode, hypoxemia, hypercarbia, and acidosis. Surgical manipulation in the right upper quadrant can reduce hepatic blood flow up to 60% from sympathetic activation or direct compression of the vena cava and splanchnic vessels. Compensatory vasodilation of the hepatic artery in response to decreased portal inflow is diminished by volatile anesthetic agents in a dosage-related manner (and absent in a denervated liver), and consequently blood flow becomes pressure dependent. Isoflurane has the least detrimental effect on hepatic blood flow. A simultaneous decrease in the liver's metabolic demand tends to balance the oxygen supply-uptake ratio. A study of hepatic circulation in pigs during surgical stress and anesthesia suggested that fentanyl and light isoflurane provided adequate hepatic oxygen supply, whereas anesthesia with concentrations of isoflurane that decreased blood pressure more than 30%, or with halothane in any concentrations studied, resulted in inadequate hepatic oxygen supply (Gelman et al., 1987). Matsumoto and colleagues (1987) examined the effects of various anesthetic agents on hepatic oxygen supply and hepatic oxygen consumption in the presence of hypoxia. Their results showed that during exposure to mild hypoxia, a dosage of isoflurane less than the minimum alveolar concentration (sub-MAC) maintained the relation of hepatic oxygen supply to hepatic oxygen consumption better than thiopental, halothane, or enflurane.

When administering drugs to patients with chronic liver disease, all dosages should be decreased and carefully titrated until the desired effect is achieved. Current practice is to administer

isoflurane alone or in combination with small dosages of fentanyl. The anesthesia management protocol used at the Children's Hospital of Pittsburgh, and the anesthesia management problems encountered during the four stages of the surgery, can be found online at www.expertconsult.com.

Physiologic Alterations during Liver Transplantation

Cardiovascular Changes

During stage I, hypotension results from major fluid shifts, bleeding, and ionized hypocalcemia (Jawan et al., 2003). Transient decreases in MAP are not unusual in this stage and result from surgical manipulation of the liver and compression of the IVC, which transiently preclude venous return to the heart. Drainage of ascites may result in hypotension if the patient is not adequately hydrated prior to incision of the peritoneum. Factors contributing to blood loss include adhesions from prior operations, coagulopathy (factor deficiency, low platelet count, abnormal fibrinogen, or disseminated intravascular coagulation), portal hypertension and collateral venous circulation, and lack of surgical hemostasis (especially a laceration to the IVC). Placement of the suprahepatic caval clamp may be associated with arrhythmia and hypoxemia because of acute right ventricular outflow tract obstruction, as the pericardium and a portion of the RV may be included in the clamp. Hypotension that is unresponsive to IV pressors should raise suspicions of absolute or relative hypovolemia (limited preload caused by vascular clotting or torsion of the liver on its vascular pedicle), acidosis, sepsis, or vasoparesis.

During stage II, classic OLT requires a trial of portal vein and IVC clamping. The hemodynamic response is characterized by a decrease in cardiac output, CVP, and PAP and compensatory increase in heart rate and SVR (Eyraud et al., 2002). Hemodynamic instability may result from decreased venous return (modified by VVB or piggyback technique) and insufficient physiologic compensation by the patient for this acute change. Therapeutic strategies include colloid or crystalloid boluses, and vasopressor support with dopamine or norepinephrine (phenylephrine or epinephrine). The goal is to maintain the lowest filling pressures compatible with an acceptable MAP in anticipation of an increase in PAP with removal of the caval and portal vein clamps. Pulmonary hypertension may result because of an increase in venous return from the gut and lower extremities and reactive changes in PVR with the release of vasoactive hormones that are recirculated systemically. The donor liver is flushed with crystalloid or colloid, or by backwashing (backflushing) the liver. The procedure for backwashing involves insertion of a red rubber cannula into the recipient/donor IVC, and then removal of the clamp from the portal vein allows washing of the liver with autologous blood retrograde from the portal vein through the donor liver, exiting through the cannula into a stainless steel graduated cylinder. If the patient become immediately and dramatically hypotensive, the surgeon must be notified immediately. Hypotension associated with this maneuver can be ameliorated with the prophylactic administration of phenylephrine or epinephrine boluses, gentle fluid administration, or transfusion of packed RBCs if the hematocrit is low. The elimination of air bubbles, hyperkalemic preservation solution, hormones, or other "evil humors" has been credited for decreasing the incidence, in adult patients,

of subsequent reperfusion syndrome that may occur with reperfusion of the liver (Fukuzawa et al., 1994). The goal for warm ischemia time is usually less than 60 minutes, so managing hypotension and preparing for reperfusion occurs over a relatively short period. Reactivation of HCV has been shown to be less if the warm ischemia time can be kept under 35 minutes, which shortens the target time for completing this portion of the operation even further (Clavien et al., 2004).

During stage III, profound hemodynamic instability may occur immediately after graft reperfusion. This instability includes severe hypotension, bradycardia, supraventricular and ventricular arrhythmias, variable cardiac output, and occasionally cardiac arrest (0% to 0.5%). These changes are caused by recirculation of the residual cold, acidotic, hyperkalemic preservation solution from the donor liver directly into the recipient's heart. The incidence of this postreperfusion syndrome (defined as a decrease in MAP and heart rate > 30% from baseline for at least 1 minute within 5 minutes of reperfusion) in adults may be as high as 30%, and epinephrine boluses are usually required to prevent cardiovascular collapse (Aggarwal et al., 1987). Immediately after reperfusion, LV function may be impaired, and PCWP, CVP, and PAP usually increase with a major decrease in SVR, and transesophageal echocardiogram (TEE) monitoring shows a stable or even decreased LV end-diastolic volume. These contradictory findings may be result from a period of deteriorated LV compliance, or cardioplegia, on reperfusion (Suriani et al., 1996; De Wolf, 1999). The etiology of PRS remains unclear, but it may be caused by the release of vasoactive mediators from the ischemic liver or decompressed portal circulation, changes in the rate of venous return (volume overload), and perhaps an increase in serum potassium. Possible mediators that are highly suspect include nitric oxide and tumor necrosis factor- α , with demonstrably increased levels after graft reperfusion (Nishimura et al., 1993), and xanthine oxidase, a generator of cytotoxic oxygen radicals, which may produce myocardial dysfunction and cellular damage. Vasoactive drugs for pressor support (norepinephrine, epinephrine, dopamine) may be required, and a balance is reached between a lowered MAP and often a very low SVR permitting increased flow to perfusable organs at a lower perfusion pressure. High filling pressures should be avoided, as they may cause congestion of the donor liver, bleeding from surgical sites, and biventricular dysfunction with pulmonary edema. Therapies for reducing filling pressures include limiting IV infusions, furosemide-induced diuresis, vasodilation (IV nitroglycerine or morphine), nitric oxide, or prostaglandin E₁.

Blood Loss, Coagulation, and Hemostasis

During liver transplantation surgery, the effects of fibrinolysis, thrombocytopenia, decreased coagulation factors, and fibrinogen deficiency on clinical bleeding are not always predictable, and transfusion requirements are variable. Portal hypertension with fragile venous collaterals, adhesions from prior operations, and lack of surgical hemostasis contribute to blood loss. Independent predictors of increased transfusion requirements include the severity of liver disease or Child-Pugh classification (especially for those hospitalized for inpatient support), preoperative PT, history of abdominal operations, preoperative hematocrit, and factor V levels. In addition, portal vein hypoplasia, the use of a reduced-size liver graft, and increased operative time make surgery technically challenging (Ozier et al., 1995;

Maurer and Spence, 2004). Usually, the greatest operative blood loss occurs during vascular dissection and the hepatectomy phase (stage II). During this stage, there is a progressive degradation of the coagulation cascade, and a dilutional coagulopathy with a progressive thrombocytopenia. The blood loss can range from 0.5 to 25 times the patient's blood volume (Borland et al., 1985).

Alterations of coagulation in the pediatric patient during OLT have been studied (Kang et al., 1989). Classic hourly monitoring of the PT, activated PTT (aPTT), and platelet counts demonstrates a progressive prolongation of the PT and PTT, as well as a significant decrease of all clotting factors. On graft reperfusion, there may be profound prolongation of the PTT, usually to greater than 100 seconds. Besides the standard coagulation tests (PT, aPTT, fibrinogen, platelets, and D-dimer), the thromboelastogram (TEG) and Sonoclot (coagulation and platelet function analyzer) are used in the evaluation of coagulation. The TEG is performed using whole blood; it assesses clot formation until an endpoint of clot lysis or retraction is determined. TEG findings have correlated with clinical bleeding and can assist in treating intraoperative hemorrhage by identifying the cause of the bleeding diathesis (factor deficiency, fibrinolysis, heparin effect, thrombocytopenia, or platelet dysfunction) (Zuckerman et al., 1981; Kang, 1986) (Fig. 28-6). Abnormalities of the reaction time (r), the alpha angle (a), or the maximum amplitude (MA) may indicate decreased clotting factors, diminished factor VIII and fibrinogen, or diminished platelet function or number, respectively (Kang et al., 1989). In contrast, a short reaction time is indicative of a hypercoagulable state. This has occasionally been observed in patients who have developed thrombosis after graft reperfusion (Kang, 1995a, 1995b; Gologorsky et al., 2001; Planinsic et al., 2004).

Increased fibrinolytic activity is observed in patients with ESLD as a result of increased tissue plasminogen activator activity and reduced synthesis of fibrinolysis inhibitors. Tissue plasminogen activator further increases during the anhepatic stages and peaks immediately after graft reperfusion. Various antifibrinolytic agents have been used to counter this accelerated fibrinolysis (evident immediately on graft reperfusion in up to 80% of patients), but their precise role remains undefined. These include aprotinin, ϵ -aminocaproic acid (EACA), and tranexamic acid. Aprotinin, a serine protease inhibitor that prevents the lysis of fibrinogen by inhibiting plasmin, kallikrein, and leukocyte elastase, is no longer available. EACA (Kang et al., 1987) and tranexamic acid prevent fibrinolysis by inhibiting plasminogen and plasmin, thus preventing the eventual degradation of fibrin. In addition, a significant heparin effect may be seen immediately on graft reperfusion for up to 30 minutes. This effect is caused by the release of endogenous heparinoids from the liver, as well as residual heparin from the preservation solution. Calcium is an important coenzyme in the coagulation cascade. During the dissection and anhepatic phases of liver transplantation, hypocalcemia may develop, especially when large amounts of fresh frozen plasma have been given. In many transplantation centers, continuous calcium infusions and magnesium supplements are routine therapy.

The approach to blood product replacement in children differs from that in adults because of two important concerns: thrombosis of the hepatic artery and postoperative hypercoagulability. Thrombosis of the hepatic artery is the most common serious complication after liver transplantation in children, so less fresh frozen plasma and platelets are routinely administered.

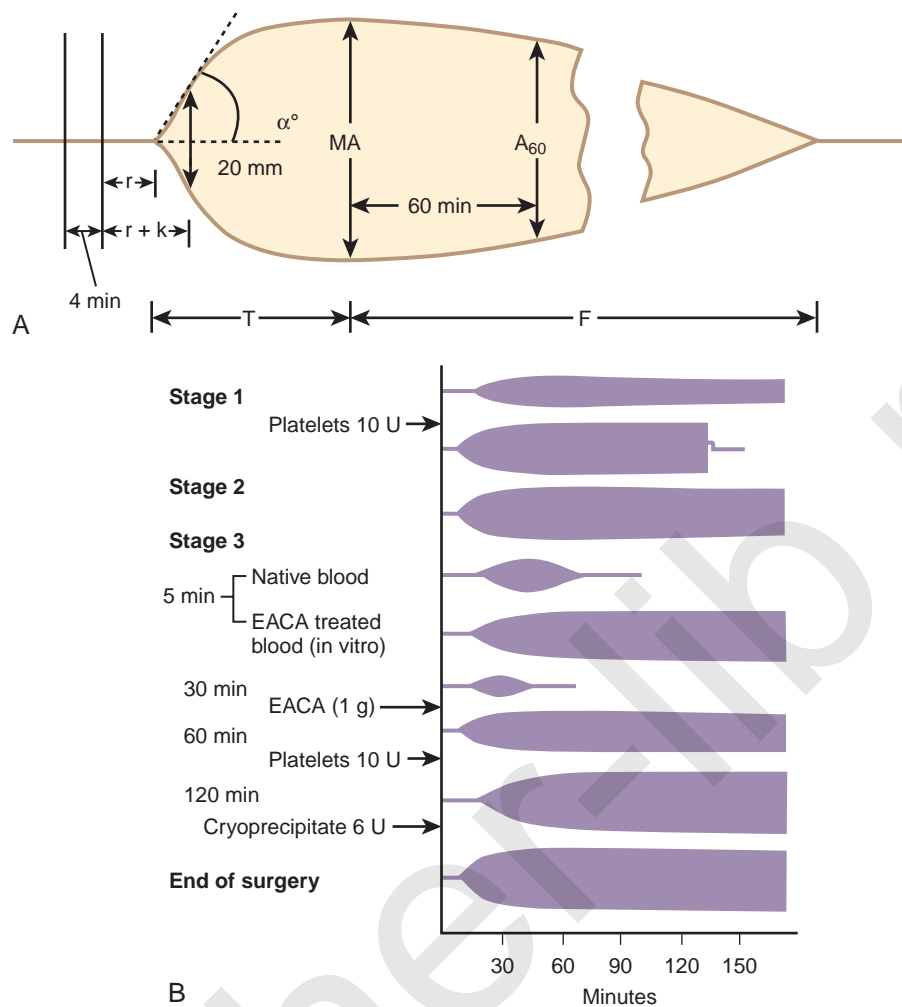

FIGURE 28-6. Thromboelastogram (TEG). **A**, The normal parameters measured and analyzed for interpretation of the TEG. **B**, The coagulation alterations noted during OLT. Note the elements of low platelets (and the improvement in the maximum amplitude after administration of platelets), and the development of fibrinolysis, which is treated by ϵ -aminocaproic acid (EACA) and detected early on the TEG (at the time of graft reperfusion). Also, the diminished alpha angle in stage 3 is treated with administration of cryoprecipitate, with noted improvement of coagulation. (From Kang Y, Gelman S: *Liver transplantation*. In Gelman S, editor: *Anesthesia and organ transplantation*, Philadelphia, 1987, Saunders, pp 139–185.)

After reperfusion, the hematocrit should ideally be maintained at 20% to 30% to minimize the increase in blood viscosity and to limit the risk for thrombotic complications (Tisone et al., 1988). Children may be at greater risk for hepatic artery thrombosis than adults because their arteries are smaller, and because of their postoperative hypercoagulable state (Heffron et al., 2003). The incidence of hepatic artery thrombosis has been reported in 15% of the mixed-age; pediatric series (Otte et al., 1990); however, it appears to be directly related to the size of the hepatic artery (smaller arteries and livers from neonates or infants having a higher incidence of this complication) (Mazzaferro et al., 1989; Jurim et al., 1995; Mas et al., 2003; Martin et al., 2004) and to technical complications during the vascular reconstruction. When a split liver is used, thrombosis is relatively rare (5% to 8%) and is similar to the adult rate (Gridelli et al., 2003). Thus, in some institutions, aggressive correction of coagulation is pursued only when there is diffuse bleeding after graft reperfusion or if monitoring reveals fibrinolysis that was not reversed by the new liver. Many transplantation centers use normalization of the PT and platelet count as indicators of recovery of donor

liver graft function. Persistent hypothermia, coagulopathy with bleeding, increased serum lactate, hypocapnia, hyperkalemia, acidosis, absence of bile production, hyperglycemia, renal insufficiency, and hemodynamic instability may suggest suboptimal graft function.

After liver transplantation in children, levels of protein C and antithrombin III decrease to below 50% of normal and stay there for 10 days. These prolonged decreases are not seen in adults. Immediately after surgery, a 10-fold increase in plasminogen activator inhibitor occurs, with a further increase 6 to 9 days later. Therefore, in the immediate postoperative period, between days 4 and 10, children are at increased risk for thrombosis (Harper et al., 1988). To minimize this, anticoagulation therapy has been administered (IV heparin, dextran 40, aspirin, and antithrombin III) (Abengochea et al., 1995). There are also differences in coagulation between the infant and adult. In the normal neonate, there is a deficiency of vitamin K–dependent clotting factors (II, VII, IX, X) for several weeks. Protein C is significantly reduced for at least 6 months (Andrew et al., 1987), and protein S concentrations do not increase to within the

normal adult range until 3 months of age (Donaldson et al., 1991). Protein C inhibits the function of factors VIII and V and enhances fibrinolysis, which is enhanced by protein S.

When the child's body weight is greater than 20 kg, use of the rapid infusion system facilitates the rapid replacement of blood products. In this instance, however, blood product replacement is similar to that for an adult. A unit each of RBCs and fresh frozen plasma, and 250 mL of either normal saline solution or neutral pH balanced salt solution (Plasmalyte) is mixed in the cardiotomy reservoir of the rapid infusion system. This mixture mimics whole blood with a hematocrit of 28% to 30%. Blood replacement may occur at a rate of up to 1500 mL/min if needed.

Hypothermia and hypocalcemia are known to contribute to coagulopathy (Kang, 1995a), and they affect platelet function and increase the incidence of fibrinolysis. Thus, temperatures below 35°C are best avoided. Finally, cell salvage may be beneficial in the patient undergoing OLT. Blood recovery of up to 30% is expected, but the need for rapid volume replacement limits its use. In addition, the use of the cell saver is contraindicated in patients with viral or bacterial infections, tumors, or FHF without an identifiable cause of the liver failure. Massive blood transfusion has an associated morbidity of more frequent bouts of sepsis, a prolonged stay in the intensive care unit (ICU), a higher rate of severe CMV infection, and higher rates of graft failure and patient mortality (Maurer and Spence, 2004).

Metabolic Function

Hepatic failure can result in impairment of numerous complex metabolic functions that may significantly impact anesthesia care. The liver plays a critical role in maintaining a normal blood glucose level; hypoglycemia frequently results from failure of gluconeogenesis, insufficient insulin degradation, and a depletion of glycogen stores. Most patients with chronic liver disease are undernourished, and fat stores are diminished with impairment of lipid transport and the integrity of cellular membranes.

Altered Glucose Metabolism

Hypoglycemia is rarely seen except in patients who present with acute FHF or have exhausted their liver glycogen stores. Patients may also be at risk during catecholamine infusions or if they require insulin for the management of hyperkalemia. During the anhepatic phase, several sources of glucose are available to the patient, such as packed RBCs (which contain a significant amount of free glucose: 84 mg/dL by day 35 of storage) (Miller, 2000), 5% dextrose in water (D₅W, used as a carrier for drug infusions), and IV methylprednisolone (used for induction of immunosuppression during the portal anastomosis). Hyperglycemia after graft reperfusion is common because of glucose release from ischemic hepatocytes, steroid-induced insulin resistance, and decreased glucose metabolism in hypothermic patients (DeWolf et al., 1987). Thus, hourly monitoring of blood glucose levels is essential (Fig. 28-7).

Acute Ionized Hypocalcemia and Hypomagnesemia

Ionized hypocalcemia results from the rapid transfusion of large volumes of blood products containing citrate, especially during periods of hypothermia and acidosis. Citrate chelates calcium and magnesium and other divalent cations. Hypotension is the usual consequence and becomes significant at an ionized calcium level

FIGURE 28-7. Glucose levels during liver transplantation, as plotted against time. Mean and standard deviation (SD) values are shown. Shaded area represents the anhepatic phase. (From Borland LM, Roule M, Cook DR: *Anesthesia for pediatric orthotopic liver transplantation*, *Anesth Analg* 64:117, 1985.)

FIGURE 28-8. Changes in magnesium and citrate levels during liver transplantation.

of 0.56 mmol/L, at which point the patient may develop cardiovascular collapse (Marquez et al., 1986; Martin et al., 1990).

The consequence of acute ionized hypomagnesemia (Scott et al., 1996) is not yet apparent, but it may result in a higher incidence of atrial arrhythmias and decreased myocardial contractility (Fig. 28-8).

Replacement of calcium is effective with either calcium chloride or gluconate in equivalent calcium dosages. Administration of calcium chloride in the central catheter may result in transient arrhythmia, but deposition into tissues from an extravasated peripheral catheter will result in severe tissue necrosis. The recipient routinely receives sodium bicarbonate and calcium chloride about 1 minute before reperfusion to counteract anticipated hyperkalemia and hypotension.

Hypokalemia

Hypokalemia is the norm in chronic liver failure. It results from the use of diuretics, altered aldosterone metabolism, and

metabolic alkalosis. If ventricular arrhythmias are noted during stages I and II, magnesium replacement is recommended. Potassium replacement is avoided because there is an expected transient twofold to threefold increase in potassium concentration immediately on graft reperfusion. Hypokalemia is common after graft reperfusion, usually as a result of diuresis, receptor stimulation with epinephrine, and uptake of potassium by the new liver (Xia et al., 2006). Cautious replacement during the biliary reconstruction phase is appropriate if the patient has no preexisting renal insufficiency and has evidence of adequate urine output.

Hyperkalemia should be treated aggressively at any point during the surgery. This electrolyte disturbance usually results from massive transfusion of RBCs, which have an estimated potassium content of 76 mEq/L by day 35 of cold storage, or from renal failure (Miller, 2000). The judicious use of diuretics as well as an infusion of glucose and insulin may be of benefit in reducing the potassium load (De Wolf et al., 1993). This is most crucial before revascularization of the donor liver. Postreperfusion hyperkalemia (7 to 12 mEq/L) is transitory, with redistribution occurring in 1 to 2 minutes, which seldom needs pharmacologic intervention other than prophylactic sodium bicarbonate and calcium intravenously (Nakasuji and Bookallil, 2000). Washed RBCs prevent the further development of this problem. When hyperkalemia is life threatening, the use of venovenous hemofiltration or removal of part of the patient's blood volume and washing by the cell saver may be beneficial.

Metabolic acidosis is progressive during OLT and peaks during graft reperfusion. It results from transfusion of blood products and becomes accentuated during the anhepatic stage when liver metabolism of citrate, lactate, and other acids is absent. Whether tissue hypoperfusion is a contributing factor remains unclear; however, this should be balanced by the fact that overall body oxygen consumption is reduced during the anhepatic stage. The threshold for bicarbonate administration is a base deficit (<5 mEq/L). Associated morbidity includes hypernatremia, hypercarbia, and hyperosmolality. Acidosis usually resolves after reperfusion of the graft. Sodium bicarbonate should be administered as indicated and any ongoing problem identified (poor perfusion with lactic acidosis, or delayed primary function or nonfunction of the graft). Metabolic alkalosis is common postoperatively as a result of diuretic therapy and metabolism of citrate or lactate. This may delay weaning of the patient from mechanical ventilation, but it is another useful marker of resumption of hepatocellular function.

Hyponatremia and Hyperosmolality

Dilutional hyponatremia is common and worrisome at serum sodium levels less than 125 mEq/L. Central pontine myelinolysis (CPM) is a frequently symmetric, noninflammatory demyelinating disorder in the brainstem pons. In at least 10% of patients, demyelination also occurs in extrapontine areas. Clinical manifestations are postoperative confusion or weakness, or a "locked-in" syndrome, after transplantation (Estol et al., 1989; Wszolek et al., 1989). The most frequent findings are delirium, pseudobulbar palsy, and spastic quadriplegia, which may result in permanent neurologic deficits. CPM occurs inconsistently as a complication of severe and prolonged hyponatremia, particularly when the sodium is corrected too rapidly. A study by Singh and coworkers (1994) demonstrated that CPM was present in 29% of postmortem examinations of

adults after liver transplantation. Risk factors included serum sodium less than 120 mEq/L for more than 48 hours, aggressive IV fluid therapy with hypertonic saline solutions, and hypernatremia during treatment.

Empirical data show that CPM is likely to occur when the total perioperative increase in sodium concentration is above 15 to 20 mEq/L (Estol et al., 1989; Yu et al., 2004). In these patients, the choice of crystalloid solution should be Plasmalyte or 0.45% NaCl. Hyperosmolality has also been considered a contributor to the development of CPM. In the presence of either of these metabolic derangements, the judicious use of tris(hydroxymethyl)aminomethane (THAM) is recommended because its osmolality is 308 mOsm/L, whereas that of sodium bicarbonate is 2000 mOsm/L. In addition, the sodium content of bicarbonate buffer is 8.4% compared with 0.9% NaCl in IV solutions.

Temperature Regulation

Surgical procedures that place these patients at risk for unintentional hypothermia involve exposure of large skin, serosal, and mucosal surfaces during lengthy procedures under general anesthesia in a cold operating room, especially with no humidification of gases and with infusion of cold IV fluids. The most significant contributors to hypothermia in the pediatric patient undergoing OLT are radiant and evaporative heat losses. In addition, the use of VVB may result in a temperature loss of 0.5° to 1.0° C when a heat exchanger is not used. Preservation of the donor liver depends on rendering the organ metabolically inert by reducing the core temperature to 4° C with cold preservation techniques. To further extend this cooling period while performing the vascular anastomosis in the recipient, the liver may be wrapped in cold compresses or ice, which will further reduce the core temperature of the patient. With reperfusion, a hypothermia-induced cardiac arrhythmia and arrest may result if the perfusate of the liver is allowed to further cool the sinus node. Modest hypothermia (to 35° C) is well tolerated with minimal effects on coagulation, but platelet dysfunction, fibrinolysis, and bleeding begin to increase in a linear fashion as the core temperature decreases. Mild hypothermia may be beneficial, as a reduction in metabolic oxygen requirements may limit warm ischemia and cerebral and myocardial injury. In pediatric patients, the detrimental physiologic effects of mild hypothermia (32° to 35° C) and the increased risk for infection clearly outweigh these minimal benefits.

Attention should be directed to aggressively maintaining a normal body temperature. This may be achieved by using forced-air warming (Bair Hugger) or raising the ambient temperature of the operating theater. In addition, protective barriers should be strategically placed to prevent the operating room table from becoming wet, because this will result in conductive cooling of the patient. Heating of the humidified gases is also an important maneuver. In some cases, intraperitoneal lavage with warmed irrigation after the completion of the arterial anastomosis can be undertaken to assist in warming. Concerns about hypothermia should be communicated with the surgical team, as hypothermia-induced coagulopathy can result in unnecessary nonsurgical hemorrhage, and time spent in warming maneuvers could result in reduced blood loss and improved hemostasis. In the patient receiving Compath, however, hyperthermia is the norm. In this instance, care should be taken to

avoid temperatures of 38° C or higher, as this may serve to augment ischemic reperfusion injury of the graft.

Pulmonary Function

Hypoxemia is common in pediatric patients with ESLD because ascites and pleural effusions cause a decrease in FRC and total lung capacity, impaired diffusion capacity, and pulmonary arteriovenous shunting. After the induction of anesthesia, difficulties in ventilation and oxygenation may occur, and diaphragmatic paralysis can result in an acute restrictive lung effect. The increased alveolar-arterial oxygen gradient usually improves after the abdominal cavity is opened. If relative hypoxemia persists, other causes of venous admixture should be sought.

Factors that may worsen oxygenation during the surgical procedure include clot or air emboli, progression of ARDS, transfusion-related acute lung injury, HPS, and pulmonary edema from excessive fluid administration. Finally, extubation of the patient at the end of the procedure is not recommended, no matter how short the duration of the surgery, because 50% to 55% (McAlister et al., 1993) of patients develop right diaphragmatic paralysis postoperatively and 25% will have pleural effusions, which compromise pulmonary function. The fast-track approach to anesthesia care may reduce the requirement for postoperative mechanical ventilation, but it does not reduce the length of stay in the ICU after liver transplantation (Findlay et al., 2002).

Renal Function

Renal insufficiency, a common finding in patients undergoing OLT, contributes significantly to postoperative morbidity, and it is an independent predictor of postoperative mortality (Gonwa, 2005). The patient who comes to the operating room with hepatorenal syndrome or ATN should not be expected to show improvement of renal function until after the graft functions (McCauley et al., 1990). Information collected by the National Institute of Diabetes and Digestive and Kidney Diseases Liver Transplantation Database support the conclusion that renal insufficiency in patients with FHF and in those requiring preoperative dialysis or liver-kidney transplantation for cirrhosis predicts lower posttransplantation patient and graft survival rates (Brown et al., 1996).

A progressive decline in urine output is expected, with little or none during the anhepatic portion of the surgery without preservation of the IVC or use of VVB. This physiologic alteration has been thought to be secondary to congestion of the kidneys from increased renal venous pressures with total cross-clamping of the infrahepatic IVC (Gunning et al., 1991). Whether the incidence of postoperative renal insufficiency is as frequent when the piggy-back technique is used remains unclear. Thus, the judicious use of the diuretics (mannitol and furosemide) is recommended in the patient who develops oliguria (Polson et al., 1987). It should be noted that furosemide may be ineffective in the patient with a low albumin level (average albumin in the patient with liver failure for OLT is 2.5 to 1.8 mg/dL). Although a renal dosage of dopamine not exceeding 1.5 mcg/kg per min is often recommended, there is no clear benefit from its use as a renal protective agent (Polson et al., 1987; Gray et al., 1991; Swygert et al., 1991; Kellum and Decker, 2001). The incidence of renal complications postoperatively in all patients

undergoing OLT remains the same with or without the use of VVB or diuretic therapy (Schwarz et al., 2001; Cabezuolo et al., 2003). Acute renal insufficiency is estimated to occur after liver transplantation in up to 67% of recipients (Rimola et al., 1987). Contributing factors include preexisting renal insufficiency, intraoperative complications (suboptimal renal perfusion associated with hypotension, massive transfusion, increased caval pressures), early graft dysfunction, sepsis, and administration of cyclosporine or tacrolimus and other nephrotoxic drugs in the immediate posttransplantation period.

Graft Reduction and Split-Liver Transplantation

With the plateau in organ availability in the past 5 years and the increased number of indications for OLT, creative techniques have been developed to increase organ availability to pediatric patients. Three techniques, living related (see Living Related Organ Donor, p. 900), split livers, and graft reduction, now account for up to 30% of all pediatric OLTs in some centers. See related video online at www.expertconsult.com.

Reduced-size liver transplantation (graft reduction) was first performed by Bismuth and Houssin (1984; Broelsch et al., 1988). This procedure involves the dissection of the graft at the back table with preparation of either the right lobe, the left lobe, or the left-lateral segment graft, depending on the size of the recipient. With a recipient-to-donor size ratio of 1:2, a right lobe graft is chosen. Similarly, if the recipient-to-donor size ratio is 1:4 or 1:8 (Thistlethwaite et al., 1991), a left lobe graft or a left-lateral segment graft is chosen, respectively. Because this technique, as with split livers, requires the preparation of the graft at the back table, it lends itself to an increased cold ischemic time of the liver. Vascular anastomoses for this procedure are usually of the end-to-end type, with the occasional need for a piggy-back technique or the direct anastomosis of the hepatic veins to the vena cava.

In split-liver transplantation, the liver is divided into left and right lobes and transplanted into two recipients (Emond et al., 1990; Otte et al., 1990; Renz et al., 2004) (Fig. 28-9). As a result, the right lobe contains the portal vein, hepatic artery, IVC, and common bile duct, and the left lobe includes the left lobar branches of the vessels and the left hepatic duct. Transplantation of the left lobe may necessitate the use of interposition vascular grafts, whereas the right lobe is transplanted in a fashion similar to that used for the whole organ. Most frequently, biliary reconstruction is by the Roux-en-Y technique because of the size discrepancy of the donor and recipient bile ducts.

Living related liver transplantation from parent to child, described in 1989 by Broelsch and coworkers (1991), has the potential advantages of increasing the availability of organs, reducing the waiting times and deaths on the recipient waiting list, allowing medical optimization of the recipient while minimizing the risk for clinical deterioration, and limiting immunosuppressive therapy by decreasing the immunogenicity of the transplanted organ. In addition, societies whose criteria for death differ from those previously described (Tanaka et al., 1993) are now able to offer organ transplantation in a socially acceptable manner. Until 1998, the majority of all living donor grafts in the United States went to children under 1 year of age. Living donation is not without risk. Mortality among healthy donors is low, but complications in the donor are relatively common. These findings then raise the issues of safety and ethics. Potential risks to the donor include transfusion complications,

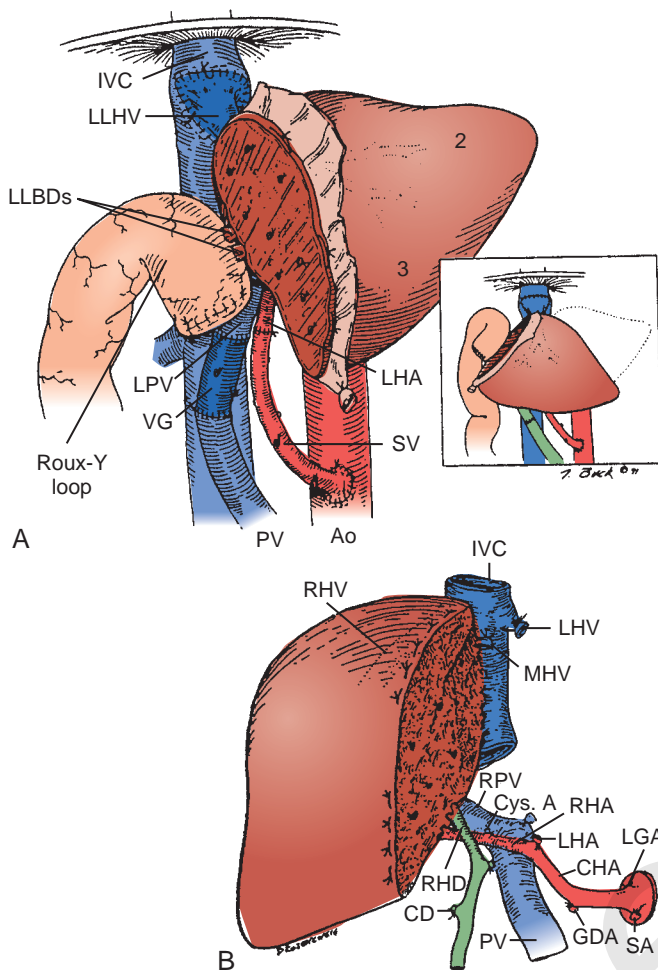

FIGURE 28-9. A and B, Split-liver transplantation. Demonstrated here is the use of either a right (**B**) or left (**A**) hepatic lobe. Note that the right lobe retains the native donor IVC, whereas the left lobe is connected to the recipient IVC by the use of the left hepatic vein. (**A**, From Broelsch CE, Whittington PF, Emond JC, et al.: *Liver transplantation in children from living related donors*, *Ann Surg* 214:428, 1991; **B**, From Broelsch CE, Emond JC, Thistlewaite JR, et al: *Liver transplantation, including the concept of reduced-size liver transplants in children*, *Ann Surg* 208:410, 1988.)

biliary complications, negative psychosocial aspects (out-of-pocket expenses, loss of income, stress on the donor and donor family, change in body image, inability to work for at least 4 to 8 weeks after donation, and poor recipient outcome), and death. Up to 20% of donors experience complications related to major abdominal surgery, including pneumonia, atelectasis, wound infection, small-bowel obstruction, incisional hernia, pressure ulcers, phlebitis, neuropraxia or peroneal nerve palsy, and reoperation. Until 1994, all living-donor liver transplantations were performed with a left-lateral segmentectomy of one or more lobes, or with a left lobectomy (20% of liver) from parent to child, or adult to small adult. Adult-to-adult transplantation of the right hepatic lobe (60% of liver) was first reported in Japan in 1994. An estimated 5% of patients on the transplant waiting list would be able to identify a suitable donor, resulting in approximately 750 living-donor liver cases in the United States each year. Adult-sized pediatric patients undergoing adult-to-adult living-donor liver transplantation may require a

right hepatic lobe to provide sufficient liver mass for the recipient. The donor is left with approximately half or less of their hepatic mass after hepatectomy, but because of the large functional reserve of the liver and its regenerative capacity, clinical evidence of hepatic insufficiency is rare. Prolonged PT, elevated serum aminotransferase levels, and increased bilirubin levels normalize after 1 week. The donor's native liver can regenerate to its original size within several weeks. The greatest concern for donor safety is the risk for donor death, which has been estimated to be between 0.28% and 2% to 3%, with ten reported cases caused by technical errors, sepsis, and pulmonary embolism (Hayashi and Trotter, 2002; Trotter et al., 2002). The actual mortality rates are probably higher than those reported.

All three of these techniques have associated complications, with split-liver grafts having the highest rates of associated complications and mortality. Because the integrity of the transected surface of the liver cannot be fully assessed until after reperfusion of the graft, these procedures have a greater associated blood loss than whole organ transplantation (Moreno et al., 1991). In addition, bile duct leaks and seroma formations are not uncommon in the transected liver. Although this specific complication was initially associated with split-liver transplantations, alterations of the surgical techniques have resulted in bile leak complications similar to those seen with reduced-size liver transplantation.

The incidence of hepatic artery and portal vein thrombosis is clearly reduced with the use of these three techniques. Survival of grafts and of patients at 1 year is better after living related liver transplantation (81%) (Epstein, 1985) than after split-liver transplantation (67%) (Broelsch et al., 1991). However, overall 5-year survival rates with all these procedures are similar.

Outcomes

In the 2006 report from Studies of Pediatric Liver Transplantation, Ng and colleagues (2008) reported on a cohort of 5-year survivors for whom the 1- and 5-year Kaplan Meier estimates of survival rates were 89.8% and 84.8%, respectively. Among the 5-year survivors, first allograft survival rates at 1, 3, and 5 years were 93%, 90%, and 88%, respectively. There was no difference in graft survival by donor type (Figs. 28-10 and 28-11). However, Diamond and colleagues (2007) reported that graft survival in 2192 children undergoing liver transplantation was decreased, and the relative risk for graft loss was increased in all of the technical variants compared with whole-organ recipients (Table 28-19, and Figs. 28-12 and 28-13). Survival also appears to be influenced by the underlying disease (Fig. 28-14).

Early studies in children undergoing OLT for a variety of conditions reported that infants less than 1 year of age had lower graft and patient survival rates than older children. However, recent trends suggest that survival rates for younger patients now approach those for older children. In children undergoing OLT for metabolic reasons, 1-, 5-, and 10-year survival rates for children older than 1 year were better than for children less than 1 year of age (Sze et al., 2009).

In a single-center study of 638 children receiving 745 grafts, Bourdeaux and coworkers (2009) noted in their 21-year experience that single liver transplantations had 5- and 10-year patient survival rates of 86% and 85%, respectively, versus 66% and 61% for recipients who needed to be retransplanted. Not

(From Ng VL, Fecteau A, Shepherd R, et al: Outcomes of 5-year survivors of pediatric liver transplantation: report on 461 children from a North American multicenter registry, *Pediatrics* 122:e1128, 2008.)

FIGURE 28-11. Kaplan-Meier probability of first allograft survival by graft type among 5-year survivors of pediatric liver transplantation. (From Ng VL, Fecteau A, Shepherd R, et al: Outcomes of 5-year survivors of pediatric liver transplantation: report on 461 children from a North American multicenter registry, *Pediatrics* 122:e1128, 2008.)

surprisingly, these authors also noted that the era in which the child received the transplant also affected survival. Patients recently transplanted had better survival rates and less need to be retransplanted than patients who received their transplant in an earlier era (Fig. 28-15). The rate of retransplantation was less (3%) for patients who received a living-donor graft than for children who received a whole (15%), reduced-size (20%), or split (12%) liver at first transplantation (Bourdeaux et al., 2009).

TABLE 28-19. Multiple Variable Predictors of Graft Loss

Factor	A	B	Relative Risk*	95% Confidence Interval
Graft type	Whole	Split	1.74 [†]	1.17-2.58
		Reduced	1.77	1.30-2.41
	Live donor	1.19	0.77-1.84

FIGURE 28-12. Kaplan-Meier probability of patient survival after pediatric liver transplantation. (From Diamond ER, Fecteau A, Millis JM, et al: Impact of graft type on outcome in pediatric liver transplantation, *Ann Surg* 246:305, 2007.)

With improved outcomes, the population of survivors has grown, and the number of survivors is more than 10-fold greater than the number of children and adolescents who undergo liver transplantation each year (Ryckman et al., 2008). Thus, the study of outcomes should focus on the side effects of immunosuppression and on quality of life issues, in addition to patient and graft survival and surgical technical issues.

Hepatic artery thrombosis (HAT) and portal vein thrombosis (PVT) are the most common vascular complications after liver transplantation, reported to occur after 4% to 15% of liver transplantations, and more frequently after pediatric liver transplantations. Factors associated with HAT include dissection of the hepatic arterial wall, technical imperfections, celiac stenosis, aberrant donor or recipient arterial anatomy, complex back-table arterial reconstruction, and organ rejection (Duffy et al., 2009). In pediatrics, type of organ graft, whole versus split, and deceased versus living donor, as well as age less than 1 year, also affect the incidence of HAT. Overall, HAT decreases both patient and graft survival.

FIGURE 28-13. Kaplan-Meier probability of graft survival pediatric liver transplantation. (From Diamond ER, Fecteau A, Millis JM, et al: *Impact of graft type on outcome in pediatric liver transplantation*, Ann Surg 246:305, 2007.)

FIGURE 28-15. Patient survival after retransplantation according to transplant era, in a series of 638 pediatric liver recipients transplanted between March 1, 1984, and December 31, 2005. The rate of retransplantation decreased from 18% to 6% between 1984 and 2005 ($P = .1218$). (From Bourdeaux C, Brunati A, Janssen M, et al: *Liver retransplantation in children: a 21-year single-center experience*, Transplant Int 22:416, 2009.)

FIGURE 28-14. Kaplan-Meier survival curves of 376 pediatric primary liver allograft recipients who survived more than 3 months after transplantation. Survival in patients undergoing transplantation for malignancy was significantly lower than in the children undergoing transplantation for other diseases ($P < .0001$). (From Wallot MA, Mathot M, Janssen M, et al: *Long-term survival and late graft loss in pediatric liver transplant recipients: a 15-year single-center experience*, Liver Transpl 8:615, 2002.)

PVT occurs about 2% of the time but is usually more detrimental to patient and graft survival. As with HAT, pediatric patients are at greater risk than adult patients. Risk factors for PVT include small portal vein size, portal vein redundancy, pretransplantation PVT, and prior splenectomy (Duffy et al., 2009). Type of graft may also influence the incidence (Diamond et al., 2007). Life-long immunosuppression with reduction in therapy remains the practice. Thus, immunosuppression balances the preservation of graft function with its side effects. Posttransplant lymphoproliferative disease occurs in 3% to

28% of children after liver transplantation. Nephrotoxicity is a well-known complication of the immunosuppressive agents. Chronic renal disease increases with increased survival. Renal insufficiency was reported as 33% and 77% in 3- and 10-year survivors, respectively (Starzl and Kaupp, 1960).

Growth is also adversely affected by both disease and immunosuppressive therapy. In children, approximately 73% were below average in height and 29% below the 10th percentile (Ng et al., 2008). Quality-of-life issues for children frequently focus on school performance. Ng reported that almost 18% of 5-year survivors had either repeated a grade or been held back more than one school year. Learning disabilities were reported in 21% of 5-year survivors.

MULTIVISCERAL AND INTESTINAL TRANSPLANTATIONS

Liver, multivisceral, and small bowel transplantations have now become widely accepted therapies for organ failure of the abdominal viscera. Small bowel transplantation has gained recognition as an acceptable therapy for intestinal dysfunction of various etiologies. As of 2010, 1091 intestinal transplantations have been performed in patients of all ages.

The technical feasibility of intestinal transplantation was first described in 1905 by Alexis Carrel (1905). After early successes with kidney transplantation in identical twins during the early 1960s, Lillehei and colleagues (1967) described experimental transplantation of the stomach, intestine, and pancreas.

Simultaneously, Starzl and colleagues described transplantation of multiple abdominal viscera in dogs and, many years later, in humans (Starzl et al., 1989). Until the late 1980s, there were no long-term (>6 months) survivors of small bowel transplantation (SBT). With the introduction of cyclosporine and tacrolimus, and with an improved understanding of graft rejection in pigs, successful long-term survival became possible (Grant et al., 1990). This procedure has a high rate of morbidity and mortality. The major cause of graft failure is acute or chronic rejection (SBT, 79%; small bowel in combination with liver transplantation [SB/LT], 71%; multivisceral transplantation, 56%). Infection, CMV enteritis, lymphoproliferative disease, and multisystem organ failure are major causes of death. The rate of graft-versus-host disease after intestinal transplantation is 0% to 16% (Abu-Elmagd et al., 1998; Reyes et al., 1998; Sudan et al., 2000; Pirenne et al., 2007). Patient and graft survival rates are lower for intestinal transplantation than for solid organ transplantation, with approximately half of the patients receiving intestinal transplants surviving 5 years.

Multivisceral transplantation may include SBT in isolation, in combination with liver transplantation, or in combination with multiple abdominal organs (Starzl et al., 1991a, 1991b). An isolated SBT is typically recommended for patients on home parenteral nutrition (HPN) who have exhausted their venous access. Combined SB/LT is recommended for patients with irreversible cirrhosis when HPN has failed, or those who have intestinal failure associated with a hypercoagulable state that can be corrected by a simultaneous liver transplantation. Multivisceral transplantations are for patients with locally aggressive tumors that necessitate evisceration of the abdominal organs (duodenal fistulae, locally aggressive tumors, multiorgan failure with a nonreconstructible GI tract) or for the patient with benign conditions involving the liver, pancreas, or stomach (Tzakis et al., 1989).

The Health Care Financing Administration's clinical indications for intestinal transplantation (implemented in 2001) includes impending liver failure because of failure of HPN, thrombosis of major central venous channels, frequent line infection and sepsis, and frequent episodes of severe dehydration. Significant bone disease, metabolic disorders, failure to thrive, and significant limitations on social and personal activities are not considered indications. As most patients function well on HPN, the risks of intestinal transplantation are warranted only with failure of HPN therapy. The goal of intestinal transplantation is to eliminate the need for TPN and to reverse or prevent TPN-associated liver disease. The first year of wait-listing candidates for intestinal transplantation with UNOS was 1993.

General Indications

In the pediatric population, chronic intestinal failure results from massive bowel resection (short bowel syndrome) or functional impairment of the bowel caused by disturbances in motility or extensive parenchymal disorders (Okada et al., 1994). Necrotizing enterocolitis, intestinal atresia (Todo et al., 1994a, 1994b), midgut volvulus, gastroschisis, microvillous inclusion disease, Hirschsprung's disease, and intestine pseudoobstruction are the primary causes of isolated small intestinal failure. This is in marked contrast to the adult population, in which intestinal failure is caused primarily by Crohn's disease and thrombotic episodes involving the major splanchnic vessels.

If the length of the small bowel is less than 60 or 70 cm, parenteral nutrition is required (normal length of a small bowel in the infant being 200 to 250 cm). For the patient to survive, HPN is essential. HPN has significant metabolic sequelae, the foremost being liver failure and bone disease (Bowyer et al., 1985; Colomb et al., 1994; Sondheimer et al., 1998; Chan et al., 1999; Wasa et al., 1999; Cavicchi et al., 2000). The hepatic dysfunction in the patient on long-term TPN most commonly includes hepatic steatosis, as well as cholestasis, phospholipidosis, or cirrhosis, which is observed in 15% to 40% of patients after 3 years. Up to 100% of patients have biliary sludge or gallstones after 6 weeks. In the pediatric population, this is a reversible form of liver dysfunction (Grosfeld et al., 1986) if the bilirubin level is less than 30 mg/dL and the patient is returned to total enteral feeding. Patients are followed through the North American Home Parenteral and Enteral Nutrition Patient Registry supported by the Oley Foundation (formerly the OASIS registry, started in 1984) (Howard et al., 1991). This registry reports survival for patients on long-term HPN to be 87% to 96% at 1 year, and 70% to 90% at 3 years. The majority of deaths are related to progression of the underlying disease.

Since 2000, over 1900 intestinal transplantations have been performed in only five centers in the United States. Over half of these intestinal transplantations have been performed in children, and more than half of the children were less than 6 years of age. Outcomes for children with isolated SBT are similar to those children undergoing SB/LT.

In patients with isolated SBTs, graft survival rates at 3 months and at 1, 3, 5, and 10 years were 83%, 68%, 57%, 36%, and 25% respectively, and patient survival rates at these same intervals were 94%, 81%, 71%, 56%, and 46%, respectively. In patients with SB/LT, patient survival rates at 3 months and at 1, 3, 5, and 10 years were 88%, 73%, 61%, 55%, and 38%, respectively.

Preoperative Assessment

The patient should be evaluated specifically for progressive liver disease and evidence of portal hypertension. Extrahepatic manifestation of the primary disease causing the patient's intestinal failure should be identified. Complications of TPN should be elucidated (infection, catheter occlusion, hepatic disease). Comorbid conditions such as infection, renal disease, electrolyte abnormalities, and gastroparesis predisposing to regurgitation and aspiration should be considered. Appropriate evaluation of patency of the large vessels of the neck (subclavian and internal jugular veins) is essential, because repeated central vein cannulation or long-term indwelling catheter use for the administration of HPN may lead to loss of vascular access resulting from venous thrombosis (Grosfeld et al., 1986). Doppler ultrasonography is sometimes useful to find central venous access, but the gold standard is a venogram.

Knowledge of the patient's prior surgeries as well as the abdominal vascular anatomy is important, particularly in a patient scheduled for a multivisceral transplantation, because these are the most technically complex surgical procedures. A discussion with the surgical team regarding the planned approach is essential, particularly because multiple blood vessels may be partially or fully crossed-clamped during the operation.

Because of the high rate of postoperative infectious complications, broad-spectrum antibiotics, antifungal drugs, and ganciclovir prophylaxis are routinely administered.

Surgical Technique: Recipient Surgery

The final decision to proceed with either a multivisceral or an intestinal transplantation is made after a laparotomy and a meticulous inspection of the native vessels and abdominal organs. Thus, continuous communication between the donor and recipient teams is essential. In addition, procurement of the donor iliac artery and vein (Starzl et al., 1991a, 1991b), as well as the thoracic aorta, is essential for vascular reconstruction of the graft. The graft is usually preserved with cold UW solution. The length of time the organ is kept in the preservation solution should be minimized because intestinal mucosal damage occurs in UW solution as a result of increased lipid peroxidation (Takeyoshi et al., 2001).

The operation begins with a midline incision, which is extended to either a unilateral or bilateral transverse subcostal incision. The choice of incision depends on the planned operation, with a bilateral incision used preferentially in the multivisceral transplantation. The procedure continues as described by Todo and coworkers (1992) (Fig. 28-16). In the patient receiving an isolated intestinal transplantation, the superior mesenteric artery is anastomosed exclusively to the infrarenal aorta. Venous blood from the isolated small bowel graft is drained into the mesenteric venous system at one of three sites: the donor SMV to the distal end of the recipient SMV, SMV to the hilar portion of the main portal vein, or donor SMV to the confluence of the SMV and splenic vein (Todo et al., 1994a, 1994b).

In the recipient of liver-intestine or multivisceral graft, the use of VVB is usually impossible because of vascular thromboses of the major vessels seen with the long-term use of HPN.

The liver is usually placed in a piggy-back fashion, and occasionally a temporary portacaval shunt is used to decompress the abdominal viscera. Vascular anastomoses are performed as illustrated in Figure 28-16.

The arterial and venous anastomoses are performed before reperfusion of the graft. Arterial anastomoses in this instance are usually with a Carrel patch (Fig. 28-17), containing both the celiac and superior mesenteric arteries for the combined intestinal and multivisceral graft to the infrarenal abdominal aorta. In some instances, an aortic conduit may be used to facilitate the anastomoses of the superior mesenteric artery and celiac axis to the abdominal aorta. If a portacaval shunt is performed, it is subsequently converted to a portaportal anastomosis to facilitate perfusion of the liver with the splanchnic hepatotropic factors.

After completion of the vascular anastomoses, the GI continuity is reestablished by anastomosing the appropriate donor intestine to recipient bowel. In the multivisceral recipient, proximal intestinal reconstruction is accomplished by anastomosing the distal esophagus to the anterior wall of the donor stomach. A pyloroplasty is routinely performed, followed by a gastrostomy, the first of three essential enterotomies, which helps to prevent delayed gastric emptying and decompress the intestine. A jejunostomy is performed for enteral feeding. The final enterotomy is achieved by exteriorization of the distal end of the donor intestine in a chimney fashion. The recipient ileum or colon is then anastomosed to the side of the graft distal to the stoma. Finally, a cholecystectomy follows, as well as biliary reconstruction by a choledochojejunostomy or Roux-en-Y procedure.

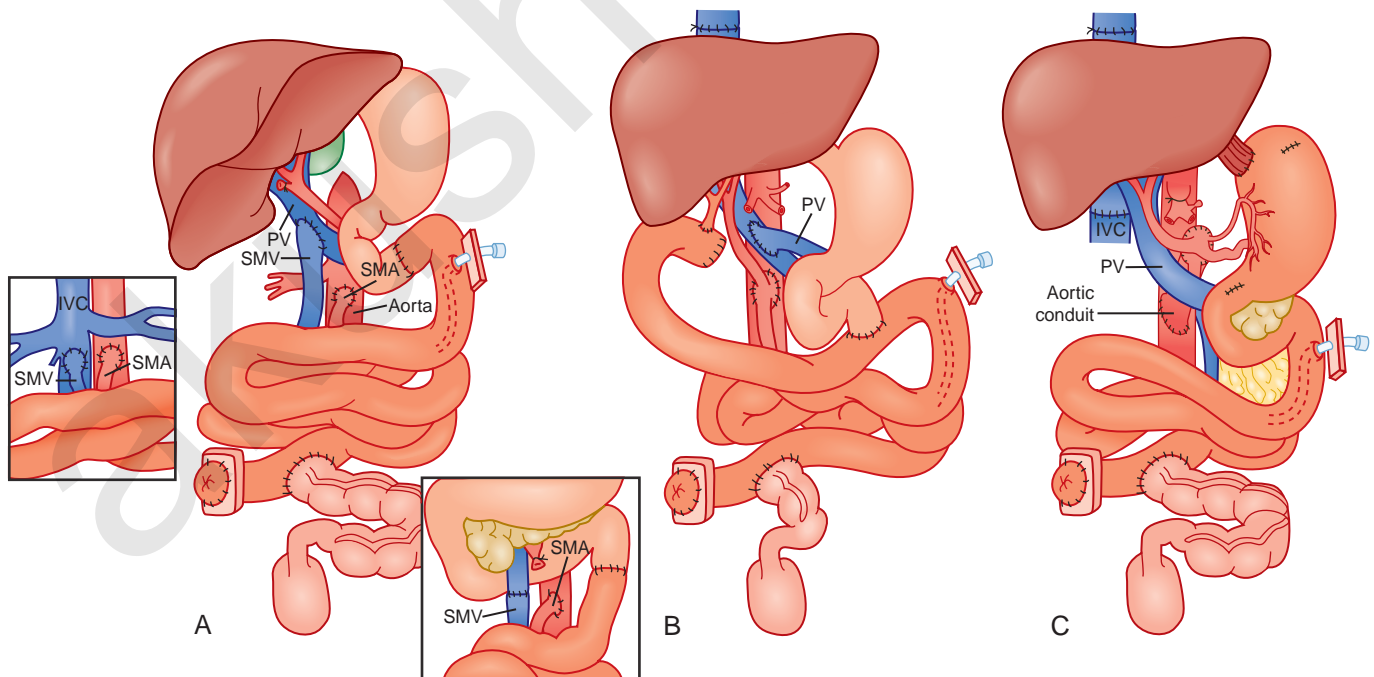

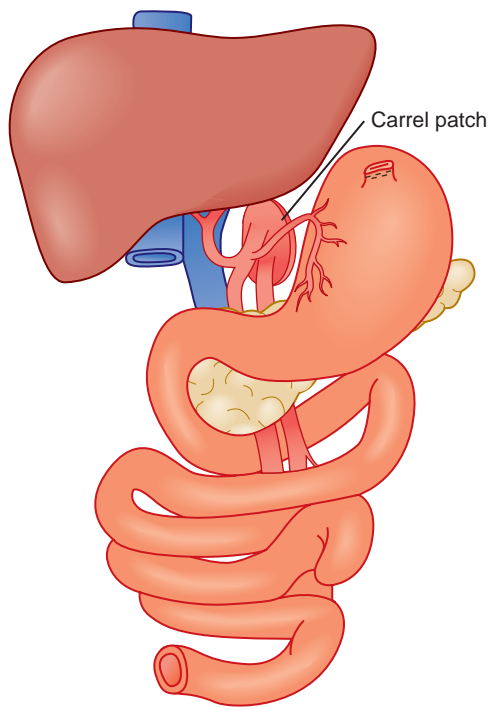

FIGURE 28-16. Intestinal and multivisceral transplantations. **A**, Isolated intestinal transplantation. **B**, Combined liver-intestine transplantation. **C**, Full multivisceral transplantation with resection of the native retrohepatic vena cava. IVC, inferior vena cava; PV, portal vein; SMA, superior mesenteric artery; SMV, superior mesenteric vein; VC, vena cava. (From Todo S, Tzaki AG, Abu-Elmagd K, et al: *Intestinal transplantation in composite visceral graft or alone*, Ann Surg 216:223, 1992.)

■ **FIGURE 28-17.** Multivisceral allograft using the Carrel patch. In this case, a Carrel patch with superior mesenteric artery and celiac axis origins has been used to cap a free graft of the donor thoracic aorta that has been used as a conduit. This is one of the several options for the surgeon. (From Todo S, Tzakis A, Abu-Elmagd K, et al: *Current status of intestinal transplantation*, *Adv Surg* 27:295, 1994.)

Anesthesia Management

Small Bowel Transplantation

In the patient scheduled for isolated SBT, the anesthesia management is similar to that for other major abdominal surgeries. The patient usually has a central venous catheter, although it is sometimes placed in an unconventional site if the subclavian and internal jugular veins are thrombosed (right atrial, transhepatic, or direct inferior vena caval catheters). These procedures are lengthy and lend themselves to significant third-space losses and major fluid shifts. Two large-bore IV catheters above the diaphragm and a radial arterial catheter are recommended. CVP should also be monitored as a guide for fluid replacement. If central vein cannulation is impossible, it is best to proceed without its use; femoral vein cannulation can be used for volume replacement. All blood products should be CMV negative and irradiated, to minimize the risk for graft-versus-host disease.

The choice of anesthesia agent depends on the patient's underlying disease and hemodynamic status. Nitrous oxide should be avoided because it may cause additional bowel distention. The choice of fluids remains controversial in patients undergoing bowel surgery. Not infrequently, significant bowel swelling and distention are noted after reperfusion of the graft. Frequently, diuresis is recommended as a means to treat this problem, although it is often ineffective. Moreover, the etiology of the intestinal edema is most likely related to the preservation of the organ. The use of colloids, preferentially albumin, is recommended when the patient had a low albumin level preoperatively.

Reperfusion of the isolated small bowel graft usually has minimal hemodynamic effects. The reperfusion syndrome seen

with liver transplantation is absent because of the relatively low potassium load and the low volume of effluent extruded from the graft. Hemodynamic stability is the norm, and coagulopathy or metabolic derangements are unusual.

Multivisceral Transplantation

Anesthesia considerations for the patient scheduled for multivisceral transplantation are identical to those for the patient undergoing OLT. There are, however, unique and specific considerations with respect to planned vascular anastomoses (Starzl et al., 1993; Todo et al., 1995) (see Fig. 28-16). The liver is usually placed in piggy-back fashion in this instance. A partial cross-clamping of the abdominal aorta should be anticipated for the placement of the arterial anastomosis using a Carrel patch (see Fig. 28-17). The surgical procedure is divided into three stages, similar to those with solitary liver transplantation. Completion of the abdominal viscera exenteration during the preanhepatic stage is the period of greatest blood loss (De Wolf, 1991). Hemodynamic alterations during this period are related to complications of massive transfusion and manipulation of the abdominal viscera. Ionized hypocalcemia, lactic acidosis, and progressive hypothermia should be anticipated. In addition, a progressive coagulopathy, as seen in patients undergoing OLT, is expected. Thus, monitoring of coagulation is essential. The anhepatic stage of the surgery is usually performed without the use of VVB. The liver is placed in piggy-back fashion, and vascular anastomosis of the intestine follows. A significant difference with respect to reperfusion of the multivisceral graft from that of the liver is that the arterial anastomoses must be performed before graft reperfusion. The graft is flushed with 50 mL/kg of cold saline or lactated Ringer's solution before reperfusion, to reduce the potassium load from the preservation solution.

Reperfusion of the multivisceral graft is similar to that of the hepatic graft. Hypotension and bradycardia are the usual observations secondary to the release of a large volume of hypothermic, hyperkalemic, acidotic preservation solution into the right heart. These changes are usually short lived, with normalization of the hemodynamics within minutes after reperfusion. The incidence of the postreperfusion syndrome in this group of patients is not well defined.

KIDNEY TRANSPLANTATION

Michon and colleagues in Paris performed the earliest kidney transplantation in a child on Christmas Eve in 1952. A 16-year-old boy had just undergone nephrectomy for a right ruptured kidney after a fall, when the surgeons made the unfortunate discovery that he had no left kidney. An ABO-compatible kidney from his mother was placed in the iliac region. Initially, the kidney excreted urine and had good renal function; however, abrupt anuria occurred on posttransplant day 21 (indicating rejection), and the patient died. Two years later, Murray and colleagues performed the first successful kidney transplantation between two identical twins. Goodwin, Mims, and Kaufman at the University of Oregon performed the first successful pediatric transplantation in 1959 between identical twins, one of whom had glomerulonephritis. Eighteen years after transplantation, the kidney was still functioning with normal morphology by biopsy (Papalois and Najarian, 2001).

Routine kidney transplantation in pediatric patients, however, awaited the development of effective immunosuppressive agents. Potent corticosteroids, calcineurin inhibitors such as cyclosporine or tacrolimus, monoclonal antibodies, antimetabolites such as azathioprine, and the purine synthetase inhibitor mycophenolate mofetil (MMF) have all been used successfully in pediatric patients to prevent rejection (Papalois and Najarian, 2001). Superior survival and improved long-term growth and development can be obtained with kidney transplantation compared with chronic hemodialysis or peritoneal dialysis. Newer immunosuppressive regimens relying less on high-dosage corticosteroids have further improved the growth and development of children receiving a renal transplant. Tan and others (2008) reported that, in 42 pediatric patients undergoing living related kidney transplantation after monoclonal antibody (alemtuzumab) pretreatment and tacrolimus monotherapy, the use of corticosteroids could be eliminated and the actuarial 1-, 2-, 3-, and 4-year patient end-graft survival rates were 97.7% and 97.6%, 93.5% and 85.4%, 93.5% and 85.4%, and 93.5% and 85.4%, respectively. In addition, pediatric patients who receive a kidney transplant are much more likely to have a normal lifestyle than those requiring hemodialysis (So et al., 1987; Beebe et al., 1991; Turenne et al., 1997; Benfield et al., 1999; Elshihabi et al., 2000; Healy et al., 2000; McDonald et al., 2000; Qvist et al., 2000, 2002; Papalois and Najarian, 2001; Smith et al., 2002; Gillen et al., 2008).

Finally, kidney transplantation using infants or small children as donors has a lower success rate because of the small size of the donor vasculature. Therefore, infants and small children usually receive a transplant from someone who is an adult or a larger child, often much larger than the recipient. In recipients who are infants or small children, the kidney may be many times larger than they would normally have (Miller et al., 1983; Beebe et al., 1991; Healy et al., 2000; Chavers et al., 2007). Nephron mass can be an important nonimmunologic factor in long-term graft survival. Giuliani and coworkers (2009) have shown that the donor-to-recipient body surface area affects 5-year graft survival.

Infants less than 2 years of age are an important subset of pediatric patients because they are at higher risk for graft loss. Unlike older children or adults, rejection in infants is not the primary cause of failure of the transplanted kidney. One of the main reasons for graft loss in the younger recipient is vascular thrombosis (Beebe et al., 1991; Singh et al., 1997; Healy et al., 2000; Neipp et al., 2002; Chavers et al., 2007).

Infants also have a higher incidence of delayed function of the renal allograft. This is important because infants and children with delayed graft function have an increased incidence of graft loss in the years after transplantation. Kidneys with delayed function are likely to have sustained permanent injury and are susceptible to failure after rejection or other insult. Providing adequate perfusion of a very large kidney relative to the recipient size to prevent vascular thrombosis and delayed graft function is one of the main challenges for the pediatric anesthesiologist caring for an infant or a small child undergoing renal transplantation (Tejani et al., 1999).

Epidemiology

End-stage renal disease (ESRD) is less common in the pediatric age group than in adults. Its overall incidence in children aged

0 to 19 is approximately 14 per million, and this has been relatively stable since 1981. The incidence is lower at 0 to 4 years of age (approximately 10 per million) than older children (15 to 19 years old) (approximately 28 per million). In contrast, the incidence of ESRD in adults 20 to 24 years of age is approximately 120 per million (Chavers et al., 2007).

Pediatric recipients of renal transplants differ from their adult counterparts in several ways. Obstructive nephropathy or hypoplastic kidneys are common causes for transplantation in the pediatric age group. Glomerulonephritis is less common, and, in contrast to adults, diabetes as a cause of renal failure in this age group is rare (North American Pediatric Renal Transplant Cooperative Study, 2007) (Table 28-20). Consequently, many of the diseases that cause renal failure in children do not recur, and successful transplantation could, in theory, be a permanent solution. Also, although most adults have received dialysis before transplantation, approximately 30% of children who receive a transplant have never had dialysis before. Of the children who are on dialysis, approximately half are receiving peritoneal dialysis, and the other half, hemodialysis (Elshihabi et al., 2000; McDonald et al., 2000; NAPRTCS, 2007).

Approximately 300 pediatric patients undergo living related kidney transplantation each year in the United States, and an equal number receive a deceased donor transplant. There has been a recent increase in the number of teenagers and older children who now receive a deceased-donor transplant, probably because a higher priority has been given to children requiring a kidney over the past decade (Magee et al., 2008). Infants and small children (<15 kg) constitute between 10% and 15% of both deceased-donor and living related transplantations in the pediatric age group (Elshihabi et al., 2000; McDonald et al., 2000). Pediatric living-donor kidney transplantations have been shown to have increased half-lives and graft survival in patients 2 to 5 years of age when compared with transplants from deceased donors (Shapiro, 2006; Hardy et al., 2009) (Figs. 28-18 and 28-19). Factors affecting graft survival in both living and deceased donors that are associated with worse outcomes include African American race of the recipient, no antibody induction, more than five transfusions, and retransplantation and pretransplantation dialysis (Shapiro et al., 2006). Of note, laparoscopically obtained donor nephrectomies may have a higher rate of delayed graft function and 6-month rejection rates (Troppman et al., 2005).

Pathophysiology of Renal Failure

The effects of chronic renal failure on infants and children result from the kidney's role as a filter of metabolic waste products and fluid regulation and its active role in hormone production. As the glomerulofiltration rate becomes reduced, the kidney's ability to clear acids, urea, and potassium diminishes, and overall poor nutrition is the result. Therefore, infants and children with renal failure have growth retardation and often developmental delay. Chronic metabolic acidosis, hyperkalemia, and hyperphosphatemia develop. The elevated phosphorus binds to the serum calcium and magnesium, resulting in hypocalcemia and magnesemia. Fractures in active children can occur as calcium is leached from the bones. Chronic uremia can result in CNS depression and congestive heart failure and can impair platelet function. Seizures and permanent neurologic damage may be a consequence of electrolyte imbalances and fluxes

TABLE 28-20. Primary Diagnoses in Pediatric Kidney Transplant Recipients

Recipient and Transplant Characteristics	Patients (N)	Patients (%)
Total	9506	100.0
Aplastic/hypoplastic/dysplastic kidney	1521	16.0
Obstructive uropathy	1486	15.6
Focal segmental glomerulosclerosis	1110	11.7
Reflux nephropathy	500	5.3
Chronic glomerulonephritis	324	3.4
Polycystic disease	281	3.0
Medullary cystic disease	263	2.8
Hemolytic uremic syndrome	254	2.7
Prune belly syndrome	249	2.6
Congenital nephrotic syndrome	246	2.6
Familial nephritis	211	2.2
Cystinosis	195	2.1
Pyelo/interstitial nephritis	173	1.8
Membranoproliferative glomerulonephritis type I	170	1.8
Idiopathic crescentic glomerulonephritis	168	1.8
Systemic lupus erythematosus nephritis	145	1.5
Renal infarct	130	1.4
Berger's (IgA) nephritis	123	1.3
Henoch-Schönlein nephritis	110	1.2
Membranoproliferative glomerulonephritis type II	81	0.9
Wegener's granulomatosis	52	0.5
Wilms tumor	51	0.5
Drash syndrome	50	0.5
Oxalosis	49	0.5
Membranous nephropathy	42	0.4
Other systemic immunologic diseases	32	0.3
Sickle cell nephropathy	15	0.2
Diabetic glomerulonephritis	11	0.1
Other	897	9.4
Unknown	567	6.0

from renal insufficiency and dialysis therapy. Volume overload can result as the kidney's ability to clear sodium and free water diminishes (Belani and Palahniuk, 1991).

Hormone function of the kidneys is affected by renal failure as well. Erythropoietin production may be severely reduced and cause anemia. Renin production becomes elevated as the kidney senses diminished perfusion, resulting in hypertension. Similarly, parathyroid hormone levels become elevated as the parathyroid gland responds to a reduced serum calcium level.

FIGURE 28-18. Survival of pediatric patient recipients after kidney transplantation. (From Shapiro R: *Living donor kidney transplantation in pediatric recipients*, *Pediatr Transpl* 10:845, 2006, with data from the North American Pediatric Renal Transplant Cooperative Study [NAPRTCS].)

FIGURE 28-19. Graft survival after living- and deceased-donor pediatric kidney transplantation. (From Shapiro R: *Living donor kidney transplantation in pediatric recipients*, *Pediatr Transpl* 10:845, 2006, with data from the North American Pediatric Renal Transplant Cooperative Study [NAPRTCS].)

These changes occur in infants and small children to various degrees despite adequate dialysis and the administration of exogenous erythropoietin and vitamin supplementation. The net effect is a child who is small and frail, hypertensive, and chronically acidotic (Beebe et al., 1991; Belani and Palahniuk, 1991).

Indications for Transplantation

Any medical condition listed in Table 28-20 is an indications for potential transplantation. Educational guidelines were published in 1998 by the Pediatric Committee of the American Society of Transplantation on the indications for pediatric transplantation. They suggested that the following pediatric patients with renal disease receive a kidney transplant: patients with ESRD unresponsive to medical management, patients with growth failure

in spite of optimal nutritional management, patients with developmental delay, children with progressive renal osteodystrophy in spite of optimal medical management, and patients who fail to thrive (Chavers et al., 2007).

The optimal age for transplantation in an infant or small child is controversial. Infants less than 2 years of age are technically more difficult to transplant and have a higher incidence of arterial thrombosis and delayed graft function. Many surgeons prefer to wait until the infant is at least 2 years of age or weighs more than 15 to 20 kg (Glessing et al., 2007). On the other hand, infants who receive kidney transplants have better growth and development than those managed on dialysis. Also, the increased risk for graft loss compared with older children and adults was mainly seen in infants who received a deceased-donor rather than a living related kidney transplant (Chavers et al., 2007). Centers that perform kidney transplantation in infants on a regular basis report graft and patient survival rates that are similar to those seen in older children or adults. Therefore, transplantation in an infant, particularly with a living related organ, is optimal as soon it is technically feasible at a center experienced with the procedure (Humar et al., 2001; Becker et al., 2006; Chavers et al., 2007).

Also controversial is whether kidneys from deceased pediatric donors should be given preferentially to pediatric recipients. Initially, kidneys from donors less than 5 years of age were not used because they had a high incidence of vascular thromboses secondary to technical difficulties. Some studies have shown that kidneys from younger donors can be successfully transplanted into pediatric patients, and they may have the advantage of being able to grow along with the recipient (Becker et al., 2006; Pape et al., 2006). Kidneys from donors weighing less than 10 kg are usually transplanted en bloc to avoid small vessel anastomosis and to increase nephron mass. The en bloc technique comprises end-to-side anastomosis of the infrarenal donor vena cava and aorta to the recipient vessels.

Surgical Technique

The surgical technique has been described in detail elsewhere (Miller et al., 1983). In larger children (>20 kg), the kidney is placed in the pelvis as in an adult renal transplant. A lower flank incision is used with a retroperitoneal approach. Systemic heparinization is usually not required because heparin can be applied directly by the surgeon through the arteriotomy and venotomy, and the anastomoses are performed quickly. The renal artery is anastomosed to the common iliac or hypogastric artery. The renal vein is usually attached to the common iliac or external iliac vein. The ureter is then anastomosed to the bladder (Fig. 28-20, A). In this approach, only one lower extremity is without circulation before reperfusion. Occasionally, hypotension results from revascularization of the kidney in the older child or teenager. In general, the hemodynamic changes are minimal.

In contrast, when transplanting an adult kidney into an infant or small child (<20 kg), the kidney is sewn directly onto the aorta and vena cava (see Fig. 28-20, B). A retroperitoneal approach to the aorta and vena cava is advocated by some surgeons, to potentially avoid bowel complications such as adhesions and bowel atony. It also maintains the possibility of peritoneal dialysis. However, the graft may be compressed by this approach, particularly if an adult kidney is used (Becker et al., 2006). Therefore, in many centers the peritoneum is opened to expose the aorta and vena cava (Chavers et al., 2007). Currently,

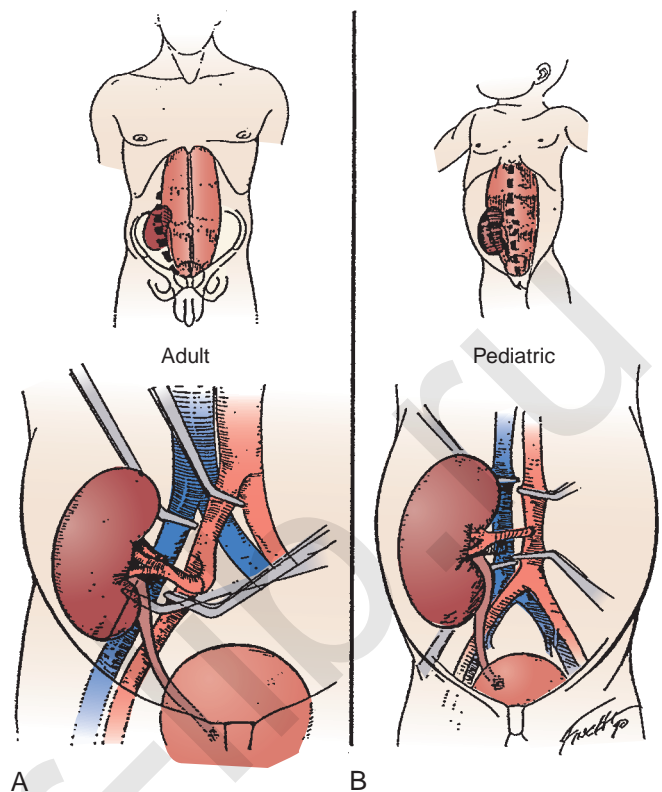

FIGURE 28-20. Surgical placement of renal allograft in adults and older children (A) versus infants (B). The vascular anastomosis of an adult-size organ in the pediatric patient is to the aorta and vena cava. (From Belani KG, Polahniuk RJ: *Kidney Transplantation*, *Internat Anesth Clin* 29:17–40, 1991.)

there are no differences in initial graft function, graft survival, or surgical complications between the approaches (Becker et al., 2006). In both approaches, the aorta and inferior vena cava are cross-clamped. Because the major vessels are clamped, low-dosage heparinization (50 to 100 mg/kg) is often used. The lower extremity is deprived of both arterial perfusion and venous drainage during the anastomoses. Because the kidney is much larger relative to the recipient than in the older child or adult, the hemodynamic changes in an infant on reperfusion can be profound (Beebe et al., 1991; Chavers et al., 2007).

Infants and small children usually require other concurrent operations in addition to the kidney transplantation. For example, if the cause of renal failure is vesicoureteral reflux with recurrent urinary tract infections, bilateral nephrectomies are often performed simultaneously to prevent graft sepsis. Concurrent splenectomy, although no longer routine, is occasionally performed if the spleen is enlarged, to allow room for the kidney. A large-bore Hickman dialysis catheter is also placed in infants before beginning the transplantation if not already present for IV access and CVP monitoring (Beebe et al., 1991).

Anesthesia Concerns

All systems are affected by ESRD. Attention must be paid to the extent of renal failure and its effects on organ function, and to the child's growth and development. Smaller tracheal tube sizes

and intravascular catheters may be needed if the child has not been growing adequately. The cause of renal failure, if a systemic disorder such as oxalosis exists, also affects the function of other organs. Agenesis or dysplasia of the kidneys may be associated with other congenital disorders such as ventricular septal defects. The presence of cardiac failure or congestive heart disease should be determined. Although most children with renal failure have a hyperdynamic circulation from chronic anemia, some do develop cardiac insufficiency from concurrent congenital heart disease, uremia, or chronic volume overload. The parents should be asked about frequent episodes of dyspnea or asthma attacks. In addition to usual reactive airways disease in children, asthma attacks in children with renal insufficiency may suggest volume overload. The presence of wheezing, rales, dyspnea, an enlarged liver, and hypertension on physical examination suggests fluid overload that may require dialysis before surgery. A history of frequent fractures suggests the child may have brittle bones from hypocalcemia and be at risk for dental injury during anesthesia. Finally, the parents or patient should be asked if the child has symptoms of acid reflux or delayed gastric emptying, because those conditions are quite common with renal insufficiency (Beebe et al., 1991; Belani and Palahniuk, 1991).

When examining the airway, the anesthesiologist must pay particular attention to the teeth, which may be fragile from chronic hypocalcemia. Vascular access is also often difficult in these patients because of frequent hospitalizations and repeated blood drawing and catheterizations. The extremities should be examined to plan where to obtain vascular access for an arterial catheter, if indicated (Beebe et al., 1991; Belani and Palahniuk, 1991).

Preoperative Dialysis

Before surgery, the anesthesiologist and surgeon should ascertain if the patient needs dialysis. The day of the last dialysis and type of dialysis, hemodialysis or peritoneal, should be determined. Some patients who have not previously been dialyzed are chronically hyperkalemic. Potassium can be transfused from the donor kidney as it is reperfused, particularly if it has been filled with a high-potassium preservative, such as the UW solution. It is therefore best to reduce the potassium to normal levels either via dialysis or ion exchange resins (Kayexalate) before transplantation in the chronically hyperkalemic patient (Beebe et al., 1991; Belani and Palahniuk, 1991).

If the patient is hyperkalemic (potassium > 6.0 mmol/L), acidotic, or volume overloaded, the surgery should be delayed and dialysis performed. Although peritoneal dialysis may be adequate for the daily treatment of patients and is commonly used in children, it may be inadequate to prepare children for surgery. Therefore, children are sometimes converted from peritoneal to hemodialysis several weeks before transplantation to ensure adequate dialysis. The large-bore (2 mm inner diameter) Hickman catheters are usually used for hemodialysis in infants and young children; they also provide excellent vascular access for the renal transplant procedure (Beebe et al., 1991).

Anesthesia Management

Many anesthesia techniques have been used successfully in the anesthesia management of renal transplantation in children. However, when planning the anesthesia, several items unique

to renal transplantation must be kept in mind (Beebe et al., 1991; Belani and Palahniuk, 1991):

- The patient suffers from chronic renal failure and may present with many of its effects, including anemia, hyperkalemia, and hypervolemia.
- The transplanted kidney may not function effectively initially. Therefore, muscle relaxants, such as pancuronium, and other drugs dependent primarily on the kidney for excretion should not be used.
- Immunosuppressive drugs need to be administered. Allergic reactions and hypotension may occur with some of the agents.
- The kidney has been ischemic before transplantation, which may increase its vulnerability to further injury.
- Adequacy of the intravascular volume status before and after reperfusion of the allograft must be ensured.
- The anesthesiologist must be prepared to deal with hyperkalemia, hyperglycemia, hypocalcemia, and other electrolyte disorders that may arise over the course of the operation and perioperative period.

Induction and Maintenance of Anesthesia

In general, most children without an IV catheter in place receive preoperative sedation with either oral or rectal midazolam (0.5 mg/kg). Ketamine (3 mg/kg) and atropine (20 mcg/kg) may be added to rectal midazolam if a greater level of sedation is desired (Beebe et al., 1992). If an IV catheter is in place, IV midazolam (0.1 to 0.2 mg/kg) may be administered for sedation.

An inhaled induction of anesthesia with sevoflurane with or without nitrous oxide may be used in stable patients with normal gastric function who have been NPO for an adequate length of time.

Often an IV induction of anesthesia is used in children undergoing renal transplantation, particularly if there is a concern that the patient may be unstable and require vasopressors or other drugs. Also, transplant surgeons often order oral immunosuppressive agents preoperatively. Sometimes the children take the drugs only with milk or juice. If the medications are necessary and the surgery cannot be delayed, an IV induction and aspiration precautions are required (Beebe et al., 1991; Belani and Palahniuk, 1991).

Intravenous propofol or thiopental may be used in healthy children. Ketamine (1 to 3 mg/kg) has proved useful as an induction agent in infants and children suspected to be hypovolemic from recent dialysis. Ketamine maintains the autonomic tone and blood pressure while the volume status is corrected. Maintenance of the blood pressure and a strong pulse with ketamine is also useful when attempting to place an arterial catheter (Beebe et al., 1991; Belani and Palahniuk, 1991).

Tracheal intubation and skeletal muscle relaxation are always provided by an agent not dependent on the kidneys for excretion, such as cisatracurium. Intermediate-acting steroidal muscle relaxants such as vecuronium or rocuronium may also be used, but their action may be prolonged because of partial renal excretion. Succinylcholine is usually not administered except in emergencies, because it can raise the serum potassium concentration by 0.5 to 0.7 mmol/L. This could be dangerous in patients who are already hyperkalemic. Also, drugs dependent on renal excretion, such as pancuronium, should not be used because prolonged neuromuscular blockade can result if the

kidney does not function properly in the perioperative period (Beebe et al., 1991; Belani and Palahniuk, 1991).

After the induction of general anesthesia and tracheal intubation, anesthesia is maintained with isoflurane or desflurane. Even if sevoflurane has been used for inhaled induction of general anesthesia, it is usually not used for maintenance because of concerns about nephrotoxicity with sevoflurane from fluoride ion or compound A production. Although nephrotoxicity in normal kidneys from sevoflurane in humans has never been demonstrated, its effects on transplanted kidneys are unknown (Artru, 1998).

Nitrous oxide was used frequently in the past and may still be used in older children. An air-oxygen mixture is usually used in infants to prevent the bowel distention that may occur with nitrous oxide in an abdomen that will be quite full with an adult kidney. Opioids such as fentanyl are also administered in moderate dosages to reduce the amount of inhaled agent required and to provide postoperative pain relief (Beebe et al., 1991; Belani and Palahniuk, 1991).

Monitoring

In addition to standard monitors (ECG, pulse oximetry, non-invasive blood pressure, end-tidal gas analysis, temperature), all children undergoing renal transplantation need monitoring of their CVP. This helps ensure that an adequate volume is administered before perfusion of the allograft, and it provides a means to administer immunosuppressive agents that can be given only centrally (e.g., thymoglobulin, OKT3). As noted earlier, in infants, the CVP is often monitored through a large-bore Hickman catheter. This also serves as an excellent, high-flowing catheter to allow transfusion directly into the central circulation as well as a means to provide dialysis should the kidney initially fail (Beebe et al., 1991; Belani and Palahniuk, 1991).

Arterial catheters are also useful in infants and small children who require cross-clamping of the aorta. Reperfusion of the kidney in this situation can result in profound hypotension. The beat-to-beat data provided by an arterial catheter allow more rapid correction of hypotension and greater stability. Arterial blood gases obtainable from an arterial catheter are also often helpful. However, because the lower extremity is not perfused during anastomosis, the arterial catheter must be placed in an upper extremity (Beebe et al., 1991; Belani and Palahniuk, 1991).

In older children who receive a kidney that is the appropriate size for their body weight, patient care during reperfusion is relatively straightforward. The hemoglobin level and electrolytes are checked after induction of general anesthesia. Older children usually do not require blood unless the hemoglobin level is less than 8 mg/dL. Similarly, children with renal failure often have a chronic metabolic acidosis; sodium bicarbonate is rarely required unless the pH is less than 7.25 despite mild hyperventilation. To ensure adequate hydration before reperfusion, normal saline or albumin is administered, provided the hematocrit is adequate until the CVP is 12 to 14 mm Hg. The systolic blood pressure is also allowed to rise to approximately 100 to 120 mm Hg before reperfusion to prevent hypotension when the clamps are released. Sodium mannitol (0.5 g/kg) and furosemide (1 mg/kg) are also administered to stimulate a diuresis. Sodium mannitol administration prior to release of the cross clamps has also been shown to reduce the requirement of posttransplantation dialysis, perhaps by releasing vasodilatory

prostaglandins in the kidney or by acting as a free-radical scavenger (Schnuelle and Johannes van der Woude, 2006). If the systolic blood pressure falls below 90 mm Hg, administration of a vasopressor such as ephedrine may be necessary. Rarely, dopamine or other vasopressors may be administered by infusion for persistent hypotension (Belani and Palahniuk, 1991). In the past, dopamine was commonly administered at low dosages in renal transplantations in children in an attempt to increase renal perfusion and blood flow. However, no long-term benefit was found in terms of graft, and its use at low dosages for renal perfusion is no longer recommended in kidney transplantation (Schnuelle and Johannes van der Woude, 2006).

Managing the perfusion of an adult kidney in an infant is more challenging. Unlike in older children or adults, both the aorta and the inferior vena cava are cross-clamped. Also unlike in adults, low-dosage systemic heparinization (50 U/kg) is required before clamping the vessels. Because blood pools in the unperfused lower extremities while the kidney is being sutured into place, release of the cross clamps causes ischemic by-products in both the kidney and lower extremities to enter the central circulation. The adult kidney itself can initially absorb up to 300 mL of blood. Vasodilation from ischemia can cause a large fraction of the infant's cardiac output to shunt through the new kidney. Occasionally, potassium from the preservative solution in the new kidney is transfused rapidly into the central circulation of the infant, resulting in cardiac arrhythmias, hypotension, and sometimes arrest. Surgeons try to prevent this by perfusing the kidney with normal saline to wash out the hyperkalemic preservative solution (UW solution), but they are not always successful. Also, in all cases, the kidney has been kept cold to preserve the organ while ischemic. Revascularization can result in significant hypothermia. Hypothermia may subsequently depress cardiac function and interfere with cardiac contractility that is needed to increase the cardiac output to perfuse the new kidney. Hypothermia also interferes with platelet and coagulation function, thereby predisposing the infant or child to increased perioperative bleeding (Beebe et al., 1991; Belani and Palahniuk, 1991).

In the past, infants receiving this operation had a high incidence of profound hypotension with perfusion of the allograft. This was often followed by vascular thrombosis or ATN. Subsequent experience in infants receiving an adult kidney has been much more successful (Beebe et al., 1991; Healy et al., 2000; Humar et al., 2001; Becker et al., 2006; Chavers et al., 2007).

The main difference in reperfusion of the kidney received by an infant compared with an older child or adult is that the CVP must be raised to a much higher level, at least 18 mm Hg, before reperfusion (Beebe et al., 1991; Chavers et al., 2007). Although there is no evidence that colloid solutions such as 5% albumin are superior to crystalloid solutions in renal transplantation, it is difficult to achieve volume expansion to CVP as high as 18 mm Hg with crystalloid solution alone because of its extravasation into the extracellular fluid (Schnuelle and Johannes van der Woude, 2006). Therefore, packed RBCs and colloids (5% albumin or fresh frozen plasma, or both, if clotting parameters are diminished) are usually required before reperfusion (Beebe et al., 1991). The use of synthetic colloid solutions such as Hetastarch has not been studied in this patient population (Schnuelle and Johannes van der Woude, 2006). The systemic blood pressure must also be at least 20% higher than the preoperative value, for the infant to tolerate cross-clamp release. Often this is achieved with transfusion to elevate the

CVP and lowering the anesthetic concentration to 0.5 MAC. However, some infants require an infusion of dopamine (3 to 5 mcg/kg per min) or other vasopressor to increase the blood pressure. As in older children and adults, sodium mannitol (0.5 to 1.0 g/kg) is administered before cross-clamp release, as well as Lasix (1 mg/kg) (Beebe et al., 1991).

The amount of volume required to raise the CVP to 18 mm Hg is often impressive. Many times, greater than 100% of the infant's calculated blood volume is administered before reperfusion of the kidney. Additional volume is often required after reperfusion to replace ongoing blood loss or to support the blood pressure if still inadequate (Beebe et al., 1991).

All blood products administered through the Hickman catheter during kidney transplantation in children require warming, because transfusion of cold blood into the central circulation can result in myocardial depression as well as worsen hypothermia (Beebe et al., 1991).

Forced-air surface warming with a device such as the Bair Hugger is also helpful to prevent hypothermia in kidney transplantation in children. However, the lower extremities should not be warmed until unclamping of renal vessels has been accomplished. Warming of the lower extremities using forced-air surface warming during aortic cross-clamping in animals resulted in hypotension, pulmonary hypertension, and myocardial depression. This was thought to result from greater production of ischemic by-products in lower extremities warmed during aortic cross-clamping (Beebe et al., 1993).

Immediately before cross-clamp release, atropine (20 mcg/kg) and calcium chloride (10 mg/kg) are administered. Atropine is administered because infants can occasionally develop vagally mediated profound bradycardia with the sudden loss of SVR. Calcium is important because potassium may be immediately transfused into the central circulation from the kidney if it has not been flushed of the high-potassium preservative solution (UW solution) before reperfusion. Often, sodium bicarbonate is administered as well (1 mmol/kg) to neutralize the acid that develops in the ischemic lower extremities and new kidney. The dopamine infusion may need to be increased, and other inotropes (e.g., epinephrine 1 mcg/kg as single aliquots) may be necessary immediately after reperfusion, but generally the pressure stabilizes at the initial, preoperative value (Beebe et al., 1991) (Fig. 28-21).

■ **FIGURE 28-21.** Systolic blood pressure (BP), heart rate (HR), and central venous pressure (CVP) during renal transplantation in infants. (From Beebe DS, Belani KG, Mergens P, et al: *Anesthetic management of infants receiving an adult kidney transplant*, *Anesth Analg* 73:725, 1991.)

In both infants and older children, the urine output is replaced milliliter per milliliter with one-half normal saline solution as soon as it can be measured. This solution is chosen because this is the concentration of sodium excreted by a kidney with some degree of ATN or one that received large dosages of diuretics. Replacement of all the urine output with IV fluid ensures a brisk diuresis, and it is continued for up to 2 days after surgery. Dextrose is not added to the replacement solution because, if large volumes are administered because of a brisk urine output, hyperglycemia often results (Beebe et al., 1991; Belani and Palahniuk, 1991).

Postoperative Management

After closure of the wounds, virtually all older children can have skeletal muscle relaxants reversed and can be extubated as soon as they are awake and strong. Infants can usually be extubated in the operating room or recovery room as well, despite the presence of a large adult kidney, which causes obvious abdominal distention. Pain relief is usually achieved by means of patient-controlled analgesia with morphine, fentanyl, or hydromorphone. Recently, some anesthesiologists have reported successfully using epidural analgesia for postoperative analgesia, as well as part of a combined technique of epidural and general anesthesia intraoperatively. This is controversial because many children receive heparin intraoperatively or in the postoperative period, and this subjects children to a risk for epidural hematomas (Bhosale and Shah et al., 2008).

Most older children are cared for in the transplantation unit or ward. Rarely is ICU admission required, although most infants and small children require care in the pediatric ICU overnight. Urine is replaced milliliter per milliliter with half-normal saline for 2 days postoperatively. In infants, fluid management is similar to that in older children, but the amount of urine output from the adult kidney can be profound (i.e., 80 mL/kg per hr). Electrolytes therefore must be closely monitored. Eventually, over several days, the kidney adjusts to the smaller size of the recipient and produces the proper amount of urine (Beebe et al., 1991). Then, these children are allowed to begin oral intake, and diuresis is no longer forced. Discharge to home varies with the patient's ability to tolerate oral feedings, but it is usually within 1 week of surgery (Beebe et al., 1991; Belani and Palahniuk, 1991).

Postoperative Complications

Chest radiographic evidence of pulmonary edema caused by the large amounts of fluid administered to infants is present in at least 25% of patients in the recovery room. Despite this, less than 10% of infants require mechanical ventilation in the ICU postoperatively because diuresis from the new kidney occurs rapidly (Beebe et al., 1991).

Delayed graft function, defined as a need for dialysis within 1 week after surgery, can be a serious complication in pediatric patients. The incidence varies from 3% to 10% in recipients of living related kidneys in the pediatric age group, and it may be three times more common in recipients of deceased-donor kidneys (Tejani et al., 1999; Troppmann et al., 2005). Patients with delayed graft function have both an increased early incidence of graft loss and more rapid long-term graft failure in both deceased-donor and living related recipients

(Tejani et al., 1999). Of concern is a study by Troppmann that suggests that pediatric recipients of grafts harvested laparoscopically may be at increased risk for delayed graft function compared with those who received a kidney harvested by the open technique. Whether this is a true complication of the procedure or a complication of surgeons learning this new technique remains to be determined (Troppmann et al., 2005).

Graft thrombosis remains the primary cause of graft loss in the first year of transplantation in the pediatric age group. The rate of thrombosis is approximately 2%, and is more common in those who received a deceased-donor rather than living related donor organ and in recipients who were receiving peritoneal dialysis. Recently, the thrombosis rate appears to have declined, perhaps because of newer immunosuppressive agents and the improved technical skill of the surgeons (Smith et al., 2006). Kidney transplantation has now been successfully performed with outcomes comparable with those in normal children with renal failure in a series of patients with thrombotic risk factors (Kranz, 2006).

Finally, rejection is still the primary cause of graft loss over the long term. In recent years, the incidence of both acute and chronic rejection resulting in graft loss has declined as a result of more potent immunosuppressive agents. However, this decline in rejection has been accompanied by an increase in the number of posttransplantation infections (Dharnidharka et al., 2004).

Outcomes

Numerous studies have shown that the overall success rate for renal transplantation in children and teenagers is similar to that in adults (Elshihabi et al., 2000; McDonald et al., 2000; Smith et al., 2002; Magee et al., 2008). The 5-year patient survival rates in patients receiving living related kidney transplants for different pediatric age groups ranged from 94.7% to 96.3%. The patient survival rates were slightly lower for recipients of deceased-donor transplants (see Figs. 28-18 and 28-19). The 5-year graft survival rates over the same time period ranged from 74% to 89% in recipients of living related transplants, and 63% to 75% in those receiving a deceased donor organ (Magee, 2008). Rejection is the main cause of graft loss (Elshihabi et al., 2000). Until recently, most reports showed that the 1-year patient survival rate after transplantation was lower if the recipient was less than 2 years of age compared with older children after living related transplantation (89%). Graft survival was also less (85%). Both the mortality and graft loss were greater in deceased-donor transplantations as well (Elshihabi et al., 2000; McDonald et al., 2000). Vascular thrombosis was much more likely to be a cause of graft loss in infants than in older recipients. However, recent reports from selected centers demonstrate results in infants and small children with success rates similar to those in older children or adults (Becker et al., 2006; Chavers et al., 2007). Although infants and small children constitute a high-risk group, kidney transplantation can still lead to a good outcome. Although corticosteroids have been an essential cornerstone of immunosuppression after organ transplantation, the side effects of steroids are significant, and in children their effects on growth can be devastating. Steroid-free immunosuppression in children after kidney transplantation has been reported

(Sarwal et al., 2003), and Sutherland and colleagues (2009) have reported that in a 5-year follow-up period, 87% remain steroid-free with patient and allograft survival rates of 96.4% and 94.1%, respectively.

ISLET CELL, PANCREAS, AND KIDNEY-PANCREAS TRANSPLANTATIONS

Diabetes mellitus (DM) has reached epidemic levels in the United States, probably related to the increased incidence of obesity, estimated at 67% in both the pediatric and adult populations. In 2009, an estimated 23.6 million people were living with type 2 DM, and an estimated 5 million undiagnosed or untreated patients in the United States (CDC Diabetes Public Health Resource, 2009). Although only 3% of type 2 DM develops in persons younger than 20 years (Fagot-Campagna et al., 2000), individuals who develop type 2 DM in childhood and adolescence are affected in early adulthood by the microvascular complications of DM (Krakoff et al., 2003; Le et al., 2008).

Based on 2005 to 2007 data from the Centers for Disease Control and Prevention and the National Institute of Diabetes and Digestive and Kidney Diseases, 15,000 youths in the United States were newly diagnosed with type 1 DM annually, and about 3700 were newly diagnosed with type 2 DM annually.

DM is one of the top five causes of morbidity and mortality in the industrialized world. The first clinical pancreas transplantation was performed in 1966 with a simultaneous kidney transplantation in a uremic, diabetic patient at the University of Minnesota, by Kelly, Lillehei, and colleagues (Lillehei et al., 1970; Sutherland et al., 1979). Since that initial event, simultaneous kidney-pancreas (SKP), pancreas after kidney (PAK), pancreas transplantation alone (PTA), and islet cell transplantations have increased dramatically. In 2008, a total of 126 U.S. centers (and nearly the same number worldwide) reported that they had performed at least one pancreas transplantation. Only three centers (2%) reported more than 50 pancreas transplantations, but 81 centers (64%) reported fewer than 10 (Gruessner and Sutherland, 2008).

Pediatric patients, however, account for a very small percentage (less than 3%) of all the pancreas transplantation procedures, which is the smallest percentile group of any solid organ transplantation (see Table 28-15). As of April 1, 2009, UNOS reported a total of 396 pancreas (PTA + PAK) and 43 SKP transplantations performed since 1988 in the pediatric patient population (UNOS, 2010); interestingly, one of these was listed as a living related transplantation. The total numbers of pediatric candidates on the UNOS waiting list, as of April 2010, are 62 for PTA and one for SKP. These numbers are markedly less than the numbers of adults on the UNOS waiting list, which currently are 1407 for SKP and 2497 for PTA.

In the United States between 1988 and 2010, 90.2% of these transplantation patients underwent SKP. The 1-year graft survival for SKP is approximately 86% to 91%; for PTA, it is 83.8%; and for PAK, it is 78.4%. The 1-year patient survival data are 95.9%, 99.2%, and 96.6% for SKP, PTA, and PAK, respectively. Long-term insulin independence is achieved in 70% to 80% of pancreas transplant recipients (Kahl et al., 2001; Bland, 2003; UNOS, 2010).

Islet Cell Transplantation

Islet cell transplantation was first performed in 1974. This procedure, like bone marrow transplantation, is dependent on the total mass or number of transplanted islet cells. Most notably, islet allotransplantation was not consistently successful until the early 1990s (Gruessner and Sutherland, 2003) in terms of the ability of patients to achieve sustained insulin independence. The number of procedures performed worldwide to date has been reported to be more than 412, with patient and graft survival rates at 75% and 65%, respectively (CITR Research Group, 2009). Islet cell transplantation as the dominant form of islet beta-cell replacement may occur in the near future; however, the needs for SKP, PTA, and PAK will remain, because of the need for exocrine pancreatic function. In addition, patients may not be able to achieve insulin independence without the critical mass of beta cells provided by a solitary pancreas transplantation. Although only a small percentage of patients are insulin independent after islet cell transplantation, graft survival is achieved in the majority of islet transplant recipients, with greater than 70% of them retaining C-peptide levels, normalized hemoglobin A1c, nearly absent severe hypoglycemia, and significantly reduced insulin requirements (compared with pretransplantation dosage) at 5 years under the Edmonton Protocol (Ryan et al., 2001, 2005a; Vantyghem et al., 2009). Insulin independence is improved after performing islet allotransplantation after kidney transplantation (IAK), 45% at 1 year, and simultaneous islet and kidney transplantation (SIK), 74% at 1 year with normalized glycosylated (glycated) hemoglobin (Ichii and Ricordi, 2009).

Islet Cell Transplantation Procedure and Anesthesia Considerations

Recent progress in the understanding of enzymatic digestion process of the pancreas, along with novel immunosuppression strategies have led to successful clinical trials of islet transplantation in humans (Ricordi et al., 2005). Automated islet cell isolation using a computerized centrifugation system and continuous enzymatic digestion of the pancreas for islet purification in discontinuous gradients has increased the yield of islet cells (Ricordi et al., 1988, 1992a, 1992b; Linetsky et al., 1997; Fiorina et al., 2008; Faradji et al., 2007; Kahl et al., 2001). Currently, the recommendations are for 10,000 cells/kg to be infused into the donor. Islet cell infusion into the liver is the most common and successful technique for this procedure (Ricordi, 1996).

Implantation of the islets is performed via a seemingly minimally invasive radiologic procedure. The portal vein is cannulated by a transhepatic percutaneous approach with angiographic guidance. General anesthesia is usually required for children. Alternatively, for SIK transplantation, an open procedure may be performed after completion of the kidney transplantation via a midline incision. In this case, the portal system is usually accessed by catheterization of a mesenteric vein. The purified islet suspension is slowly infused with continuous monitoring of the intraportal hydrostatic pressure (Oberholzer et al., 1999). Because it is necessary to cannulate the portal vein percutaneously and there is the potential for massive blood loss, central venous access and a large-bore IV catheter are usually recommended. Additionally, arterial cannulation may be necessary to monitor electrolytes and

glucose every 30 to 60 minutes after the infusion of the beta cells. Infusions of insulin and glucose may be equally necessary to maintain the serum glucose between 80 and 120 mg/dL, which is best for cell viability. The morbidity and mortality associated with intraportal islet infusion are minimal (Hering and Ricordi, 1999; Ricordi et al., 1997; Hogan et al., 2008). However, as with all allogeneic cellular infusions, foreign antigen recognition by the recipient means the possibility of a reperfusion-type syndrome, which may require bolus doses of epinephrine or phenylephrine and an infusion of a vasoactive agent (e.g., dopamine). These hemodynamic changes have been noted in 14.6% of patients undergoing autologous islet cell transplantation (Manciu et al., 1999).

Through December 2010, more than 450 islet allografts have been performed worldwide, including 306 since 1990 (Oberholzer et al., 1999; Thierry and Ricordi, 2000). Cumulative 1-year patient and graft survival rates of 96% and 35%, respectively, were obtained in 200 C-peptide negative, type-1 diabetic patients transplanted from 1990 through 1997. The persistence of graft function can be assessed by measurable levels of basal serum C-peptide, at a threshold of 0.5 ng/mL. The observation that 32% of recipients lose graft function within 1 month of transplantation (and 46% within 3 months) indicates that primary nonfunction might be a major cause of islet graft loss (Meyer et al., 1998; International Islet Transplant Registry Newsletter, 1999, 2000).

Although the evidence of measurable C-peptide in the serum indicates survival of the islet graft, it does not necessarily imply that patients can survive long term without supplemental insulin. However, islet graft function in the absence of insulin-independence is still associated with markedly improved metabolic control, glucose counterregulation, and hypoglycemia awareness (Meyer et al., 1998).

In 2000, the Edmonton Protocol introduced several modifications to the transplantation procedure, such as the use of a steroid-free immunosuppression regimen and transplantation of a mean islet mass of 11,000 islet equivalents per kilogram. These modifications improved 1-year outcomes. Although the results of a 5-year follow-up in 65 patients demonstrated improvement in glycemic stability in a significant portion, only 7.5% of the patients have reached insulin independence. In addition to the scarcity of organs available for transplantation, islet transplantation still faces major challenges, especially those related to cell loss during the process of islet isolation and the losses related to the graft site, apoptosis, all rejection, autoimmunity, and immunosuppression. The function of transplanted islets has often been defined on the basis of C-peptide values, (Ryan et al., 2005a, 2005b) the presence of which in before-transplantation C-peptide-negative patients seems to be the best function marker for engrafted islets. C-peptide is also correlated with the reduction of exogenous insulin requirement, confirming that it may be representative of engrafted cell mass and function (Shapiro and Ricordi, 2004; Shapiro et al., 2006).

Pancreas and Kidney-Pancreas Transplantations

Pathophysiology of Pancreatic Failure

Type 1 DM (insulin-dependent diabetes mellitus [IDDM]) is usually the result of the synergistic effects of genetic, environmental, infectious, and immunologic factors leading to pancreatic

beta cell destruction and the resultant absolute absence of insulin production or secretion (Powers, 2001). Its U.S. incidence appears to be about 30,000 new-onset cases per year, and it has been the predominant cause of DM in the pediatric population for the past decade.

Type 2 DM (noninsulin-dependent diabetes mellitus [NIDDM]) is most often associated with obesity and is seen in the elderly population, albeit not exclusively. It has, however, been noted to be occurring with increasing frequency in the pediatric population and is linked to the increased incidence of childhood obesity. Furthermore genetic differences exist between IDDM and NIDDM, as evidenced by twin studies (Barnett et al., 1981). In this classic publication by Barnett and coworkers, the concordance rate (both twins affected) of IDDM was 50%, as contrasted with a concordance rate of greater than 90% for twins having NIDDM, demonstrating that genetic factors play a much larger role in this variant of the disease.

The primary objective of pancreas or islet beta-cell transplantation is to restore endogenous insulin secretion to a diabetic individual, by the provision of the missing normal beta cell function. Achieving euglycemia, as well as the release of glucagon in response to hypoglycemia, allows patients to be insulin free and to eat a regular diet, and it ultimately prevents the multisystem organ complications of diabetes. Occasionally, exocrine pancreatic function is also desired to restore both types of pancreatic hormonal function, possibly lost as a result of total pancreatectomy or in patients with cystic fibrosis (Kiberd et al., 2000; Kahl et al., 2001; Paty et al., 2001; Powers, 2001; Coosemans and Pirenne, 2003; Hakim, 2003). Carbohydrate, fat, and protein metabolism is expected to normalize after pancreas transplantation and may eventually stabilize and even prevent the development of microvascular disease (Coosemans and Pirenne, 2004).

For diabetic patients with imminent or established ESRD who have had or plan to have a renal transplantation, the American Diabetes Association now recommends pancreas transplantation as an acceptable therapeutic alternative to exogenous insulin therapy (American Diabetic Association, 2000). Additionally, diabetic patients should be considered for pancreas transplantation (PTA) in the absence of indications for kidney transplantation in the setting of frequent, acute, and severe metabolic complications, incapacitating clinical and emotional problems with exogenous insulin therapy, and consistent failure of insulin-based management to prevent complications. In the majority of cases, pancreas transplantation is performed in patients with type 1 DM and ESRD. Patients eligible for PTA or PAK procedures must have stable and adequate kidney function at the time of transplantation, as both the operative procedure and the immunosuppressive agent may produce a further decline in the patients' renal function.

Absolute contraindications to transplantation include active malignancy or infection, recently treated malignancy not meeting the minimum disease-free observation period as suggested by the Clinical Practice Guidelines of the American Society of Transplantation (Diabetes Control and Complications Trial Research Group, 1993), psychiatric disease so severe or unstable that the stress of a large surgery would probably result in marked decompensation, and inability or unwillingness to take immunosuppressant medications regularly so that graft failure would be certain.

Preoperative Evaluation

As with kidney transplantation, patients with pancreatic failure for any of the group of procedures for islet-beta cell replacement will require a thorough evaluation given the constellation of hyperglycemic complications seen in the diabetic patient; these include ischemic heart disease, cardiomyopathy, renal failure, autonomic neuropathy and gastroparesis, hypertension, and cerebrovascular, ophthalmologic, and macrovascular diseases. In addition, a meticulous review of the current list of medications and allergies must be undertaken. The patient selected to receive a deceased donor organ requires urgent attention, evaluation, and preparation for the procedure, as the procured organ has a limited life in the preservation solution, usually not to exceed 24 hours. Hence, the anesthesia evaluation, if not previously completed as part of the pretransplantation evaluation, requires a *de novo* thorough evaluation in a timely manner.

The degree of renal dysfunction, if any, is of particular importance, as it will dictate the particular type of procedure that the patient should receive (i.e., SKP versus PTA). SKP transplantations account for 79% of pancreas transplantations, whereas PAK transplantations account for 14%. Most often, this decision has been made as part of the preoperative evaluation so as to have the patient placed on the waiting list. Moreover, a determination of the patient's acid-base status, daily serum glucose, electrolyte concentrations, and time of last hemodialysis is of great importance. Anemia associated with ESRD, resulting from diminished production of erythropoietin and chronic bone marrow suppression, is often associated with an increased morbidity and diminished graft success (Koehtop et al., 2000).

The principal cause of perioperative mortality in adult pancreas recipients is coronary artery disease (Bland, 2003). Thus, mandatory screening tests for the preoperative cardiovascular evaluation include coronary angiography in addition to the usual noninvasive studies, which often include a dobutamine stress echocardiogram (Rabbat et al., 2003). Moreover, depending on the findings, pretransplantation coronary revascularization reduces the risk for subsequent cardiac events (Rabbat et al., 2003).

The pediatric patient facing pancreas transplantation, however, is usually devoid of cardiovascular or significant renal complications, as the disease process is usually of a shorter duration than in the adult population. Nonetheless, all end-organ damage must be fully assessed and excluded.

A history of gastroparesis needs to be addressed appropriately in the pediatric patient, as it may warrant an IV rapid-sequence induction as opposed to an inhalation induction. Aspiration prophylaxis with H₂ antagonists, metoclopramide, and possibly a nonparticulate antacid should be considered. Additionally, autonomic neuropathy, which results in gastroparesis, may predispose these patients to episodes of hypotension during the transplantation or any anesthesia.

Airway evaluation is of special importance, because diabetics have an increased incidence of difficult intubations (Hogan et al., 1988). This finding has been correlated with the stiffness of the interphalangeal joints, which results in difficulty in opposing the fingers (Hogan et al., 1988). This too correlates with longevity of the disease and may prove irrelevant in the pediatric population.

Surgical Procedure

Several surgical techniques for pancreas transplantation have been described, and the approach depends on whether the

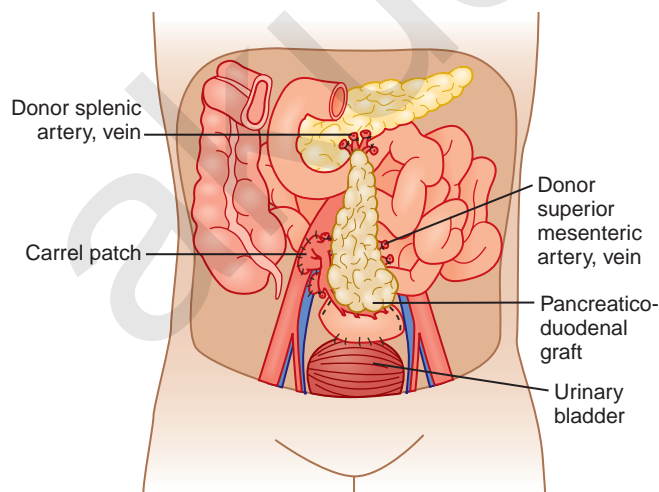

procedure is an SKP or a PTA. After appropriate blood and tissue typing for human lymphocyte antigen (HLA) markers and ABO compatibility, the organ is prepared on the back table. Vascular grafts, if needed, are anastomosed at this time, and the organ is maintained in cold preservation solution (to minimize warm ischemic preservation injury).

After induction of general anesthesia and the placement of monitors and arterial and central venous catheters, a surgical midline incision is made to facilitate implantation of the pancreas graft and the kidney if necessary. The right colon is mobilized by incising the peritoneal reflection, allowing positioning of the right colon cephalad. The right iliac vessels are then dissected, and in patients undergoing bladder drainage (BD), the right iliac vein is completely mobilized by ligating and dividing all posterior branches. Mobilizing the sigmoid colon and reflecting it medially exposes the left iliac system. Ligating and dividing the posterior branches as on the right side then allow mobilization of the iliac vein. The graft is then implanted with the head of the pancreas and the duodenum directed toward the pelvis. In BD grafts, the site for the vascular anastomosis is usually the common iliac vein and the common iliac artery. The graft, with a duodenal “button,” is then anastomosed to the bladder (Fig. 28-22).

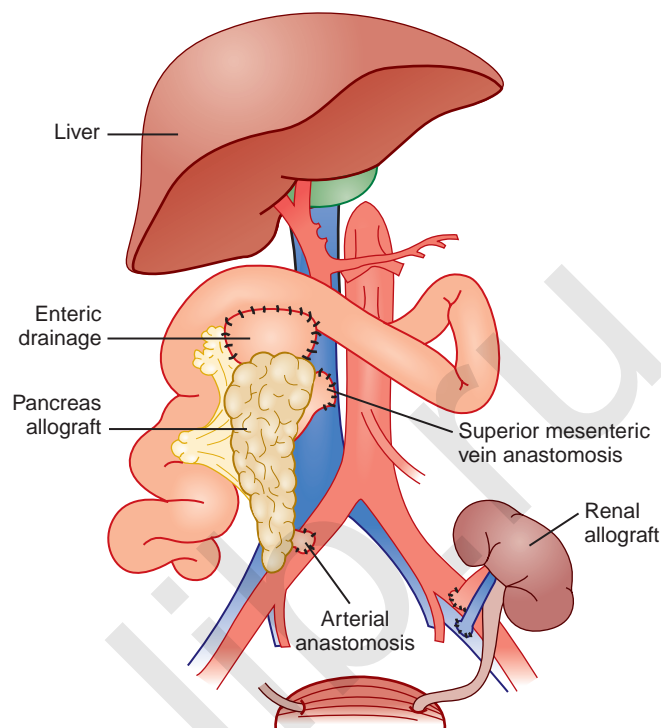

Compared with BD pancreatic allografts, the vascular anastomoses of enteric drainage grafts are achieved using the more proximal iliac vasculature. Usually, the venous anastomosis is performed in the area of the distal IVC, and the arterial anastomosis is to the proximal right common iliac artery. The organ is then anastomosed to a proximal portion of the jejunum (Fig. 28-23).

A crucial element at the time of graft reperfusion is the sequence of slow releases of the vascular clamps. Over the course of several minutes, the clamps are removed in the following sequence: proximal venous clamp, distal arterial clamp, proximal arterial clamp, and distal venous clamp. After each clamp is removed, careful hemostasis of bleeding vessels on the surface of the pancreas and at each vascular anastomosis, if necessary, is accomplished before any further clamps are removed.

The surgical approach to pancreas engraftment depends on whether exocrine secretions will be managed by enteric or by

■ **FIGURE 28-22.** Solitary pancreas transplant (PTA), with the urinary bladder being used for exocrine drainage (bladder drainage technique). Note the native pancreas is in situ (see text).

■ **FIGURE 28-23.** Pancreas and kidney transplants (PAK or SKP) with the donor pancreas vascularized to facilitate enteric exocrine drainage to a proximal portion of the jejunum (enteric drainage technique). The donor kidney is implanted in the left iliac fossa anastomosed to the femoral vessels, and a ureteroneocystostomy is performed (see text). (From Larson-Wadd K, Belani KG: *Anesthesiol Clin North America* 22:663, 2004.)

bladder drainage. Between 1987 and 1995, more than 90% of pancreas transplantations were performed using BD, initially described by Sollinger and colleagues, (1998) and later modified by Corry and associates to include the duodenal button, which acts as a reinforcement of the anastomosis of the graft to the bladder. This approach allows serial measurements of urinary amylase, one method of monitoring graft rejection (Bloom et al., 1997; Cattral et al., 2000; Bland, 2003; Coosemans and Pirenne, 2003). Additionally, pancreatic biopsies are less risky, as the organ is placed lower in the pelvis.

Chronic loss of pancreatic secretions into the bladder can result in associated complications of metabolic acidosis, a finding in the majority of patients with BD, and perhaps dehydration. Electrolyte abnormalities, which are the results of the loss of sodium bicarbonate-rich pancreatic secretions, are not infrequent. Moreover, local bladder irritation, hematuria, urethritis, bladder leak, neurogenic bladder, chemical cystitis and urethritis, allograft pancreatitis, duodenitis, bladder calculi, urethral erosions, prostatitis, urethral strictures, and infections are all possible complications (Bloom et al., 1997; Cattral et al., 2000; Kahl et al., 2001). In fact, the frequency of urologic complications is high, 50% to 77%, with this approach, but this rarely results in either patient mortality or graft loss.

The kidney, if implanted as in the SKP procedure, is positioned in the left iliac fossa and an ureteroneocystostomy performed. Vascular anastomoses are to the dissected left iliac vessels in the child weighing more than 20 kg (see Fig. 28-23).

However, in the infant weighing less than 20 kg, the graft is implanted with anastomoses of the vasculature to the aorta and vena cava.

More recently, the enteric drainage technique has become the surgical technique of choice (Bloom et al., 1997; Cattral et al., 2000; Bland, 2003; Coosemans and Pirenne, 2003), although initially it was associated with a high morbidity rate because of peritoneal leakage and the need for frequent reoperations. In this procedure, the pancreatic duct is inserted into the small bowel using a button of duodenum, or with a Roux-en-Y limb (see Fig. 28-17). Although Roux-en-Y was once used predominantly for enteric drainage at most centers, its role has diminished, primarily as a result of the reduced need for monitoring of graft rejection as immunosuppressive regimens have improved and the frequency of rejection episodes has decreased. Over 55% to 77% of pancreas transplantations are with enteric drainage, as reported to UNOS for the period from 1999 to 2002.

Enteric drainage avoids the complications associated with BD (Bloom et al., 1997; Cattral et al., 2000; Coosemans and Pirenne, 2003). Vascular management of the pancreatic graft has also evolved. Venous graft effluent can be drained into either the systemic or the portal circulation. Portal venous drainage was used in approximately 25% of pancreas transplantations from 1996 to 2002 (Bland, 2003). Both portal and systemic drainage is associated with excellent glycemic control; however, fasting serum insulin levels are significantly lower in portal drainage, without effect on graft survival rates at 1 year for SKP or PAK (Cattral et al., 2000; Bland, 2003); and PTA has a slightly higher graft survival rate with portal drainage (Bland, 2003). A postulated advantage of portal venous drainage is the avoidance of hyperinsulinemia, which has been associated with advanced atherosclerosis and vasculopathy. Pancreas grafts have been associated with the highest surgical complication rate of all routinely transplanted solid organs. Causes for technical failure of the deceased-donor primary pancreas transplantations include vascular thrombosis, pancreatitis, anastomotic leak, bleeding, rejection, and infections (Laftavi et al., 1998; Troppman et al., 1998; Humar et al., 2000a, 2000b; Sutherland et al., 2001; Michalaka et al., 2003).

Vascular thrombosis is the most commonly sited cause of graft failure, and it was assumed to be associated with technical complications of the operation. However, after a thorough pathologic evaluation of sequential cases of massive thrombosis, it is now evident that unrecognized hyperacute rejection is far more common than had been appreciated in this setting. Thus, organ rejection may in fact be the most common cause of graft loss. Significant risk factors for graft loss include older donor age, retransplantation, and relaparotomy for infection, leakage, or bleeding (Troppman et al., 1998; Humar et al., 2000a, 2000b). The quality of a deceased-donor graft can directly affect graft performance. As experience with pancreas transplantation has increased, the incidence of relaparotomy has decreased (Humar et al., 2000a, 2000b). Risk factors for recipient death include older recipients, retransplantation, and relaparotomy for thrombosis, infection, leakage, or bleeding (Troppman et al., 1998).

Anesthesia Management

After appropriate positioning and placement of the standard monitors, anesthesia is induced either with an IV technique or an inhalation technique with agents appropriate for the patient's baseline metabolic condition, followed by orotracheal intubation. In children, a central venous catheter and prefer-

ably a radial arterial catheter are inserted (as both iliac arteries may potentially be used for vascular anastomoses). After the induction, the volatile anesthesia agent should be isoflurane or desflurane for patients with renal dysfunction, as they appear to be virtually devoid of nephrotoxicity and physiologically do not diminish renal arteriolar blood flow. Nitrous oxide is avoided because it increases the size of gas-containing spaces such as the bowel. A balanced anesthesia technique may also be used to maintain general anesthesia.

Morphine-6-glucuronide and normeperidine, the metabolites of morphine and meperidine, respectively, may lead to toxicities, with seizures in the case of normeperidine in the setting of renal failure, and hence should be avoided. Hydromorphone may be used in preference to these agents, as it is less dependent on renal excretion. However, intraoperatively and immediately postoperatively, fentanyl is the narcotic of choice, because it has minimal associated hemodynamic alterations. The choice of muscle relaxant depends on the degree of renal impairment.

In patients with significant cardiovascular disease, direct arterial pressure monitoring and right heart monitoring with a pulmonary artery catheter should be considered, as well as continuous TEE monitoring as needed. This, however, is rarely necessary in the pediatric patient. Serum glucose levels must be carefully monitored at least hourly during general anesthesia, particularly after graft reperfusion, with maintenance of the serum glucose between 100 to 200 mg/dL (Koehtop et al., 2000), as hyperglycemia triggers early islet cell dysfunction (Clark et al., 1982; Imamura et al., 1988). Maintaining serum glucose levels in an acceptable range is accomplished by continuous infusion of regular insulin at a rate of 1 to 5 U/hr, with concurrent dextrose infusion when serum glucose levels are 150 mg/dL. The addition of dextrose ensures uninterrupted intracellular fuel to avoid perioperative ketosis. Pancreatic beta cells may function as early as 5 minutes after reperfusion with the release of insulin (Troppmann et al., 1996, 1999; Jung et al., 2009; Koh et al., 2008). Delayed graft function may be treated postoperatively with an insulin infusion titrated to keep blood glucose levels 150 mg/dL (Sealey, 1988; Kin, 2010; Anazawa, 2009). Somatostatin may also be administered to decrease exocrine pancreatic secretion (Bloom et al., 1997).

Prior to allograft reperfusion with release of the vascular clamps, the hemodynamics are optimized to ensure adequate perfusion and prevent hypotension. IV fluids, either crystalloid or colloid, are administered to achieve a CVP in the range of 12 to 14 mm Hg and a systolic blood pressure of at least 140 mm Hg (Koehtop et al., 2000). Alternatively, in patients with a pulmonary artery catheter, careful titration of volume versus filling pressures and cardiac output can be used to optimize intravascular fluid status before vascular unclamping. Additionally, the end-tidal concentration of the inhaled agents may need to be reduced, because reperfusion of both grafts may result in short-lived hypotension as a result of vasodilation, cytokine release, transient myocardial dysfunction, and metabolic acidosis. This may require the administration of fluids, the use of a vasopressor (preferably dopamine), IV bicarbonate or thamsol, and blood products when appropriate.

It is imperative to maintain adequate and even supranormal perfusion pressure and blood flow to the new allograft (see Kidney Transplantation, earlier). This may help to prevent graft vessel thrombosis, the most common cause of technical pancreatic graft failure (Bland, 2003). However, as noted previously, this complication is probably related to organ rejection.

Most patients should be extubated in the operating room at the end of surgery, if the usual criteria are met for this. Serum glucose, hemoglobin, electrolytes, and troponin levels should be checked, along with a baseline arterial blood gas for the determination of any residual acidosis immediately on arrival in the ICU or the recovery room. Patients with a bladder anastomosis often require supplemental sodium bicarbonate to treat the metabolic acidosis caused by the loss of pancreatic secretions into the bladder (Sudan et al., 2000; Kahl et al., 2001; Coosemans and Pirenne, 2003; Troppmann et al., 2004). Postoperatively, patients receive 5% dextrose in normal saline as maintenance fluid. Nasogastric and urine output losses are replaced in equivalent amounts with normal saline. Pancreas transplant recipients have a higher incidence of acute rejection and immunologic graft loss than any other solid organ recipients. They are at risk of developing infection for numerous reasons, including immunosuppression, contamination from the duodenal segment of the graft, and serum glucose irregularity because of DM (Troppmann et al., 2004). Infection prophylaxis with broad-spectrum antibiotics targeting *Staphylococcus*, gram-negative bacteria, anaerobes, and CMV is routine in many centers (Bloom et al., 1997; Humar et al., 2000a, 2000b; Coosemans and Pirenne, 2003). Prophylaxis against vascular thrombosis consists of either low-dosage IV heparin (300 to 500 U/hr) or subcutaneous administration of heparin followed by aspirin (Humar et al., 2000a, 2000b; Coosemans and Pirenne, 2003).

HEMATOPOIETIC STEM-CELL TRANSPLANTATION

The first hematopoietic stem-cell transplantation (HSCT) was an allograft procedure performed in 1968 in a 2-year-old boy who received HLA-matched bone marrow from his sister to treat Wiskott-Aldrich syndrome (Bach et al., 1968). *Stem-cell transplantation* is a generic term that includes several different techniques. When an allogeneic transplantation is performed, hematopoietic stem cells are taken from the bone marrow, peripheral blood, or umbilical cord of a healthy donor matched for HLA type (either a family member or an unrelated volunteer). During cord blood harvesting, cord blood is collected from an umbilical vein under sterile conditions, without physical risk to the mother or infant donor, from the delivered placenta (ex utero) or during the third stage of labor (in utero). An experienced collector can harvest an average of 110 mL of blood. This contains approximately 1×10^9 nucleated cells from a single placenta (Kurtzberg, 2009). When an autologous transplantation is performed, the child's own stem cells are taken from either the bone marrow or peripheral blood, and preserved for later transplantation. In both instances, the child is prepared prior to transplantation, by a process known as conditioning, with either chemotherapy or chemoradiotherapy. The term *syngeneic* transplantation refers to transplantation of stem cells obtained from an identical twin (Stein et al., 1990; Beebe et al., 1995). Figure 28-24, from the Center for International Blood and Marrow Transplant Research registry, provides information about the source of stem cells used for HSCT in children. As seen in the figure, there is an increase in the use of cord blood and peripheral blood as a source for stem cells in the pediatric age group. Bone marrow as a source of stem cells is usually used for autologous transplantation, whereas mobilized peripheral blood stem cells are used in the majority of cases in

FIGURE 28-24. Allogeneic stem-cell sources used in different eras. (From the Center for International Blood and Marrow Transplant Research (CIBMTR): Newsletter. 13(2), Dec 2007 [see www.cibmtr.org]. Also see www.marrow.org/PHYSICIAN/Outcomes_Data/index.html.)

allogeneic settings (Machaczka et al., 2009). Banked cord blood is usually used for unrelated donor transplantation (Kurtzberg, 2009). Cord blood has several advantages: prompt availability of stem cells, decrease of graft-versus-host disease (GVHD), and better long-term immune recovery resulting in equivalent long-term survivals even when compared with HLA-matched bone marrow-obtained stem cells (Gluckman, 2009). Bone marrow harvesting from both adult and pediatric donors is usually done under general anesthesia. The harvesting of mobilized peripheral blood stem cells on the other hand requires a deep venous catheter for performing a plasmapheresis procedure (Demeocq, 1994; Kanold et al., 1999). This is usually done under sedation and requires processing of one to three blood volumes (Kanold et al., 1999), and the procedure can take up to 8.5 hours (Demeocq, 1994). During autologous harvest of bone marrow, Perez de Sa and colleagues (1991) were able to avoid the use of RBC transfusion by performing hemodilution with 6% dextran during the removal of 24 ± 6 mL/kg of bone marrow. However, in some instances, autologous or allogeneic blood may be required (Machaczka et al., 2009).

HSCTs are now performed for various illnesses, ranging from hematologic and oncologic disorders to metabolic and genetic defects (Kurtzberg, 2009). Most commonly, HSCT is performed in patients with leukemia, lymphoma, neuroblastoma, and multiple myeloma (Box 28-5). HSCT was performed to treat children with epidermolysis bullosa dystrophica (Tolar et al., 2009). An 18-month-old boy with recessive dystrophic epidermolysis bullosa was one of the first patients transplanted for this disease. He received umbilical cord blood and bone marrow in 2007 from a perfectly matched sibling, at the University of Minnesota. Epidermolysis bullosa dystrophica is a progressive disease of the skin that is ultimately fatal. The children are a challenge for the anesthesiologist. No adhesive tape can be used on the skin, and the skin has to be carefully protected with lubricants and steroid cream. Scarification can result in significant difficulties in mouth opening and can also result in lesions in the mouth and pharynx, making airway care a challenge (Karabiyik et al., 2009) (see Chapter 36, Systemic Disorders).

Although the death rate from graft failure, infection, and GVHD is still high (approximately 40%), the success rate of

HSCT has improved over time with advances in immunosuppression, chemotherapy, antibiotics, and supportive care (Beebe et al., 1995). Between 1989 and 2006, the number of children receiving bone marrow transplantation for various disorders has reached a steady number—between 4000 to 4500 per year (CIBMTR, 2007).

The cord blood of newborn donors has become popular as a marrow source for both pediatric patients and adults (Tse et al., 2008). There is minimal risk for viral exposure with cord blood, and the donor is not at risk. The primary benefit to cord blood transplantation, however, is for reasons related to the immaturity of the newborn stem cell, and the incidence of GVHD is markedly lower than with standard bone marrow or peripheral stem cell transplantations (Cohen and Nagler, 2003; Kurtzberg, 2009).

Before receiving HSCT, children require bone marrow ablation with chemotherapy and occasionally total body irradiation (TBI). The intensity of this protocol varies and is dependent on several factors (Riordan et al., 2007). After successful preparation, the processed donor marrow or stem cells from peripheral or cord blood are administered intravascularly into the HSCT recipient, where they circulate and settle into the patient's bone marrow beds. Occasionally, engraftment fails to occur. Even if engraftment is successful, complications are frequent and include infection, GVHD, toxicity from chemotherapy or radiation therapy, and venoocclusive disease of the

TABLE 28-21. Noninfectious Pulmonary Complications after Hematopoietic Stem-Cell Transplantation

Complication	Interval after Transplantation
Diffuse alveolar hemorrhage	1 day to 3 mo
Idiopathic pneumonia syndrome	1 day to 15 mo
Pulmonary cytolytic thrombi	15 day to 11 mo
Peri-engraftment respiratory distress syndrome	3rd to 4th wk
Bronchiolitis obliterans organizing pneumonia	1 mo to 13 mo
Bronchiolitis obliterans	3.5 mo to 15 mo
Delayed pulmonary toxicity syndrome	4 mo to 5 mo

From Afessa B, Litzow MR, Tefferi A: Bronchiolitis obliterans and other late onset non-infectious pulmonary complications in hematopoietic stem cell transplantation, *Bone Marrow Transplant* 28:425, 2001.

liver (Gentet et al., 1988; Stein et al., 1990; McDowall, 1993; Beebe et al., 1995; Schure and Holzman, 2000; Wah et al., 2003; Thiruvankatarajan and Rebecca, 2007). Furthermore, several noninfective pulmonary complications (Table 28-21) can occur soon after HSCT and even up to 15 months after transplantation (Afessa et al., 2001).

Infection is one of the main causes of morbidity and mortality in bone marrow transplant recipients. Ablation of the bone marrow renders a child neutropenic for as long as several weeks before full engraftment occurs. T- and B-cell function may also be depressed for several months after HSCT, causing recipients to be susceptible to viral and fungal infections (Stein et al., 1990; Beebe, 1995).

GVHD occurs when the T lymphocytes derived from the donor's bone marrow react against the host. Acute GVHD has an incidence of 40% to 60% and occurs within 100 days after transplantation and may manifest with skin rash, watery or bloody diarrhea, or hepatic involvement with hyperbilirubinemia. Fever is common. Chronic GVHD has an incidence of 20% to 40% and occurs after day 100 following allogeneic HSCT. It occurs most commonly in patients who have previously had acute GVHD. Chronic GVHD may manifest with scleroderma, oral mucositis, interstitial pneumonitis, polymyositis with contractures, and thrombocytopenia (Stein et al., 1990; Schure and Holzman, 2000; Wah et al., 2003; Thiruvankatarajan and Rebecca, 2007).

The TBI used in preparation for HSCT may cause pneumonitis, restrictive cardiomyopathy, pulmonary fibrosis, and oral mucositis. Chemotherapeutic agents such as doxorubicin can result in cardiomyopathy and other toxicities (see Chapter 36, Systemic Disorders). In addition, venoocclusive disease of the liver may develop after intensive chemotherapy and radiation therapy. This complication, which is most often fatal, occurs approximately 2 weeks after transplantation, when the small hepatic venules become fibrotic and develop pericentral hepatocyte necrosis and congestion (Gentet et al., 1988).

Before receiving HSCT, pediatric patients often require anesthesia for indwelling central venous catheterization, bone marrow biopsies, baseline diagnostic testing (eye examinations, magnetic resonance imaging, CT, pulmonary washing for macrophage function evaluation) and TBI. After HSCT, children

often require anesthesia for (1) biopsies to evaluate the status of the transplanted graft and to determine if GVHD has developed, and (2) treatment of the surgical complications that may follow the HSCT procedure and for complications related to GVHD.

Most children tolerate anesthesia for these procedures without difficulty. However, complications can occur, particularly in recipients less than 2 years of age and those with metabolic and storage diseases, so anesthesia providers must keep in mind the unique medical problems associated with children undergoing HSCT (Stein et al., 1990; Beebe et al., 1995; Thiruvankatarajan and Rebecca, 2007).

Preoperative Assessment

Before anesthesia is administered, HSCT recipients must be examined for potential difficulties from the patient's underlying disease and for the complications arising from HSCT. For example, tracheal intubation and airway care are often difficult in patients with Hurler's syndrome (Belani et al., 1993). Before anesthesia, especially when mucositis is present, the airways in all children before and after HSCT must be examined for feasibility of the approach, and for the presence of mucositis. Mucositis usually develops when these patients become neutropenic prior to the marrow's becoming functional. This leads to oral infections and mucositis, which can lead to difficulty in visualizing the laryngeal inlet. Mucositis is also associated with an increased incidence of postextubation laryngeal edema in the postoperative period. Cardiopulmonary evaluation must be undertaken in all children before HSCT. Cardiac disease is common in many children with mucopolysaccharidosis (Belani et al., 1993), and anthracycline therapy used in children needing HSCT can exert detrimental cardiopulmonary effects (Uderzo et al., 2007). Thus, all children need an ECG evaluation, an echocardiogram, and pulmonary function tests (PFTs) when indicated. Uderzo and associates (2007) suggest that after 5 years, the cumulative incidence of respiratory function abnormalities is 35%, and impairment of the cardiac shortening fraction occurs in 26% of children. Similarly, thrombocytopenia and other coagulopathies resulting from liver dysfunction may require attention prior to anesthesia care. Because of GVHD, there may be significant pulmonary involvement, which needs to be defined before anesthesia for potential intraoperative complications and for planning a postoperative ventilation strategy. Chemotherapy-related cardiac dysfunction needs to be documented but is usually not a big concern in pediatric HSCT patients. Both radiation and chemotherapy are associated with a higher likelihood of nausea and vomiting, and the need for airway protection may favor endotracheal intubation (Stein et al., 1990; Beebe et al., 1995; Schure and Holzman, 2000; Wah et al., 2003; Thiruvankatarajan and Rebecca, 2007).

Anesthesia Management

A variety of anesthesia techniques can be safely used to anesthetize a child for HSCT. No drug, agent, or technique is absolutely contraindicated (Stein et al., 1990; Beebe et al., 1995; Thiruvankatarajan and Rebecca, 2007). Several anesthesia providers have raised concern about the use of nitrous oxide in HSCT recipients because it suppresses methionine synthetase, which is required for nucleotide synthesis (Thiruvankatarajan

and Rebecca, 2007). However, a randomized study of cellular function and marrow engraftment of stem-cell recipients exposed to short-term use of nitrous oxide anesthesia failed to show any deleterious effects (Lederhaas et al., 1995). One of the major concerns of anesthesia care for HSCT recipients is the anatomic morbidity from their underlying problems (mucopolysaccharidosis, epidermolysis bullosa dystrophica) and the acquired mucositis that they develop after HSCT. The incidence of mucositis is quite high, and it occurs when the patient becomes severely neutropenic. Techniques should thus be chosen to minimize mucosal damage in the oropharynx. For example, IV propofol and, more recently, dexmedetomidine with or without ketamine are suitable choices to provide sedation for simple procedures. Propofol has proved useful for anesthesia for TBI using spontaneous ventilation without airway instrumentation. It not only has a rapid recovery profile but is also an antiemetic and therefore promotes adequate nutritional intake when compared with thiopental or ketamine (Beebe et al., 1995). In some instances, the laryngeal mask airway may be used to provide a more secure airway during TBI or other procedures when children have a preexisting condition such as Hurler's syndrome and a difficult upper airway. Significant lubrication and caution must be used when using the laryngeal mask airway in these children, because trauma can occur with it (Marjot, 1991).

Patients who have already developed mucositis and require anesthesia present a challenge to the pediatric anesthesia provider. Most of these children require tracheal intubation to prevent aspiration of infected mucus. The preoperative airway examination may be difficult because of significant discomfort. For the same reason, awake intubation is less likely to be an available option. Movement and struggling during the procedure may initiate bleeding and edema and obscure the laryngeal inlet. Unless the mouth is anatomically fixed and unable to be opened, a rapid-sequence induction often provides the best option for atraumatic access to the trachea, and this approach also minimizes the time in which aspiration of infected secretions can occur.

In other cases, especially when stridor or other signs of airway obstruction are evident, an approach that is often practiced in children with supraglottitis is favored. This often requires that the child be transported to the operating room for ideal intubating conditions, the presence of a trained pediatric otolaryngologist, and all the necessary tools to handle a difficult airway. After an effective dosage of an anticholinergic and carefully titrated sedation, the child is allowed to breathe sevoflurane in oxygen in the position that best promotes spontaneous breathing. Controlled breathing is attempted at the appropriate time, and when this is possible, a decision is made about whether the use of neuromuscular blockers is appropriate.

Care must be taken with extubation as well. Most patients with mucositis can be extubated when fully awake. Often these patients develop croup in the postoperative period, which may require treatment with dexamethasone (0.5 to 1.0 mg/kg) and one or more courses of racemic epinephrine treatment. However, patients with mucositis and severe edema of the laryngeal inlet may require prolonged intubation until the edema has resolved (Beebe et al., 1995; Thiruvankatarajan and Rebecca, 2007).

Outcome

Outcome after HSCT depends on numerous factors and is related to disease type, response to chemotherapy, phenotype,

■ **FIGURE 28-25.** Three-year survival curves after stem-cell transplantation for malignant and nonmalignant disorders. (From Gluckman E: *History of cord blood transplantation*, Bone Marrow Transplant 44:621, 2009.)

molecular genetics, and conditioning protocols (Buchholz and Ganser, 2009). The Center for International Blood and Marrow Transplant Research (CIBMTR) publishes a newsletter that provides survival and outcomes information for transplantations facilitated by the National Marrow Program. The 3-year overall results for survival after transplantation in children with nonmalignant disorders are better than for those with malignant disorders (Fig. 28-25) (Gluckman, 2009), and the results significantly improved after 1998 (Fig. 28-26).

HEPATOCTYCE TRANSPLANTATION

Since the development of techniques for the isolation of individual cells from the liver, transplantation of isolated hepatocytes has been considered a potential therapy for the treatment of

liver disorders. Over the past decade, several investigators have shown that hepatocyte suspensions can successfully engraft into the liver or splenic parenchyma or into the peritoneal cavity and other extrahepatic sites. These hepatocytes have been shown to function after transplantation, have partially corrected liver-based errors of metabolism, and have reproducibly prolonged survival of animals with liver failure. Although hepatocyte transplantation (HT) is in its infancy, abundant preclinical studies and small series of patients suggest great value in acute liver failure and in the treatment of liver-based metabolic diseases, such as urea cycle disorders. From a technical standpoint, HT is begun with cannulation of the portomesenteric circulation. This can be performed using open exploration and isolation of mesenteric venous tributaries or by percutaneous access to the intrahepatic portal vein. Slow infusion of the hepatocyte suspension occurs over several hours. Infusion-related complications include transient reductions of portal venous flow and hemodynamic instability. In addition, portosystemic embolization of hepatocytes into the pulmonary circulation can result in transient increases in pulmonary pressures and hypoxia (Fox, 1998; Horslen and Fox, 2004; Strom, 1997, 1999).

To date, human HT has been attempted in patients with acute and chronic liver failure, and in some patients with liver-based metabolic disease. Clinical experience suggests that in contrast to animal studies, transplanted hepatocytes have a markedly diminished regenerative ability in humans (Strom, 1997, 1999; Fox, 1998; Horslen, 2003). Despite this, HT remains an alternative experimental therapy that has been used to bridge patients to orthotopic liver transplantation with potential reductions of the preoperative morbidity and mortality associated with severe liver failure and poorly controlled metabolic deficiencies.

POSTTRANSPLANTATION SIDE EFFECTS

Posttransplantation Lymphoproliferative Disease

Posttransplantation lymphoproliferative disease (PTLD) is one of the most life-threatening complications of immunosuppressive therapy in this era of organ transplantation, even with the use of newer immunosuppressive agents and regimens for induction and maintenance. It is seen after both solid organ and bone marrow transplantation. Patients receiving bone marrow, liver, or kidney transplants have an estimated incidence of PTLD of 1% to 3%; heart and heart-lung recipients, 5% to 13%; and intestinal transplantations, 30%. Recently, the incidence of PTLD has been reduced to 8% in intestine and 3% in liver transplantations (Bond et al., 2008). Mortality is reported to be as high as 50% (Faye and Vilmer, 2005). Epstein-Barr virus (EBV) is confirmed in greater than 50% of pediatric and 85% of adult patients. The interval to presentation of this disease ranges from months to years after transplantation.

The most common sites of involvement are the lymph nodes and GI tract, with homograft involvement dependent on the organ transplanted. The heart is usually spared from involvement with heart transplantation. However, with heart-lung transplantation, the lungs are the most frequently involved sites (Sklar, 1991). Similarly, the liver is a frequent site of involvement in recipients of bone marrow transplantation.

Because lymphoproliferative disease requires active viral infection of the B cell, it seems that pediatric patients have a

higher likelihood for the development of lymphoproliferative disease, the rationale being that pediatric patients have not been exposed to the virus and thus have no antibodies for the prevention of infection. The risk for PTLD is five times greater in patients who are EBV seronegative at the time of transplantation (Kirk et al., 2007). Cyclosporin A (CyA)-induced suppression of the suppressor T lymphocyte is responsible for continued uncontrolled polyclonal proliferation of the transformed B lymphocyte, infected with the episomal EBV DNA. Tumors generated in response to the virus are varied. Non-Hodgkin's lymphomas are the usual lymphomas.

Treatment of PTLD is by several modalities, with reduction of the immunosuppressive agent being the most efficacious. This allows the improvement of immunosurveillance; however, the reestablishment of the host defense may exacerbate organ rejection. Approximately two thirds of patients will be responsive to this maneuver in EBV-related PTLD. Alternatively, cytokines and immune globulin have been used to enhance the immune response. Fischer-Froehlich and coworkers (2002) reported the use of anti-B-cell antibodies in controlling B-cell lymphomas. Interferon- γ in conjugation with gamma globulin has also proved to be efficacious. Surgical resection of tumors has also improved survival in selected cases, with survival reported at 74%, relative to the 31% overall survival after the presentation of PTLD (Stieber et al., 1991). Acyclovir inhibits EBV replication. Prophylaxis with this agent may prove to be beneficial because the drug does not prevent proliferation of EBV-infected cells already transformed.

Immunosuppression under tacrolimus apparently does not appear to confer protection from the development of PTLD. The time to development of the disease with its use appears to be similar to CyA.

For the anesthesiologist, perioperative concerns of children with PTLD involve the airway. Tonsillar hypertrophy is a frequent presentation of this disease in the pediatric patient and often requires bilateral tonsillectomy for diagnosis of the disease as well as management of upper airway obstruction. Occasionally, these patients have been treated with chemotherapeutic agents, which may result in additional organ dysfunction.

Infectious Diseases

The risk for infection in the transplant patient is directly influenced by two factors: the patient's environmental exposure and the patient's immunosuppressive regimen. The spectrum of viral causative agents included CMV, the most deleterious (Ho, 1991; Patel et al., 1996). Antirejection therapy is the most important contributor to the development of infection, with CyA at the top of the list of implicated agents. A clear example is the incidence of CMV infection, which has increased from 15% in the pre-CyA era to greater than 50% (Rubin and Tolkoﬀ-Rubin, 1991).

Patients who experience increases in immunosuppression for acute and chronic rejection are at increased risk for all types of infection (Fishman, 2007). Opportunistic viral infections can affect both patient and graft survival. Ganciclovir and valganciclovir are used in the treatment of CMV and in EBV infections. The spectrum of presentation of CMV infection is bimodal and has two sources. The virus may be reactivated from a latent phase, or there may be active infection. Although prior infection confers acquired immunity, this may also be the source of latent infection in the immunosuppressed patient. The donor

organ has been shown to act as a source of latent infection. The effects of CMV infection may be quite devastating, and damage to the grafted organ is frequently encountered. Obliterative bronchiolitis, chronic coronary atherosclerosis, and vanishing bile duct syndrome are often attributed to CMV infection of the lungs, heart, and liver, respectively. The greatest risk for both CMV and EBV infections occurs in seronegative patients who receive allografts from seropositive donors. Completion of vaccination series with virus vaccines is important in children. Live-virus series (e.g., mumps, measles, and rubella [MMR], and varicella) should ideally be completed before transplantation.

Other viral infections with significant consequence to the host are hepatitis viruses B and C and HIV infection. There is a significant reinfection rate of the hepatic graft in patients known to be ϵ -antigen positive before transplantation. This has raised the question of whether this group of patients should have transplants. Hepatitis B is devastating to all graft recipients, and a higher than normal rate of overwhelming hepatic failure is the rule. Hepatitis C is also a significant problem, with approximately 10% of solid organ recipients acquiring the virus. Data suggest that up to 50% of organ recipients from donors who are antibody positive progress to develop active infection.

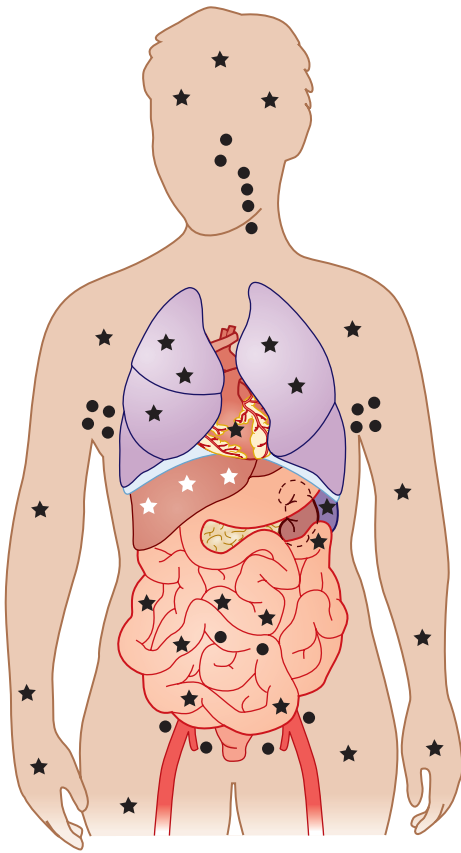

Fungal infections remain a major concern in organ transplantation (Castaldo et al., 1991a, 1991b). Divided into two categories, these infections may be invasive and opportunistic, or represent geographically restricted systemic mycoses. Amphotericin, the mainstay of therapy for systemic infections, has now been joined by fluconazole. Fluconazole is far less toxic than amphotericin and represents a significant advance in antifungal therapy.

Bacterial infections have a devastating consequence, cover a wide spectrum, and include atypical agents such as *Nocardia asteroides* and *Mycobacterium*. Prophylactic therapy for several infections has gained wide acceptance. For example, low-dosage trimethoprim-sulfamethoxazole has been quite efficacious in the prevention of *Pneumocystis carinii* infection in all organ transplantations, as well as in the prevention of urosepsis in the renal transplantation patient.

Chimerism and Tolerance

In the past three decades, a particular subgroup of patients who no longer required immunosuppression, along with the apparent development of clinical immunotolerance, gave genesis to the idea of chimerism. It became evident that solid organ transplant recipients could be, and were, transformed into chimeras, to varying degrees irrespective of the organ transplanted. A chimera was thus defined as the acquisition by the recipient of the donor leukocytes, lymphocytes, and dendritic cells, which spread via vascular conduits to the host's lymphoid tissue and organ systems from the transplanted organ.

In the early stages after transplantation, donor antigen-presenting cells, mainly immature dendritic cells, migrate out of the allograft toward secondary lymphoid organs, where they mature and encounter recipient alloreactive naive T cells and resting or central memory T cells, a direct pathway for normal tissue allorecognition. Furthermore, the engrafted organ acquires the recipient's immune system and a population of the recipient's leukocytes. This was clearly demonstrated in liver transplantation, when the entire macrophage system, including the Kupffer cells of the graft (one component of the liver's

■ **FIGURE 28-27.** Result of donor and recipient lymphoreticular cell traffic after successful liver transplantation. White, recipient cells; black, donor cells. (From Starzl TE, Demetris A, Murase N, et al: *Cell migration, chimerism, and graft acceptance*, Lancet 339:1579, 1992.)

dendritic cells), is replaced by that of the host (Starzl et al., 1992). This became the first actual biochemical realization of a chimera (Fig. 28-27).

Transplantation tolerance indeed refers to a state of sustained specific nonresponsiveness of the recipient's immune system to donor alloantigens, allowing long-term allograft survival in the absence of potentially harmful chronic immunosuppressive therapy. More specifically, it is the unambiguous evidence of normal graft function without features of graft rejection and the need for any immunosuppressive agents. Since the pioneering work of Billingham, Brent, and Medawar (1953) more than half a century ago, many experimental animal models, as well as some clinical data in specific settings, support the concept that transplantation tolerance could be an achievable target for selected patients.

The early thoughts and dismissal of leukocyte chimerism-associated mechanisms were diversionary, in view of the early recognition that implanted organ allografts promptly become mixtures of donor and recipient cells (i.e., organ chimerism). The evidence was first presented in 1968 by karyotyping studies of livers that had been transplanted to female recipients from male deceased donors (Kashiwagi et al., 1969). Whereas the rest of the allograft remained male, the bone marrow-derived

passenger leukocytes including Kupffer cells were largely replaced with recipient female cells within 100 days of transplantation. These alterations were incorrectly assumed to be a unique feature of the transplanted liver until it was demonstrated that most of the lymphoid tissues of the engrafted rat (Murase et al., 1991) and human intestine (Iwaki et al., 1991) were replaced by recipient cells of the same lineages. An epiphany occurred when comparable findings were confirmed in successfully transplanted human kidney, pancreatic (Randhawa et al., 1993; Starzl et al., 1993), and thoracic organ allografts (Randhawa et al., 1993), and thus it became unambiguously clear that all engrafted organs were chimeric structures.

Chimerism and tolerance can be viewed as central or peripheral. The concept of *central tolerance* and mixed chimerism involves the recognition of the critical important role the thymus plays in the maintenance of tolerance to self-antigens, and many experimental data support its role in the induction of sustained robust tolerance to alloantigens. During the physiologic maturation process in the thymus, central tolerance is achieved by intrathymic deletion of T cells with high avidity for thymic expressed self-antigens (negative selection), so that potentially deleterious antigen-reactive T cells will not reach the periphery. In the transplantation setting, this process can be exploited by the delivery of donor alloantigens to the thymus prior to solid organ transplantation. This can be achieved either experimentally by direct intrathymic injections of donor-derived allopeptides or by the induction of a state of hematopoietic mixed chimerism in the recipient's repertoire (the presence of cells from both recipient and donor origin) allowing donor antigen-presenting cells to migrate to the recipient's thymus and induce negative selection of donor-reactive T cells. For mixed chimerism to occur in the recipient, the infused bone marrow cells from the donor and recipient must engraft, implying the need for preconditioning treatments that allow the creation of "space" for engraftment, combined with deletion of preexisting cross-reactive peripheral T cells that could reject the donor bone marrow.

T cells are crucial in the initiation and coordination of the rejection response and to promote *peripheral tolerance*. The alloreactive effector T-cell pool must be minimized, and regulatory mechanisms enhanced. Various strategies have been explored to achieve peripheral tolerance to alloantigens in experimental transplantation models:

- Deletion of peripheral effector T cells (lymphocyte-depleting protocols)
- Inhibition of T-cell activation by blocking or modifying costimulatory signals (costimulatory blockade, manipulation of dendritic cells)
- Interference with the effector function or homing of activated T cells (anticytokines, antichemokines)
- Active regulation of effector T cells by antigen-specific CD4 and CD25 cells

Most of these approaches have been extensively studied in experimental models and are now being progressively transposed to the clinical arena.

Calne and colleagues (1998) first divulged interesting clinical data using lymphocyte depletion with alemtuzumab (Campath), which provided long-term rejection-free allograft survival with minimal maintenance therapy (low-dosage cyclosporine) in

most patients. Because these recipients did not exhibit true operational tolerance, Calne and colleagues coined the term *prope tolerance* (near tolerance) to describe this immunologic state. The targeted immunomodulation has led to the development of several immunomodulating agents, which are targeted at a number of the cell-surface markers of T and B lymphocytes. These agents offer real prospects for the realization of the holy grail of successful long-term transplantation. The model of HLA matching in kidney and bone marrow transplantation has helped to establish the role of these cell-surface markers for all solid organ transplantation, which is important if success is to be achieved with respect to chimerism, tolerance, and the reduction if not elimination of GVHD.

Selective immune tolerance of alloantigens and transplanted tissues will improve significantly in the future. The strategies to induce tolerance to foreign tissues may include clonal T- and B-cell deletion, induction of bone marrow chimerism, manipulation of regulatory cytokines, and blockade of T-lymphocyte-specific-mediated costimulation. Additionally, newer pharmacologic agents have certainly enhanced our understanding and the advancement of this field. Induction of selective immune tolerance could make it possible to minimize, or dispense with, immunosuppressive regimens that now cause end-organ toxicity, life-threatening infections, and neoplasm development. With the exponential growth in the area of stem-cell and xenotransplantation, the dream to have a transgenic pig for every human who needs a specific organ or multivisceral transplantation may become reality in the not too distant future.

SUMMARY

In the past 25 years, solid organ transplantation has gained acceptability as a viable form of medical therapy for many forms of end-stage organ disease in the pediatric patient, as well as early therapy for congenital anomalies and varied inherited genetic diseases otherwise without a cure. Advances in immunosuppression protocols have enhanced the survival of children from otherwise deadly diseases. The challenge for the future is the development of more specific immunomodulation, and better understanding of chimerism.

Improved patient survival will probably come not from advances in surgical technique but from advances in immunology, and from advances in hepatocyte and stem-cell transplantation. Consensus protocols with randomized arms of immunosuppressive therapies need to be considered to further advance the specialty. The effects of anesthesia agents during organ harvest need to be further explored. Finally, in addition to the medical and surgical challenges, organ transplantation imposes ethical and quality-of-life issues that must constantly be assessed and reassessed.

Anesthesia for conjoined twins may range from a very straightforward pediatric anesthetic procedure to one of the most daunting and challenging procedures faced by any pediatric anesthesiologist.

This rare but fascinating congenital problem is of considerable importance to anesthesiologists. In recent medical literature, there are ever-increasing reports of anesthesia for conjoined twins, both general and regional. From the twins' initial admission, anesthesiologists should be involved in the care and decision-making procedures planned for these infants. At any stage of their time in the hospital, anesthesiologists may be called on to provide resuscitation for the infants or to anesthetize them for investigations or procedures. These may be related to their conjoined state or for some other pathology in one or the other twin, such as pyloric stenosis, or adenoidectomy for upper airway obstruction (Thomas, 2004). Management of conjoined twins is a multidisciplinary exercise involving many specialties, and the anesthesiologist is an integral part of this team. Likewise, it is essential that the anesthesiologists establish a team approach within their own discipline, so that each specialist knows precisely the roles of all individuals at the various stages of the procedures. The separation of a set of conjoined twins is the best example of teamwork that any hospital staff will experience.

Four major centers in the world have described their experiences and outcomes in their management of conjoined twins

(Spitz and Kiely, 2003; O'Neill, 1998; Rode et al., 2006; Millar et al., 2009; Rabeeah, 2006) (Table 29-1). Many of the cases and examples used and described in this chapter are from the Red Cross War Memorial Children's Hospital in Cape Town, South Africa, where over a period of 44 years (1964 to 2009) 49 sets of symmetric and asymmetric conjoined twins have been managed.

INCIDENCE

Because of the significant number of conjoined twins who are aborted or who are stillborn, the exact incidence is not known, but the reported incidence worldwide is estimated at 1:50,000 to 1:100,000 live births, with a higher incidence of 1:14,000 to 1:25,000 experienced in Africa and Asia (Hoyle, 1990). Of those that are born, many may have congenital abnormalities that are incompatible with life. The presence of associated congenital anomalies in live twins is common. Congenital diaphragmatic hernia, pulmonary hypoplasia, congenital heart disease, anomalous hepatic arterial and venous drainage, biliary tree anomalies, bowel atresia, Meckel's diverticulum, complex urogenital anatomy, and spinal dysraphism have all been reported.

HISTORICAL PERSPECTIVES

Conjoined twins are one of nature's greatest enigmas. Cave drawings, pottery, figurines, and folklore indicate that conjoined twins have occurred since prehistoric times. Embryonic duplication also occurs in plant and other animal forms of life (Fig. 29-1) (Thomas and Lopez, 2004). The famous and most celebrated pair of conjoined twins, Chang and Eng Bunker, who were joined at their xiphisterna, was born in Siam (now Thailand) in 1811. Because of their fame and the rarity of this pathology, the term *Siamese twins* has become synonymous with conjoined twins. Over time, the bridge of skin and tissue between them stretched, and they were able to stand side by side. The twins were taken to America, where they were on

■ **FIGURE 29-1.** Conjoined twinning occurs in plants and animals, as well as in human life. This photograph is of twin roses of the Double Delight variety.

display by Phineas T. Barnum in his circus. Surgery for separation was deemed too risky unless one of the twins was to die. The Bunker twins lived very interesting lives—they married sisters and fathered 22 children between them. They died within hours of each other at the age of 63 (Spitz, 2003). Interestingly, the twins who have become most famous have all remained conjoined, whereas there is very little literature on the lives of those who have been separated. Votteler and Lipsky (2005) have reported on the long-term results of ten separations, as have Hoyle and Thomas (1989) with their experiences studying ischiopagus twins over 23 years. The first set of omphalopagus twins separated at the Red Cross Children's Hospital now each has children of their own (Cywes and Louw, 1967; Cywes et al., 1982).

The first successful separation of conjoined twins was performed by König in 1689, when he separated omphalopagus twins by slowly tightening an encircling band around the connection until it necrosed the connecting bridge. The first successful separation of thoracopagus twins with a conjoined heart was reported in 1979 when, after the interatrial bridge was interrupted, there was a single survivor (Synhorst et al., 1979).

During the 1960s and 1970s, emphasis in the perioperative management of conjoined twins was on preoperative discussions and planning, dress rehearsals, and on the then-new techniques of invasive intraoperative monitoring for blood loss and hemodynamic status (Diaz and Furman, 1987). From the 1980s onward, most improvements have occurred in obstetric and fetal ultrasound; fetal and neonatal surgery; magnetic resonance imaging (MRI); contrast computed tomography (CT); numerous radiographic technological options to help delineate anatomic variations in different twins; in the anesthetic advances of oximetry, capnography, agent analysis; and in techniques for monitoring brain oxygenation and blood flow.

For the induction of omphalopagus twins, Allen et al. (1959) described the use of cyclopropane and oxygen, supplemented by ether via the open-drop method. He describes the attempts at intubation by holding one infant above the other to facilitate easier intubation as a "near fatal mistake." In this position, the upper twin became pale and apneic, whereas the condition of the lower infant rapidly deteriorated and it became plethoric. Once they were returned to their normal position, they were successfully intubated. He comments that "there are few vital signs available for monitoring infants of this size. The most important signs are respirations, color, and muscle tone." Both infants survived the surgical separation.

The anesthesia provided to separate the first set of twins in 1967 in Cape Town, South Africa, was described as “uneventful” (Cywes and Louw, 1967). Preoperative investigations in these omphalopagus twins indicated that there was no cross-circulation between the infants and this was confirmed at the induction of anesthesia, when the pancuronium given to one infant had no effect on the other.

In Furman’s report (Furman et al., 1971), intubation on a set of xiphopagus twins was performed when both infants were awake, and vascular cannulation was done when they were under local anesthetic. Jarem (Jarem et al., 1977), in his classic paper, describes the double breathing circuit fashioned from readily available parts of anesthetic equipment.

Roy (1980) described his experience with craniopagus twins. His group used two anesthetic teams, but only one anesthetic machine with a non–rebreathing Jackson-Rees breathing system from the gas outlet leading to two T pieces. Monitoring included: electrocardiograph (ECG), Doppler arm-cuff pressures, esophageal stethoscopes, and rectal telethermometers. Each infant received preoperative atropine, and they were induced simultaneously with halothane, nitrous oxide, and oxygen. He continued to describe the 15-month preparation time before their separation. This was successfully achieved, but he describes the anesthetic challenges as severe hemorrhage and maintenance of a clear airway with obstruction from secretions, kinking, or accidental extubation. Harrison and his team (1985) commented on the need for modification of the breathing circuit to accommodate the process of ventilating neonatal conjoined twins simultaneously and stated that adequate intravascular fluid replacement was essential to prevent hypotension at separation. They also commented on the intraoperative challenges of these infants.

Diaz and Furman, (1987), in their well-known paper on the perioperative management of conjoined twins, highlighted many factors that are now integral to the care of these patients. Advances in anesthetic equipment, monitoring, and drugs (inhalational or intravenous) give us options for anesthesia that earlier anesthetic specialists did not have. Similarly, outcomes for surgical procedures in these patients have improved. The developments in pediatric intensive care have had a positive impact on both the preoperative and postoperative care and outcomes of these children.

EMBRYOLOGY

Two theories have been proposed as to the etiology of conjoined twins: fusion and fission. Although the differences between these theories have yet to be resolved, fission is the generally accepted and older theory, where the fertilized egg fails to split completely (Kaufman, 2004). The theory of fusion, proposed by Spencer (2000a, 2000b, 2003), suggests that the fertilized egg splits completely, but a secondary union of two separate embryonic discs at the dorsal neural tube or ventral yolk sac takes place at 3 to 4 weeks’ gestation. This theory was also held by Aristotle (Millar et al., 2009).

Monozygotic twins are the result of one ovum being fertilized by one sperm and then dividing into two embryos. In conjoined twins, this division, at the 13th to 17th day of the blastocyst stage, is incomplete.

Conjoined twins are identical, with what has always been thought to be an identical chromosomal pattern. With new

molecular genetics, this has been shown to not necessarily be the case, and the twins may neither be completely identical nor have the same chromosome pattern (Hall, 2003). It has been hypothesized that monozygotic twinning occurs at four possible phases: up to 3 days’ postconception, after 4 to 6 days, after 7 to 12 days, and finally after 13 to 17 days. It is during this latter period that conjoined twins, fetus-in-fetu, or a teratoma may arise (Hall and Lopez-Rangel, 1996). Parasitic twins are thought to result from the embryonic death of one twin, with the remaining parts of the body vascularized by the surviving autocyte. Fetus-in-fetu are asymmetric monozygotic diamniotic intraparasitic twins (Hall and Lopez-Rangel, 1996). Conjoined triplets and quadruplets have been documented, although all have been aborted (O’Neill, 1998; Rode et al., 2006). These cases are exceptionally rare, with an even more obscure pathogenesis.

Conjoined twins are always the same gender. There is a 3:1 female-to-male incidence in live births, but more males are stillborn (Hoyle, 1990; Rejjal et al., 1992). They are monozygotic, monoamniotic, and monochorionic. Despite this, the infants usually vary in size, appearance, personality, internal anatomy, and degree of organ-sharing and duplication. Many of the challenges for all disciplines relate to the vast diversity in the anatomic variations that may possibly occur. Organs may be conjoined, duplicated, or absent. Investigations are crucial to clarifying these differences in order to make decisions about surgery, interventions, and survival. Even then, surprises occur at the time of surgery, and innovative techniques may be necessary.

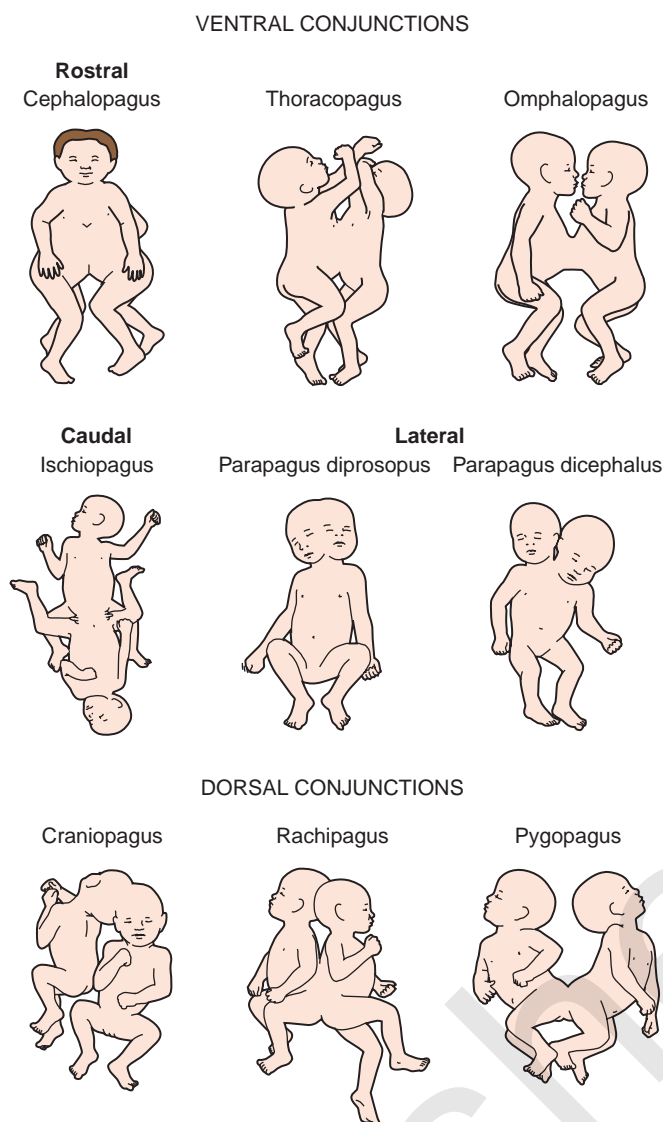

Survival depends on the site and complexity of conjunction, the degree of organ sharing, and the presence of other congenital anomalies, with the extent of cardiac fusion and lung development being major determining factors (Andrews et al., 2006).

CLASSIFICATION, NOMENCLATURE, AND TERMINOLOGY

Conjoined twins are typically classified by the anatomic site of conjunction (which may be complex) followed by the suffix *-pagus*—the Greek word meaning *that which is joined* (Box 29-1). There is an international collaboration attempting

■ **FIGURE 29-2.** Illustrations depicting the anatomic relationships of the different types of symmetric conjoined twins. (Modified from Spencer R: Conjoined twins: developmental malformation and clinical implications, Baltimore, 2003, John Hopkins University Press.)

to create a more uniform classification of conjoined twins (Spencer, 1996). This considers a ventral (front, caudal, or lateral) or dorsal (back-to-back, sacrum-to-sacrum, or head-to-head) fusion, with further classification described in the following paragraphs (Fig. 29-2).

Twins are described as being *symmetric* or *asymmetric*, although these terms are often misleading, because even when the twins are fully formed they are seldom truly symmetric. According to the most prominent site of conjunction, the following sites of conjunction are the most common: the chest (thoracopagus twins), the abdomen (omphalopagus twins), sacrum (pygopagus twins), pelvis (ischiopagus twins), and back (rachipagus twins) (Table 29-2).

Symmetric twins are two anatomically identifiable infants with a physical appearance suggestive of two possible survivors. With asymmetric, or parasitic, twins, one twin is a potential survivor and usually appears normal, but the other is incomplete and attached as a parasite. This may be externally visible,

or it may be internal. Where there is an attachment of an anatomically identifiable part, but not of a total individual, the term *heteropagus* is used. It is in this group, that regional anesthesia is particularly useful. Within a classified group, especially with complex conjunctions, the external physical appearance and spatial arrangement of the infants may be very different (Figs. 29-3 and 29-4).

Conjoined twins are further classified by the number of limbs present and the internal organs that are involved in the conjunction. The following list shows this classification system:

- Two arms: dibranchius
- Three arms: tribranchius
- Four arms: tetrabranchius
- Two legs: bipus
- Three legs: tripus
- Four legs: tetrapus

The degree of cardiac fusion, or degree of cardiopagus, can be considered as follows (Andrews et al., 2006):

- A: Separate hearts and pericardium
- B: Separate hearts and a common/shared pericardium
- C: Fused atria and separate ventricles
- D: Fused atria and ventricles

Outcomes for separation in groups C and D are poor.

Twins Joined at the Head

There are three types of twins joined at the head (Spencer, 2003).

Parapagus twins have two faces lateral to each other on the same side of one head, with a single neck and body.

Cephalopagus twinning is a rare form of conjoined twins in which the infants are united from the tops of the heads down to the umbilicus, with two separate lower abdomens and pelvises (also referred to as *cephalothoracopagus*). The two fused faces are on opposite sides of the head, so named after the two-faced god Janus, this type of conjunction is sometimes referred to as *Janiceps*. The brains and spinal cords are abnormal, and the number and type of limbs vary. This type of conjoined twins is not separable, and early diagnosis allows for termination of the pregnancy.

Craniopagus twins are united only at the cranial vault, with two completely separate faces and bodies. O'Connell (1976) described a practical approach to classifying craniopagus twins—partial and total. In the partial form, union is limited and separation is feasible with a good chance of survival; however, in the total form, significant intracranial abnormalities may be present and make attempted separation hazardous. Blood loss may be considerable, making death(s) on the operating table highly likely. Bucholz et al. (1987) reported higher perioperative mortality in the temporoparietal and occipital junctions, with parietal junctions having an intermediate mortality, and frontal craniopagus having the lowest mortality. Winston (1987) described a classification based on the deepest structures shared:

- Type A: Share only scalp and subcutaneous structures
- Type B: Share dura mater
- Type C: Share dura mater and arachnoid and pia mater
- Type D: Share brain structures as well as structures from types A, B, and C

In predicting the outcome, the extent of fusion of venous structures is almost as important as the degree of brain conjunction. For twins who come to surgery, this also has considerable impact on intraoperative blood loss.

TABLE 29-2. Types of Symmetric Conjoined Twins

Type	Area(s) Conjoined	Consequences
Thoracopagus Thoracoomphalopagus	Upper to lower chest Heart and pericardium always involved Chest and abdomen	High mortality Usually face-to-face Complex anatomy of heart, diaphragm, GI tract
Thoraco-omphaloischiopagus	Chest, abdomen, and pelvis	Face-to-face Four arms; two, three, or four legs; variable genitalia
Xiphopagus	Xiphoid cartilage, upper abdomen	Possible liver fusion Simple conjunction
Omphalopagus	Lower chest, upper abdomen	Heart not involved Liver, proximal GI tract, diaphragm, other organs variable
Ischiopagus	Fused lower bodies, spinal and urogenital system involvement	Four arms; two, three, or four legs
Pygopagus (pyopagus/ileopagus)	Back-to-back at pelvis Sacrum and coccyx fused	Spine often involved, distal GI tract often fused
Parapagus	Fused side-by-side with a shared pelvis Dithoracic: fused abdomen pelvis, not thorax Diprosopic: one trunk, one head, two faces with varying fusion Dicephalic: one trunk, two heads, two, three, or four arms	Organ sharing variable Limbs variable
Craniopagus	Fused skulls, separate bodies Fused back (occipital), front (frontal), side (temporoparietal) or top (parietal) of head, not face or base of skull	Extent of brain fusion variable Venous connections important
Rachipagus	Dorsal fusion, back to back Face away from each other	Extremely rare Spine involvement variable; fusion terminates above sacrum Occiput possibly involved

GI, Gastrointestinal.

ETHICS

In broad terms, ethics are a set of standards of professional conduct (Atkinson, 2004). Whenever planned separation of conjoined twins takes place, and when there is a possibility or probability that one twin may not survive the procedure, moral, ethical, and legal arguments are raised. Many of these issues have been addressed in the literature (Pearn, 2001; Unknown

■ **FIGURE 29-4.** This set of twin boys has a complex conjunction at the thoracic, abdominal and pelvic levels, and despite also being ischiopagus, show no physical resemblance to the twins in [Figure 29-3](#).

author, 2000; Spitz and Kiely, 2000; Spitz, 2000; Bratton and Chetwynd, 2004). The Hastings report identified three cardinal issues (London and Knowles, 2001):

- If one twin would not (be able to) survive, surgical separation is justified to provide life for the other twin.
- Survival is determined by the premorbid condition and not by surgery.
- Parents have the right to refuse separation.

In his review of this subject, Atkinson (2004) commented that the birth of a handicapped child is an immense burden to any parents. If they are to avoid greater challenges, the clinicians require sensitivity and patience as they steer the family along a pathway to survival. The question most often asked is whether it is justified to sacrifice one life to save another, or should both infants be allowed to die? Answers are seldom simple, and each case should be assessed on its own merits. Decisions depend on the type and complexity of the conjunction, the overall health of both infants, the laws of the country, and the religion and beliefs of the parents. If the sacrifice of one twin is necessary for the other twin to survive, it is important to recognize that both would die without separation. If they were separated, at least one would live (O'Neill et al., 1988).

Especially in centers where these operations are done more often, medical staff is more confident of their ability to provide insightful management decisions pertaining to these care of conjoined twins. They are supported by investigations that provide valuable information, allowing rational decisions to be made about the immediate and long-term futures of these infants. These investigations, performed to clarify anatomic structures include radiologic imaging, ultrasonography, CT, MRI, radioisotope studies, echocardiography, cardiac catheterization, and neuroradiologic imaging. As a consequence, in the perioperative period the pediatric surgeons and anesthesiologists in these centers have reported much higher rates of success in operating on these infants. Developments in intensive care also have a positive impact on these improved outcomes.

Ian Aird (1954, 1959) wrote that if there was a possibility of at least one twin surviving, surgery should be performed. The operation does not decide which twin will survive; this is determined by their relative conditions (O'Neill et al., 1988).

Great Ormond Street Ethical Guidelines for Conjoined Twin Separation has been adopted by a number of units. Where separation is feasible with a reasonable chance of success, it should be carried out. When surgery is not possible, custodial care should be offered, and nature should be allowed to take its course. When one twin is dead or has a lethal abnormality and cannot survive independently from its normal twin, and if there is no surgery both twins would die, separation to save the healthy twin should be attempted (Rode et al., 2006; Millar et al., 2009).

PERINATAL CONSIDERATIONS

Improved techniques of antenatal diagnosis and fetal imaging have allowed the diagnosis of conjoined twins to be made during pregnancy, so that counseling of the parents may allow them the option to have the pregnancy terminated. Conjoined twins can be identified as early as 11 weeks' gestation, and in this series of cases studied by Sebire et al. (2000), all the

parents opted for termination. Complex craniopagus and cardiopagus anatomy in particular may tilt the decision in this direction. Conjoined hearts are easier to study via ultrasound in utero, because the amniotic fluid acts as a buffer, whereas after birth the lungs inflate with air and prevent optimal visibility (Kingston et al., 2001).

Obstructed labor with difficult vaginal delivery may necessitate an emergency cesarean section, but this can be avoided by antenatal diagnosis and elective cesarean section at 36 to 38 weeks' gestation (Millar et al., 2009). In many developing countries, the birth of conjoined twins may come as a surprise to the mother and the attending midwife or medical practitioner (Thomas, 2004; Thomas and Lopez, 2004).

Perinatal management of conjoined twins involves a close collaboration between anesthesiologists, obstetricians, and pediatricians so that birth trauma for both the mother and the infants can be minimized. Unborn conjoined twins may be referred to pediatric surgeons for advice in order to plan the delivery and the immediate perinatal management.

Careful prenatal investigations may identify cases in which emergency separation at birth is life saving (MacKenzie et al., 2002). Advances in prenatal ultrasound, as well as the use of color-flow Doppler and prenatal MRI, have improved the antenatal diagnosis of conjoined twins. In particular, prenatal and postnatal echocardiography has been shown to accurately delineate the extent of cardiac fusion, the intracardiac anatomy, and the ventricular function (Andrews et al., 2006). Planning of the antenatal course and the perinatal management of twins can be facilitated by identifying those twins at particular risk, such as twins with twin reversed–arterial perfusion sequence. In this situation, vascular communications between the two fetuses allows deoxygenated blood from one fetus (the pump twin) to perfuse the other fetus (the perfused twin), resulting in reversed flow in the umbilical vessels and the development of multiple anomalies, including acardia, in the perfused twin (Norwitz et al., 2000). Antenatal surgical intervention, removing the acardiac twin in utero, may allow for the survival of the remaining (pump) twin. If they are conjoined, however, this is not possible, and immediate surgical intervention at birth is necessary. In order to make rational and sound decisions as to the anesthetic management, anesthesia for fetoscopic fetal surgery requires knowledge of the pathophysiology of the fetus, the fetoplacental unit, and the condition of the mother (Galankin et al., 2000).

Plans may be necessary, in those units providing that option, for an ex utero intrapartum treatment (EXIT) procedure (Bouchard et al., 2002). In this operation, access to the fetus is achieved when the fetus is brought into the surgical field while it is still attached to the mother's placenta. The planned procedure, whether for access to the fetal airway in the case of an airway tumor, or to allow separation of a conjoined twin from its non-survivable twin, is then carried out. Once it has been completed, the infant is then delivered from the mother and separated from its placenta. This procedure has also been used for airway control of both twins when the antenatal airway and cardiopulmonary status of the twins was not known (Ossowski and Suskind, 2005).

At delivery, it is optimal to have two sets of all neonatal resuscitation equipment available and a pediatrician (or anesthesiologist) present for each infant. A conventional open incubator usually provides a large enough surface area to accommodate both infants. If one twin is doing poorly,

it should be attended to first. Especially with thoracopagus twins, over-vigorous ventilation of one may compromise the other because of the chest contents moving across into the chest cavity of the other. If intubation is necessary, this should be performed on one infant at a time, with the other twin being supported, if necessary, with bag face-mask oxygen and ventilation. A T piece and small mask is easier to use than an Ambu bag. While laryngoscopy is being performed on one twin, care must be taken to protect the infant who is not being intubated from trauma to the face and eyes by the laryngoscope. The aim of immediate postnatal management should be the resuscitation and stabilization of both infants, thorough physical examination and special investigations that will allow for definition of the relevant anatomy, and subsequent medical and surgical management.

Cardiopulmonary resuscitation (CPR) in conjoined twins has significant limitations. Not only can it be physically challenging, but it may also be unreliable because the anatomy is distorted and access to the heart, especially in thoracopagus twins, is limited. Damage to other organs, particularly the upper gastrointestinal tract and liver, may occur (Millar et al., 2009). The basics of neonatal and pediatric resuscitation should be followed.

MEDICAL AND SURGICAL MANAGEMENT

Spitz and Kiely (2002) describe the management of conjoined twins in the prenatal and postnatal stages. When complex thoracopagus or craniopagus twins are diagnosed, termination of pregnancy is recommended. The postnatal management involves the following options:

- Nonoperative care: palliative care until the twins die or raise the twins in their conjoined status (i.e., no attempt is made to separate them).
- Emergency operative care: surgery that may include separation is performed.
- Operative or surgical management aimed at elective separation: elective separation may be performed as a staged procedure, or separation may occur with a single operation.

Some overlap occurs when the twins arrive for emergency surgery before the results of all the investigations have enabled decisions around survival to be made (e.g., when intestinal obstruction develops). Emergency surgery is then performed, but later findings may indicate that other anomalies that are incompatible with life are present. In all studies, emergency surgery for separation is associated with a poor prognosis.

Indications for emergency separation include the following (O'Neill, 1998, Millar et al., 2009; Rode et al., 2006; Cywes et al., 1997):

- Where there is damage to a connecting bridge (e.g., omphalopagus). This may occur at the time of delivery.
- When the condition of one twin threatens the survival of the other (e.g., complex congenital heart disease, cardiomyopathy, sepsis).
- Deterioration of both twins because of hemodynamic and respiratory compromise. This occurs typically in thoracopagus twins.
- When the condition of one twin is incompatible with life (e.g., anencephalic, acardiac, stillborn, or complex congenital anomalies) but the other twin has a good chance of survival.

Elective separation for simple conjunctions can be performed in the neonatal period with minimal problems. No benefit is gained from waiting for the infants to grow or for further investigations to be done. The maternal hormonal influences are still present; thus, the skin is more pliable to cover the wound defect. In general, separation is planned for some time between 4 and 11 months of age when the infants are bigger and their investigations are more meaningful and when they have had adequate tissue expansion to allow closure of the skin defect (O'Neill et al., 1988).

INVESTIGATIONS

Accurate preoperative imaging is essential to surgical planning and prognosis, and the area(s) of fusion determine the imaging modality used. MRI and CT provide very good anatomic and bone detail and show organ positions, shared structures, and limited vascular anatomy (Kingston et al., 2001). Radiography with contrast material provides excellent gastrointestinal and urogenital evaluation. When there is liver conjunction, its anatomy, the vascular supply, and assessment of the biliary tree are required. Angiography helps clarify the vascular supply of organs and determine blood supply between the twins. Careful use of contrast material is important, because there may be overenthusiastic administration of this in an attempt to achieve better views. Evaluation of vascular shunts and cross circulation is vital for anesthesiologists—loss of blood from these during surgery can be catastrophic.

Cardiac catheterization is required to identify intracardiac connections and to clarify cardiac chambers. Echocardiographic technology is constantly improving, so the need for catheterization (and therefore anesthesia) is becoming less common. When cardiac surgery is required, however, this is the preferred investigation (Fig. 29-5).

■ **FIGURE 29-5.** A cardiac catheterization image of complex cardiopagus thoracopagus twins with a catheter and contrast material in each heart. These twins could not be separated.

Results of these tests clarify anatomic variations in each infant. Understanding the complexity of organ conjunctions enables investigators to identify those structures that are present or missing. The results of complex investigations are best evaluated by a multidisciplinary team, because many factors are raised that anesthesiologists do not consider but that are important for both anesthetic management and good overall care of the infants. Each test has its own role for all of these requirements. **Box 29-2** details investigations for craniopagus twins. The order in which procedures occur is also determined by the results of the investigations.

Sedation Techniques for Investigations

The anatomic evaluations of conjoined twins require multiple tests that commonly require the administrations of sedative medications or anesthetic agents. These techniques or options may vary from a simple feed to a full general anesthetic. Regardless of the choice, a full and comprehensive pre-sedation evaluation should be carried out. The choice of technique depends on the following factors:

- Age and size of the twins
- Site and complexity of the twins' conjunction
- Airway anatomy of the twins
- Venue for the investigation
- Accessibility to the twins
- Level of pain caused by procedure
- Length of time taken for the investigation
- Availability and achievability of an intravenous catheter line

Options for simple sedation used include a feeding before CT or MRI, sucrose on a pacifier, swaddling and physical support, chloral hydrate, trimeprazine (with or without droperidol), and midazolam (Thomas, 2004; Thomas and Lopez, 2004). Two pediatric anesthesiologists should be present from the beginning of these investigations, rather than them having to be called in an emergency situation.

Commonly used agents include propofol, ketamine, fentanyl, dexmedetomidine, and inhalational agents. For MRI evaluations, the safest option may be a general anesthetic to ensure airway control for the procedure (Sury et al., 1994). The use of laryngeal mask airways may not always provide the ideal

airway management, and rescue maneuvers in this environment are fraught with potential complications (Shank et al., 2005; Szmuk et al., 2005).

Whether simple or advanced techniques are used, monitoring should include pulse oximetry, ECG, blood pressure, and where possible, capnography. For CT scanning in particular, a capnography limb attached to the nasal cannule providing oxygen has been a very useful monitor for these twins. Again, there should be at least two anesthesiologists present—one for each infant.

PLANNING BEFORE SURGERY

Preparation of Parents

Congenital abnormalities in singleton children are challenging enough for parents; parenting a set of conjoined twins can be daunting, with the burden of decision making being overwhelming (Atkinson, 2004). This is especially problematic when one infant is not expected to survive or when both may die. Even for infants with a simple conjunction, every effort should be made to make this experience as atraumatic as possible. This may include the involvement of child-life specialists, play therapists, physiotherapists, occupational therapists, and social workers. Where physical challenges and deformities will be present after surgery, involvement of these caregivers before surgery is essential. These principles of care are often overlooked, and it may be necessary during planning meetings to remind the multidisciplinary team of their importance.

Preparation of the Environment and Equipment

An important emphasis for anesthesiologists is the adequate preparation of the area where the procedure will occur. This may involve sites distant from the anesthesia suite or operating rooms (and will thus present all the problems of this type of pediatric anesthesia), or surgery may take place in the operating room environment.

This stage of the planning should also include involvement of the hospital management, the public relations department, and plans to avoid extensive media involvement. Privacy of patients and parents should be protected.

When procedures on these twins are to be performed outside the operating rooms, these venues or areas should be visited and scrutinized for suitability for sedation, general anesthesia, and appropriate monitoring. If general anesthesia is planned, the supply of two sources of oxygen, medical air, nitrous oxide, suctioning, and scavenging must be available. It may be necessary to have the maintenance department make up equipment to facilitate this, such as splitters from the wall gas supply. Innovative techniques have been devised to provide ventilation of both twins with one ventilator using a Carlen's Y-adaptor for ECG-gated MRI angiography (Szmuk et al., 2006). The use of bispectral index (BIS) for detecting cross circulation in thoracopagus twins is also described (Szmuk et al., 2006).

Total intravenous anesthesia (TIVA) may be the preferred option in these circumstances. Space for anesthesia and other personnel is often a limiting factor, because it may be necessary to bring two anesthesia machines into a small area (e.g., the cardiac catheterization laboratory). Meticulous attention to detail

Box 29-2 Investigations for Craniopagus Twins

Routine blood tests and urinalysis
 Neuroimaging and neurointerventional radiologic procedures
 3-Dimensional CT imaging
 MRI scan and angiography
 Cerebral echography; color Doppler echo via the fontanelles
 Cerebral angiography
 Preoperative neuroendovascular techniques to occlude shared vascular anastomotic channels allow for safer surgery for separation as a one-staged operation.
 CT angiography reconstruction
 Neurophysiology: electroencephalograms, visual evoked potentials, and somatic sensory evoked potentials

is essential. Previous experience in these scenarios is extremely valuable. When space is an issue, instead of two full anesthesia teams, a team leader (coordinator) and two pediatric anesthesiologists or hands-on anesthesia care providers (fellows, residents, or certified registered nurse anesthetists [CRNAs]) (one each per infant) are usually sufficient. Investigations for MRI and CT scan are particularly challenging, but with planning and insight as to the possible problems, many potential catastrophes can be avoided.

Temperature control should be as for any pediatric anesthesia procedure, and all facilities to prevent heat loss and provide warmth should be available. To maintain their heat, the infants should be appropriately covered for transportation. The anesthetic should be started in a warm operating room (28° C), and the operating room should be cooled as soon the infants are draped. Intraoperative use of plastic drapes prevents the infants from getting wet and cold. Fluids may be warmed, and warm-air convection devices are very beneficial.

Multidisciplinary Team Preparation

Although the surgeons take the primary responsibility for the twins, it is often the anesthesiology team that assumes the role of the perioperative operating room organizers. Anesthesiologists are the caregivers who are present from the very beginning of the anesthesia, through each stage of surgical intervention (especially when more than one or two surgical disciplines are involved), until the end when handover to the intensive care unit staff occurs. Communication with the nursing personnel is imperative. The following list details all the disciplines that should be present at preparatory meetings:

- Anesthesiology: Head of department team leader, specialists, technologists (especially when technical assistance is anticipated), trainees, and anesthesia nurses
- Surgeons: General, plastic and reconstructive, cardiothoracic, orthopedic, neurosurgical, urologic, and ophthalmologic
- Nursing: Operating-room manager or operating nurse leader
- Intensive Care: Head of department or representative, nursing staff, pediatricians, cardiologists, and pulmonologists
- Other Disciplines: Physiotherapist, occupational therapist, child life specialist
- Hospital Management
- Public Relations

In multidisciplinary meetings, the following should be discussed: the results of all investigations of all disciplines; an assessment of how they overlap in the different specialties; the order in which these surgical specialties will operate; any planned changes in the positions of the infants; locations where intravenous lines may or may not be placed; any anticipated problems or concerns; and whether or not intensive care will be necessary after the procedure. An example to illustrate the importance of such a discussion is a pair of ischiopagus twins who require defunctioning colostomies for intestinal obstruction. The pediatric general surgeon needs to perform the colostomies, the urologist needs to do an examination of the urogenital system under anesthesia, the orthopedic surgeons and neurosurgeons may require input for assessment of the sacrum and pelvis, and finally, the otolaryngologic surgeon has to assess one of the twins for upper airway obstruction and possible adenoidectomy. The use of diagrams of the anatomy,

■ **FIGURE 29-6.** This is a CT reconstructed image of a surviving ischiopagus twin's spine after emergency separation when the other twin did not survive. This twin has required a number of surgical procedures to correct the abnormal anatomy of both the spine and pelvis.

three-dimensional or CT-reconstructed models, and rehearsals in the operating room allow the process to proceed as smoothly as possible (Fig. 29-6).

ANESTHETIC CARE OF CONJOINED TWINS

General Principles

Anesthesia services for conjoined twins are required for various situations (Box 29-3). Anesthetizing conjoined twins is demanding and complex. The anesthesiologists must treat each

Box 29-3 Anesthesia Services for Conjoined Twins

Obstetric anesthesia for the mother
 Mother and infants for the EXIT procedure
 Resuscitation of the newborn infants
 Airway management
 Acquisition of vascular access
 Intensive care management, neonatal or pediatric
 Examinations under anesthesia
 To facilitate investigations, cardiac catheterization, MRI, CT scans
 Emergency surgery: intestinal obstruction, palliative heart surgery on one twin (Tirota et al., 2005).

SURGERY FOR SEPARATION

Reconstruction and rehabilitation procedures
 Chronic pain syndromes

child as a separate individual. The general principles of pediatric anesthesia, including factors predicting a difficult anesthesia, apply in all of these cases. Any deterioration in the condition of the twins should be anticipated, so intubation and emergency resuscitation measures can be taken in a controlled manner. Two anesthetic teams are always involved in the management of the two patients, with duplication of all equipment necessary for their care.

If an urgent resuscitation is required in the ward, two anesthesia providers must attend, with one provider for each infant. No induction agent, especially a muscle relaxant, should be administered to one infant until the airway of the second twin can be maintained and supplemental oxygen and ventilation can be provided.

Reviews of operative procedures before separation provide ideal dress rehearsals for the management of these patients.

Anesthetic Challenges in the More Common Types of Conjoined Twins

Thoracopagus Conjunctions

Thoracopagus conjunctions are the most common form of conjunction. They are associated with a significant risk of complications, either when they are an isolated abnormality or when they are part of a complex cephalad or caudal conjunction. Sudden unexpected deterioration in respiratory and cardiovascular function in the preoperative period may occur, resulting in the untimely demise of both infants. Early intubation and ventilation with cardiac support may be necessary. Sudden death in this group is not uncommon.

Airway management is difficult because of the extreme lordosis and hyperextension of the infants, with variability of the proximity of their faces (Fig. 29-7). The higher the conjunction, the more difficult airway access becomes. This improves as they grow. Emergency intubation in either or both twins should be avoided. Their deterioration and the need for intervention should be anticipated, and the procedures should be carried out in a quiet and controlled way. Intubation should be done on

■ **FIGURE 29-7.** This lateral photograph of a thoracopagus twin demonstrates the typical hyperextension of the head and neck and the exaggerated lordosis of this group of conjoined twins.

one infant at a time, taking care not to damage the other twin in the process. It is not advisable to paralyze either infant until there is airway support and control in both infants. Except in moribund patients, awake intubation may be very difficult. It is usually easier to intubate the infants when they are on their sides, turned with the face upward. Positioning one infant above the other causes adverse hemodynamic and respiratory consequences in both infants and is not recommended.

The use of laryngeal mask airways is not as successful in this group as in those twins whose heads face away from each other or in twins whose heads are at opposite ends of the body. Once the infants have been anesthetized, fiberoptic intubation has been used with success, but most intubations can be performed without it. It may be useful to insert a nasopharyngeal tube (a short endotracheal tube [ETT]) into one nostril to provide oxygen and an inhalational agent while attempting to intubate the trachea, either orally or nasally. Direct laryngoscopy and distal airway evaluation may be of value in the work-up before separation, but it is often difficult to insert a rigid bronchoscope without causing damage to the infants (Strocker et al., 2005). A fiberoptic technique is easier. There is little emphasis placed on investigating the respiratory systems of these infants. Lung abnormalities have been identified and include tracheomalacia and the presence of aberrant bronchi (Strocker et al., 2005).

Cardiac complications, especially cardiac failure in the neonatal period, are common. Anatomic possibilities include twins with a single normal heart, twins with two conventional hearts, or twins with compound hearts. The anatomy of major vessels may be extremely variable. With compound hearts, the extent of sharing may vary from minimal to almost complete (Gerlis et al., 1993). Coronary artery sharing usually coexists, even with minor venous sharing, and fusion may occur at the level of the sinus venosus, at the atrial level, or at the atrial and ventricular levels. Cruciate connections from the right atrium of one infant to the right atrium of the other, or from the left ventricle of one to the left ventricle of the other, may be present (Gerlis et al., 1993). Many of the components may only be determined at surgery (or postmortem). For technical reasons, it is often difficult to differentiate whether the ventricles are contiguous or fused.

Electrocardiograms (ECGs) in these infants are interesting, but are not conclusive. The presence of two complexes does not rule out significant abnormalities, and a single complex does not necessarily mean significant sharing of heart structures. Reciprocal complexes, or those appearing as a mirror image, usually indicate shared hearts. (Fig. 29-8)

Cardiovascular and respiratory instability may occur with any maneuver that alters the intrathoracic pressures and moves the hearts and lungs of each infant back and forth between them. Coughing, crying, and breath-holding are all contributing factors. Positive pressure ventilation should be timed in both infants to avoid this complication. This can be achieved with manual ventilation, synchronized intermittent positive pressure ventilation, or with the use of circuits made up to ventilate both infants with a single ventilator. With the latter method, good chest movement (and capnography) is a vital clinical indicator of adequate ventilation.

Central vascular access, whether subclavian, internal jugular, or femoral, is difficult because of variable anatomic differences, which make the usual anatomic landmarks unreliable. Ultrasound has been helpful in identifying these vessels. Blood loss, as with most conjoined twins, may be significant (two to three times the estimated blood volumes).

■ **FIGURE 29-8.** This is the ECG of thoracopagus twins who share a pericardium but have separate hearts. The complex of one twin is superimposed on that of the other.

After separation, postoperative ventilation is generally the rule rather than the exception. The repair of deficits in the anterior chest wall needs to be planned, because most require some sort of structural support to facilitate normal ventilatory mechanics and to avoid the development of a flail segment (Hoshina et al., 1987).

Omphalopagus Conjunctions

Omphalopagus twins range from a very simple conjunction containing fibrous tissue or a sliver of liver, to an extremely complex conjunction. If the livers are extensively fused, blood loss may be considerable. Complex hepatobiliary fusion and proximal gastrointestinal sharing of organs may complicate surgery. Airway access may be difficult but not as hazardous as it is in thoracopagus twins. In more complex conjunctions, ventilatory challenges are the same as those for thoracopagus twins (i.e., coughing and straining in one twin affects the other's ability to breathe properly).

Ischiopagus and Pygopagus Conjunctions

Airway management is not usually a problem except in those cases where a compound or complex conjunction is present. In general, the twins' faces, heads, and necks are easily accessible for intubation. As with thoracopagus twins, if their abdomens are joined, abdominal contents can move between the infants with Valsalva maneuvers and may compromise the ventilation and diaphragmatic excursion of the other infant. In ischiopagus twins before separation, bowel surgery for intestinal obstruction may be necessary.

Especially in twins where posterior osteotomies are required for pelvic ring closure, blood loss may be extensive. This may also occur suddenly and unexpectedly with dural incision and when vascular structures are unpredictable (Fiegggen et al., 2004).

Tethering of the cord, spinal dysraphism, cord fusion, and syringomyelia, in association with anorectal and urogenital abnormalities, are often encountered in ischiopagus, pygopagus, and dipagus twins (Peter et al., 1996). This may preclude the use of spinal or epidural anesthesia in these twins unless ultrasound views clearly identify the anatomy.

If nerve stimulation is required by the surgeon to identify the nerve routes, muscle relaxation should not be used. Preoperative documentation of the neurologic status is essential.

Preoperative bowel preparation may cause fluid losses that need to be factored into preoperative and intraoperative fluid-administration requirements.

Neurosurgeons are experts in the management of craniopagus twins, but their expertise is also required for both ischiopagus and pygopagus conjoined twins who may have a variety of spinal abnormalities (Peter and Fiegggen, 2004). These may present challenges both at the time of separation as well as for long-term management. In the presence of hemivertebrae, asymmetric or small chest cavities, or spinal anomalies, progressive scoliosis may develop and will require diligent follow-up care and possible intervention (Fig. 29-9) (Fiegggen et al., 2004; Rode et al., 2006).

Duplication of an anatomic area (e.g., ischiopagus dipagus, a single trunk but four legs) is amenable to surgical correction with a good outcome (Fig. 29-10). Anesthetic problems in this group are similar to those that would be experienced with tumors of that region, namely vagal stimulation with manipulation of the mass and blood loss.

Craniopagus Conjunctions

Because of the proximity of the infants' heads and faces, airway management of these twins is often a challenge. Stabilization of the ETT requires particular attention, and fluid or blood from

■ **FIGURE 29-9.** This is the surviving infant of ischiopagus twins with spinal deformities who requires follow-up surgery. His CT is shown in [Figure 29-6](#).

■ **FIGURE 29-10.** Ischiopagus dipagus twins are seen here. One with lower extremity duplication, where the abnormal segment comprises the middle two limbs. A pelvic osteotomy is usually performed to facilitate rotation of the legs into a normal position. If a heteropagus parasite occurs at this site, an osteotomy is not usually necessary.

the surgical field can result in dislodgement or displacement during surgery with potentially catastrophic consequences. Especially if significant flexion is anticipated, a reinforced ETT may be the best option. Many of the principles of pediatric neurosurgery apply, including the potential for venous air embolism, and these are affected by the complexity of the conjunction (Girshin et al., 2006). Walker and Browd (2004) provide a comprehensive approach to the embryology, classification, surgical anatomy, and separation of craniopagus twins.

If the venous sinuses of the twins are in communication in the fusion, blood loss may be enormous, and it is often this

factor that limits the possibility of surgery for separation. The abnormal development of the arteriovenous system is one of the greatest challenges faced during the separation procedure. To reduce blood loss and allow each child to develop adequate independent vascular drainage and to prevent perioperative cerebral edema, staged separation may be indicated (Walker and Browd, 2004; Girshin et al., 2006). These staged operations have been attempted to encourage the development of a collateral circulation before final separation and to improve outcome.

The preoperative neurologic status needs meticulous documentation, because the degree of neurologic deficit after surgery depends on the extent of brain, vascular, and meningeal conjunction and the complexity of the procedure.

Central vascular access may be limited to the femoral route.

Preoperative Evaluation

Each type of conjoined twins has challenges specific to their type of conjunction. A comprehensive knowledge and understanding of the pathophysiology of conjoined twins is essential to good anesthetic management. Procedural planning sessions and rehearsals are invaluable to identifying potential or actual stumbling blocks.

The preoperative visit should be as that for any pediatric patient, but there should be particular emphasis on a number of the factors previously described. For urgent operations or separation, rapid preoperative evaluation and assessment before transportation to the operating room is necessary. Prior experience with conjoined-twin management provides considerable advantages at this time.

A thorough goal-directed review that includes the history of perinatal events and growth since birth, exposure to infectious diseases (e.g., human immunodeficiency virus), and whether or not and what prophylaxis was taken (mother-to-child transmission medication), as well as previous intubation experience for respiratory or cardiovascular pathology, is required. An understanding of the complexities of each investigation and the implications of these for surgery (and therefore anesthesia) is vital. It is especially important to understand the degree of cross circulation between the twins and at what anatomic level this may be present (e.g., heart, liver, brain, or bowel) ([Table 29-3](#)).

Especially in thoracopagus twins, signs of cardiovascular decompensation should be sought. These include tachypnea, tachycardia, decreasing saturations, loss of appetite, and failure to thrive.

Regardless of the degree of cross-circulation, drugs should be administered as they would be for two separate individuals. The weight of a heteropagus infant, however, should include the weight of the parasitic part until it is removed and can be regarded in the same light as a pediatric patient who has a tumor that requires resection. For most symmetric twins, the two infants are more or less the same size, so it is appropriate to take their combined weight and halve it to arrive at the weight of each infant.

Careful consideration should be given to where catheter lines should be placed, which cannulae should be used, and how many will be necessary for the particular procedure. Doppler ultrasound has been useful in identifying the site of central vessels, but because of space limitations in some sets of twins, it is not always easy to insert the catheter lines under direct vision. In these infants, it is easier to identify the vessels, place the ultrasound

TABLE 29-3. Summary of Multidisciplinary Investigations Commonly Required for Conjoined Twins

System	Investigation
Cardiorespiratory Cross circulation	Radiography: total body X-ray Electrocardiogram Echocardiography/Doppler ultrasound in all conjoined twins MRI/CT with contrast Angiogram Radioisotope scan Tc-99-DMSA, radiolabeled albumin, or red blood cells ⁴⁵
Alimentary tract	Contrast meal and enema Ultrasound Radioisotope scans ⁵³ (liver); technetium Tc-99m-(Sn), colloid and excretion Tc-99m mebrofenin Radioisotope scintigraphy
Genitourinary	Ultrasound Isotope renography Micturating cystourethrography Genitogram
Skeletal system	Radiography MRI (spinal cord) Ultrasound
Vascular	Doppler ultrasound Angiography

probe aside, and then attempt cannulation, or to have an assistant hold the probe while cannulation is attempted.

Physical Examination

Importance must be given to assessing the following:

The Airway

Managing the airway is crucial to good anesthetic management, and certain types of patients have predictably more difficult airways than others. In general, airway management of ventrally conjoined twins is more difficult. Problems with the airway in conjoined twins include:

- Access to the mouth and larynx is difficult.
- Visualization of the vocal cords may be impossible. Close faces leave little room to move to insert instruments in the airway.
- Placement of the ETT through the cords is challenging, because it tends to get caught on the subglottis. Rotation of the tube through 180 degrees as it passes through the cords facilitates this maneuver. Fiberoptic intubation, either directly or via a laryngeal mask, may be a valuable adjunct. Other techniques that may help include all the usual pediatric anesthesiologists' tricks to bring the larynx into view: the use of one's little finger, having an assistant provide rotational pressure on the larynx; and the use of a stitch into the infant's

■ **FIGURE 29-11.** Intubation of thoracopagus twins demonstrating the use of an assistant's finger to bring the vocal cords into view. This photograph also shows the airway of the other twin being managed while the intubation is taking place.

tongue to pull the hypomandibular structures forward and allow visualization of the epiglottis and cords (Fig. 29-11). The successful use of the Magill's forceps is often compromised by lack of space both inside and outside the mouth, but oral intubation is usually easier than the nasal route. Once placed correctly, secure strapping of the ETT is critical.

Thoracopagus Twins. Thoracopagus twins have difficult airways until proven otherwise. There is invariably some degree of opisthotonus and hyperextension of the head and neck, making visualization of the vocal cords very difficult. Plans for fiberoptic-assisted intubation may be necessary. In order to facilitate long-term ventilation, tracheostomy has been described in one set of twins, but this should not be regarded as the routine recommendation of airway management (Mair and Mair, 2006). Depending on the relative positions of the heads and faces, craniopagus airway access may also be problematic.

Mechanisms of Ventilation

It is important to ascertain whether or not the diaphragm is involved in the junction, or whether its function will be affected by surgery. In those twins where conjunction involves the chest wall and its contents, serious consideration needs to be given to breathing and ventilation. Lung compliance is affected, areas of atelectasis develop because of the limited space between the two infants and the abnormal anatomy of thoracic structures, the hearts are usually abnormal, and cardiac failure is common in thoracopagus twins. As one twin develops cardiorespiratory compromise with tachycardia, tachypnea, and coughing, the other is also affected. This has significant short- and long-term consequences and should be a major consideration when planning for separation. New synthetic substances that enable reconstruction of an unstable sternum and anterior chest wall are now available. Muscle flaps and skin grafts may be needed (Rabeeah, 2006). In the postoperative period, these grafts avoid the development of a flail chest, which causes significant respiratory compromise and affects long-term survival and quality of life. In cases where one twin has not survived, autologous tissue has been used to cover the deficit caused at separation (Rode et al., 2006; Spitz and Kiely, 2002; Fisherman et al., 2002).

Cardiovascular System

Assessment of the heart and major vascular anatomy is crucial, because this impacts anesthesia and vice versa. Craniopagus twins may, as with thoracopagus twins, have cardiac failure. Because many of these infants will have spent considerable time in the hospital, venous access may be a challenge, and ultrasound guidance for central venous access may be necessary. Intravenous catheters within the surgical field should be avoided.

Disability

In craniopagus twins or any of the types where the spinal cord may be involved in surgery, a full neurologic examination is required. This is especially the case if any neuroaxial intervention or procedure is planned as part of the anesthetic. Bowel and bladder function must be documented. It may not always be possible to place a urinary catheter, and urine output may not always come from the kidneys of that infant. This problem occurs when one or both ureters cross over from one infant to the other's bladder.

Gastroesophageal Reflux

Gastroesophageal reflux is most common in thoracopagus twins, although it may occur in any type of conjoined twins. Nursing the infants with their heads up is helpful, and the use of antireflux medication should be considered.

While they are waiting for separation, good nutrition is crucial to the infants' growth. The body composition differs between the two twins, as does their resting energy expenditure and caloric intake. This difference stabilizes after separation, with both twins having similar requirements (Powis et al., 1999; Spitz and Kiely, 2002).

Skin Cover: Tissue Expanders

Tissue expanders are inserted to facilitate skin closure when surgery will leave a significant area uncovered. There are numerous reports in the literature of the use of tissue expanders in many sets of all types of conjoined twins. The advantage of their use includes the provision of autologous tissue to cover the defect, thus avoiding the need for the use of foreign material. The disadvantages are the effects of pressure exerted by the expanders in all directions on contiguous tissue where pressure is not desirable. Areas of skin covering the expanders may become necrotic or infected, and the expanders may need to be removed. The inward pressure may affect cardiorespiratory function and result in twins with preexisting lung disease requiring ventilation before separation (Losee et al., 2009). Immediately after insertion, intraabdominal tissue expanders may initially cause an ileus, and they may cause anorexia as the volume in the expanders increase. For craniopagus twins' skin expansion, especially in younger infants, the pressure effects may impact the growth of underlying bone, resulting in a deformed skull. Depending on the age of the infants, the site chosen for placement of the expanders, the number of expanders inserted, the length of time they will be in place vary, as does the volume of fluid injected (100 to 1,000 mL) to expand the tissue sufficiently. The smaller the infant, the more critical is the volume injected. The shape of the expanders are determined by

the age of the infants and the sites chosen for their placement. Depending on the decision of the surgeon, the expanders may remain in situ for anything from 6 weeks to several months.

Wound closure in craniopagus twins is critical, because skin, dura, and bone cover are necessary to prevent perioperative wound breakdown, cerebrospinal leaks, and meningitis. Skull defects may be left to granulate closed, or bone from other sites such as ribs may be used. Fascia lata may be used for dural cover, and prosthetic material (e.g., a titanium plate) may be considered. Malformation in the skull configuration may not allow or accommodate tissue expanders. The risks associated with the prolonged time necessary for tissue expansion may preclude their use (Walker and Browd, 2004).

The site(s) for tissue expanders need to be chosen carefully, and everything possible should be done to avoid complications that may necessitate their removal because this leaves areas of fibrosis and scarring, thus limiting availability of suitable skin for cover later. Skin sepsis and wound breakdown are the most common reasons for the removal of expanders, and this delays surgery for separation.

An important consideration for all medical staff caring for children with tissue expanders is that of pain at the injection port when injecting fluid into the expanders. The port(s) may be on only one or on both of the infants, and before injection of the expanders local anesthetic should be used on the skin covering the port. In one set of twins, this problem was ignored, and at the time of each injection the twin with the port developed significant anxiety, whereas the other remained unconcerned. This also impacted on the management of postoperative pain and anxiety of the same twin.

Alternatives to the use of tissue expanders include the use of pedicle flaps, periosteal flaps, and skin grafts. Methods for reconstruction of the deficit caused by separation continue to be explored.

The size of the deficit can be measured preoperatively by physical assessment of the size of the potential defect (measuring with a tape measure and three-dimensional CT reconstruction), as well as by the use of acrylic models (Campbell, 2004). This information may then be used to facilitate reconstruction.

Anesthetic implications of the use of tissue expanders include preoperative assessment of the pressure effects of the expanders on the different organ systems. This includes the effects on the skin and the cardiovascular system. The need to remove the expanders may present significant logistic implications for the operating room staff. All of the challenges of anesthetizing these infants, albeit for a relatively small operation, present themselves—two teams, two sets of equipment, and the need for vascular access are just a few to mention.

ANESTHESIA FOR NON-SEPARATION PROCEDURES

A variety of preseparation or palliative procedures and investigations can be expected. These may include surgery to remove an inappropriately sited limb, place tissue expanders, perform laparotomy for intestinal obstruction, divert stomas, repair an inguinal hernia in one twin, perform gastroschisis, complete urologic procedures such as vesicostomy, do an adenoidec-tomy for adenoidal hypertrophy and obstructive sleep apnea in one twin, and to repair necrotizing enterocolitis (Hoyle, 1990; O'Neill, 1998; Jaffray et al., 1999; Seefelder et al., 2003; Lonnee et al., 2007). The possible investigations are listed in [Table 29-3](#). Anesthesia preparation and preoperative evaluation for these

Box 29-4 Preoperative Questions About Conjoined Twins

What procedure(s) is/are the surgeons planning?
 Will the surgery affect both infants?
 Will the anesthetic impact each infant equally?
 Will the procedure necessitate the insertion of invasive monitoring?
 In what position will the infants be placed?
 Will it be necessary for the infants to be moved or have their positions changed during the operation?
 Will they require admission to the intensive care unit?

procedures should be based on the same principles of management as for separation, but the planning for separation involves a more comprehensive approach to the intraoperative and postoperative care.

To prevent confusion and to allow all medical staff to understand the procedure, simple but accurate diagrams of the anatomy should be provided at preoperative discussions.

The questions that need to be answered preoperatively are listed in Box 29-4. Routine pediatric anesthetic preoperative blood tests are required, and blood should be cross-matched according to the procedure planned.

The size, age, and state of health of the infants; the site and complexity of their conjunction; the anatomy of organs involved; the organs or structures that are missing; the presence of other congenital anomalies; and the degree and location of cross circulation are all vital factors in planning for anesthesia and surgery. Regardless of the procedure or operation, neonatal conjoined twins are a considerable challenge. The younger and smaller the patients are, the more complex the conjunction, and the presence of associated congenital anomalies may complicate all aspects of the anesthetic management. Thoracopagus and craniopagus twins have a higher perioperative morbidity and mortality. The greater the extent of the junction, the more organs are affected by fusion or by being absent.

A dead or dying twin, if not quickly separated from its twin, aggravates the acidosis and causes deterioration and death of both infants (Fig. 29-12). That error was made in one set of twins. By the time they were prepared for surgery nearly 24 hours after birth, one of the twins was regarded as moribund and was not resuscitated or ventilated in the intensive care unit, and this nearly resulted in the death of his brother. As the ill twin deteriorates and dies, there is extensive vasodilation and acidosis, so the intravascular volume of the surviving infant transfuses into the dead twin, causing the healthier twin to succumb. The biochemical challenges are similar to those of a reperfusion syndrome.

Airway difficulties are more common in those infants where the conjunction is high on the chest, where the heads face each other and are close together, where the head and facial anatomy is abnormal, when hyperextension of the head and neck with exaggerated lordosis is present, and where the parasite of a heteropagus twin is around the head, neck, or upper chest (Fig. 29-13). Vascular access is anticipated to be difficult in this group.

Vascular access, especially central venous access, is challenging, because deviation from normal anatomic relationships of arteries and veins is common. When available, ultrasound guidance is recommended.

■ **FIGURE 29-12.** A set of ischiopagus twins where one twin deteriorated rapidly before surgery, necessitating emergency separation. To minimize the metabolic consequences, the dying twin should also have been intubated and ventilated.

■ **FIGURE 29-13.** A heteropagus conjunction of the upper chest may have an impact on airway management. This one did not cause any problems.

The greater the extent of the fusion, and the more complex the organ involvement, the greater is the propensity for significant blood loss (more than one estimated blood volume) at the time of separation. Blood loss may be obvious (e.g., with thoracopagus or craniopagus), but it may also be covert, as occurs in ischiopagus twins, where posterior osteotomies result in a slow, constant ooze under the dressing and out of sight of the anesthetist. Appropriate preoperative cross-matching of blood and products for intraoperative use is essential.

The need for cardiopulmonary bypass brings with it technical difficulties in inserting cannulae, space in the operating room, and all the consequences and complications of open heart surgery (Suan et al., 1998). Preoperative planning is critical for successful outcomes.

During the week before surgery, in order to ascertain whether the infants will fit onto the operating table, their length and width must be measured. This is especially important in larger, older sets of twins, who will have grown since their previous

procedure. In consultation with each of the surgical specialties (especially if the positions need to be changed) and nursing staff, positioning of the infants for surgery must be defined and accommodated. All catheter lines, monitoring, and diathermy should be placed accordingly.

Support materials, such as sponge supports for upright twins or a special chair, may take time to prepare (Fig. 29-14) (Mair and Mair, 2006). When extra limbs or abnormally sited limbs are present, careful protection of these limbs during surgery should be ensured.

Anesthesiologists should prepare for numerous changes in position. When conjunctions are very complex and a number of surgical specialties are involved, the changes in position require forethought and planning. Color coding is of particular value at this time. Meticulous care of the ETTs is essential. Arterial and venous lines need to be moved in an orderly fashion so as to avoid the otherwise inevitable tangle that takes a long time to unravel. Certain equipment, such as diathermy, may need a new site after each change in position.

A rehearsal in the operating room may be very useful to all concerned. Infants should be handled gently and safely; as they grow, they are heavier and more active. If they are fed immediately before their arrival for this exercise, the infants are usually very cooperative.

A preoperative discussion with all role players is necessary, but especially among those anesthesiologists involved in the procedure; they should display a diagram of the anatomy and the planned surgery and discuss the extent of circulatory mixing, the positions required, and the order of the procedures. This discussion allows rational ordering of blood and blood products based on

■ **FIGURE 29-14.** Thoracoomphaloischiopagus twins, with tissue expanders in the upper abdomen and lower chest. Because of the unusual positioning during surgery, careful attention to blood pressure, oxygen delivery, and cerebral perfusion is necessary.

calculations of anticipated blood and fluid losses. It is also useful to have a written agenda to follow during the procedures.

Anesthesia providers should be sure to have a double supply of all necessary equipment: anesthesia machines, monitoring, infusion devices, blood warmers, and temperature control modalities. Point-of-care blood analyzing facilities must be checked and ready for use.

As space is often a problem, a drug cart may be shared between the two anesthesiology teams, but drugs should be drawn up independently for each infant. The routine drugs available should include analgesics, anesthetic agents, muscle relaxants, inotropes, and other specific requirements of any of the surgical specialties. Emergency drugs include epinephrine, phenylephrine, norepinephrine, sodium bicarbonate, calcium, and steroids. Aggressive cardiac resuscitation may be necessary in all but the simplest conjunctions.

The operating room should be arranged to suit the type of twins; thoracopagus and craniopagus twins tend have the anesthetic machines at the same end of the table, whereas ischiopagus twins' surgery necessitates that the machines be at opposite ends of the operating room table (Fig. 29-15).

Color coding of each infant's equipment with all the lines, monitors, equipment, and drugs is very useful (Fig. 29-16). Color coding for each team is also valuable, especially when there are two surviving infants to be operated on in two operating rooms or on two separate operating tables.

At the separation of ischiopagus or pygopagus twins, posterior osteotomies may be performed to facilitate pelvic ring closure (Verrier et al., 2000). The approach to the iliac spines is from the back of each infant, and appropriate positioning may be a problem. Positions are rehearsed when the infants are awake, and innovative plans may be necessary to achieve the correct positioning of the infants for surgery (Fig. 29-17). Postoperatively, the legs of the infants are anteromedially rotated and strapped in position for 6 weeks; this will impact their diaphragmatic excursions with the potential for atelectasis and pneumonia (Fig. 29-18). Physiotherapy is crucial to their recovery.

Drug pharmacokinetics and pharmacodynamics may be inconsistent. The use of contrast, radioisotopes, and drugs have all been used to determine the extent of cross circulation, but

■ **FIGURE 29-15.** The arrangement of the operating room for thoracopagus twins' separation is shown here. A single operating table but duplicate anesthetic machines, monitoring and warm air devices, syringes drivers, and drug carts were used.

■ **FIGURE 29-16.** Color coding of each child, equipment, lines, and monitoring provides easy identification and prevents drug and fluid administration errors.

■ **FIGURE 29-17.** For many of the surgical procedures on conjoined twins, innovative positioning for the operation may be necessary. Because of their complex conjunction, this was the most ideal position possible to expose the back of each infant for its posterior osteotomies.

■ **FIGURE 29-18.** After pelvic ring closure in ischiopagus twins, the legs need to be kept in the same position for up to 6 weeks after surgery. This requires firm bandaging of the legs and pelvis, as shown in this photograph.

it is safest to assume some degree of it until proven otherwise. In practical terms, thoracopagus and craniopagus twins have a considerable degree of cross circulation, and few have none at all. The option of local and regional anesthesia use should always be considered, and it should be used whenever possible. Where there is the potential for considerable blood loss, or where there are other contraindications, these techniques should be used with caution.

Control of traffic in the operating room is essential. Noise and congestion are distracting and not in the patients' best interests. Strict guidelines, drawn up by operating room staff and hospital management, must be in place well before embarking on any surgical procedure. Advances in communication technology allow for operations to be viewed via constant in-operating room camera feed, to a distant venue where interested parties can observe proceedings. This also provides a valuable teaching experience for students of all disciplines who cannot be directly involved in the anesthesia and surgery.

Everyone should take time to check everything as a team just before the twins are brought into the operating room.

ANESTHESIA FOR SEPARATION

Nonemergency surgical separation is usually planned for between 4 and 11 months, when the infants are larger and the investigations have given information that is clearer and more meaningful. After this age, psychological issues with separation become more problematic (O'Neill et al., 1988). This operation is the culmination of a multidisciplinary preparation that hopefully will end in the successful separation of a pair of conjoined twins.

Premedication

Sedative or anxiolytic premedication is generally not required, but when the infants are older this may be a consideration. Each set of twins should be assessed individually. In older sets of twins, sedation options include midazolam, trimeprazine, chloral hydrate—each of these has been used successfully in some twins over 6 months of age (Thomas and Lopez, 2004). Atropine has been used for neonatal twins, but this is only necessary when vagal stimulation is likely to occur (e.g., with laryngoscopy or bronchoscopy) or when the use of ketamine is planned.

If an intravenous induction is planned, the use of a topical local anesthetic cream before venipuncture should be encouraged and placed before the twins are transported to the operating room.

Transport

Transportation of the infants to operating room may well be a simple process, and they may be brought to the operating room door by the parents and accompanied by a nurse. In ill twins who have been in intensive care and who are intubated with all invasive catheter lines in place, transportation to the operating room involves the use of a transport monitor and a ventilator for each twin, and the accompaniment of two anesthesiologists. Maintaining normothermia in transit is essential,

and meticulous attention to the airways and intravascular lines reduces the possible risk of disconnection or dislodgement at this time. Each anesthesiologist must clearly understand his or her role during this process. Box 29-5 gives a preparatory checklist for the anesthesiologists before caring for conjoined twins.

Box 29-5 Preoperative Conjoined Twin Checklist

- Preparation of operating room (duplicates of all equipment): anesthetic machines; infusion pumps; temperature of operating room set between 26° and 28° C; warm air devices and blankets; grounding pads (one between two at the beginning of surgery is acceptable and changed to one each after separation); a second operating room table to be brought into the operating room (or preparation of another operating room if one of the twins is to be moved); invasive monitoring equipment ready for use; egg-box sponge; silicone pads or rings or an equivalent for pressure protection during the procedure (Fig. 29-19); labels to distinguish drugs and equipment for each twin
- Vascular access devices (central and peripheral)
- Ultrasound machine for intravenous access
- All drugs, routine and emergency, drawn up in duplication for each infant
- Intravenous fluid and blood administration sets for each twin
- Blood cross-matched and immediately available
- Techniques to minimize blood loss, such as the use of cell savers or a protocol for major blood loss, should be considered when massive or sudden blood loss is anticipated (Paterson, 2009)
- Confirmed availability of intensive care beds

■ **FIGURE 29-19.** The use of soft bandages and plastic protect the legs during surgery and prevent heat loss.

Induction

Techniques for induction of anesthesia are determined by the airway, the availability of intravenous access at induction, the state of health of each infant, the drugs available, and the preferences of the attending anesthesiologists. In those twins with potentially difficult airways, spontaneous respiration with inhalational induction with sevoflurane or the intravenous use of ketamine is helpful (Fig. 29-20) (Thomas, 2004; Thomas and Lopez, 2004; Diaz and Furman, 1987). In this same group, a lidocaine “gargle” before induction to partially anesthetize the airway is a useful technique (2% lidocaine sprayed into the infant’s mouth before starting the anesthetic). In infants with cyanotic congenital heart disease or in those with complex anatomy, intravenous ketamine is a safe option (Thomas and Lopez, 2004; Diaz and Furman, 1987).

Muscle relaxation must not be used until airway access is assured. Rapid sequence induction is often not possible in ventrally conjoined twins. Ideally, intravenous access should be established in the ward before transfer to the operating room, but because many of the infants have been in the hospital for some time, this may not always be possible. When this is the case, inhalational induction may be followed by the use of topical local anesthetic spray (2% lidocaine) to the vocal cords to facilitate intubation. The type of ETT and the route used (oral or nasal) are determined by the type of conjunction (nasal is not suitable for craniopagus twins surgery, and this route is often very difficult in thoracopagus twins), whether or not postoperative ventilation is planned, whether the surgical position requires the use of a reinforced tube, and how accessible the infants’ faces and ETTs are during surgery. To facilitate postoperative ventilation, oral tubes may be changed to nasal tubes at the end of the procedure. Good securement of the ETT is crucial, and inadvertent extubation during surgery may be disastrous.

In cases when the airway is not a problem and the infants are hemodynamically stable, any agent commonly used for pediatric anesthesia is suitable. Intravenous inductions using propofol, etomidate, thiopentone, and ketamine have all been used successfully.

■ **FIGURE 29-20.** This inhalational induction in thoracopagus twins with a high conjunction demonstrates the close proximity of the airways of many of these infants.

Intraoperative Management

Intraoperative care of these twins should aim to provide ideal surgical conditions in a safe and appropriate way for the type of conjoined twins undergoing the procedure. Analgesia, amnesia, and muscle relaxation should be provided, with control of the airway, ventilation, hemodynamic stability, and temperature regulation as for any pediatric anesthetic. Challenges with cardiovascular depression, difficult ventilation in thoracopagus twins, and unpredictable drug absorption and responses with uncertain degrees of cross circulation all necessitate regular adjustments in anesthetic agents and muscle relaxation. Especially if extubation is planned after anesthesia, short-acting drugs by constant infusion to each infant may well be the preferred option. This may also be the case with operations that have significant blood loss and a constantly changing hemodynamic status. For most operations, long-acting drugs such as pancuronium may be used.

During anesthesia, vasodilation in one infant may result in blood being diverted to this infant, causing a significant drop in the blood pressure of the other twin. Vigilant attention to each twin compared with the other is essential. This function is often best performed by the coordinator, as the other anesthesiologists are each busy with their own infant.

Cardiac support may be required early in any twins, but thoracopagus twin are at particular risk for this intervention. Early use of inotropes may be required.

All techniques, such as color coding of patients and their infusions, cannot be overstated. When positions are changed, the process should be carried out slowly to avoid dropping or damaging the infants or inadvertently pulling out catheters or ETTs.

The use of local anesthesia should always be considered. Epidural, caudal, and combined epidural-spinal anesthesia have all been used successfully for surgery and postoperative pain relief (Greenberg et al., 2001). There are definite advantages and disadvantages to the use of neuroaxial blocks and regional anesthesia, and each set of twins needs to be assessed individually as to the feasibility of this option. Where regional anesthesia is not possible, the use of infiltration of local anesthetic, together with a vasoconstrictor, should be considered and also helps reduce blood loss.

Blood loss is always mentioned in both the surgical and anesthetic literature with good reason. Vascular structures may not always be predictable, and blood loss may be sudden. Fluid and blood loss may be anything from half to more than five times each infant's estimated blood volume. Blood loss may be massive in craniopagus or cardiopagus twins, in those whose livers are extensively fused, and in those where a significant bony fusion is to be separated. This should be anticipated and monitored, with blood products immediately available. The blood bank and the laboratories should be informed of the surgery, and all point-of-care monitors checked and functioning. Fluid administration is determined by many aspects, but in general, a balanced electrolyte solution with the possible addition of 1% dextrose for neonatal surgery is most suitable. Colloids and blood products should be used early rather than later in the procedure and administered as required.

Circulatory collapse at separation was described in early reports, and adrenal suppression was cited as the cause. This led to the recommendation for use of perioperative steroids (Hoyle

and Thomas, 1989; Synhorst et al., 1979; Aird, 1959), but this is no longer relevant, and steroids are only advised for specific surgical specialties such as neurosurgery. Other causes of circulatory collapse at separation are considered to be unappreciated blood loss resulting in an inadequate intravascular volume a vagal response (especially with bony separations of ischiopagus, pygopagus, or dipagus twins) and undiagnosed cardiac abnormalities. Where intravascular blood volume replacement is sufficient and vagal responses is preempted, this has not been a problem.

Monitoring

Routine noninvasive neonatal or pediatric monitoring is used until invasive lines are inserted. Urinary output from each infant is monitored, recognizing that in some twins with urogenital abnormalities the kidney function may not be accurately reflected by this test. For each infant, temperature monitoring is essential.

For control of the airway and breathing, routine pediatric ventilatory monitoring is required, with special attention being given to those infants in whom synchronized ventilation prevents hemodynamic consequences. Cardiovascular invasive monitoring is required in all but the simplest of conjunctions. This takes time to place, because the anatomic relations in most twins are unpredictable.

Monitoring of neurologic function is crucial in all cases. Recent developments in the use of BIS, near infrared spectroscopy (NIRS), and transcranial Doppler (TCD), makes these attractive options in monitoring cerebral blood flow and oxygenation during separation.

Arterial blood gases, electrolytes, and clotting parameters should be regularly checked. If it is available, a thromboelastogram (TEG) should be used.

Temperature monitoring should aim at normothermia, and all techniques available should be used to ensure proper temperature control. The use of plastic drapes, padded bandages around the limbs, and waterproof plastic bandages makes a significant difference to temperature control during the surgery. After each surgical group has operated and the positions have changed, these measures also need to be moved.

Reconstruction after Separation

For all disciplines of surgery, this phase is of the utmost importance for immediate and long-term outcomes. This surgery takes a long time, and blood loss may be covert and prolonged. It is vital to stabilize all aspects of both infants physiologically and to optimize their conditions before transfer to the intensive care unit. Primary closure that is too tight may compromise cardiac, pulmonary, gut, or renal function. Maintaining normothermia during this phase may be difficult.

Postoperative Care

Problems in the immediate postoperative period relate to the consequences of massive blood transfusion, tight closure, prolonged surgery, and alterations in preoperative anatomy. Cardiovascular and respiratory complications remain the most common causes of death. Monitoring for bleeding, hypoxia,

hypercarbia, acidosis, hypothermia, hypotension, and electrolyte imbalance is mandatory. Ongoing volume losses, cardiac instability, and respiratory impairment are common at this time. When weaning the infants from mechanical ventilation, attention must be paid to sternal insufficiency, diaphragmatic dysfunction, and to the mechanics of breathing. Gastroesophageal reflux may be an additional complication. Sepsis is both a short- and long-term problem and may impact morbidity and mortality.

Good pain relief is obligatory and may include the use of intravenous acetaminophen (paracetamol), which can be given orally or rectally, as well as the more traditional options of morphine or clonidine. If chronic pain syndromes are anticipated, the early use of gabapentin should be considered. Further anesthetics may be required for vascular access, secondary wound closure, and wound dehiscence (Rode et al., 2006).

Especially in older sets of twins, nursing care in the same bed as soon as is practical and safe attends to the problems of separation anxiety.

Prognosis

Immediate and long-term survival of conjoined twins is extremely variable. Outcomes are better in twins who do not share vital organs, but many of these children still have considerable rehabilitation requirements. Despite tissue expansion, the use of prosthetic materials, skin grafts, complex plastic surgical flaps, and innovative methods to provide skin cover to close those areas exposed by the separation remains an ongoing challenge.

Hidden long-term morbidity and mortality occur with unresolved aspiration after thoracopagus separation; bronchopneumonia, arrhythmias, and embolic cerebrovascular pathology occurred in one survivor when the entire cardiac complex had been assigned to one infant (Rode et al., 2006; Millar et al., 2009).

For many years after their separation, some patients must undergo further surgery to reconstruct shared pelvises and urogenital systems, to improve wound closure with skin grafts, and to revise their anatomic abnormalities in an ongoing effort to improve the quality of their lives. Some survivors will be disabled and require lifelong follow-up care. For many others, life goes on with minimal sequelae (Figs. 29-21 and 29-22).

CONCLUSION

Many lessons have been learned over generations, and these include the need to consult widely—locally and internationally. The Internet makes this extraordinarily easy. It is important to search using both the American and English spellings of *anesthesia* and *anaesthesia*, because different references appear as the result of a search, and there is very little overlap. Descriptions of anesthetic challenges are being reported from all over the world in different socioeconomic and political circumstances, and each article teaches something of value (Bloch and Karis, 1980; Norsidah et al., 1996; Huanc et al., 2004; Leelanukrom et al., 2004). Whether surgery for separation is an option or not, an experienced multidisciplinary team approach to the management of these infants results in the overall improved handling of the patients and their parents. Success requires an

■ **FIGURE 29-21.** The ischiopagus twin girls from Figure 29-3, 5 years later.

■ **FIGURE 29-22.** An ischiopagus dipagus survivor, 4 years after surgery to remove the duplicate segment, riding his tricycle in the ward.

experienced team functioning in a tertiary referral center with the full range of medical, surgical, and anesthetic specialties (Spitz and Kiely, 2003).

As technologies improve, anesthesia and intensive care will continue to positively impact the surgical outcomes of this fascinating and challenging group of patients. Some of these infants and children will grow up to become adults, so a greater understanding of the long-term outcome of this extraordinary pathology is essential. Although the physical needs of these children are usually addressed, the emotional consequences of their pathology should always be kept in mind and addressed.

Many of the basic principles of anesthetic care have not changed much in 60 years, but advances in anesthetic equipment, monitoring, investigative technology, pharmacology, and surgical materials make the desirable outcome of surgery, as well as the long-term prognosis for a good quality of life for conjoined twins, an attainable reality.

ACKNOWLEDGMENTS

Numerous colleagues, both past and present, have contributed to our knowledge of this extraordinary group of patients.

The importance of a multidisciplinary team with good communication cannot be overemphasized. This includes sharing of patient data and photographs, and I thank all those surgeons and anesthesiologists who have allowed me to use their information. These include Professors Syd Cywes, Heinz Rode, Alastair Millar, Jonathan Peter, and Graham Fieggen, who are inspirational in their knowledge, technical skills, and teaching; Drs. Rob Dunn, John Lawrenson, and Jonathan Karpelowsky for clinical material; and Dr. Mike Porter for his assistance with the manuscript. To all those anesthesiologists who have assisted me over the years, and to those who have reported their experiences in the literature, I thank you. Most of all, I am deeply indebted to those parents and their children who have contributed so much and have enabled us to learn much of what we now know about this fascinating and challenging subject.

		Summary	1002

Trauma is the forceful disruption of bodily homeostasis that affects physical, psychological, and family functioning, and it remains the number one pediatric public health problem worldwide (Jurkovich et al., 2004). Each year injuries kill more children in the United States than the combined number of pediatric deaths from cancer, congenital anomalies, heart and chronic respiratory diseases, influenza, pneumonia, septicemia, and cerebrovascular disease (Centers for Disease Control and Prevention [CDC], 2002). Over 6 million children are evaluated and treated annually in emergency departments for their injuries, and of these, 500,000 children require hospitalization. Approximately 92,000 children annually become permanently physically disabled as a result of their injuries (Baker et al., 1992; Department of Rehabilitation Medicine, 1995; Tuggle, 1998; CDC, 2002; National Center for Injury Control and Prevention, 2005). Many children who survive their injuries are burdened with lifelong physical limitations

or disabilities. For every 400 pediatric injuries, 250 require treatment in the emergency room, 16 are admitted to the hospital, and 1 dies as a result of the injuries (National Center for Injury Control and Prevention, 2005). Trauma care for children includes prevention, treatment and resuscitation, and rehabilitation.

Risk of death from injury can occur during any of three critical times. The first occurs at the time of injury, the second is within the first few hours after trauma, and the third is some time later as a result of complications from the injuries sustained at the time of the traumatic event. Development of effective regional trauma systems and educational programs, such as the Advanced Trauma Life Support for Doctors course, has contributed significantly to the reduction in mortality during the second and third of these critical periods (Tuggle, 1998; Rogers et al., 1999). Unfortunately, however, over 70% of mortality from trauma occurs at the time of injury.

EPIDEMIOLOGY

In 2006, approximately 6 million children received treatment in emergency departments for nonfatal injuries, and of these over 500,000 children needed hospitalization (Child Trends Data Bank, 2005). Injuries can be classified as either intentional or unintentional; most children's injuries are unintentional. Falls (32.4%) are the leading cause of nonfatal, unintentional injuries among hospitalized children 1 to 14 years of age, followed by injuries sustained as a result of being an occupant in a motor vehicle crash (12.3%) (National Center for Injury Control and Prevention, 2006). The rate of injury and the morbidity and mortality rates remain relatively stable until age 14, when they begin to increase substantially. Males are injured more commonly than females. Motor vehicle accidents are responsible for 75% of pediatric traumatic deaths (DiScala, 2002). Intracranial injuries are the cause of most pediatric traumatic deaths. Unintentional injuries are more prevalent among children who are male, poor, and black or Native American (Safe Kids USA, 2005). In 2004, there were 654,647 (715/100,000 population) nonfatal intentional injuries and 4738 (5.8/100,000 population) fatal intentional injuries in children 19 years and younger. Abuse (physical and sexual), followed by self harm were the major causes of intentional injuries (National Center for Injury Control and Prevention, 2005).

Injuries can be classified as either blunt or penetrating. Blunt injuries far outnumber penetrating injuries (12:1), and whereas most are unintentional, up to 7% of injuries are a result of physical assault or abuse (DiScala, 2002). See related video online at www.expertconsult.com.

PEDIATRIC TRAUMA SYSTEMS

Historical Development

In North America, improvements to trauma care began in the 1960s and 1970s (Trunkey, 1983; Haller, 1995; Mullins, 1999; Morrison et al., 2002). Pediatric trauma systems did not develop in isolation but in concert with adult care. Trauma care was advanced in both the Korean and Vietnam wars, with the military experiences of treating injured soldiers. A report by Howard (1966) highlighted the enormity of the injury problem and stressed its significance as a neglected public health problem. Furthermore, a series of "preventable death studies" was published that provided fodder for community and political support of coordinated care for injured patients. Funding for emergency medical services first became available in 1966 with the National Highway Safety Act, and further support followed with the Emergency Medical Services System Act in 1973 (Mullins, 1999). In 1968, Cook County hospital in Chicago (for adult care) and Kings County hospital in Brooklyn (for pediatrics) were recognized as the first specialized centers for civilian trauma care in the United States. In 1969, the University of Maryland and the Maryland State police developed a coordinated transport system for injured patients to preferentially take them to a hospital with specific interest in caring for injured patients (Cowley et al., 1973; Cowley and Scanlan, 1979). Illinois is credited as the first state to develop a comprehensive state-wide trauma system that included categorization of trauma hospitals and the establishment of a communication system and a trauma registry (Boyd et al., 1973). In 1984, the Department of Health and Human Services, in conjunction with the National Highway Traffic Safety Administration, began the Emergency Medical

Services for Children Program in the United States. This funding has been a critical resource for developing programs and research to improve emergency service systems for children.

The American College of Surgeons Committee on Trauma (ACSCOT) has also strived to improve trauma care in North America. This has been accomplished through the publication of standards for trauma systems, the creation of educational courses for health care professionals, and the establishment of and verification programs to ensure published standards are met. In 1976, the first version of the Optimal Resources for Care of Seriously Injured was released (Committee on Trauma: American College of Surgeons, 1999). The most recent version of this publication (2006) is currently in use and has been retitled "Resources for the Optimal Care of Injured Patient." It remains a dynamic and important document. This publication established criteria for defining levels of trauma centers (I through III) and trauma systems (I and II), and it defined resource requirements for prehospital care through discharge, as well as specific pediatric needs. Level I centers offer the widest range of services for the most severely injured patient, whereas level III centers allow for stabilization and triage. With respect to trauma system development, eight criteria were defined and have become accepted benchmarks for trauma care (Boxes 30-1 and 30-2). Recently, designation of a level IV trauma center has occurred in some states where the resources do not exist for a level III trauma center. Level IV trauma centers are able to

Box 30-1 American College of Surgeons Trauma Center Levels and Descriptions

LEVEL I

The center provides comprehensive trauma care, serves as a regional resource, and provides leadership in education, research, and system planning.

A level I center is required to have immediate availability of trauma surgeons, anesthesiologists, physician specialists, nurses, and resuscitation equipment.

American College of Surgeons' volume performance criteria further stipulate that level I centers treat 1200 admissions a year or 240 major trauma patients per year or an average of 35 major trauma patients per surgeon.

LEVEL II

The center provides comprehensive trauma care either as a supplement to a level I trauma center in a large urban area or as the lead hospital in a less populated area.

Level II centers must meet essentially the same criteria as those for level I, but volume performance standards are not required and may depend on the geographic area served.

Centers are not expected to provide leadership in teaching and research.

LEVEL III

The center provides prompt assessment, resuscitation, emergency surgery, and stabilization with transfer to a level I or II center as indicated.

Level III facilities typically serve communities that do not have immediate access to a level I or II trauma center.

Box 30-2 American College of Surgeons Criteria for Trauma System Development

1. State authority to designate, certify, identify, or categorize trauma centers
2. Existence of a formal process to designate or otherwise identify trauma centers
3. Use of the ACS standards to designate and identify trauma centers
4. Inclusion of onsite verification during the designation and identification process and use of out-of-area surveyors
5. Authority to limit the number of trauma centers based on the need for trauma services
6. Existence of a process for monitoring trauma-center performance
7. State-wide coverage of a trauma system

From Adler P: *Directorate for epidemiology*, Washington, DC, 1994, U.S. Consumer Product Safety Commission.

provide initial evaluation, stabilization, preliminary diagnoses, and transportation to a center with a higher level of care. These centers may also provide surgery and critical care services (as defined in the scope of services of trauma care). A trained trauma nurse and physicians are available on the patients' arrival to the emergency department.

In 1986, the ACSCOT established its consultation and verification program to ensure that these standards were being met. At present in North America, there are 94 verified level I centers for adult care and 46 level I centers for pediatrics.

Another valuable contribution by the ACSCOT is the Advanced Trauma Life Support course (ATLS). First released in 1979, the course is now taught all over the world (American College of Surgeons Committee on Trauma, 1997). The first pediatric chapter was introduced in 1983. Although initially designed for surgeons, a wide variety of health care professionals involved in trauma care participate today. The ATLS course provides a common language, framework, and approach to injured patients that facilitate communication between health care professionals in order to optimize and prioritize care. Regular recertification is mandated to keep physicians current with new advances in trauma management. Similar to other ACSCOT programs, the ATLS course is constantly evolving. The current version is the seventh edition.

Trauma System Components

A trauma system is not simply an isolated hospital that cares for injured patients but a broad coalition of participants that includes an integrated approach to trauma. This includes prevention, prehospital care, and hospital care through rehabilitation (Ehrlich et al., 2001, 2002).

A primary step in developing an effective trauma system is a needs assessment of the community that it serves. For example, rural trauma systems differ from those in urban settings—each have different mortality rates, injury patterns, geographic areas, available resources, and expertise (Rogers et al., 1999; Ehrlich et al., 2004). Community responsibility and involvement (particularly with injury prevention) are essential for political support and funding. Studies support the concept that community-based injury-prevention programs play a substantial role in reducing morbidity and mortality (Hulka et al., 1997; Nathens et al., 2000).

A second important consideration in developing a regional trauma system is to understand that all facilities have a role in treating injured patients. A tiered approach (e.g., Levels I through IV) with specific hospitals designated to care for the varied complexity of injured patients is essential. Level I hospitals are tertiary or quaternary centers, with levels II and III centers having fewer capabilities and resources. Level IV hospitals are distinct because of their remote nature (rural trauma). A list of recommended requirements for each level of care can be found in the ACSCOT publication *Resources for the Optimal Care of the Injured patient: 2006* (Committee on Trauma: American College of Surgeons, 1999). A basic tenet and overarching requirement for this tiered system is a central communication (central command) structure and a well-developed triage system so that the most severely injured patients go first to the appropriately designated hospital. In addition, a trauma registry system is essential for outcomes analysis and quality-assurance programs.

A third point is that a trauma system is not an isolated surgical program but a multidisciplinary team of physicians, nurses, technicians, and allied health professions. A large trauma program uses a significant percentage of hospital resources for everything from the blood bank to social work. Regular meetings of all stakeholders are needed to solve problems and respond to changing injury patterns and community needs.

Anesthesiologists play a variety of roles in trauma response. These roles span from assisting as primary responders in airway management and vascular access to coordinating operating-room resources to ensure that patients are treated in a timely and effective fashion. A pediatric anesthesiologist is an invaluable resource when treating injured children. A 1993 report from the Institute of Medicine identified specific pediatric emergency medical service deficiencies in rural states (Institute of Medicine, 1993), including the pediatric airway management, vascular access, and special resuscitation needs of injured children. Airway control is a primary tenet of trauma care, and proper endotracheal intubation (ETI) is recognized as a definitive method to achieve airway control. ETI, however, in injured children is required less often than in adults; hence, maintaining skills can be difficult for health care providers (Baker et al., 2009). Several studies have looked at airway management in pediatric trauma and examined significant aspects, including how success and complication rates of ETI vary by location (e.g., field, transferring hospital, or trauma center) and personnel, whether bag-mask ventilation is effective with respect to oxygenation and ventilation before ETI, and whether multiple attempts at intubation adversely affect patient care or outcomes (Cooper et al., 1992; Gausche et al., 2000; Glaeser, 2000; Ehrlich et al., 2004). These studies have demonstrated that field intubation success rates are poor. Successful pediatric intubations relate to the skill of the person performing the intubation, and anesthesiologists' airway management skills are considered superior to those of all other health care professionals. Failed attempts at ETI appear to produce a spiral effect that results in multiple failed attempts and delayed transfer to definitive care. Complications resulting from ETI seem far more common when the intubation is attempted in the field and the risk of complication is exacerbated with each attempt. Increased complication rates do impact patient recovery, as shown by longer durations of hospitalization (Cooper et al., 1992; Gausche et al., 2000; Glaeser, 2000).

TRAUMA SCORING SYSTEMS

Trauma scoring systems form an integral component of the trauma care structure. Many scoring systems have been described in the literature, and understanding the differences between each can be confusing. To further complicate matters, most trauma scoring systems for pediatric care are derived from adult data. Some of the most commonly used scoring systems are discussed in this chapter.

Trauma scoring systems serve two specific functions. The first is to help determine where is best for an injured patient to be treated. These scores help “triage” the injured child, and therefore help determine the necessity of requiring a trauma center to care for the injury. The best-known and most widely used is the Glasgow Coma Scale (GCS). The second type of scoring system quantifies the severity of illness (SOI), or the risk of mortality. These are typically determined retrospectively and serve as markers for quality assurance, benchmarking, and research, particularly for health services and outcome studies. Triage scores can also form a component of an SOI tool. For example, the GCS is used both as a triage tool and in outcome models. These models rely on a variety of variables, including the diagnosis (using the International Classification of Diseases [ICD-9-CM]), the demographic of the injured patient, and anatomic, physiologic, and laboratory variables. Triage scoring systems are designed to help make quick decisions; they tend to have few data points to assess and are therefore simple to use. Alternatively, the SOI scoring systems have many variables, are more cumbersome, and are often computer generated.

Triage Scores: Where Is the Injured Child Best Treated?

An ideal triage scoring system would have few data points, be easy to apply, have limited subjective assessments, and have a high sensitivity and specificity. Unfortunately, no triage

score accomplishes all of these tasks, but each system does have strengths and limitations. For example, studies have shown that assessments made in the field by paramedics are less accurate and reliable for pediatric trauma patients when compared with adults (Engum, 2000). Alternatively, comparisons between adult and pediatric trauma triage scores have not shown that a pediatric specific trauma score provides a significant advantage over the original adult measure.

Glasgow Coma Scale

In 1974, Teasdale and Jennett first introduced the GCS. A lower score reflects a lower level of consciousness and therefore a potentially more serious head injury. Scores can range from 3 to a maximum of 15 (normal). The GCS measures three specific components of consciousness (eye movement, verbal, and motor responses) with higher scores (up to 5) given to the best response. A patient with a GCS of 13 to 14 is considered to have a mild head injury; 9 to 12 indicates a moderate injury; and a score of 8 or lower indicates a severe insult. Adaptations of the GCS for the pediatric population have occurred, and a Pediatric GCS is now widely used (Table 30-1).

GCS scores determined in the field are less predictive of outcome than those generated at a hospital (Meredith et al., 1995). When each individual component of the GCS is evaluated, the motor component is the strongest predictor of outcome.

Revised Trauma Score

The revised trauma score (RTS) is a physiologic-based triage score (Table 30-2). The RTS was derived from two earlier versions of a triage scores, the Triage Index and the Trauma Score (Champion et al., 1980, 1981, 1989). The RTS has three variables—respiratory rate, systolic blood pressure, and GCS. The RTS is the sum of each variable multiplied by a weighted coefficient.

TABLE 30-1. Glasgow Coma Scale Adult and Pediatric Variables

Best Response	Adult GCS	Pediatric GCS	Score
Eye	No eye opening	No eye opening	1
	Eye opening to pain	Eye opening to pain	2
	Opening to verbal command	Eye opening to speech	3
	Open spontaneously	Open spontaneously	4
Verbal	No verbal response	No vocal response	1
	Incomprehensible	Inconsolable, agitated	2
	Inappropriate	Inconsistently consolable,	3
	Confused conversation	moaning	4
	Orientated	Cries but is consolable, inappropriate interactions	5
		Smiles, orientated to sounds, follows objects, interacts

From Centers for Disease Control and Prevention: *Traumatic brain injury in the United States: a report to Congress*, Atlanta, 1999, Department of Health and Human Services National Center for Injury Control and Prevention.

* The Revised Trauma score is the sum of the weighted variables (see formula in text). The higher the score, the better the prognosis.

$$RTS = 0.9368(GCS) + 0.7326(SBP) + 0.22908(RR \text{ value})$$

where *GCS* is the Glasgow Coma Scale; *SBP* is systolic blood pressure; and *RR* is respiratory rate. These variables were determined to correlate statistically with survival and mortality. A higher RTS is associated with a better chance of survival. An injured patient with a RTS score of 11 or lower is recommended to be treated at a designated trauma center. Eichelberger established and developed pediatric coefficients for the RTS that was then validated in the pediatric population (Engum et al., 2000). The RTS is also recommended as one of the triage tools in the American College of Surgeons trauma guidelines, *Resources for the Optimal Care of the Injured Patient* (Committee on Trauma: American College of Surgeons, 1999).

Alert, Verbal, Painful, or Unresponsive Scale

This is a simple scale that categorizes a patient's condition as alert, verbal, painful, or unresponsive (APVU). No numeric scores are given, but an injured child with a P or U should be taken to the designated trauma center. Subjective interpretation is inherent in this score, so it is best used as a component of the triage process, especially for children in whom the age and development of the child can impact the response. There is a significant risk of undertriaging patients when using this score.

Pediatric Trauma Score

The Pediatric Trauma Score (PTS) was first introduced by Tepas in 1987 (Tepas et al., 1987; Nayduch et al., 1991). Its design was thought to be more reflective of pediatric injuries (Table 30-3). Six variables comprise both physiologic and injury attributes. After a number for each variable is totaled, a score of 8 or lower is considered to be a marker for children requiring care at a designated trauma center. A limitation of the PTS

TABLE 30-3. Pediatric Trauma Score

Clinical	Parameter	Score*
Weight (kg)	>20	2
	10-19	1
	<10	-1

	Open or multiple fractures	-1

Data from Tepas JJ III, Mollitt DL, Talbert JL, et al: The pediatric trauma score as a predictor of injury severity in the injured child, *J Pediatr Surg* 22:14–18, 1987; Tobias JD, Ross AK: Intraosseous infusions: a review for the anesthesiologist with a focus on pediatric use, *Anesth Analg* 110:391–401, 2010.

*A total score of 8 or less suggests care at a designated trauma center.

is that some variables are subjectively scored, particularly the central nervous system (CNS) assessment. Therefore, there is a risk of interrater and intrarater variability. The PTS has been compared with the RTS with surprisingly few apparent differences or inherent advantages (Tepas et al., 1987, 1988; Nayduch et al., 1991).

Age-Specific PTS

The most recent proposed triage score is the Age Specific PTS (Table 30-4). First described by Potoka et al. in 2001, the main addition is the use of age-specific physiologic variables.

TABLE 30-4. Age-Specific Pediatric Trauma Score*

GCS	SBP	Pulse	RR	Score
14-15	Normal	Normal	Normal	3
10-13	Mild to moderate hypotension (SBP < -2SD)	Tachycardia (pulse > mean + SD)	Tachypnea (RR > mean + SD)	2
4-9	Severe hypotension (SBP < -3SD)	Bradycardia (pulse > mean - SD)	Hypoventilation (RR < mean -SD)	1
3	0	0	0 or intubated	0

From Potoka DA, et al.: Development of a novel age-specific pediatric trauma score, *J Pediatr Surg* 36:106, 2001.

* Age-specific variables are stratified by degree of severity, and coded values (0-3) are assigned to each variable. The integer scores are then added (maximum score is 12).

To date, long-term data are lacking and only a single study suggests that it is better than traditional adult scores; therefore, the clinical utility as a triage score still remains to be proven. This score is, however, a pediatric-specific tool that addresses areas where other adult scores become less accurate (e.g., extremes of age).

Abbreviated Injury Scale

$$\text{AIS Score} = \sum (\text{AIS body region 1 to 9})$$

The Abbreviated Injury Scale (AIS) emerged from the automotive industry in 1969 (JAMA, 1971; Association for the Advancement of Automotive Medicine, 1990). It was initially designed as an epidemiologic tool to describe motor-vehicle crashes but has been adapted to all types of trauma (JAMA, 1971; Association for the Advancement of Automotive Medicine, 1990). Revised and updated several times over the years, the first version published was the AIS-90 (for the year 1990) in 1998 (Association for the Advancement of Automotive Medicine, 1990). This score evaluates nine body regions. A scale from 1 to 6 is used to define injuries (1, minor; 2, moderate; 3, serious; 4, severe; 5, critical; and 6, maximal.) The underlying premise is an association of injury with threat to life. A body region with a score of 6 is considered an unsurvivable injury. The scores are determined retrospectively and based primarily on ICD-9-CM codes. A significant amount of expertise is required to assign these ratings, and interrater and intrarater variability is common. To help limit this phenomenon, software has been developed to convert the ICD-9-CM codes directly to an AIS score. Unfortunately, ICD-9-CM coding itself is inherently variable (MacKenzie et al., 1985, 1989).

Injury Severity Score

$$\text{ISS} = (\text{AIS body region 1})^2 + (\text{AIS body region 2})^2 + (\text{AIS body region 3})^2$$

The Injury Severity Score (ISS) is one of the most widely used scoring systems in the trauma literature. It correlates well with several important trauma outcomes such as mortality and duration of hospitalization. Developed in 1974, the ISS is a method of characterizing the trauma patient with multiple injuries (Baker et al., 1974; Baker and O'Neill, 1976). The ISS is based on the AIS, which describes the severity of injury to different body regions (see the previous section). For example:

$$\text{ISS} = (\text{A})^2 + (\text{B})^2 + (\text{C})^2$$

The above formula shows AIS scores of the three most injured of the following body regions: A, the head, neck, and face; B, the thorax and abdomen, and C, the extremities (including the external pelvis). The ISS takes scores from 0 to 75 (i.e., AIS scores of 5 for each category). However, if any of the three scores is a 6, the score is automatically set at 75, because a score of 6 indicates that an injury is unsurvivable.

Two modifications have been reported to the ISS score—the modified ISS (MISS) incorporating the GCS, and the New ISS, focusing on injuries over body regions. However, evaluations of both the MISS and new ISS have not shown advantages

over the standard ISS; therefore, in many centers and registries the AIS-90 still remains the standard severity of injury scoring system.

Survival Probability: Trauma Score and Injury Severity Score

The Trauma Score and Injury Severity Score (TRISS) is not a score but rather a method of predicting mortality. It was first proposed in 1987 and combines the physiologic variables of the RTS with the anatomic severity-of-injury scores generated by the ISS (Boyd et al., 1987). The final result is that a probability of survival (P_s) is generated.

$$P_s = 1 / (1 + e - b)$$

Where e is the base of the natural log 2.72183, and b is derived from the following formula:

$$b = b_0 + b_1(\text{RTS}) + b_2(\text{ISS}) + b_3(\text{age factor})$$

The age factor is 0 for those younger than 55 years of age, and 1 for those who are 55 years of age. The variables b_0 , b_1 , b_2 , and b_3 are blunt and penetrating trauma coefficients for adult and pediatric populations (Eichelberger et al., 1993).

TRISS is the most widely used predictor of survival in the trauma literature. As with other statistical processes, limitations exist. These are specifically noted in patients older than 55 years of age (extremes of age), and with trauma patients whose ISS is greater than 25. In fact, some authors suggest that because of the TRISS deficiencies, this method of calculating survival probabilities should be abandoned completely, particularly in urban centers (Cayten et al., 1991; Demetriades et al., 1998).

Application of the TRISS Results (W and Z Scores)

A common application of the TRISS and P_s is to compare practice-based outcomes with population-based outcomes. Typically, this comparison uses a group of national norms that were identified in the Major Trauma Outcomes Study (MTOS) (Champion et al., 1990b). The MTOS data set is derived from 160,000 hospitalized patients at 139 centers between 1982 and 1989. Children represented 11% of this population. From 80,544 adult patients in this data set, regression coefficients for predicting mortality were derived based on the revised trauma score and ISS (TRISS methodology). A single data set can be compared with the MTOS. A “Z score” is generated, whereby

$$Z = (A - E) / S$$

where A equals the actual outcomes, E equals expected outcomes ($E = \sum P_i$), and S is a scale factor that accounts for statistical variation ($S = \sqrt{\sum P_i [1 - P_i]}$). P_i is the TRISS survival probability for each patient. Z norms should be between 1.96 and -1.96 . If the Z statistic is greater than 1.96, survival is better than the MTOS norms, whereas if it is less than -1.96 , survival is less than MTOS norms.

A probability slope (PRE) is calculated using the RTS vs. the ISS. A $P_{s_{50}}$ slope can be calculated that represents a 0.50 probability of survival (based on MTOS data). Survivors whose data fall above this line and those with fatal injuries whose data fall below this line represent statistically unexpected outcomes.

W Scores

W is used when the Z score is found to be significant. W measures the statistical differences between the actual (A) and expected (E) survivors in a patient group. Sample size plays an important role in delineating the clinical significance of the difference between the actual and expected numbers of survivors (Taylor et al., 1986). Consider the following formula:

$$W = \frac{(A - E)}{(N/100)}$$

A and E carry the same values as they did for the Z score. N represents the number of children analyzed, and W represents the number of survivors^{+/-} that would be expected per 100 children.

Both the W and Z scores are limited by the same factors that limit TRISS data.

A Severity Characterization of Trauma Score

A Severity Characterization of Trauma (ASCOT) score is an attempt to revise and fix the limitations found using TRISS methodology (i.e., severely injured patients and extremes of age) (Champion et al., 1990b). ASCOT uses individual components of the RTS (not totaled) and incorporates a modification of AIS entitled *The Anatomic Profile*. Furthermore, it excludes those patients with either very severe or nonserious injuries (a maximum AIS score of less than 2 and an RTS score of greater than 0; an AIS score of 6 and an RTS score equal to 0). The Anatomic Profile categorizes the AIS scores that are greater than 2 into three groups: head, brain, and spinal cord injuries; thorax or neck injuries; and all other serious injuries. A comparison of ASCOT vs. TRISS with a pediatric population did not provide more reliable or accurate scoring over the TRISS.

Pediatric Age-Adjusted TRISS

This is a recent tool used to describe mortality that applies the pediatric-specific, age-adjusted PTS. Although it may be a more promising predictor of mortality, its data are limited and it has not been validated by other investigators (Schall et al., 2002).

The multitude of scoring systems reflect the reality that no single approach addresses all aspects of pediatric trauma accurately or provides the necessary tools to effectively answer all research questions. Many scoring systems suffer from inherent inaccuracies of coding (e.g., related to discharge diagnoses, ICD-9-CD diagnoses, and data on death certificates). Although physiologic variables generally seem to outperform anatomic variables in these systems, codification requires experience and training. Finally, certain elements of the laboratory data have been shown to be a strong predictor of mortality, yet these variables are not included in the prediction models.

PRIMARY AND SECONDARY SURVEYS

Although children have unique characteristics that distinguish them from adults, the principles of initial management of the injured child and adult are identical.

The first priority is to save a life through identifying and treating all life-threatening illnesses and injuries. To understand and acquire the necessary clinical skills for the management of

injured adults and children, it is best to become certified by completing the ATLS course designed by the American Colleges of Surgeons (Schall et al., 2002). The ATLS course is a well-recognized certification for trauma care and is now used worldwide to teach physicians and other health care providers. The ATLS course gives a common approach and language to the care of injured patients, thus allowing a framework for physicians and allied health personnel to communicate.

The initial management of the injured child can be divided into two phases. The first is the primary survey that incorporates the “ABCs” and where all life-threatening injuries are identified and treated. The second phase is the secondary survey, where other injuries that contribute significantly to illness and deaths are identified and treatment is instituted. The ABCs are defined in the following list, and the priorities of the primary survey are further detailed in [Box 30-3](#).

- A: Airway Ensure a patent airway.
- B: Breathing Assess and provide adequate respiration.
- C: Circulation Assess and assist the circulation with intravenous (IV) fluids and cardiopulmonary resuscitation (CPR) as needed.

During the resuscitation of the injured child, many processes are conducted concurrently ([Fig. 30-1](#)). It is important to continually assess, intervene, and reassess within the priorities of the primary survey. The final components of the primary survey are the placement of a Foley catheter and gastric tube unless contraindicated. The contraindications to placing a Foley catheter include pelvic fracture and blood at the tip of the meatus.

The secondary survey is comprised of a complete physical examination, patient history, laboratory tests, and radiologic imaging. This phase may be delayed or completed in the operating room in patients who require urgent interventions. Historical information about the patient and the event should be collected during the secondary survey. The acronym SAMPLE (standing for *Symptoms, Allergies, Medications, Past illnesses, Last meal, Events, and Environment*) may be helpful in guiding the trauma team. Definitive care occurs in the intensive care unit or operating room and often involves care by pediatric surgical subspecialists (e.g., neurosurgeons or orthopedic surgeons). Patients may also require transfer to comprehensive trauma centers during this phase (Krantz, 1996).

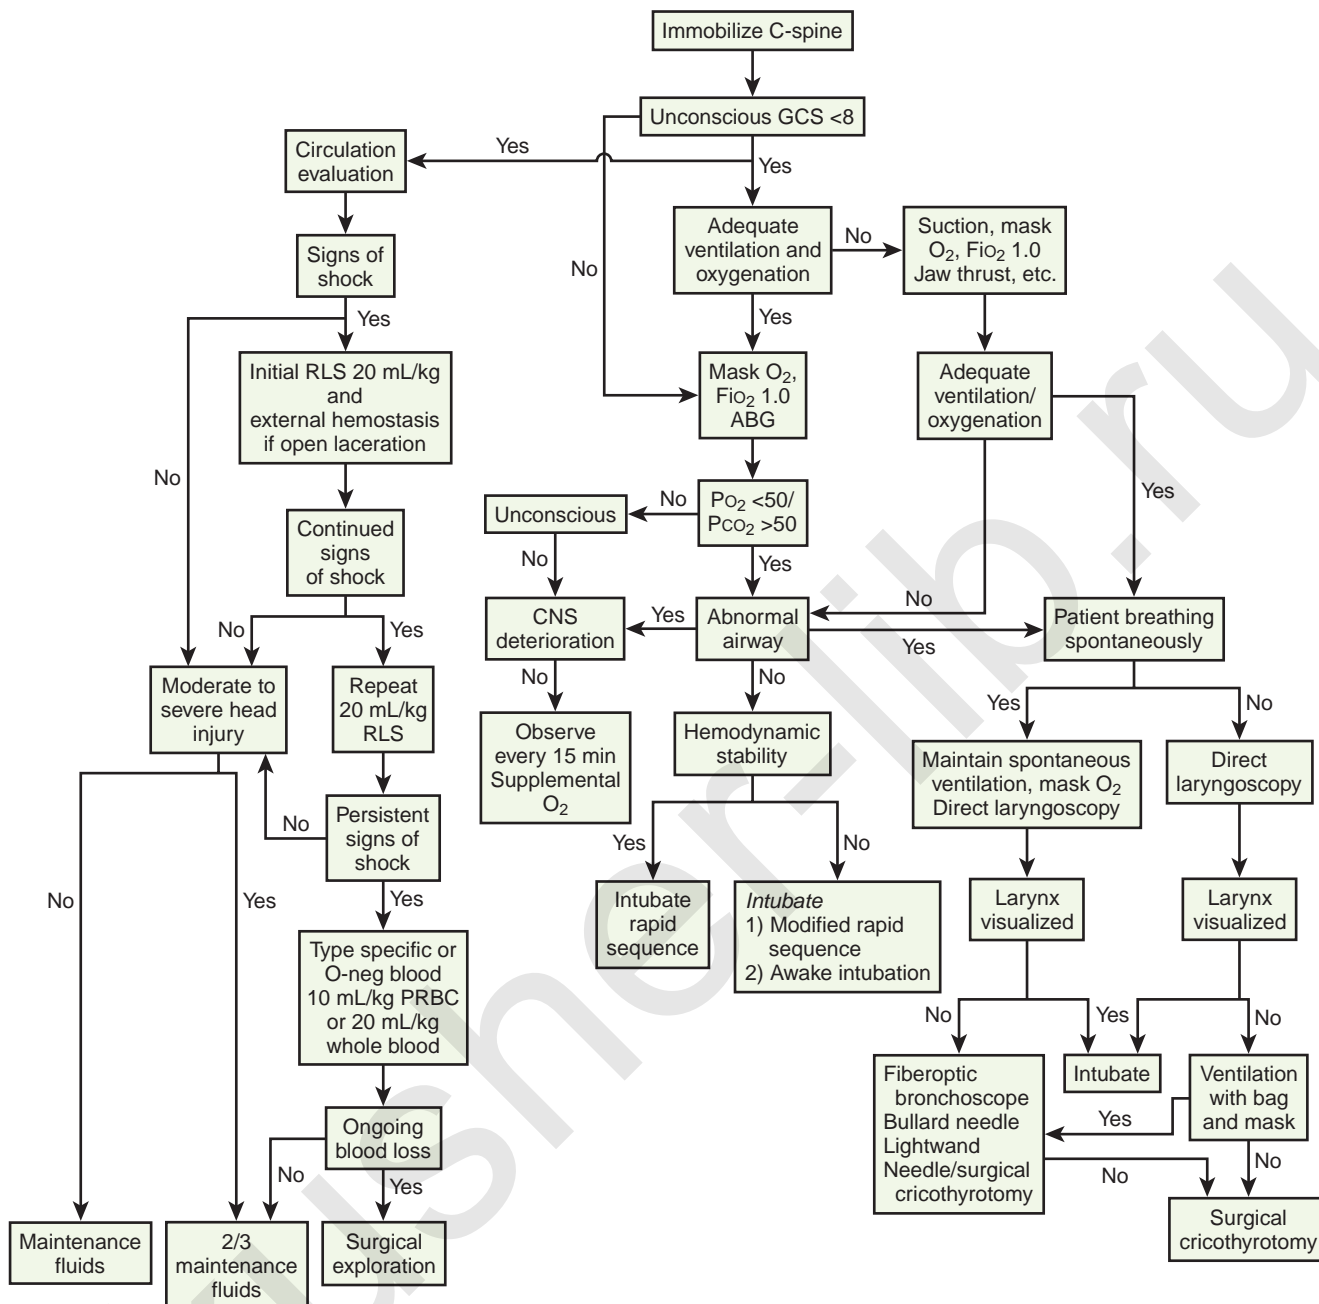

Airway

The first step in trauma resuscitation is to assess the airway and then secure it when necessary to assure respirations. Indications for ETI include inability to oxygenate and ventilate and the need to protect the airway against aspiration.

Box 30-3 ABCs of Resuscitation

- A = Airway with cervical spinal control
- B = Breathing and ventilation, pulse oximetry and oxygen
- C = Circulation with hemorrhage control
- D = Disability and neurologic control
- E = Exposure/environmental control

Data from Tepas JJ 3rd, Mollitt DL, Talbert JL, et al: The pediatric trauma score as a predictor of injury severity in the injured child, *J Pediatr Surg* 22:14–18, 1987; Tobias JD, Ross AK: Intraosseous infusions: a review for the anesthesiologist with a focus on pediatric use, *Anesth Analg* 110:391–401, 2010.

■ FIGURE 30-1. Guidelines for airway and cardiovascular assessment in the traumatized pediatric patient.

Appropriate management of the airway may be challenging or difficult without proper preparation and familiarity with the unique characteristics of the pediatric airway. In a young child or infant, the tongue is relatively large and the larynx and glottic opening are more anterior. A child's airway has a smaller diameter and a shorter length. Airway edema occurring in an already small airway results in significant changes in the internal diameter of the airway and in increased resistance to airflow. The short length of the trachea makes right mainstem intubations more likely and increases the likelihood of extubation from small positional changes of the ET tube. Because the pediatric mid-face is small compared with the tongue, airway obstruction is common. Blood, vomit, teeth, and foreign bodies are common causes of airway obstruction. In addition, children are often placed in cervical collars that may be too large for

them. This can make it hard see a child's face and can present a challenge to identifying an airway obstruction. The first step to making the obstructed airway patent (while keeping the cervical collar on) is a jaw thrust with suction. Oral or nasal airways may be required if a jaw thrust is unsuccessful. If the airway is still not patent after these maneuvers, there should be consideration of a possible airway foreign body.

The initial management of the pediatric airway involves bag-valve-mask ventilation with a jaw-thrust maneuver. Intubation is indicated in patients with respiratory or cardiac compromise or an altered level of consciousness. All pediatric trauma patients should be considered to have a full stomach and possible cervical spine injury. See related video online at www.expertconsult.com. Because of this, the airway should be secured after a rapid-sequence induction (RSI) (that may include cricoid pressure)

with manual inline stabilization and an oral ETI. Nasotracheal intubation may be suboptimal and difficult because of the small size and acute angle of the nasopharynx and the more anterior and cephalad position of the glottic opening.

The RSI for pediatric trauma patients can be accomplished with an induction agent that is immediately followed by a muscle relaxant. Standard induction agents for trauma patients include etomidate (0.2 to 0.3 mg/kg) and ketamine (2 to 4 mg/kg) or the combination of fentanyl (2 to 3 mcg/kg), midazolam (0.05 to 0.1 mg/kg) with lidocaine (1 mg/kg). Sodium thiopental (STP) and propofol should be reserved for patients who are not hemodynamically unstable. STP is an ideal induction agent for patients with head trauma, provided they are not hypovolemic. Ketamine is relatively contraindicated in patients with increased intracranial pressure (ICP). Although etomidate provides hemodynamic stability in trauma patients who are hypovolemic, it may decrease survival in patients with sepsis secondary to adrenal suppression (Annane et al., 2002). Muscle relaxation can be achieved with rocuronium (0.8 to 1.2 mg/kg) or succinylcholine (1 to 1.5 mg/kg). Succinylcholine is contraindicated in crush injuries, long-bone fractures, and patients susceptible to malignant hyperthermia. In patients who are hemodynamically stable, the combination of propofol (4 mg/kg) and remifentanyl (3 mcg/kg) can be used for rapid-sequence intubation and has an onset and offset similar to propofol and succinylcholine (1 mg/kg) (Crawford et al., 2005).

ETIs have been deemphasized in the prehospital setting, because they are often unsuccessful. Gausche and others (2000) reported a success rate of only 57%. All intubated trauma patients that come to the emergency department should have the placement of their endotracheal tubes (ETTs) confirmed with either end-tidal carbon dioxide (CO₂) or direct laryngoscopy.

If initial intubation attempts are unsuccessful after an RSI, the patient should be ventilated with bag-mask ventilation. If a patient cannot be ventilated or if it is very difficult, a laryngeal mask airway (LMA) can be placed to facilitate ventilation and subsequent intubation. However, it must be recognized that the LMA does not protect the airway from aspiration and must be replaced by an ETT as soon as skilled personnel become available. The stomach should be decompressed with a nasogastric or orogastric tube after intubation, and a chest x-ray should be obtained to verify the ETT position (Fig. 30-2).

Depending on the nature of the underlying injury, securing the airway in a patient who has sustained multiple injuries or even isolated facial injuries can be extremely complicated, as illustrated in Figure 30-3. The management of such cases calls upon the resourcefulness and skills of the anesthesiologist and requires careful consideration of damage to surrounding structures such as major blood vessels and the airway structures themselves. The ability to maintain a patent airway via face mask, and the potential for an expanding hematoma that may subsequently compromise an airway that may be patent at the current time, must be anticipated. Additional considerations include the risks of increased ICP with concomitant head trauma, exacerbating an existing cervical spine injury, and aspiration during airway manipulation. The presence of rhinorrhea, otorrhea, or ecchymoses around the eyes should raise suspicion about a possible basilar skull fracture, and any instrumentation of the nasal passages, including passage of a nasal ETT or an N/G tube, should be avoided. Similarly, crepitus at the neck may herald the presence of a tracheal disruption, and intubation under direct vision using a fiberoptic scope should be considered to avoid false passage of the ETT. See related video online at www.expertconsult.com.

■ **FIGURE 30-2.** Gastric dilation often occurs after crying or positive-pressure ventilation by gas and mask.

■ **FIGURE 30-3.** An 11-year-old girl fell 10 to 15 feet while sliding down the school banisters onto a plant supported by a thick wooden pole. She eventually was intubated orally with direct laryngoscopy. (From Melillo EP, et al: *Difficult airway management of a child impaled through the neck*, *Paediatr Anaesth* 11:615, 2001.)

In cases in which airway difficulty is anticipated, it may be prudent to transport the child to the operating room with an anesthesiologist and otolaryngologist once the child has been stabilized hemodynamically and additional injuries have been ruled out. The airway may then be secured with preparations to perform an emergent tracheostomy in case of failed laryngoscopy. An inhalational induction may be tolerated by the patient who has been volume resuscitated. This permits direct laryngoscopy or flexible fiberoptic intubation while the patient is breathing spontaneously. In patients who have suffered loss of consciousness or head injury, there should be a high index of suspicion for cervical

■ **FIGURE 30-4.** Manual axial inline stabilization during direct laryngoscopy.

spine injury, even with the absence of radiologic evidence. When performing laryngoscopy, inline axial stabilization must be performed (Fig. 30-4). Inline axial stabilization is performed by an assistant during laryngoscopy. The assistant should place both arms on either side of the patient's head while gripping the patient's shoulders. The assistant's function is to maintain the patient in a neutral position during laryngoscopy, avoiding flexion, extension, or rotation of the cervical spine. The use of muscle relaxants is best avoided until the airway is secured. If intravenous agents are required to induce anesthesia, it is preferable to use short-acting agents such as propofol and remifentanyl that effectively blunt ICP responses to direct laryngoscopy yet permit return of spontaneous respiration in case of failed intubation.

Breathing

Assuring adequate ventilation is the next task after securing the airway. Breathing is best assessed by auscultation and observation of chest motion. During the primary assessment the patient should be assessed for the presence or absence of breathing, respiratory rate, and work of breathing. The chest should also be observed for symmetry of chest motion and breath sounds. The chest wall should also be observed for evidence of direct chest trauma resulting in abrasions, penetration, or chest-wall instability. The back needs to be assessed as well for posterior chest wall trauma. Although there are no concrete recommendations to guide intubation, pediatric patients with increased work of breathing or life-threatening injuries (head injuries) may require ETI. Immediately after ETT placement, the position should be confirmed with end-tidal CO_2 . Patients in cardiac arrest or very small patients may require direct laryngoscopy. A portable chest x-ray and arterial blood gas should be obtained before leaving the trauma bay to determine the position of the ETT and its adequate delivery of oxygenation and ventilation. Continuous end-tidal CO_2 monitoring and pulse oximetry are useful adjuncts. Many injuries that impair respiration include simple, tension, and open pneumothorax; massive hemothorax; flail chest; and pulmonary contusion. A sudden change in the respiratory status after successful intubation should prompt an

immediate evaluation for a reversible cause. An enlarged pneumothorax or development of a tension pneumothorax can occur after converting from spontaneous ventilation to positive pressure ventilation. Other causes for a decline in respiratory status include a displaced ETT (e.g., extubation or right mainstem intubation), obstruction in the ETT (e.g., blood or secretions), and equipment failure.

Circulation and Access

Children who sustain multiple injuries often arrive in hypovolemic or hemorrhagic shock that must be promptly recognized and treated. Unlike adults, children maintain an almost normal blood pressure until 25% to 35% of their circulating blood volume is lost (Fig. 30-5). This is likely because of their high sympathetic tone that causes peripheral vasoconstriction in an effort to maintain blood pressure in the face of a diminished blood volume. Therefore, tachycardia is an earlier sign of impending shock than hypotension. Additionally, signs of poor peripheral perfusion such as delayed capillary refill (more than 2 seconds), weak or thready pulses, mottling or cyanosis of the skin, and impaired consciousness are earlier indicators of shock than low blood pressure. The presence of hypotension as a result of hypovolemia should be considered an ominous sign that usually heralds impending cardiovascular collapse. Table 30-5 describes the stages of pediatric shock and clinical signs seen at these stages.

It is imperative to rapidly assess the pediatric trauma patient for signs of shock upon arrival in the trauma center and at regular intervals thereafter. The initial fluid bolus administered in the trauma setting is warmed isotonic crystalloid (lactated Ringer's solution or normal saline) in a bolus of 20 mL/kg, IV (see Fig. 30-1). The pulse, capillary refill, and blood pressure are

■ **FIGURE 30-5.** Increase in systemic vascular resistance in response to hypovolemia preserves blood pressure until 25% of blood volume is lost. Hypotension is a late sign of hypovolemia. (From Rasmussen GE, Grandes CM: *Blood, fluids, and electrolytes in the pediatric trauma patient*, *Int Anesthesiol Clin* 32:79, 1994.)

TABLE 30-5. Stages of Pediatric Blood Volume Loss (Shock) and Associated Clinical Signs

Blood Volume Loss	Clinical Signs
<20%	CV: Tachycardia; weak, thready pulses Skin: Cool to touch, capillary refill 2-3 sec Renal: Slight decrease in urine output, increase in specific gravity CNS: Irritable, may be combative
25%	CV: Tachycardia; weak, thready distal pulses Skin: Cold extremities, cyanosis, and mottling Renal: Decrease in urine output CNS: Confusion, lethargy
40%	CV: Frank hypotension; tachycardia may progress to bradycardia Skin: Pale, cold Renal: No urine output CNS: Comatose

From Rasmussen GE, Grandes CM: Blood, fluids, and electrolytes in the pediatric trauma patient, *Int Anesthesiol Clin* 32:79-101, 1994.
CV, Cardiovascular; CNS, central nervous system.

reassessed. A second bolus of 20 mL/kg is administered if there is no significant response or only a transient improvement in these parameters. A third crystalloid bolus may be given if necessary to maintain appropriate vital signs and circulation. Blood (10 mL/kg) should be administered next if additional fluid resuscitation is required. The need for blood transfusion initially is uncommon and usually signals surgical bleeding that may require an operation.

If shock persists and fails to respond to fluid therapy, other causes should be sought. Such causes may include long bone or pelvic fractures. Pericardial effusion and tamponade are less common occurrences in blunt trauma compared with penetrating injuries. The classic clinical signs of cardiac tamponade are shock, muffled heart sounds, pulses paradoxus, electrical alternans, and distended neck veins. Treatment requires immediate pericardiocentesis.

Pneumothorax is a common complication of blunt chest injury in children, with nearly one fourth of pneumothoraces under tension (Nakayama et al., 1992). Unilateral or bilateral tension pneumothoraces may produce hypotension and hypoxemia. The classic signs of tension pneumothorax are ipsilateral tympany, shift of the trachea to the contralateral side, and distended neck veins.

Significant occult blood loss may be overlooked on the initial examination of the small child and infant. Because the absolute blood volume of a child is small, the significance of external blood loss may be underestimated. In addition, blood accumulation in the infant's large, expandable head and open fontanels can produce shock. Careful assessment of the abdomen is also central in the evaluation of the injured patient in shock.

Adequate large-bore IV access must be established as early as possible in the course of the resuscitation. Although peripheral routes offer the most rapidly accessible sites, such access may be difficult or impossible to obtain in the child with depleted intravascular volume or shock and resultant peripheral vasoconstriction. In such cases, a central venous catheter may be placed in the femoral or neck vessels if personnel with the necessary skills are available. Delays in establishing vascular access may be lifethreatening; therefore, if the above routes fail,

intraosseous (IO) access should be rapidly initiated to expedite the administration of volume expanders and necessary pharmacologic agents. Once the child has been resuscitated, additional vascular access should be obtained.

IO access is placed in the medial surface of the proximal tibia 1 to 3 cm below the tibial tuberosity or the distal femoral metaphysis. IO has been used as a lifesaving measure to establish short-term vascular access in critically ill or injured children (Fig. 30-6).

The use of IO infusions in the algorithm of trauma and cardiopulmonary resuscitation has evolved over the years and now takes a more prominent role for providing vascular access to children. The subject of IO has been reviewed by Tobias and Ross (2010).

Access needles for IOs include manual devices such as butterfly needles, spinal needles, bone marrow biopsy needle such as Susfast (Cook Critical Care; Bloomington, Indiana) and the basic Jamshidi needle (Baxter Healthcare Corporation; Deerfield, Illinois). More recently, automated devices have been marketed (Fig. 30-7). The EZ-IO (Vidacare; San Antonio, Texas) functions like a battery-powered drill, with a beveled drill and a preset depth. It is designed to be used in the tibia. The Bone Injection Gun (BIG; Waismed; Kansas City, Missouri) is a spring-locked device also designed to be used in the tibia. It comes in a range of sizes for use in infants, small children, and adults. A device specifically designed for entry into the bone marrow of the sternum is the FAST1 (First Access for Shock and Trauma, PYN6 Medical Corporation; Vancouver, British Columbia). It is approved for patients ages 12 and older. Table 30-6 summarizes these devices. Details regarding instructions on the use of these devices can be viewed on the manufacturers' websites.

A review of the use of IO access in pediatric trauma patients up to 10 years of age reported successful placement of access in 28 out of 32 attempts in the prehospital setting and in the trauma care center (Guy et al., 1993). In this study, IO access was placed successfully by paramedics, nurses, and physicians with only one incident of minor extravasation of fluid and no long-term complications in the survivors. The commonest complication of IO access is subperiosteal infiltration that in most cases resolves spontaneously without further problems. The most feared complication—osteomyelitis—occurs in 0.6% cases (Rosetti et al., 1985). Other rare complications include fractures and emboli. Although few complications have been

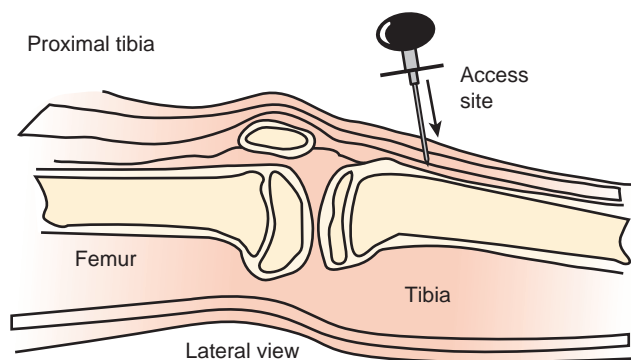

FIGURE 30-6. Appropriate placement of the IO infusion needle on the medial surface, distal to tibial tuberosity. (From Ellemunter H: *Intraosseous lines in preterm and full-term neonates*, Arch Dis Child Fetal Neonatal Ed 80:74F, 1999.)

■ **FIGURE 30-7.** Automated devices. **A**, EZ-IO. **B**, Bone Injection Gun. (**A**, Courtesy Vidacare, San Antonio, TX; **B**, Courtesy Waismed, Kansas City, Mo.)

TABLE 30-6. Comparison of Intraosseous Devices

Device	Summary of Features	Recommended Ages for Use	Sizes Available
Butterfly needles	Simple needle design	All ages	Variety of lengths and gauges
Spinal needles	Straight needle with stylet	All ages	Variety of lengths and gauges
Bone marrow biopsy needles	Hand-held hollow needle with stylet and handle	All ages	16- and 18-gauge needles; varying lengths
EZ-IO	Lithium-powered drill leaving metal catheter in place	All ages down to 3 kg	15-gauge needles; length 25 mm (>40 kg) and 15 mm (<40 kg)
Bone injection gun (BIG)	Spring-loaded device using “position and press” action	All ages	15-gauge needles (≤12 years), 18-gauge needles (>12 years); varying lengths
FAST1	Sternal needle device that inserts plastic catheter	No pediatric device at present	

From Tobias JD; Ross AK: Intraosseous infusions: a review for the anesthesiologist with a focus on pediatric use, *Anesth Analg* 110:391–401, 2010.

reported with this technique, it must be recognized that the high mortality in patients who require IO access prevents the assessment of long-term complications.

Disability (Neurologic Assessment)

A brief rapid neurologic evaluation is performed as part of the primary survey. It should include assessment of the patient’s level of consciousness and pupillary function. The AVPU method or the more detailed GCS should be performed. If AVPU is selected, the GCS calculation is performed during the secondary survey with a detailed neurologic examination. Periodic reassessment of the level of consciousness is necessary to detect neurologic deterioration caused by progression of traumatic brain injury (TBI), hypoxemia, or hypovolemia. Changes in mental status require prompt reevaluation of the ABCs. If they are adequately managed, then deterioration in mental status should be considered to be a result of TBI, prompting further brain imaging and consultation with a neurosurgeon.

Exposure

Exposure involves removing the trauma patient’s garments, usually with shears, to allow detailed physical examination and detect injuries. Rolling the patient, while maintaining

cervical spine precautions, is necessary to identify injuries to the dorsal surface of the body that would otherwise be occult. Padding should be placed on the backboard at this time to prevent decubitus ulcer formation. This assessment should be rapid, and the patient should be covered in warmed blankets or with a warming device to prevent hypothermia. In addition, IV fluids should be warmed, and the room temperature should be raised. This is especially important in small children, who are more prone to hypothermia because of their larger surface area-to-volume ratio.

Secondary Survey

Diagnostic Evaluation

The diagnostic evaluation of the injured child involves clinical examination supplemented by radiologic examinations and laboratory testing. Imaging plays a major role in the evaluation of the injured child (Vane, 2002). Improvements in imaging techniques have allowed progress in the nonoperative management of abdominal and thoracic trauma, supplanting exploratory laparotomy and diagnostic peritoneal lavage in many hemodynamically stable patients.

Initial plain-film screening examinations in children with mechanisms that may cause significant injuries are generally limited to a chest x-ray, pelvis x-ray, and lateral cervical

spine films obtained in the emergency department trauma bay. Further plain films are directed by physical findings (e.g., extremity deformity or spine tenderness). Spine films are obtained when spine tenderness, deformity, neurologic deficits, or inadequate examination with significant mechanisms prevent clinical spine clearance.

Computed tomography (CT) is widely used in the evaluation of pediatric trauma. CT scans of the head are routinely obtained in children with a history of loss of consciousness, altered mental status, and focal neurologic deficits. CT scans of the neck are obtained to supplement cervical plain-film studies or when a cervical-spine injury may exist on clinical grounds. Whenever cervical-spine injuries may exist based on clinical grounds or the mechanism of injury, cervical-spine precautions should be maintained. Cervical-spine clearance in the patient with brain injury may not be possible until the patient's mental status has improved.

The most common cause of a distended abdomen in a child is swallowed air (see Fig. 30-2). Distention can be massive and can appear as if the child has an acute abdomen condition. Placement of a nasogastric tube is imperative. Often that alone improves both abdominal and respiratory status. Abdominal distention or tenderness despite nasogastric-tube decompression suggests a possible solid-organ or hollow-viscus injury. Hemodynamic instability with abdominal tenderness or distention mandates immediate surgical consultation and operation. Ultrasound is increasingly being used in the emergent assessment of injured patients. Focused Assessment by Sonography in Trauma (FAST) is used to detect intraabdominal blood; however, the clinical significance in children of this finding and the management are unclear. FAST has largely replaced the diagnostic peritoneal lavage that has no role in the diagnosis of pediatric abdominal injury. CT scanning of the abdomen is still the most effective method to diagnosis solid-organ injuries and intraabdominal blood. FAST may not add much to the care, because most stable patients with or without blood loss are managed conservatively (Thourani et al., 1998; Miller et al., 2003; Soundappan et al., 2005). Unstable patients may require surgical intervention.

Pelvic fractures are assessed clinically by pressing on both anterior superior iliac spines at the same time to see if the wings spread apart and with the pelvic radiograph. Pelvic fractures can be a significant source of bleeding, although most bleeding can be controlled with fixation and interventional radiology. The presence of a pelvic fracture with blood at the tip of the meatus or a high-riding mobile prostate is a contraindication to placing a Foley catheter. An urethrogram should be performed before placement of a catheter. In rare situations a suprapubic catheter is needed. The pediatric bladder is more susceptible to injury, because it rides higher and there is a shallow pelvis. A pelvic fracture increases the risk of a bladder injury.

Because most injured children are generally healthy and take few or no medications, laboratory screening examinations are limited and focused. Children with minor injuries (e.g., upper extremity fractures) may require limited or no laboratory testing. In more significantly injured patients, laboratory testing may generally be safely limited to specific clinical indications rather than a generalized routine trauma panel (Chu et al., 1996). A complete blood count, blood gas, blood type and screen, and urinalysis are suggested for initial testing in significantly injured patients. Routine testing of

liver functions, pancreatic enzymes and coagulation parameters is of limited value and should only be obtained when clinically indicated.

ANESTHETIC PERIOPERATIVE MANAGEMENT

Children with multiple injuries often arrive with an unusual combination of anesthetic problems that present a challenge to the anesthesiologist. It must be emphasized that the likelihood of a successful outcome is greatly enhanced by the initial stabilization efforts that must include early initiation of critical-care management in the emergency department based on appropriate and rapid physical examination and diagnostic studies rather than an urgent rush to the operating room for emergency surgical interventions (Meyer, 1999). Respiratory stabilization and suitable hemodynamic support, including volume resuscitation can prevent further decompensation as well as the development of secondary injuries. This in turn requires a well-coordinated effort by all members of the health care team including the anesthesiologist, the emergency department physician, surgeons of the relevant specialties, respiratory therapists, and critical-care nurses. Only in rare instances is there little time for initial stabilization and a child must undergo emergency surgery to ensure a favorable outcome. In such cases there must be clear communication between the anesthesiologist and surgeon regarding the time available for resuscitation, securing vascular access, and placement of invasive monitoring catheters, keeping in mind the need for immediate surgical intervention.

Ideally, the role of anesthesiologists in the care of the child who has sustained significant trauma should begin with securing the airway in the emergency department when necessary. However, failing this, it is imperative that they become familiar with the immediate resuscitative efforts, the extent and nature of the injuries, and details regarding the use of analgesics, sedatives, and neuromuscular blocking agents so that the intensive care may be continued throughout the perioperative period. This section addresses the anesthetic management of the child who comes for emergency surgery after multiple traumatic injuries.

Fasting Duration

It is common practice to consider all trauma patients at risk for aspiration regardless of the time of last oral intake. The rationale for this approach is that major injury, the presence of pain and anxiety, and the administration of opioid analgesics delay gastric emptying. Additionally, bag-and-mask ventilation at the scene of the accident or in the emergency department that leads to gastric distention and the use of oral contrast solutions for diagnostic imaging studies may further increase the risk for aspiration. Indeed, previous investigators have demonstrated that patients who come for emergency surgery are at five times the risk for aspiration compared with those who undergo elective surgery (Olsson et al., 1986). Other investigators reported a 17% incidence of vomiting and 3% incidence of aspiration in 60 children younger than 19 years of age who required emergency ETI after they sustained a severe traumatic injury (Nakayama et al., 1992). Interestingly, residual gastric volume has been previously found to have a greater correlation with the interval from oral intake to injury than with actual fasting interval (Bricker et al., 1989).

These data raise two questions regarding the management of anesthetic induction for the trauma patient: whether it is possible to predict the safe interval between oral intake, injury, and induction of anesthesia, whether imposing a fasting duration once the trauma has already occurred offers any benefit in terms of reduction in aspiration risk. Goodwin and Robinson (2000) surveyed 167 practicing anesthesiologists in the United Kingdom regarding their practice in three different scenarios after a forearm fracture in a child. Approximately one third of the respondents did not believe there was any benefit in delaying the procedure and would perform a RSI and ETI regardless of the fasting duration, whereas almost two thirds of the respondents would delay the procedure if it was not emergent and then use a LMA or face mask as they would for elective cases. Such variability in clinical practice related to the management of the trauma patient is likely because of the difficulty in predicting a safe interval between oral intake, injury, and induction of anesthesia with regard to aspiration risk. A conservative and practical approach would be to proceed with surgery when an operating room becomes available and do a RSI and intubation if airway difficulty is not anticipated.

Induction of Anesthesia

Anesthetic induction techniques should be individualized according to the nature of the injuries, whether the airway has been secured before arrival in the operating suite, anticipated airway difficulty, hemodynamic status of the patient, and the presence of ongoing hemorrhage. The child with head trauma merits special consideration because of the risk of increased ICP during induction of anesthesia. Selection of an induction technique in these patients must be made with the goal of avoiding secondary brain injury. IV-induction agents such as thiopental, propofol, or etomidate may be preferred because of their beneficial effects on ICP and cerebral oxygen consumption ($CMRO_2$). On the other hand, a child with an anticipated difficult airway may be better managed with an inhaled route of induction so that spontaneous respiration is assured. Induction of anesthesia in a patient with dehydration or hypovolemia may lead to cardiovascular collapse. It is therefore imperative to have adequate IV access and rehydrate these patients before induction of anesthesia. A brief description of commonly used induction agents and pitfalls with the use of each in a child with trauma follows. Additional details about anesthetic agents are described in Chapters 7 and 22, Pharmacology of Pediatric Anesthesia and Anesthesia for Neurosurgery.

Thiopental

The barbiturates have a long history of use as neuroprotectants. Thiopental has been extensively used as an induction agent in patients with head-injuries, because it is a cerebral vasoconstrictor and decreases cerebral blood flow (CBF), $CMRO_2$, and ICP in a dose-dependent manner. Another beneficial CNS effect is reduction in epileptiform activity. Furthermore, thiopental reliably attenuates the increase in ICP caused by noxious interventions, such as direct laryngoscopy and ETT placement. However, thiopental should be used with caution in a child with multiple traumatic injuries, because it is a direct myocardial depressant and may produce a decrease in cardiac output and systemic blood pressure, with a resultant decrease

in cerebral perfusion pressure (CPP). These effects are more pronounced in patients who have been inadequately volume resuscitated, and the use of alternative induction agents such as etomidate should be strongly considered in patients with a questionable volume status or with uncontrolled, ongoing hemorrhage.

Propofol

Induction of anesthesia with propofol in healthy children is commonly associated with a significant (10% to 20%) decrease in mean arterial pressure (MAP) because of its direct relaxant effects on vascular smooth muscle that cause a reduction in systemic vascular resistance and preload (Aun et al., 1993). It should, therefore, be used with caution, if at all, in patients with depleted intravascular volume. Its beneficial effects of cerebral vasoconstriction, reduced CBF, and $CMRO_2$ in patients with head trauma are offset to an extent by a reduction in CPP because of a decrease in systemic blood pressure. It has been further hypothesized that the decrease in CPP may lead to reflex cerebral vasodilation to maintain CBF, thereby also negating its beneficial effects in reducing ICP (Spitzfaden et al., 1999).

The literature evaluating the use of propofol in adult neurosurgery patients has yielded conflicting results. Previous studies have demonstrated that whereas propofol effectively lowered ICP in patients with elevated ICP after TBI and during cerebral aneurysm surgery, there was a significant reduction in overall CPP because of a greater decrease in MAP than ICP (Herregods et al., 1988; Ravussin et al., 1988; Pinaud et al., 1990). Other investigators reported no reduction in ICP with propofol sedation in adults with head trauma (Stewart et al., 1994).

Etomidate

Etomidate provides both hemodynamic stability as well as cerebral protection, making it the ideal anesthetic induction agent for emergency surgery in a child with multiple traumatic injuries. Although it does cause a direct myocardial depressant effect, it does so to a significantly lesser extent than equipotent doses of other induction agents, including thiopental, propofol, and ketamine (Stowe et al., 1992). Etomidate, however, maintains sympathetic outflow and produces no significant changes in blood pressure, making it the agent of choice in the hemodynamically unstable patient. Similar to thiopental and propofol, it is a cerebral vasoconstrictor and causes a reduction in ICP, CBF, and $CMRO_2$. However, because MAP is maintained with etomidate, CPP is also maintained. Perhaps the only concern with its use has been adrenal suppression; however, this is believed to have questionable clinical significance with brief use (Crozier et al., 1987). A recent retrospective review reported successful fracture reduction in 52 of 53 patients who received etomidate alone or in combination with midazolam or opioids (Dickinson et al., 2001). This study found a low incidence of minor side effects, including nausea and vomiting, mild hypotension, and prolonged sedation in one patient each.

Ketamine

Ketamine is a dissociative anesthetic that is commonly selected for induction in children who are hypovolemic, because its sympathomimetic actions result in increases in blood pressure and

heart rate. However, like the other induction agents described above, ketamine has direct myocardial depressant effects as well as direct vasodilatory effects. In fact, significant hypotension has been reported after ketamine administration in critically ill patients, likely as a result of its direct myocardial depressant effects predominating in the presence of depleted catecholamine stores (Waxman et al., 1980).

Ketamine, however, is a potent cerebral vasodilator and causes a marked increase in CBF. Although $CMRO_2$ usually remains unchanged after ketamine administration, ICP may increase, especially in patients with intracranial pathologic conditions. However, data regarding the effects of ketamine on ICP remain inconclusive, with some studies demonstrating modest decreases in ICP after ketamine administration, particularly when they are administered concomitantly with other sedatives (Mayberg et al., 1995; Albanese et al., 1997). A recent controlled, randomized, double-blind trial found no differences in mean daily values of ICP, CPP, and the number of episodes of ICP elevations in patients with severe TBI who were sedated with ketamine and midazolam compared with those who were sedated with sufentanil and midazolam (Bourgoin et al., 2003). Yet, its cerebral vasodilatory effects preclude the use of ketamine as an induction agent in patients with head trauma.

Maintenance of Anesthesia

Selection of agents for maintenance of anesthesia should be based on the nature and duration of the proposed procedure; the extent of injuries; the child's ventilatory, hemodynamic, and neurologic status; and whether postoperative mechanical ventilation is anticipated. In hemodynamically stable patients, a standard general anesthetic may be used, including volatile agents, opioids for postoperative pain relief, and muscle relaxants as needed to provide good operating conditions. On the other hand, a technique using an opioid, a hypnotic, muscle relaxant, and oxygen may be more suitable in a child with unacceptably low blood pressure and who may not tolerate the negative inotropic effects of potent volatile anesthetics. In such cases, fentanyl or sufentanil are the preferred opioids, because they do not significantly alter hemodynamic parameters especially blood pressure. In children whose injuries are not completely determined, nitrous oxide is best avoided because it may diffuse into closed air spaces such as the pleural cavity.

In a child with severe head trauma, efforts must be directed at preventing secondary brain injury and protecting the injured brain from further ischemic injury by selecting anesthetic techniques that maintain blood pressure while reducing ICP. All volatile anesthetics cause cerebral vasodilation, which has been correlated with increasing minimum alveolar concentration (MAC) in children (Vavilala and Lam, 2002). Isoflurane affects CBF and cerebral autoregulation to a lesser extent than halothane. Sevoflurane offers greater advantages in that CBF velocities do not increase significantly with less than 1 MAC, and cerebral pressure autoregulation is maintained up to 1.5 MAC sevoflurane (Gupta et al., 1997; Monkhoff et al., 2001). For these reasons, sevoflurane may be the preferred volatile anesthetic for the child with TBI, and it would be prudent to limit its use to 1 MAC.

Opioids (fentanyl, sufentanil, or remifentanyl) are often administered as intermittent bolus doses or infusions to supplement volatile anesthetics, for postoperative analgesia, and

as additional measures to lower ICP. However, increased ICP has been reported in an 11-year-old child with closed head injury after bolus doses of fentanyl that responded to hyperventilation and barbiturates (Tobias, 1994). In addition, recent studies in adults have reported a transient but significant increase in ICP accompanied by a decrease in MAP and CPP after bolus doses of morphine, fentanyl, sufentanil, and alfentanil (Albanese et al., 1999; de Nadal et al., 2000). The exact mechanism of these changes remains unknown; however, impaired cerebrovascular autoregulation and direct cerebral vasodilatory effects of opioids have been implicated. Such effects may have significant implications in the management of the child with traumatic head injuries; however, until additional data become available, the judicious use of opioid infusions with careful monitoring of hemodynamic parameters is recommended.

Monitoring

In addition to routine monitors, placement of invasive monitors, including arterial and central venous catheters and a urinary catheter must be placed in the child with extensive injuries and in children with head trauma. Placement of monitoring catheters should be efficient, and in some cases when the surgery must be performed expeditiously, invasive catheters may need to be placed when the procedure is already underway. An arterial catheter is invaluable for continuous blood-pressure monitoring and frequent monitoring of arterial blood gases, acid base status, electrolytes, and serial hematocrits. Central venous pressure monitoring is useful when large fluid shifts are expected and in cases of rapid ongoing blood loss. Urine output is an important measure of fluid status. Additional monitors, such as ICP monitors in cases of head trauma and somatosensory evoked-potential monitors as a measure of spinal-cord function in a child with spinal injury, must be individualized. In some cases of chest trauma, transesophageal echocardiography may be useful in diagnosing injury and guiding surgical repair.

Temperature Maintenance

Temperature maintenance is an important part of trauma resuscitation but one that is often overlooked because of other priorities, such as resuscitation. In the traumatized child, several factors contribute to ongoing heat loss, including exposure to a cold environment at the scene of the accident, large open wounds, rapid infusion of fluids and blood, and exposure of body cavities during operative procedures. Hypothermia has significant deleterious effects that may hinder resuscitative efforts. Such effects include myocardial dysfunction, cardiac irritability, and dysrhythmias. Other effects of hypothermia include acid-base disturbances, a leftward shift of the oxyhemoglobin dissociation curve, and coagulopathies that can exacerbate ongoing hemorrhage. Continuous temperature monitoring in all pediatric trauma patients is therefore essential. Every effort should be made to maintain temperature, including the use of warm IV fluids, keeping the child covered once initial evaluation is completed, maintaining a warm environment, use of radiant warmers for infants, and forced-air warming devices.

Fluid Resuscitation

Shock is defined as a metabolic demand that exceeds either oxygen supply or oxygen delivery (Rasmussen and Grandes, 1994). When a child who has sustained multiple injuries arrives for surgical intervention, the fluid status must be assessed quickly (before induction of anesthesia) based on a physical examination as well as a history of fluid resuscitation received before arrival in the operating suite. The anesthesiologist must be prepared to continue the resuscitation in case of ongoing blood loss or third spacing of fluid. The goals of fluid resuscitation should be to maintain normovolemia as well as the osmolar and oncotic pressures in the intravascular space. Isotonic crystalloid solutions such as lactated Ringer's solution or normal saline are most commonly used in the initial stages of resuscitation. Hypertonic saline solutions have also been used in this setting, based on the premise that they increase serum osmolality and thereby maintain intravascular volume for longer periods and with smaller volumes administered than isotonic solutions (Rasmussen and Grandes, 1994). However, the data that support these arguments are inconclusive and further work in this area is needed. The decision to administer glucose-containing solutions must be based on serial blood-glucose values (Sharma et al., 2009). This is of greatest importance in the presence of head trauma, because elevated blood-glucose levels have been found to correlate significantly with indicators of the severity of brain injury and poor neurologic outcomes in children with severe brain injuries (Michaud et al., 1991).

Colloid solutions such as 5% albumin and hydroxyethyl starch have also been used for fluid resuscitation. Hydroxyethyl starch may exacerbate existing coagulopathy by interfering with platelet function, decreasing fibrinogen activity, and interfering with factor VIII. It is therefore unsuitable for the pediatric trauma patient. The purported benefits of colloid solutions include their ability to increase colloid oncotic pressure and prolonged maintenance of intravascular volume and smaller volumes required compared with crystalloid solutions (Rasmussen and Grandes, 1994). For these reasons, colloids may also be beneficial in children with head trauma because the smaller volume of fluids administered may reduce the likelihood of cerebral edema. One of the major concerns with the use of colloids has been the cost. In most patients who require massive fluid resuscitation, the cost of using colloids to supplement crystalloids may be justified. The Saline vs. Albumin Fluid Evaluation (SAFE) study, a randomized, controlled trial conducted in 16 intensive care units in Australia and New Zealand, concluded that albumin and saline should be considered clinically equivalent treatments for volume resuscitation in intensive care patients (Finfer et al., 2004). Further discussion of crystalloid and colloid use in pediatrics has been reviewed by Bailey et al. (2010).

Blood Product Transfusion

The primary purposes for transfusion of blood products in a pediatric trauma patient are to maintain oxygen delivery and to ensure hemostasis (see Chapter 36, Systemic Disorders). Packed red blood cells are required when oxygen-carrying capacity is inadequate to meet tissue demands and metabolic rate. Losses of up to 40% of blood volume can usually be replaced with isotonic crystalloid solutions or colloids

without physiologic signs of inadequate oxygen delivery (Solheim and Wesenberg, 2001). When estimated blood volume losses exceed 40%, the decision to transfuse blood should be based on an overall assessment of the patient, including the hemodynamic status, the extent of ongoing blood loss and the underlying comorbidity. Some children may require blood transfusion with blood-volume losses of less than 40% if the blood loss has been rapid or if they have significant underlying medical conditions such as congenital cyanotic heart disease or blood dyscrasias. Although there can be no fixed numeric transfusion trigger in all trauma patients, **Box 30-4** presents formulas that may be used as general guidelines to calculate allowable blood losses (Rasmussen and Grandes, 1994). Blood banks in most centers supply blood components rather than whole blood. The primary advantage of component therapy is more efficient and cost-effective use of resources by eliminating the transfusion of unnecessary components and making components from a single blood donation available to several patients. It also permits improved preservation of individual components (**Table 30-7**).

Packed Red Blood Cells

The reason to transfuse packed red blood cells (PRBCs) is to increase oxygen carrying capacity. PRBCs are supplied in units of approximately 250 mL with hematocrit values ranging from 60% to 80%. The units are preserved either in citrate, phosphate, and dextrose (CPD) with a shelf life of 21 days or in citrate, phosphate, dextrose, and adenine CPD-A with a shelf life of 35 days. The citrate in the preservative chelates calcium, therefore, calcium chloride must be readily available when transfusing PRBCs especially at a rapid rate. The usual starting dose of PRBCs is 10 to 20 mL/kg, depending on rapidity of blood loss.

Fresh Frozen Plasma

Fresh frozen plasma (FFP) must be separated from whole blood within 6 to 8 hours of collection. It generally takes approximately 45 minutes to thaw, because it is stored at -18°C , and it must be used within 24 hours once it has been thawed. FFP provides factors II, V, VIII, IX, X, XI, and antithrombin III. In general, FFP should be transfused when clotting studies become abnormal with a prolonged prothrombin time (PT) or activated partial thromboplastin time (APTT). Nonsurgical bleeding in

Box 30-4 Formulas to Use as a General Guideline to Calculate Allowable Blood Loss

Calculation 1: $ABL = EBV \times (HCT \text{ initial} - HCT \text{ target}) / HCT \text{ initial}^*$
 Calculation 2: $ERCM = EBV \times HCT \text{ starting}$
 $ERCM \text{ target} = EBV \times HCT \text{ target}$
 $ARCL = ERCM - ERCM \text{ target}$
 $ABL = ARCL \times 3$

From Rasmussen GE, Grandes CM: Blood, fluids, and electrolytes in the pediatric trauma patient, *Int Anesthesiol Clin* 32:79, 1994.

* The ABL, in milliliters, must be multiplied by 3 if replacement is by crystalloid and replaced, 1:1 if blood is to be used.

ABL, Allowable blood loss; EBV, estimated blood volume; HCT, hematocrit; ERCM, estimated red cell mass; ARCL, allowable red cell loss.

TABLE 30-7. Differences in the Compositions of Major Blood Products

	Normal Whole Blood (in vivo)	Citrated Whole Blood (2 Weeks Old) CPD	Citrated Packed Red Blood Cells*	Frozen Packed Red Blood Cells	FFP
pH	7.4	6.6-6.9	6.6-6.9	6.6-7.2	6.6-6.9

* Citrated whole blood and citrated packed red blood cells have the same chemical composition, but citrated red blood cells have considerably less plasma volume. CPD, Citrate-phosphate-dextrose; FFP, fresh frozen plasma.

children who receive more than one blood volume of PRBCs often require FFP because of factors V and VIII deficiency. The recommended initial dose of FFP is 10 to 15 mL/kg (see Chapter 36, Systemic Disorders, Table 36-25).

Platelets

Platelets are prepared by centrifugation and recentrifugation of fresh whole blood. Dilutional thrombocytopenia is the most likely cause of nonsurgical or microvascular bleeding after massive blood transfusion, and usually platelets are required before FFP for this condition. To raise the platelet count by approximately 20,000, 0.1 units/kg of platelets are needed. Because platelet counts of 50,000 are adequate to achieve surgical hemostasis, doses in excess of 0.2 units/kg are rarely required (see Chapter 36, Systemic Disorders, Table 36-25).

Cryoprecipitate

Cryoprecipitate that is produced by refreezing the insoluble portion of plasma is rich in factor VIII and fibrinogen. The residual component from 1 unit of FFP yields 100 units of cryoprecipitate. The primary indications for cryoprecipitate in the trauma patient are bleeding abnormalities after massive transfusion, disseminated intravascular coagulation (DIC), and decreased fibrinogen levels. The recommended initial dose of cryoprecipitate is 0.1 units/kg (see Chapter 36, Systemic Disorders, Table 36-25).

Massive Blood Replacement

Massive blood replacement is defined as the administration of one blood volume or more within 24 hours. It causes a number of physiologic derangements that can be detrimental in the child with multiple injuries, including coagulation defects, electrolyte and acid-base abnormalities, and hypo-

thermia (see Chapter 36, Systemic Disorders). Dilutional thrombocytopenia and clotting factor deficiencies have been primarily implicated in the etiology of nonsurgical bleeding after massive blood transfusion. However, mathematical models have demonstrated that a third of the patient's own blood remains after a single blood volume exchange, thereby retaining sufficient platelets and clotting factors to permit hemostasis (Marsaglia and Thomas, 1971). Therefore, other factors, such as incompatibility of transfused blood and DIC, have also been implicated in the etiology of nonsurgical bleeding in the trauma patient.

The ratio of fresh frozen plasma to PRBCs may be an important determinant of outcome in trauma patients who receive massive transfusions. Sperry and others (2008) demonstrated in adults that during massive transfusions, an FFP/PRBC ratio of greater than or equal to 1:1.5 decreased the number of transfusions and one-day mortality more than did an FFP/PRBC ratio of less than 1:1.5. This means that those patients who received close-to-equal volumes of FFP and PRBCs had decreased 24-hour mortality rates over those who received significantly more PRBCs than FFP, although patients receiving larger quantities of FFP had a higher incidence of ARDS. The likely explanation for the reduction in mortality is the early correction of coagulopathy and reduction in hemorrhage.

Monitoring the coagulation status is vital in patients who require massive transfusions. Hypothermia, acidosis, and hemodilution with hypofibrinogenemia further exacerbate any coagulopathy. Massive transfusions decrease fibrinogen, decrease platelets, and dilute coagulation factors. Intraoperative evaluation of the bleeding patient can be assessed by classic tests (PT, PTT, and platelet count). However, the coagulation system, including clot formation and clot dissolution, can also be assessed by thromboelastography. Thromboelastography is a global measure of hemostasis and is further described in Chapter 36, Systemic Disorders.

Factor VIIA

Recombinant Factor VIIA (rFVIIA) is currently approved by the FDA for treatment and prevention of bleeding disorders in patients with hemophilia A or B who have developed inhibitors to factor VIII or factor IX, respectively (Novo Nordisk, 2005). However, rFVIIa is increasingly being used as an off-label drug for patients, both children and adults, when conventional therapies have failed to control bleeding after trauma. A retrospective case series published in *Pediatrics* in 2009 concluded that administration of rFVIIa to bleeding surgical trauma patients is associated with a significant decrease in blood-product administration, with low associated mortality and adverse events (Alten et al., 2009).

SPECIFIC INJURIES

Head Injuries

TBI is the leading cause of morbidity and mortality resulting from trauma in children (Langlois et al., 2006). A TBI is caused by a blow or jolt to the head or a penetrating head injury that disrupts the normal function of the brain. Severe TBI often includes an extended period of unconsciousness or amnesia after the injury and is associated with the poorest outcomes (Adelson et al., 2006). Among children ages 0 to 19 years, TBI results in an estimated 7441 deaths, 62,000 hospitalizations, and 564,000 emergency-department visits annually (CDC, 1999). The leading causes of TBI in children are falls (39%) and motor-vehicle crashes (11%) (Fig. 30-8) (National Center for Injury Control and Prevention, 2005).

Most preventable deaths and deficits after pediatric head injury are secondary to subsequent complications, including diffuse brain swelling and resultant elevated ICP, which are independent predictors of mortality (Jurkovich et al., 2004). Poor CPP, often related to elevated ICP and trauma related systemic hypotension, are also known to worsen outcome. See related video online at www.expertconsult.com.

Problems that result from TBI, such as diminished cognition and memory loss, are often not visible (Langlois et al., 2006). TBI can cause a wide range of functional changes that affect thinking, sensation, language, and emotion (CDC, 2003). TBI can also cause epilepsy and increase the risk for conditions that become more prevalent with age, such as Alzheimer's or Parkinson's disease (CDC, 2003). The impact of a TBI not only affects the child but the whole family. The two age groups at highest risk for TBI are children between the ages of 0 and 4 years and those between 15 and 19 years old. Males are 1.5 times more likely to sustain a TBI, and African Americans have the highest death rate from TBI. The outcomes and the treatment of children with a severe TBI remain a great challenge. The CDC estimates that at least 5.3 million Americans, approximately 2% of the U.S. population, currently have a long-term or lifelong requirement for assistance with daily living activities as a result of a TBI (Langlois et al., 2006). Each year, 56,000 children are discharged home with a permanent disability from a TBI, whereas another 5000 require intensive inpatient rehabilitation facilities. The economic burden of head injury to patients is substantial—estimated to be \$56.3 billion, with the highest rate of injuries reported among the lower socioeconomic classes. TBI is the most common reason a child requires intensive care or develops a significant life-long disability.

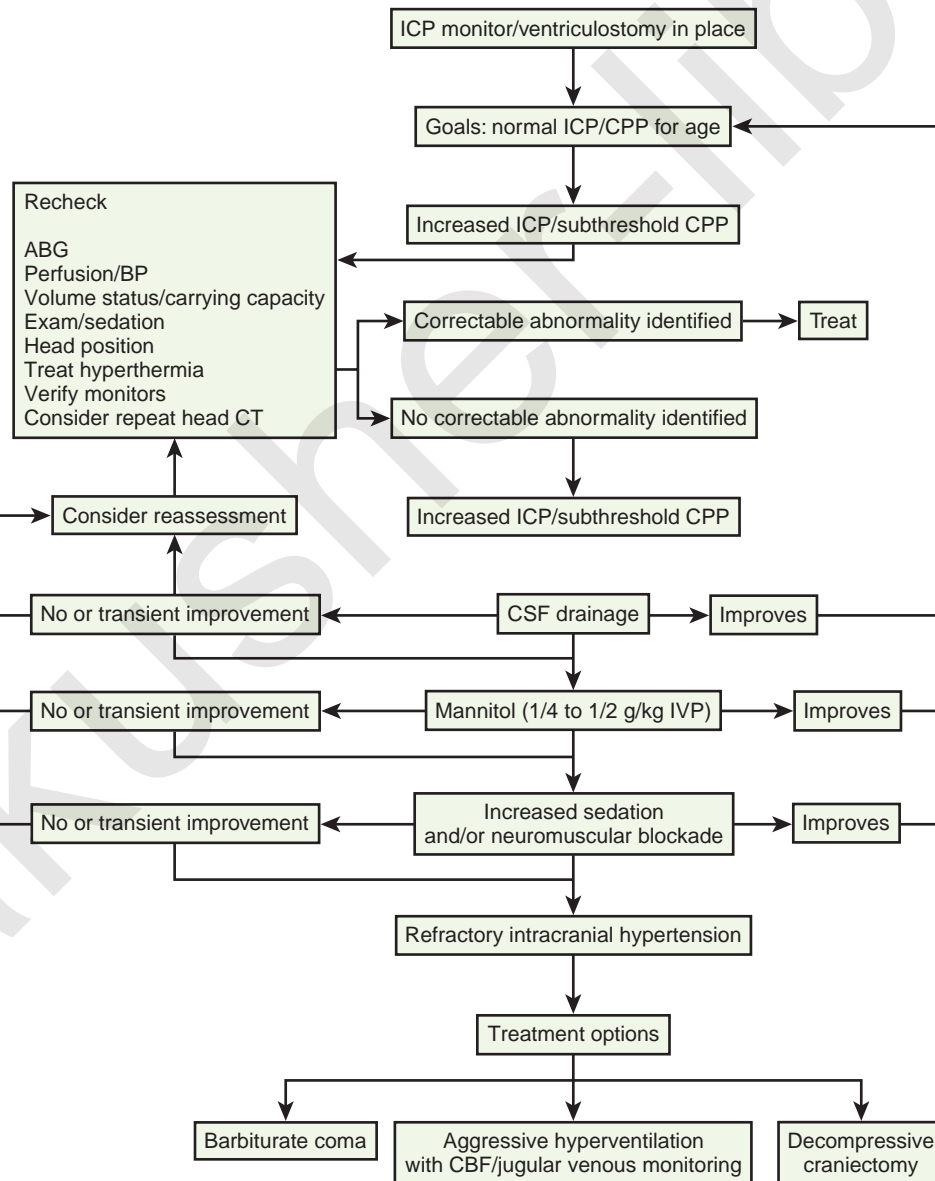

FIGURE 30-8. **A**, CT scan of the head a 15-year-old girl who fell off a motor vehicle while “car surfing.” Note the skull fracture, epidural hematoma, and the midline shift of the brain before surgery. **B**, Same patient during craniotomy after drainage of her epidural hematoma; she was noted to have cerebral contusions in the area of her injury.

There are important differences between a TBI in a child compared with a TBI in an adult (Luerssen, 2006). Because of the smaller body mass of children, the energy received from an injury (e.g., fall) results in a greater force applied per unit body area and to a body with less fat and less connective tissue that might absorb or diminish the energy. The brain of a child is also anatomically different from that of an adult; the subarachnoid space is smaller and offers less protection because there is less buoyancy. Thus, head momentum is more likely to impart parenchymal structural damage. Additionally, the brain is proportionately larger to the rest of the body and therefore a bigger target for injury. Children are particularly susceptible to the effects of secondary brain injury that may be produced by hypovolemia with reduced cerebral perfusion, hypoxia, seizures, or hyperthermia. Alternatively, the young child with open fontanels and mobile cranial suture lines is more tolerant of an expanding intracranial mass lesion. Overall, children with a TBI have better outcomes than adults with a TBI.

Monitoring of ICP and CBF are essential in the head injured patient. ICP can be measured with intraventricular catheters, subarachnoid bolts, and epidural sensors. CBF can be assessed by Doppler, and brain metabolic demands can be evaluated with the use of internal jugular bulb catheters and near-infrared measurements of mixed venous oxygen saturation $S\bar{v}O_2$ (see Chapter 22, Anesthesia for Neurosurgery). In general, efforts are made to insure adequate venous drainage (30-degree, head-up position), adequate oxygenation, avoidance of hypotension, and maintenance of slight hypocarbia (partial pressure of CO_2 [$Paco_2$] of 35 to 38).

At present, there is insufficient evidence-based medicine to provide standards of care in children with head injuries. However, a number of interventions have become mainstay as guidelines for treatment of the pediatric patient with head injuries. Most of these guidelines emanate from data in adults (Krantz, 1996; Gupta et al., 1997). An algorithm for the treatment of intracranial hypertension in children is shown in Figure 30-9.

■ **FIGURE 30-9.** The University of Michigan C. S. Mott Children’s Hospital algorithm for the treatment of intracranial hypertension in children. (Courtesy C. S. Mott Children’s Hospital, Ann Arbor, Mich.)

Primary and secondary brain injuries are the major variables affecting outcomes. Primary injury describes the immediate disruption of neuronal, axonal, and supportive structures and vascular tissue and is essentially untreatable except by prevention (Luerssen, 2006). If the primary injury is not fatal, it triggers a cascade of intracellular and extracellular biochemical changes that can augment and accelerate the injury. This is known as secondary injury. Secondary injury produces new damage to the tissue at the primary injury site as well as in other areas of the brain (Luerssen, 2006). For example, hypermetabolic responses related to neuronal tissue injury occur that may outstrip local or regional substrate supply. Ischemia is the final pathway that produces brain-tissue damage and poor clinical outcomes; it is caused by hypoxia, hypotension, seizures, hyperglycemia, and hyperthermia. Despite a lack of systematic evidence, there has been a trend toward improved outcomes by aggressively treating ischemia. The key features of such therapy are support of MAP, reduction of ICP to ensure CPP, and surgery for compressive lesions (such as epidural hematoma) (Alberico et al., 1987; Downard et al., 2000). **Figure 30-10** depicts changes in MAP, CPP, and ICP with age. In addition to basic interventions of normal-to-slight hypocapnea, adequate perfusion pressure and oxygenation, the use of hyperosmolar therapy and hypothermia to treat increased ICP has been examined. **Table 30-8** lists some of the commonly used interventions (excluding hyperosmolar therapy, discussed in the next section) and the strength of supporting data.

Hyperosmolar Therapy

In areas where the blood brain barrier (BBB) is disrupted, the flow of proteins and electrolytes across the membrane is facilitated. Hydrostatic pressure becomes the dominant driving force for fluid movement from the intravascular space to brain tissue (Klatzo, 1967; Harukuni et al., 2002). This leads to brain swelling with an increase in ICP, a decrease in CPP, cerebral hypoxia, and secondary brain injury.

The beneficial effects of osmotherapy on ICP are thought to result from brain shrinkage after the shift of water out of brain parenchyma. This has been confirmed in animal studies

FIGURE 30-10. Age-related increases in MAP, CPP, and ICP.

TABLE 30-8. Evidence-Based Medicine for Pediatric Trauma

Condition	Standards	Guidelines	Evidence
BP and O ₂	None	Rapid correction of hypotension SBP > than 70 mm Hg + (2 × age in years)	Class II Class III
ICP monitoring	None	None (vs. adult) Options: ICP monitoring appropriate Children with GCS < 9 Children with GCS > 8 (selected)	Class III
CPP	None	Maintain CPP > 40 mm Hg	Class III
Sedation/paralytics	None	None	Class II
CSF fluid drains	None	None	Class III
Hyper-ventilation	None	None Options: avoid prophylactic mild hyperventilation (Pco ₂ < 35 mm Hg); Consider therapeutic mild hyperventilation (Pco ₂ = 30-35 mm Hg) for refractory ICP; Consider aggressive therapeutic hyperventilation (Pco ₂ < 30 mm Hg) for refractory ICP Suggest monitoring for ischemia	Class II

Class I data are based on randomized controlled trials, and class II trials are prospective nonrandomized and retrospective studies based on “clearly reliable data.” These are typically observational, cohort, and case-control trials. Class III data, the weakest source of data, are retrospective studies based on clinical series, registry surveys, and expert opinion.

where osmotherapy after brain injury led to shrinkage of normal, but not injured, brain tissue (Wisner et al., 1990; Shackford et al., 1992).

Mannitol and hypertonic saline (3% normal saline) are the two most commonly administered osmotic agents. Mannitol is used in 70% of pediatric intensive care units (two class III studies); however, it has not been subjected to controlled clinical trials vs. placebo or other osmolar agents in children (Wakai et al., 2007). Mannitol lowers cerebral blood volume and ICP by reducing blood viscosity while maintaining CBF. It osmotically dehydrates the brain parenchyma to decrease intracranial volume and pressure, and therapy can be titrated to a serum osmolality of 320 mOsm/L. Although it has been the predominant osmotherapeutic drug for the past four decades, mannitol has several limitations. Hyperosmolality is a common problem, and a serum osmolality greater than 320 mOsmol/L is associated with adverse renal and CNS effects (Dorman et al., 1990; Roberts et al., 2003). The osmotic diuresis that accompanies mannitol administration may lead to hypotension, especially in hypovolemic patients. Although controversial, accumulation of mannitol in cerebral tissue may lead to a rebound phenomenon and increased ICP. A 2007 Cochrane Database review evaluated mannitol for acute TBI in adults. Only four studies met the eligibility criteria. The review concluded that compared with

pentobarbital, mannitol may have a beneficial effect on mortality in patients with raised ICP, but mannitol may have a detrimental effect on mortality when compared with hypertonic saline (Wakai et al., 2007).

Hypertonic saline (3% normal saline) has a similar mechanism of action as mannitol with the added theoretic benefits of restoration of normal cellular resting membrane potential and cell volume, stimulation of atrial natriuretic peptide release, inhibition of inflammation, and enhancement of cardiac output (Moss and Gould, 1988; McManus and Soriano, 1998; Dickinson et al., 2001). It has also been suggested that it may help patients who are refractory to mannitol infusions. The serum osmolarity may be allowed to rise as high as 360 mOsm/L. Proposed beneficial effects of hypertonic saline in TBI may result because the permeability of the BBB to sodium is low (Betz, 1983). Hypertonic saline produces an osmotic gradient between the intravascular and intracellular/interstitial compartments, leading to shrinkage of brain tissue (where BBB is intact) and therefore a reduction in ICP; the reflection coefficient (selectivity of the BBB to a particular substance) of NaCl is more than that of mannitol, making it potentially a more effective osmotic drug (Fenstermacher and Johnson, 1966). Hypertonic saline also augments volume resuscitation and increases circulating blood volume, MAP, and CPP, and it restores the neuronal membrane potential, maintains the BBB integrity, and modulates of the inflammatory response by reducing adhesion of leukocytes to endothelium (Schmoker et al., 1992; Hartl et al., 2002). The detrimental effects of hypertonic saline include central pontine myelinolysis, coagulopathies, excessive intravascular volume, and electrolyte abnormalities. Electrolyte abnormalities are common. Careful monitoring is required, because hyperkalemia and natriuresis may develop after intravascular administration. Hypertonic saline also tends to reduce the plasma strong-ion difference, and a nonanion-gap metabolic acidosis may result (Bruegger et al., 2005). A number of studies suggest that hypertonic saline may be more effective than mannitol in reducing ICP and have a longer duration of action (Berger et al., 1994; Mirski et al., 2000). Whether this leads to improved outcomes is not known. Clinical studies in children using 3% normal saline are limited (Berger et al., 2004; Viallet et al., 2003).

Cervical Spine Injuries

Cervical spine injuries remain one of the most devastating consequences of trauma. The incidence of cervical spine injury in pediatric trauma patients is low (1% to 2%), but the morbidity and mortality of these injuries are substantial. Kokoska et al. (2001), in a 5-year review from the National Pediatric Trauma Registry, reported a 1.6% incidence (408 out of 24,740, 17% mortality) of blunt cervical spine injuries. Injury patterns were different by age with children less than 10 years of age having a higher incidence of C1-C4 injuries vs. C5-C7 injuries (85% vs. 57%; $p < .01$) (Kokoska et al., 2001). Brown et al. (2001) reviewed the experience of 103 pediatric cervical spine injury patients over 9 years and found an 18% mortality rate. Subluxation of cervical vertebrae and odontoid fractures are more common in children (Fig. 30-11). See related video online at www.expertconsult.com. Distinguishing between a true subluxation and a pseudosubluxation in a young child

can be challenging (Table 30-9). In 40% of children younger than 7 years of age, pseudosubluxation-anterior displacement of C2 on C3 less than 3 mm is a normal variant. Pseudosubluxation becomes more prominent when a child is supine (i.e., on a backboard). Another normal variant is an increased distance between the dens and the anterior arch of C1 found in 20% of children (Bohn et al., 1990). The combination of a child's proportionately large head, elastic interspinous ligaments, and horizontal position of the vertebrae is thought to explain both the pattern of injury and the normal variations (Bohn et al., 1990).

Current issues that relate to pediatric cervical spine issues include identifying who needs to be imaged, how that imaging should be performed, and what combination of imaging and clinical examination constitutes a "cleared" cervical spine.

One method to reduce excess and unnecessary imaging is to use Clinical Decision Rules (CDRs). CDRs are developed to reduce the uncertainty of medical decision-making by standardizing the collection and interpretation of clinical data (Laupacis et al., 1997; Stiell and Wells, 1999; McGinn et al., 2000).

The National Emergency X-Radiography Utilization Low Risk Criteria (NLC) and the Canadian C-spine Rule (CCR) are two clinical decision rules developed to assist with cervical spine imaging after a trauma. Their goals are twofold: to identify patients at risk for a cervical spine injury and to reduce unnecessary imaging. The NLC criteria were developed and then validated in a mixed population of adults and children; however, only 9% of the patients were considered pediatric.

Studies have shown that although CCR and NLC criteria may reduce the need for cervical spine imaging in children 10 years old and younger, the criteria are not sensitive or specific enough to be used as currently designed (Viccellio et al., 2001; Stiell et al., 2003; Ehrlich et al., 2009). Neither clinical decision rule is performed at a high enough level to be used with confidence.

A second issue pertaining to cervical spine clearance revolves around determining which imaging modality to use to assess the cervical spine. Physical examination in alert patients has been proven to be reliable; however, controversy remains as to which imaging studies to perform on pediatric CSI patients when the patient has altered mental status or is intubated (Marion et al., 2008). Most data for the diagnosis of cervical spine injuries have been derived from the adult literature. Griffen et al. described a retrospective study of 3,018 blunt trauma patients of whom 1199 (40%) were at risk for CSI (Griffen et al., 2003). Plain radiographs (3 views) and a CT cervical spine were performed. Of 116 patients with spinal injuries, there were 41 patients whose injuries were missed by plain films, but diagnosed by CT scan. More significantly, all of the 41 patients with missed injuries required treatment. A prospective study from Schenarts et al. (2001) compared the use of cervical-spine CT for the upper cervical spine (C₁-C₃) to plain films for adult trauma patients with altered mental status. Plain films identified only 54% of the injuries to the upper cervical spine in their series, compared with 96% diagnosed with CT scan. In contrast to the previous study, a different study found that three injuries seen on plain films were missed on CT, including one atlantooccipital dislocation in a patient with quadriplegia and two subluxations (Schmoker et al., 1992).

Rana et al. (2009) recently examined their experience with cervical-spine imaging using either CT or conventional films in cervical-spine clearance with intubated children. Plain

The patient died. (**B**, From *Netter F, editor: The Ciba collection of medical illustrations, vol 1: nervous system, Summit, NJ, 1953.*)

TABLE 30-9. Upper Normal Limits of Cervical Spine Measurements in Adults and Children

	Adults	Children
Predental space	2.5 mm	4 to 5 mm
C2-3 override (flexion)	3 mm	4 to 5 mm
Prevertebral space	7 mm	½ to ⅔ AP distance (extension) vertebral body

From Eichelberger MR: *Pediatric trauma prevention, acute care, rehabilitation*, St. Louis, 1993, Mosby.

radiographs missed injuries and had a significantly lower sensitivity compared with CT scan (61% vs. 100%). In addition, all patients who remained intubated for 24 hours received flexion and extension views, but no new injuries were detected.

This result is supported in adult trauma literature; Insko et al. (2002) reviewed the use of flexion-extension films and demonstrated that 30% of the patients were unable to flex and extend adequately, leading to further imaging with CT or MRI. They concluded that these films are of limited diagnostic utility in the acute setting for evaluation of the cervical spine at a Level I pediatric trauma center (Insko et al., 2002; Rana et al., 2009).

Radiation exposure from CT scans is an important concern and driving force for the rational use of imaging in children. Adelgais et al. (2004) examined this issue in a prospective study reviewing the differences of radiation exposure between conventional radiographs and CT. In this study, the patients receiving CT had 1.25 times the effective radiation dose compared with plain films. However, the comparison groups were markedly different; the patients undergoing CT scan were significantly more ill than the patients who only received plain films. The CT group had higher numbers of abnormal head CT (41% vs. 20%), intubation (20% vs. 2%), and transfer to

intensive care or operating rooms (46% vs. 23%), compared with the group only receiving plain films. Keenan et al. (2001) examined this issue from another perspective by reviewing the number of excess radiographs required to clear the cervical spine of injury compared with the use of CT scan. Patients who underwent CT of the neck on initial evaluation had significantly fewer repeated radiographs than patients without cervical-spine CT (mean, 2.1 ± 2.6 vs. 3.6 ± 2.7 repeated radiographs, $p = 0.04$). The amount of radiation exposure was also determined, and the authors concluded that the children with initial CT did receive a higher effective dose ($p < 0.001$); however, patients with a GCS of less than 8 received equivalent doses compared with those not undergoing early cervical-spine CT ($p=0.15$) (Keenan et al., 2001). Although radiation exposure is increased in patients undergoing CT imaging, the actual increased risk of cancer above the natural background rate is low at 0.25% (Bier, 1990).

Child Abuse

The CDC defines child maltreatment as any act of commission (abuse) or omission (neglect) by a parent or other caregiver that results in harm, potential for harm, or threat of harm to a child. Unfortunately, such harm perpetrated on children permeates society. Even worse, child abuse remains to a great extent concealed or inadequately appreciated. Many experts believe that the number of annual referrals filed probably represent less than one third of actual cases; in fact, some sources describe as much as a tenfold difference between victim or parental self-reports and official estimates of incidence (Coté et al., 2009; Gilbert et al., 2009). Whether participating in the resuscitation and stabilization of a victim of acute pediatric trauma or assisting in the serial procedures required of more chronic medical conditions, anesthesiologists should step back and view their pediatric patients in a larger context that includes the possibility of child maltreatment.

Epidemiology

The U.S. Department of Health and Human Services collects and publishes data on child abuse in an annual report (U.S. Department of Health and Human Services, 2006). Of the estimated 3.2 million referrals made to Children's Protective Services (CPS) in 2007, 61.7% progressed to investigation or assessment. Approximately 25% of these investigations indicated or substantiated child maltreatment, leading to an estimated 794,000 children being counted as victims of abuse or neglect. The most recognized forms of maltreatment are generally categorized as physical abuse, sexual abuse, psychological or emotional abuse, and neglect. During 2007, 59% of the victims suffered from neglect, whereas 11% were physically abused, 8% were sexually abused, and 4% were psychologically maltreated. Maltreatment is inversely related to age, as victimization is most prevalent among children under 1 year of age.

Perhaps even more disturbing is the high recidivism rate for perpetrators, because maltreatment often develops into a repetitive pattern of offense. In one study, 75% of victims younger than 24 months of age demonstrated evidence or history of previous trauma or injury (Kellogg, 2007). Children who

are prior victims are 96% more likely to experience a repetition of abuse compared with those who are not previous victims. These trends are also inversely related to age, as adolescents from 16 to 21 years old are 51% less likely to experience recurrence compared with infants (U.S. Department of Health and Human Services, 2006).

Clearly, the most tragic outcome associated with maltreatment is a child's death. Such cases often go unrecognized and unreported because of poor coordination and communication between various agencies, as well as a lack of standardized terminology and investigation techniques. Nevertheless, in 2007, 1760 children's deaths were attributed to maltreatment. Again, the most fragile and defenseless children endure the greatest risk. Children younger than 1 year old accounted for 42% of fatalities, and 76% of the deaths attributed to maltreatment were associated with children under 4 years old (U.S. Department of Health and Human Services, 2006).

Many of these children have already been seen by various branches of the health care system, but the practice of pediatric anesthesiology provides a further level of screening for some of the most at-risk children. Children with disabilities, chronic illnesses, or special needs are at an increased risk for maltreatment and make up 8% of all child abuse victims (U.S. Department of Health and Human Services, 2006). It has been observed that compared with children who are not disabled, children with disabilities are 3.76 times more likely to be neglected, 3.79 times more likely to be physically abused, and 3.14 times more likely to be sexually abused (Hibbard and Desch, 2007).

Although child abuse affects children of all ages, genders, cultures, and socioeconomic strata, certain children are statistically predisposed to increased risk. Some of the indicative characteristics include the child's age (infants and preschoolers) and whether the child was born premature, is developmentally delayed, possesses special health needs, or succumbs to behavioral problems. Also, given that greater than 80% of documented abuse cases are perpetrated by parents or caregivers, these victims' home or care environments demonstrate other clear risk factors (Box 30-5) (Honor, 2005; Kellogg, 2007). Obviously, bias should be avoided, because these risk factors in isolation do not indicate child abuse. Such characteristics should instead aid and guide further investigation as well as prevention strategies and treatment plans.

Box 30-5 Risk Factors for Child Abuse

PARENTAL OR CAREGIVER CHARACTERISTICS

- Poverty
- Unemployment
- Lack of or minimal education
- Social isolation
- Single parenting or unrelated caregivers

CAREGIVER HISTORY

- Substance abuse
- Domestic violence
- Mental illness
- Their own neglect or abuse as children

For the anesthesia provider, a patient's preoperative or preprocedure evaluation is often streamlined and focused on the impending operative physiology and risks; however, certain information should raise a level of concern for possible abuse:

- There is a lack of or inadequate explanation for the injury or condition.
- The details of the explanation change.
- There are differing accounts from witnesses.
- The explanation does not fit the pattern, age, or severity of the injury.
- The explanation does not fit the child's developmental capacity.
- There are delays in seeking medical attention for the injury or condition.
- The concern expressed by caregivers is inappropriate for the condition or injury sustained.

It must be noted that children may be naturally prone to injury as they test the limits of their autonomy. Most childhood injuries are not the result of maltreatment; hence, common sense should apply when considering each child's ability to sustain observed bruising or trauma (Fig. 30-12). The same injury in a mobile 4-year-old child may be diagnostic of physical abuse

in an infant. Likewise, outside of infancy, superficial injuries or bruising should be consistent with the hazards of daily living activities. Bruising to skin over bony prominences (e.g., shins, knees, forehead, chin, and forearms) is more consistent with normal activities, whereas injuries to protected, padded areas (e.g., neck, abdomen, buttocks, genitalia, cheeks, and ears) should always be suspect.

Anesthesiologists are perfectly positioned to routinely complete a full-body survey in the course of each patient's positioning in the operating room and for anesthesia. The key is to recognize a pattern or constellation of physical findings that may point to possible abuse or neglect. Some compelling or indicative findings are noted in Table 30-10. Complete documentation of injuries, including diagrams and photographs, is paramount to facilitate peer review as well as CPS and law enforcement intervention and court proceedings.

If abuse is suspected, other tests may be appropriate to assess for additional injuries or to elucidate other medical etiologies for injuries. These diagnostic studies may be more easily determined in consultation with child-abuse specialists. Regardless, the younger the child or the more severe the injury, the greater the need exists to evaluate for other injuries. And if one child is a suspected victim, other siblings or children in contact with the caregivers should also be assessed.

■ **FIGURE 30-12.** **A**, Severe bruising with underlying muscle damage. This toddler was covered from head to toe with severe looped-cord contusions and lacerations. He had secondary myoglobinuria, necessitating intensive care management to prevent renal failure. **B**, This boy was struck with a chain, leaving a clear imprint of the links. **C**, A deep, circumferential rope burn on the wrist with considerable edema and early skin breakdown of the hand is seen in this infant, who was tied to the siderails of her crib. **D**, This circumferential cord burn was the result of an attempted strangulation.

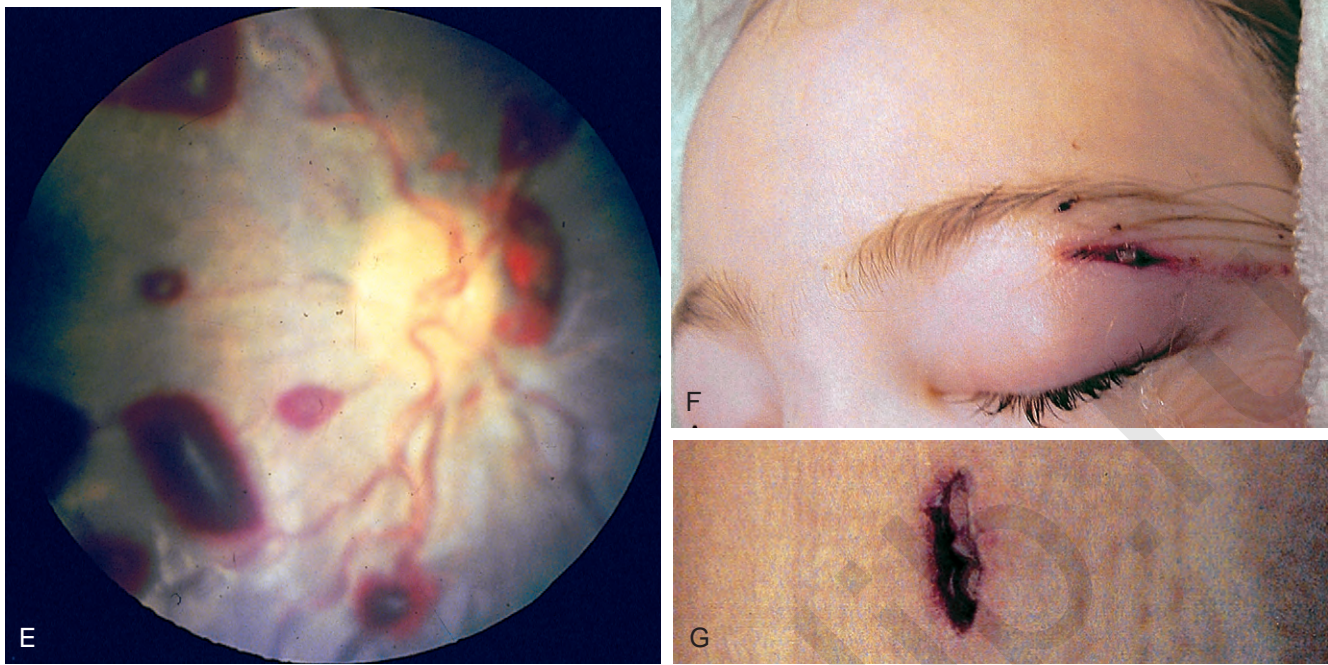

FIGURE 30-12—cont'd. E, Multiple retinal hemorrhages are seen on funduscopy examination of this infant who was a victim of the shaken-baby syndrome. Subdural hematoma and multiple metaphyseal “shake” fractures are typical associated findings. F, A superficial laceration is seen over the left eyelid. G, A deeper stab wound over the right flank penetrated into the subcutaneous tissue. (From Zitelli BJ, Davis HW, editors: Atlas of pediatric physical diagnosis, ed 4, St. Louis, 2002, Elsevier.)

TABLE 30-10. Physical Examination Findings Associated with Maltreatment

General	Notes
Extensive dental caries	Examples of general neglect
Severe diaper dermatitis	
Derelict wound care	
General uncleanliness	
Failure to thrive (may manifest in nutritional neglect)	
Anxiety and reluctance when the child is asked about abuse	
Skin	In groups or patterns, especially around soft, protected, padded areas
Bruises	
Bites	
Lacerations	
Burns	
<ul style="list-style-type: none"> • Immersion: genital, “stocking,” or “glove” pattern from dipping the afflicted body part • Contact: from cigarettes, irons, curling irons, etc. (especially branding pattern) • Chemical: ingestion (may indicate neglect or abuse) 	
Head	
Bruising or injury to ears, nose, or mouth	
Fontanel: fullness or asymmetry (may indicate step-off fracture or intracranial pathology)	
Eyes not tracking: may indicate head injury	
Retinal hemorrhage (by funduscopy exam)	
Thorax/Abdomen	
Any significant bruising or trauma, especially in infant or nonambulatory child	

Continued

TABLE 30-10. Physical Examination Findings Associated with Maltreatment—cont'd

General	Notes
Skeletal	
Specific fractures carry higher specificity for abuse (especially in infants)	
<ul style="list-style-type: none"> • Posterior ribs fractures • Sternum fractures • Scapular fractures • Spiral long-bone fractures (from torsion or twisting of extremities) • Metaphyseal fractures (from whole traction forces on limbs; may be seen with shaking) 	
Genitalia/Anus	
Should be examined in any child when abuse is suspected	

Management Issues

Laws mandating the report of suspected abuse and neglect exist in all 50 states. Proof is not required before reporting, and good-faith reporting has immunity in some form or another (Kellogg, 2007).

Almost all states have what are nominally called *child-protection teams*. Such teams are composed of specialists who are well versed and trained in the medical, social, and legal aspects involved with these cases. The members of these teams are composed of social workers and physicians or medical providers with specific experience in the field. In fact, the American Academy of Pediatrics has recently implemented and accredited a new board subspecialty in Child-Abuse Pediatrics. Such child-protection teams should be available to concerned clinicians and typically work in conjunction with emergency departments, primary care practitioners, law enforcement agencies, and county CPS. These teams may offer onsite assistance and provide consultation on specific case questions.

In most tertiary care or academic centers, assistance may be readily available. However, in other health care facilities, there may not be any familiarity with these processes, so providers should solicit assistance from hospital social workers, administrators, or regional tertiary care centers. In the absence of any other source or after normal business hours, law enforcement and CPS are available to provide information and assure child safety. The U.S. Department of Justice also furnishes applicable information (<http://www.ojp.usdoj.gov/ovc/help/ca.htm>) and advertises a child-abuse hotline (1-800-4-A-Child) for referral information.

In order to recognize child maltreatment, anesthesia providers must understand and acknowledge that abuse and neglect occur on a regular basis, that such victimization occurs in any segment of society, and that maltreatment must be considered as part of the differential diagnosis when assessing any instance of childhood trauma.

Facial Trauma

Although severe facial trauma in children is a relatively uncommon event, it does occur, and it can make ETI challenging if not impossible (Fig. 30-13) (Zerfowski and Bremerich, 1998). Blood, secretions, hematomas, damaged tissues, or dentition may all obstruct the airway during respiration, ventilation, direct laryngoscopy, and fiberoptic intubation. Facial injuries can be categorized (in order of decreasing incidence)

■ **FIGURE 30-13.** Photograph of a 3-year-old child who was backed over by a riding lawnmower and sustained massive facial trauma and amputation of the left foot.

as soft-tissue injuries, dental injuries, and facial fractures. As depicted in Figure 30-14, the incidence of these injuries varies with the age of the child. See related video online at www.expertconsult.com. In all instances, injuries are more common in males than females. Facial trauma in children under 5 years of age is less severe because of the protective environment supported by parental supervision (Kaban, 1993). However, Shaikh and Worrall (2002) found that 42% of the pediatric population sampled with facial injuries were younger than 5 years of age, where soft-tissue injuries were more common. The vast majority of these injuries were caused by falls, where insecurity of motion and lack of coordination prevented victims from shielding their faces or turning their heads. In such cases, the injury is then focused on a relatively small area of the face, from the nose to the mentum, which is referred to as *the falling zone* (Zerfowski and Bremerich, 1998). The rates

FIGURE 30-14. Type of injuries per year of age, demonstrated separately for soft-tissue injuries, dental trauma, and fractures. (From Ferfowski M, Bremerich A: *Facial trauma in children and adolescents*, Clin Oral Invest 2:120, 1998.)

of soft-tissue injuries increase in adolescence. This trend may be explained by more aggressive, risky behavior that may be related to alcohol consumption or sports activities. Compared with soft-tissue injuries, the incidence of dental injuries is diminished throughout childhood. It should nevertheless be noted that accidental aspiration of teeth before or during resuscitation can complicate care and necessitate removal via bronchoscopy. Facial fractures were the least common form of pediatric facial trauma. Facial fractures accounted for only 8% of patients in the study by Zerfowski and Bremerich (1998). Nasal fractures are the most common facial fractures in children. Anderson (1995) noted that nasal fractures accounted for over 50% of all facial fractures, followed by mandibular fractures and lastly maxillary fractures.

Another form of pediatric facial injury that can pose a challenge to anesthesiologists is laceration or impalement of oropharyngeal structures or tissues. It is not uncommon for children to fall with foreign objects in their mouths (e.g., pencils or toothbrushes), sometimes sustaining abrasions or lacerations to the soft palate or oropharynx. Most of such injuries are mild and spontaneously heal without intervention (Hellmann et al., 1993). However, some injuries raise concerns of vascular involvement and require angiographic studies before surgical extraction of the foreign body (Fig. 30-15). Carotid artery thrombosis and stroke have been reported after blunt pharyngeal trauma (Moriarty et al., 1997).

Extrusion of eye contents through a full-thickness–penetrating ocular laceration may result in permanent loss of vision (Fig. 30-16). Intraoperative anesthetic management of open globe injuries is discussed further in Chapter 27, Anesthesia for Ophthalmic Surgery.

Dog Bites

Dog-bite victims represent another common instance of facial injury in children. In a study by McHeik et al. (2000), the

FIGURE 30-15. The left tonsillar bed of a 6-year-old girl was impaled after she fell with a toothbrush in her mouth. She was intubated orally with direct laryngoscopy.

FIGURE 30-16. Open-eye injury in children is often caused by a projectile object.

majority of children suffering dog bites (68%) were younger than 5 years of age. It was believed that the increased rate of dog bites in this age group was as a result of young children's lack of caution and comprehension regarding animals, coupled with the fact that their heads and necks are on the same level as that of a dog. A study by Bernardo et al. (2002) revealed that younger children (younger than 6 years old) commonly sustained dog bites from their family dogs in their own homes and confirmed that these injuries typically involve facial structures. The goals of immediate surgical repair are to diminish scarring and decrease the rate of wound infection.

As with other trauma, facial injuries in children should be evaluated in the field or the emergency room during the primary survey. If there is any evidence of airway obstruction or respiratory insufficiency, the airway should be secured

immediately with LMA, ETT via direct laryngoscopy, LMA, or surgery. As mentioned previously, special attention to cervical spine stability during direct laryngoscopy should be accomplished with inline stabilization of the neck. Once the airway is secured, a secondary survey can be performed to ascertain the extent of the facial injury and the need for surgical intervention.

Soft-Tissue Neck Trauma

Soft tissue injuries to the neck can occur in children. As mentioned earlier in the chapter, blunt trauma is much more common than penetrating trauma in the pediatric patient. Although rare, penetrating trauma can occur in this area also. Atta and Walker (1998) divided the neck into three anatomic zones. Zone I is the area between the thoracic outlet and the cricoid cartilage and contains the proximal common carotid, vertebral, and subclavian arteries, the trachea, the esophagus, the thoracic duct, and the thymus (Fig. 30-17). Zone II is between the cricoid cartilage and the angle of the mandible. Contents include the internal and external carotid arteries, jugular veins, pharynx, larynx, esophagus, recurrent laryngeal nerve, spinal cord, trachea, thyroid, and parathyroids. Zone III is between the angle of the mandible and the base of the skull. Its vascular structures include extracranial carotid and vertebral arteries and the uppermost segments of the jugular veins. Zone I injuries have the worst prognosis with regard to morbidity and mortality. Zone II injuries are the most prevalent but have the best prognosis because of their accessibility (Levy and Gruber, 2008).

■ **FIGURE 30-17.** Neck CT angiography of a 4-year-old girl who was accidentally shot in the neck (zone I) with a BB gun. She suffered an aneurysm of her right common carotid artery, with a midline shift of her trachea (because of a hematoma) in both zones I and II. She underwent successful repair of this injury without sequelae.

Chest Trauma

Pulmonary contusions are the most common thoracic injury in children (Vane, 2002; Miller et al., 2003; Soundappan et al., 2005). Because most of the bony support or rib cage in a child is cartilaginous, significant forces may be transmitted to the lung and mediastinum without external signs. Pulmonary contusions may signal a simple isolated lung injury that includes pneumothorax, hemothorax, and rib fractures. Life-threatening injuries that impair ventilation include open or tension pneumothorax, flail chest, or injuries to the trachea or bronchi. A thoracotomy is rarely required, although chest tubes have been placed in up to 50% of reported case series. Injuries to the heart, diaphragm, great vessels, bronchi, and esophagus are rare. A chest tube stabilizes most life-threatening pulmonary lesions (e.g., tension pneumothorax). An important consideration when managing pulmonary trauma in children is that when a child suffers a significant pulmonary injury the mortality rate increases tenfold (Chu et al., 1996; Thourani et al., 1998; Soundappan et al., 2005). Tension pneumothorax is an urgent yet manageable complication of chest injury that produces diminished breath sounds, tracheal deviation, hypotension, and increased ventilation pressure. It occurs because of accumulation of needed air in the pleural space under pressure. An area in the injured lung acts as a one-way valve, leaking air into the pleural space. The leaked air becomes trapped in the pleural space, and each successive breath introduces more air under progressively increasing pressure. This impairs ventilation and venous return to the heart. It should be treated immediately with decompression by bore-IV catheter insertion in the midclavicular second intercostal space and followed by chest tube placement.

Open pneumothorax occurs when injury has produced a chest-wall defect. This equalizes the pressure between the pleural space and the environment, causing collapse of the lung and movement of air through the chest-wall defect rather than the trachea. It is managed by covering the defect with an occlusive dressing taped on three sides. This allows ventilation and prevents the air accumulation consistent with a tension pneumothorax.

Another consequence of a cartilaginous rib cage is that rib fractures and flail chest are less common in children than adults; however, significant intrathoracic injury, such as pulmonary contusion, may occur in the absence of a rib fracture. Flail chest occurs when four or more ribs are each fractured in two places by blunt trauma. The floating fracture segments produce paradoxical movement of the chest wall so that spontaneous ventilation is impaired. Any underlying pulmonary contusion further impairs gas exchange or ventilation. Although penetrating chest wounds in children are rare, as in an adult they can be immediately life threatening (Fig. 30-18). Hemothorax can occur when intercostal vessels or lung parenchyma are injured. It is important to have a high index of suspicion because blood in the pleural space can be asymptomatic; however, a hemothorax can cause significant hemodynamic compromise, because each hemithorax can hold 40% of a pediatric patient's blood volume (Grisoni and Volsko, 2001).

Although the chest cavity is compliant, the child is still at risk for tension pneumothorax, mediastinal shifts, and cardiac tamponade leading to respiratory and circulatory collapse. Because of the mobility of the mediastinum, aortic tears in children are

■ **FIGURE 30-18.** **A**, This child came to the hospital with a widened mediastinum after blunt chest trauma. **B**, An immediate arteriogram revealed a disrupted aortic arch.

rare. A widened mediastinum, fracture of the first rib, and presence of an apical pleural cap on the left side all raise concerns about an aortic disruption.

Abdominal Trauma

A rapid deceleration or shearing injury (e.g., motor vehicle crash) is the mechanism most commonly associated with abdominal injuries. Solid organs (e.g., the liver, spleen, and kidneys) are the most commonly injured, followed by the hollow visceral organs (Baker et al., 1992; Soundappan et al., 2005; Adelson et al., 2006; Langlois et al., 2006). Among these visceral injuries, the third and fourth parts of the duodenum, terminal ileum, and sigmoid colon are most at risk to injury because of their relative fixation. Death from abdominal injuries is usually secondary to hemorrhage. Injuries to the great vessels, genitourinary tract, pancreas, and pelvis are rare and account for proportionately fewer deaths. The body of the pancreas as it crosses the vertebrae column is the most susceptible portion of the pancreas injured by blunt force or compression (e.g., from a bicycle's handle bar or seat belt) (Fig. 30-19).

The abdomen of a child is vulnerable to injury for several reasons. The liver and spleen are less protected by the lower

thoracic cage, and the bladder rides higher in the immature shallow pelvis. Gastric dilation in children is commonly encountered after trauma as a result of crying or swallowing air. It is important to recognize, because it can simulate peritonitis, limit diaphragmatic excursion (thereby hindering breathing), increase the risk of aspiration, and inhibit the vagally mediated tachycardia response to hypovolemia.

The management of solid-organ injuries in children has evolved over several years from an operative to a nonoperative approach (CDC, 1999). Success rates for nonoperative management of liver, spleen, and kidney trauma now exceed 90%. The relatively new use of interventional radiology techniques has further decreased the need for emergency surgery in children with solid abdominal injuries (CDC, 2003; Jankowitz and Adelson, 2006; Wakai et al., 2007). Furthermore, evidence-based guidelines now exist for critical care, radiographic procedures, follow-up care, and return to activity (CDC, 1999). The extent of the injury is scored on a scale from 1 to 5, based on radiographic findings, with a higher number representing increasing severity. However, the decision to operate is solely determined by the clinical situation. The only indication for operative intervention is hemodynamic instability—not the radiographic stage.

■ **FIGURE 30-19.** **A**, CT of a child with a disrupted rectus muscle and lateral-wall hematoma after a lap-belt injury. **B**, The same child with a perforation in the anterior abdominal wall.

■ **FIGURE 30-20.** The same child after repair. Note the abdominal bruising pattern from the lap-belt injury.

A common mechanism of injury in children is motor-vehicle crashes. The lap-belt complex is a pattern of injury commonly encountered after a motor-vehicle crash (Fig. 30-20). The lap-belt complex describes a pattern of injury to intestinal viscera and its mesentery, with concomitant fracture, dislocation, or subluxation of the thoracic, lumbar, sacral spine, or the iliac wing. It was first described by Garrett and Braunstein (1962) to denote distinctive pattern of injury resulting from the use of lap-style safety belts (Luerssen, 2006). The lap-belt complex is characterized by soft-tissue injury, intraabdominal injury, and orthopedic injuries. The soft-tissue injury may be a slight bruise, ecchymosis, or a degloving injury with fascial dehiscence. The abdominal injury may be a solid organ, hollow viscus hematoma or perforation, mesenteric bleeding, or a bladder or aortic injury. Orthopedic injuries may include fractures, dislocation, or subluxation of the lumbar, sacral, thoracic spine or the iliac wing.

The orthopedic and abdominal injuries may be subtle and hard to detect at first. Paraspinal tenderness is suggestive of a spinal injury and mandates further radiographic investigations. Hollow-viscus injuries may appear clinically or radiographically (despite contrast) for a few days. Repeated physical examination is needed. In some situations, a healing hematoma may result in scarring and bowel obstruction 4 to 6 weeks after the injury.

Lawnmower Related Injuries

Lawnmowers cause more than 9400 injuries annually in the United States in children younger than 18 years of age, with almost one quarter of these injuries occurring in children younger than 5 years of age (U.S. Consumer Product Commission, 1990–1999). The age distribution is bimodal, with peaks at 2 and 15 years, probably representing injuries to bystanders vs. operators. Over 7% of children who incur mower-related injuries require hospitalization, a higher rate than injuries incurred from any other consumer product (U.S. Consumer Product Commission, 1990–1999). Riding mowers, commonly used for lawn and field maintenance in this country, are more powerful and complex to operate than walk-behind mowers. They carry a much higher risk of injury

and possible death than walk-behind mowers (more than three times higher) (Adler, 1994). In 1993, a U.S. Consumer Product Safety Commission report identified four mechanisms of injury caused by riding mowers: loss of mower stability, blade contact, layout and function of the mower controls, and running over or backing over young children (Adler, 1993). Back-over injuries occur approximately twice as often as run-over injuries, with about 85% of these injuries occurring in children between 15 months and 10 years of age. Typically, this occurs when the child is playing in the area, following the mower, or falls off the back of the mower (Deppa, 1994). The type of injuries children incur from lawnmowers range from lacerations (41%) to amputations and avulsions (7%) (U.S. Consumer Product Commission, 1990–1999). Aside from initial stabilization and treatment, children with these injuries may require repeated anesthetics for wound débridement, reductions of bony fractures, skin grafts, or reconstructive surgery. A child with a lower extremity injury may benefit from combined epidural and general anesthesia, with continued epidural analgesia in the postoperative period. Because of infection, consideration for antibiotic prophylaxis and tetanus must be considered. In addition, emotional trauma both to the patient and family is considerable. The following list shows some of the recommendations of the American Academy of Pediatrics Committee on Injury and Poison Prevention (Smith, 2001):

- Manufacturers of riding lawnmowers should only sell tractors that will not mow in reverse without a manual override.
- Children younger than 6 years of age should be kept indoors when lawnmowers are being operated.
- Children must not be allowed to ride as passengers on mowers.
- Children should not operate lawnmowers until they have displayed the necessary levels of judgment, strength, skill, and maturity. Most children will not be ready to operate a walk-behind mower until 12 years of age, and a riding mower until at least 16 years of age.

Skeletal Injuries

Musculoskeletal injuries are rarely life threatening, except when they are associated with ongoing severe hemorrhage. Still, they are a leading cause of morbidity and long-term disability, and if not managed appropriately and in a timely manner, long-term sequelae may result, including limb deformities, permanent neurologic and joint dysfunction, and loss of limb viability. See related video online at www.expertconsult.com. Additional considerations in children include premature growth arrest and potential for growth-plate injuries. In the child with multiple injuries, it is important to identify the priorities of treatment. Control of bleeding as a result of skeletal injuries should occur as part of the primary survey. Once life-threatening injuries such as head and chest injuries are addressed and initially stabilized, the extent of skeletal injuries should be carefully assessed based on symptoms, physical examination, and radiography. Appropriate initial measures include functional bracing or splinting to alleviate pain and immobilization of bone fragments to prevent further injury of adjacent neurovascular structures, allow safe transport of the patient, and minimize impairment of limb function. In patients with adequate alignment of fracture segments, this may be the only necessary treatment. Other interventions

that may be needed in case of displaced fractures include external traction, external fixation, and internal fixation.

Urgent or emergent surgical interventions are usually indicated in the case of complex or displaced fractures associated with vascular damage and potential for limb ischemia, neurologic dysfunction, open fractures, joint dislocations that cannot be reduced, and compartment syndromes (Musgrave and Mendelson, 2002). Vascular injuries in conjunction with limb fractures are, fortunately, rare in children. Although the majority of vascular injuries are associated with supracondylar distal humerus fractures, they may also occur in conjunction with fractures of the distal femur, proximal tibia, displaced pelvic fractures, and knee dislocations. Children with suspected vascular injuries may require an angiogram to delineate the extent of the injury and to determine the need for revascularization. In the case of open fractures, wound irrigation and débridement with extensive removal of contaminated and necrotic tissue are required. Children with open fractures often require repeated débridement under general anesthesia every 48 to 72 hours until all of the devitalized tissue has been removed. Pain out of proportion to the extent of the injury should raise concern about compartment syndrome. In these cases, emergent fasciotomies of all involved compartments is indicated because significant muscle necrosis can occur if intracompartment pressures exceed 30 mm Hg for longer than 8 hours (Musgrave and Mendelson, 2002).

Fractures of the femur in children most commonly involve the femoral shaft or the distal femoral physis. Femoral-shaft fractures can result in significant blood loss from the fracture segments, and such blood loss may not be readily recognized because the blood accumulates in the large thigh compartments. Serial hematocrits should be obtained in children with femur fractures, and they should be adequately volume resuscitated before the induction of anesthesia to avoid cardiovascular collapse on induction. A high index of suspicion for compartment syndrome should be maintained, particularly in the patient with concomitant head trauma who may be difficult to evaluate. Children with distal femur fractures are at risk of arterial injury and compartment syndrome; attention should be focused on the neurovascular status of the limb (Musgrave and Mendelson, 2002).

The issue of early vs. delayed stabilization of femur fractures in children with closed head injuries remains contentious. Interpretation of the existing literature is confounded by variability in study design, small sample size of patients studied, differences in severity of head injury in the early vs. late treatment groups, and variable definitions of early vs. late treatment. Previous studies in adults have found that early fixation significantly reduced the incidence of severe pulmonary complications, including respiratory distress syndrome, pneumonia, and pulmonary emboli (Bone et al., 1989; Behrman et al., 1990). Pediatric studies found that early stabilization did not lessen the risk of pulmonary complications in the child with multiple injuries. A retrospective study by Hedequist and others (1999) identified 25 children with femur fractures and CNS injury (GCS score of 8). Seven of these children underwent early stabilization, of whom 4 (57%) experienced a respiratory complication compared with 8 complications out of 18 (44%) who underwent delayed fixation. In another retrospective study in children, Mendelson and others (2001) reported twice the number of respiratory complications in the late treatment group (4 out of 13 vs. 2 out of 12, $p = ns$). This difference may be clinically significant, but the groups were dissimilar in that children in the late-treatment group had a higher incidence of increased ICP. Other purported benefits of

early fixation include early patient mobilization, shorter hospital and intensive care unit stays, improved predictability of fracture outcome, and decreased costs.

Proponents of late stabilization argue that minor hemodynamic changes, including shifts in blood pressure and volume status, may potentiate secondary brain injury and lead to adverse neurologic outcomes. Previous investigators have reported a greater incidence of intraoperative hypotension and hypoxemia and lower mean GCS scores in patients undergoing early fracture stabilization (Jaicks et al., 1997; Townsend et al., 1998). Other studies have found no relation between timing of fracture fixation and head trauma outcome (McKee et al., 1997; Kalb et al., 1998; Mendelson et al., 2001). The Committee on Trauma of the American College of Surgeons has recommended that femoral fractures be treated early provided hemodynamic stability has been achieved (Burgess and Cates, 1993). The appropriate timing of fixation for a femur fracture in a child with a head injury remains open to further investigation. Until more definitive data become available, it may be prudent to delay operative fixation of femur fractures until stabilization of hemodynamic and neurologic status are achieved. Also, adequate volume resuscitation and careful monitoring of end-organ perfusion and pressure, including blood pressure and ICP monitoring, should be strongly considered to guide intraoperative interventions that reduce the risk of secondary brain injury.

Another potential complication of long-bone fractures is compartment syndrome. Acute compartment syndrome can be both a limb- and life-threatening surgical emergency. Compartment syndrome is defined as a condition where the circulation of blood through tissue is compromised within a closed space by increased pressure within that space (Matsen, 1975). Fractures that are most commonly associated with compartment syndrome are of the tibia and forearm (Namias, 2007). The classic signs and symptoms of compartment syndrome are the seven "Ps": pain, pallor, parasthesias, paralysis, pulselessness, pressure, and poikilothermia. Patients exhibit pain out of proportion to the clinical situation. Treatment should include elevation of the extremity, removal of restrictive dressings, and maintenance of normotension. Definitive surgical management of compartment in the extremity is fasciotomy (Fig. 30-21).

FIGURE 30-21. A 12-year old girl who was crossing the freeway as a shortcut to school and was hit by a semi truck. Note extensive bilateral thigh swelling that resulted in bilateral compartment syndromes.

SUMMARY

Pediatric trauma accounts for 25% of all traumas in the United States. Advanced trauma life support should be thought of as a continuum, beginning with the traumatic event; continuing through resuscitation and stabilization in the emergency room, diagnostic areas, and the operating room; and ending with the discharge of a stable patient into the recovery room or intensive care unit. Careful evaluation with good teamwork and meticulous attention to detail can contribute to a positive outcome.

EPIDEMIOLOGY

The most recent edition of the American Burn Association's National Burn Repository includes a comprehensive analysis of data from acute burn admissions within the United States that were collected between 1998 and 2007. Pediatric burn patients account for almost one third of the total projected volume. Burn-related trauma is the second leading cause of accidental death in children between 1 and 4 years of age and remains the third leading cause of accidental death in individuals younger than age 18 years, exceeded only by motor vehicle accidents and drowning. Approximately 70% of pediatric burns up to the age of 4 years old are the result of scald injuries, whereas flame burns are the most common pattern among children 5 years of age and older (American Burn Association, 2007). In general, younger children are at higher risk for sustaining burn injuries, and abuse or neglect may account for as much as 15% to 20% of these cases (Tucker, 1986; Sheridan et al., 1997a).

The mortality previously associated with severe burn trauma has been significantly reduced since the 1980s. Current survival expectations associated with management of burn wounds may be attributed to improved access to emergency medical care and targeted resuscitation, advanced ventilation modalities and a more comprehensive understanding of the

pathophysiology of inhalation injury, rigorous infection control practices, enhanced nutritional support, early burn wound excision and grafting, and the attenuation of the hypermetabolic response (Herndon and Spies, 2001). The development of evidence-based practice guidelines and multidisciplinary care models available at regional burn care centers have aided these efforts. Long-term outcomes have subsequently improved, and pediatric burn survivors are able to report a satisfying quality of life as measured by several psychometric tools (Sheridan et al., 2000; Baker et al., 2007, 2008).

BURN-WOUND ASSESSMENT

Injury depth, size, and location are the three components that contribute to the overall severity of burn wounds and are the direct results of exposure to thermal, chemical, electrical, ultraviolet, and radiologic sources. Regardless of the medium, the protective functions of the skin are impaired or destroyed. Burn wounds are dynamic, in that dermal changes evolve over time with damage extending to adjacent or deeper tissues (Palmieri and Greenhalgh, 2002).

The traditional classification of burn depth (first through fourth degrees) has been supplanted by the use of more

TABLE 31-1. Burn Injury Characteristics

First degree	Superficial	Epidermal layer only Mild pain No scarring Barrier functions preserved (Sunburn)
Second degree	Superficial/partial thickness Deep/partial thickness	Epidermal layer with varying degree of dermal extension Wet appearance Hyperemic Edematous Blistering Painful Heals in 7 to 10 days Scar formation is uncommon (Scald) Dry May appear red or pale Moderate-severe blistering Less pain (nerve damage) May advance to full-thickness injury Heals in 2 to 8 weeks Probable scar formation without surgical therapy (Flame/chemical exposure)
Third degree	Full thickness	Epidermal and complete dermal layer involvement Dry Waxy white or leathery appearance Painless (nerve destruction) Evolving wound site Excision and grafting required (Prolonged flame contact)
Fourth degree	Full thickness	Epidermal/dermal loss Fascia violation down to tendon or bone Muscle necrosis (Electrical injury)

Modified from de Campo T, Aldrete JA: The anesthetic management of the severely burned patient, *Int Care Med* 7:55, 1981.

comprehensive terminology to include the superficial, partial-thickness, and full-thickness categories, although there remains considerable overlap between these designations (Table 31-1). First-degree (superficial) burns are restricted to the epidermis and generally heal quickly without scarring, pigmentation changes, or contractures. Sunburn is the most common example and is associated with erythema, mild pain, and possible minor blistering (Fig. 31-1, A). Second-degree (partial-thickness) burns involve the epidermis and variable portions of underlying dermal structures and are further categorized as superficial or deep partial-thickness injuries, with different implications for the progression of tissue damage and the level of anticipated care. A superficial partial-thickness burn poses minimal risk of scar formation, because the dermal structures (e.g., nail beds, hair follicles, sebaceous glands, and nerves) are largely unaffected, allowing for injuries to heal within 2 weeks (Fig. 31-1, B). In contrast, deep partial-thickness injuries disrupt portions of the dermal matrix, and epithelial regeneration is commonly associated with scar formation. Pain may not be severe, despite extensive injury, which probably reflects variable degrees of nerve dysfunction or loss. Many of these wounds require excision and grafting in order to heal properly (Fig. 31-1, C). Full-thickness burns (formerly third-degree burns) are characterized by deep-tissue destruction where the necrotic debris adheres tightly to the dermal-matrix remnant as a thick, waxy layer of eschar (Fig. 31-1, D). In the absence of normal regenerative capabilities, wound

healing can only occur by prolonged peripheral granulation and contraction, with a significantly increased incidence of infection and debilitating scar formation. Surgical intervention is required to reestablish normal barrier functions and prevent infectious sequelae (Sheridan, 2002). Even with early excision and grafting, hypertrophic scarring persists years after the original injury. Fourth-degree burns are full-thickness burns with extensions beyond the fascia and include the destruction of gross muscle mass or the disruption of major joint-capsule integrity (Fig. 31-1, E). Injuries of this type are often a precursor to surgical amputation.

Reassessments of burn-wound size and depth are necessary, because injuries have the potential to evolve from their initial presentation (dermal dysfunction worsens and affects a broader and deeper area than originally observed). Therapeutic fluid administration, nutritional requirements, and prognostic determinations are dependent on the physician's ability to perform consistent serial evaluations and can be influenced to varying degrees by a clinician's experience and subjectivity. Several methods have been developed to minimize potential inaccuracies and include laser Doppler, thermography, vital dye fluorescence, and video angiography (Mandal, 2006; McGill et al., 2007; Monstrey et al., 2008). These techniques are used to identify viable tissue by documenting the presence of adequate vascular flow to the site of injury.

Estimates of dermal involvement are recorded as a percentage of total body surface area (TBSA), and several clinometric instruments are available (Wachtel et al., 2000; Jose et al.,

FIGURE 31-1. Depth of thermal injury. **A**, Patient with sunburn of the lower extremity (superficial or first-degree burn with associated blister on anterior tibial surface). **B**, Partial-thickness injury of the hand (superficial second-degree burn). **C**, Partial-thickness injury extending beyond subcutaneous layers (deep second-degree burn). **D**, Full-thickness (third-degree) burn. **E**, Full-thickness injury with extensive tissue loss (fourth-degree burn).

2004). Each method seeks to balance ease of use with consistent assessments among different care providers. The Lund-Browder diagram remains a commonly used tool, because it addresses the differences observed with patient size and body proportions in relation to growth (Fig. 31-2) (Lund and Browder, 1994). It has been adapted for the evaluation of pediatric patients. The “rule of nines” is well-suited for a rapid field-estimate of burn injuries to facilitate prehospital management and identify criteria for transfer to a regional burn center. This technique has also been modified to appropriately account for the alterations in body proportions observed with infants, small children, and the morbidly obese (Livingston and Lee, 2000; Smith et al., 2005).

Pediatric burn patients have also been evaluated using the palmar method, in which the size of the patient’s palm represents the equivalent of 1% TBSA (Sheridan et al., 1995b; Rossiter et al., 1996). Complex burn wounds often have highly irregular distributions across multiple body segments, introducing additional inaccuracies to surface-area assessments. Newer techniques have been pioneered to improve the precision and reproducibility of clinician assessments. They include a flexible single-use nomogram that can be applied directly to the patient’s wound sites and an advanced graphics software platform that creates a three-dimensional virtual display (Neuwalder et al., 2002; Dirnberger et al., 2003; Malic et al., 2007).

FIGURE 31-2. Comparison of the Rules of Nines and the Lund-Browder burn diagrams. **A**, The Rule of Nines is applicable to most adult burn patients. **B**, The Lund-Browder charts improve the accuracy of burn estimates for infants and young children, because body-surface area values correlate well with the patient's age. (Modified from Orgill DP: *Excision and skin grafting of thermal burns*, N Engl J Med 360:893, 2009.)

TABLE 31-2. Burn Wound Severity

Minor	Superficial burns <15% TBSA
Moderate	Superficial burns = 15%-25% TBSA Superficial burns = 10%-20% TBSA in children Full-thickness burns <10% TBSA and burns not involving eyes, ears, face, hands, feet, or perineum
Major	Partial-thickness burns >25% TBSA Full-thickness burns >10% TBSA Concomitant inhalation injury Electrical burns Any complicated burn injury, i.e., patients with co-morbid conditions, patients with burns to the eyes, ears, face, hands, feet, or perineum Burns involving the face, eyes, ears, hands, feet, or perineum that may result in functional or cosmetic impairment

Modified from the American Burn Association: Guidelines for service standards and severity classifications in the treatment of burn injury, *Am Coll Surg Bull* 69:24, 1984.
TBSA, Total body surface area (%).

Burns are further classified by their overall severity (minor, moderate, or major) as defined by the American Burn Association and the American College of Surgeons Committee on Trauma (Table 31-2). These parameters may serve as useful indicators of the anticipated degree of physiologic derangement, but their prognostic value has not been validated.

PATHOPHYSIOLOGY

An evidence-based, multidisciplinary approach directed by a pediatric specialist is the most effective way to minimize mortality and improve long-term, functional outcomes

among pediatric burn-trauma victims (Thombs et al., 2006; Gore et al., 2007). The spectrum of burn-related physiologic abnormalities includes, but is not limited to, loss of thermal insulation and antimicrobial barriers, distortions of airway anatomy and pulmonary derangements, fluctuating intravascular volumes and the need for individualized fluid replacement, hypermetabolism accompanied by grossly elevated caloric needs, septicemia, altered responses to common anesthetic agents, and a prolonged inflammatory response to systemic trauma. Most patients benefit from the capabilities of a regional burn unit to deal with these complex pathophysiologic changes, and the American Burn Association has forwarded selection criteria to facilitate referrals (Box 31-1).

Dermal Barrier Disruption

The epidermis is an effective barrier to heat loss, evaporation, and infection; the dermis and its supporting neurovascular structures provide elasticity, flexibility, and the mechanism for epithelial regeneration. Burn trauma induces localized tissue coagulation and microvascular reactions in the underlying dermis that can lead to injury extension (Aggarwal et al., 1994a, 1994b). Protective functions are immediately lost with dermal disruption and result in significantly increased risk of infection and hypothermia. The risk of hypothermia is particularly high in infants and young children because of their disproportionate surface area/body mass ratio; burn patients benefit from aggressive control of ambient temperature and humidity to restrict heat loss and limit the caloric expense of shivering.

The severity of skin damage is a function of temperature and its duration of contact. Burn wounds have three zones

Box 31-1 Burn-Center Transfer Criteria

Partial- and full-thickness burns on more than 10% TBSA in patients under 10 or over 50 years of age
 Partial- and full-thickness burns on more than 20% TBSA in other age groups
 Partial- and full-thickness burns affecting the face, hands, feet, genitalia, perineum, and major joints
 Partial- burns on more than 5% TBSA in any age group
 Electrical burns, including lightning injury
 Chemical burns
 Inhalation injury
 Burn injuries in patients with comorbid conditions that could complicate management, prolong recovery, or affect mortality
 Any patient with burns and concurrent trauma (e.g., fractures) in which the burn injury poses the greatest risk of morbidity or mortality; in such cases, if trauma poses the greater immediate risk, the patient may be treated initially in a trauma center until stable before being transferred to a burn center; physician judgment is necessary in such situations and should be in concert with the regional medical control plan and triage protocols
 Hospitals without qualified personnel or equipment for the care of children with burns should transfer children with burns to a burn center with these capabilities
 Burn injury in patients who require special social, emotional or long-term rehabilitative support, including cases involving suspected child abuse and substance abuse

Modified from the American Burn Association: Hospital and Prehospital Resources for Optimal Care of Patients with Burn Injury: Guidelines for development and operation of burn centers, *Burn Care Rehab* 11:980, 1990; American College of Surgeons: *Resources for optimal care of the injured patient*, 1993, American College of Surgeons, p 64.

of heterogeneous tissue damage, radiating from the epicenter of maximal tissue destruction (Jackson, 1953). The zone of edema and stasis is of particular importance, because it represents affected tissues that are potentially salvageable with supportive care. Successful management helps reduce the final TBSA measurement (Fig. 31-3) (Hettiaratchy and Dziewulski, 2004). During the first 24 to 48 hours, systemic hypotension, acidosis, and developing sepsis contribute to injury extension. These conditions are likely to exacerbate tissue edema, impaired microcirculation, and perfusion deficits. Serial examination is the most prudent method to address the variability of burn-wound progression. Early detection of nonviable areas with subsequent surgical excision and grafting has been consistently demonstrated to decrease morbidity and mortality in this patient population (Ong et al., 2006).

Respiratory Abnormalities

It is often difficult to definitively distinguish respiratory insufficiency caused by the toxic products of combustion from the pulmonary derangements that are commonly observed with systemic responses to severe burn trauma. *Inhalational injury* is a term that encompasses both the direct thermal and subsequent inflammatory damage to the upper and lower airways. Several studies have demonstrated that inhalation injury associated with burns increases mortality, although no specific indicators are reliably predictive of the overall degree of pulmonary dysfunction (Shirani et al., 1987; Hollingsed et al., 1993; Ryan et al., 1998; Edelman et al., 2006; Endorf and Gamelli, 2007).

■ **FIGURE 31-3.** Zones of thermal injury. Burn injuries create three distinct zones of tissue reaction. The zone of necrosis is caused by tissue-protein denaturation. The zone of injury is associated with edema and reduced blood flow. The extent of this zone is variable, and appropriate burn management may limit its progression to necrosis. (Modified from Orgill DP: *Excision and skin grafting of thermal burns*, *N Engl J Med* 360:893, 2009.)

Upper-Airway Effects

Direct-heat injury caused by superheated gas inhalation and toxic smoke exposure may manifest as rapidly progressive edema of the tongue, epiglottis, and aryepiglottic folds (Pruitt et al., 1970). Macroglossia, micrognathia, and tonsillar hypertrophy are common findings in previously healthy children, and the normal presence of these features may further restrict airway patency (Benjamin and Herndon, 2002). Reduced cross-sectional area and increased flow resistance are poorly tolerated by infants and young children because of their elevated baseline minute ventilation, oxygen consumption, and limited endurance of the major respiratory muscle groups (Keens et al., 1978). Large-volume intravenous fluid administration is likely to accelerate oropharyngeal edema and convert a marginal airway into a severely compromised one, with subsequent anatomic distortions that make successful direct laryngoscopy challenging or impossible. Avoiding the “lost airway scenario” in the pediatric burn patient is a critical step during initial management, and the clinician should be guided by serial examinations to avoid airway catastrophe. Early, definitive control of the airway using context-appropriate methods is preferable for patients with evidence of progressive respiratory distress. This principle also applies to other clinical circumstances where the oropharyngeal architecture has been altered (e.g., ingestion of caustic agents such as lye).

Lower-Airway Effects (Smoke-Inhalation Injury)

Lower-airway injury is a clinical diagnosis supported by the presenting history and serial examination. Chest radiographs and bedside pulmonary function tests usually remain normal until infectious complications arise, and then their results often show an underestimation of the severity of lung damage (Lee and O’Connell, 1988; Wittram and Kenny, 1994). Fiberoptic bronchoscopy and bronchoalveolar lavage can be used to document the presence of carbonaceous debris and mucosal sloughing, although the absence of these findings should not preclude the diagnosis (Hunt et al., 1975). Technetium scanning is an assessment of pulmonary vascular endothelium damage represented as abnormal lung/liver uptake ratios of the isotope. In the future, this method may be accepted as a more objective diagnostic tool to detect lung injury in those patients with pulmonary signs and symptoms (but negative chest radiographs or pulmonary function test [PFT] findings), although it will require additional study (Shiau et al., 2003).

Toxicologic analysis of the victims with smoke-inhalation injury has demonstrated exposure to many poisonous aerosols, including carbon monoxide (CO), hydrogen cyanide, various aldehydes, hydrogen chloride, and other aromatic hydrocarbons (e.g., benzene). Even a brief exposure has significant adverse effects on the ciliated respiratory epithelial cells; toxic gases induce separation of cells from basement membranes, leukocyte migration, and exudate formation with severe impairment of the mucociliary-clearance mechanism (Fein et al., 1980). Severe ciliary dysfunction permits the accumulation of cellular debris, secretions, and bacteria. Endobronchial sloughing and edema contribute to small airway narrowing. Diminished flow capacity promotes widespread atelectasis that is magnified by surfactant loss (Herndon et al., 1985). Leukocytes aggregate in the affected lung tissue and release potent inflammatory mediators and other chemotaxins that increase endothelial

TABLE 31-3. Pulmonary Dysfunction Evolving from Burn Injury

permeability (Wright and Murphy, 2005). Dyspnea, tachypnea, diffuse rhonchi, and bronchospasm are common clinical signs observed with evolving pulmonary insufficiency and impaired gas exchange in the presence of persistent aerosolized irritants (Table 31-3).

The cascade of endobronchial cell destruction and protracted inflammatory changes predispose the patient to barotrauma (lung injury secondary to elevated ventilatory pressures and air trapping in the smaller airways), significant ventilation-perfusion distortions, and the potential for bacterial infection that leads to bronchopneumonia after several days (Pruitt et al., 1975; Rue et al., 1993). Lower-airway injuries also substantially increase systemic fluid requirements. Paradoxically, efforts to minimize pulmonary edema with fluid restriction increase mortality in these patients because inadequate intravascular volume invariably results in systemic hypoperfusion and multiorgan dysfunction (Ansermino and Hemsley, 2004).

During this period, clinical efforts must focus on the maintenance of effective gas exchange to provide time for the resolution of pulmonary tissue injury. Vigorous pulmonary toilet is needed to clear accumulated endobronchial debris, purulent exudates, mucous plugs, and residual particulates (Demling, 2008). A number of studies have reported that the administration of aerosolized heparin and mucolytics may reduce cast formation and attenuate respiratory failure (Desai et al., 1998; Holt et al., 2008). Ventilation modalities should be selected to minimize barotrauma and reperfusion injury, because elevated peak inspiratory pressures and hyperoxygenation worsen pulmonary insufficiency (Shapiro et al., 1980; Slutsky, 1993). Low-volume, pressure-limited ventilation with permissive hypercapnia (allowing for the deliberate elevation of measured arterial carbon dioxide tension [P_{aCO_2}] while maintaining pH greater than 7.25 and an arterial oxygen saturation of hemoglobin [SpO_2] of greater than 90%) is one method that may preserve tissue oxygenation in the presence of severe pulmonary dysfunction and is associated with a reduction in short-term mortality (Hickling et al., 1994; Sheridan et al., 1995a). Other methods (e.g., high-frequency percussive ventilation) have also been used, but outcomes data remain unclear (Rodeberg et al., 1994; Micak et al., 1997; Sheridan et al., 1997b; Cortiella et al., 1999; Silver et al., 2004).

Infection is the most common complication after the accumulation of denuded endobronchial tissue, small-airway obstruction, persistent edema, and extended intubation intervals (Rue et al., 1995). The incidence has been reported as high as 30% in

pediatric burn patients, with infection occurring after the loss of antimicrobial barriers and the onset of generalized immunosuppression that follows severe burn trauma (Fitzpatrick et al., 1994). Fever, mucopurulent secretions, and lobar consolidation documented by chest radiographs support the diagnosis of pneumonia (or tracheobronchitis if no x-ray changes are noted). Bronchoalveolar lavage and brushings may help support the diagnosis (Ramzy et al., 2003; Wood et al., 2003; Goldberg et al., 2008; Malhotra et al., 2008). Culture-guided and Gram-stain-guided antibiotic therapies should be reevaluated often and adjusted to optimize bacteriocidal effects and limit the development of antibiotic resistance.

Tracheostomy for pediatric patients has been advocated as a useful adjunct for airway and ventilatory management, but its application is not without risk (Sellers et al., 1997; Coin et al., 1998; Palmieri et al., 2002). The typical challenges encountered during pediatric direct laryngoscopy are made considerably more difficult in the presence of facial burns and progressive edema. Tracheostomy provides a stable, definitive airway and should be considered when the treatment plan requires multiple transports to and from the operating room or frequent repositioning of the patient for wound care. Improved secretion clearance, dead-space reduction, decreased airway resistance, and facilitation of the weaning process are also perceived benefits of a tracheostomy. However, surgical airways in small children may be associated with a greater incidence of structural abnormalities (e.g., subglottic stenosis and tracheoesophageal fistula), and subsequent life-long restricted tolerance of exercise. The routine use of this technique is not recommended (Calhoun et al., 1988; Desai et al., 1993; Barret et al., 2000).

Carbon-Monoxide Exposure

CO is a by-product of incomplete organic combustion and a persistent toxin of heme-containing species because of its strong binding affinity. Although CO reversibly binds hemoglobin, it does so at approximately 200 times the strength of oxygen, producing a functional anemia. Only a brief exposure is necessary to produce clinical symptoms (Fig. 31-4). A person exposed to

■ **FIGURE 31-4.** Measured blood levels of COHb after CO exposure. COHb accumulates rapidly after minimal exposure to CO. This effect becomes more pronounced with higher inspired concentrations of CO. (Modified from Stewart RD, et al.: *Rapid estimation of carboxyhemoglobin level in fire fighters*, JAMA 235:390-392, 1976.)

1% CO vapor attains measured carboxyhemoglobin (COHb) levels of 30% within 2 minutes. Severe CO poisoning may occur even without evidence of overt burn trauma, and delayed diagnosis contributes to significant morbidity and mortality after exposure (Cone et al., 2008; Stefanidou et al., 2008). The half-life of CO in a patient breathing room air approaches 200 minutes, but by applying 100% oxygen therapy this time can be reduced to approximately 40 minutes (Weaver et al., 2000). The clinician should always maintain a high index of suspicion for occult CO intoxication.

CO binding of hemoglobin and cytochrome P450 produces a leftward shift of the oxygen-hemoglobin dissociation curve and subsequently interferes with erythrocyte transport and oxygen use within the mitochondria (Fig. 31-5). CO-induced alterations of oxygen delivery and cellular usage have the greatest impact on those organ systems with the highest baseline oxygen requirements (i.e., the brain and heart). Ambient levels of 100 ppm are sufficient to produce acute neurologic symptoms (e.g., agitation, dizziness, lethargy, and seizures) in addition to chest pain, dyspnea, and noncardiogenic pulmonary edema. In animal models, CO has been observed to have direct myocardial depressant properties that are independent from the effects of global hypoxemia (Suner and Jay, 2008). The classically-described cherry-red appearance of patients with CO toxicity is rare and should actually be considered a late sign associated with high mortality (“when you’re cherry red, you’re dead”). Most patients have pallor that reflects the functional anemia previously described.

Standard peripheral oximetry overestimates oxygen saturation in the patient with acute CO intoxication and masks profound hypoxemia (Kao and Nañangas, 2004). Arterial sampling of P_{aO_2} is also misleading, because this technique quantifies plasma levels of dissolved oxygen rather than actual hemoglobin saturation. COHb may be assayed with blood samples

■ **FIGURE 31-5.** Leftward shift of hemoglobin dissociation curve. Accumulating levels of COHb interfere with normal oxygen transport and create a functional anemia with subsequent reduction of tissue oxygen delivery. (Modified from Fein A, et al.: *Pathophysiology and management of complications resulting from fire and the inhaled products of combustion: review of the literature*, Crit Care Med 8:94, 1980.)

or measured directly with a noninvasive cooximeter (Masimo Rad-57, Masimo Corporation; Irvine, Calif) that measures and compares multiple light wavelengths to identify COHb and methemoglobin levels (Suner and McMurdy, 2009).

Long-term sequelae may manifest as chronic headaches, memory disturbances, learning disabilities, and neuromotor dysfunction in as many as 10% of those patients who experience severe exposure (Ginsberg, 1985). Some studies suggest that CO induces brain-lipid peroxidation and leukocyte-mediated inflammation, which culminate in white matter demyelination or focal necrosis (Wang et al., 2009). Neuropsychiatric effects may appear days to weeks after the initial exposure, and although most patients eventually achieve complete clinical recovery, radiographic evidence of CO-induced changes persist for far longer.

Currently, it is difficult to determine the precise risk of long-term neurologic effects, although some clinicians have advocated the use of hyperbaric oxygen therapy (HBOT) to limit neuropsychiatric changes. There is conflicting evidence pertaining to the efficacy of HBOT, in part because the neurocognitive symptoms may be attributable to several factors other than CO exposure (Chou et al., 2000; Gilmer et al., 2002). The benefits of this treatment remain controversial, and HBOT is often impractical for those patients with severe comorbid injuries.

Cyanide Toxicity

Cyanide inactivates cytochrome oxidase and prevents mitochondrial oxidative phosphorylation, even in the presence of adequate oxygen; therefore, normal cellular aerobic metabolism is altered to an anaerobic state (Geller et al., 2006). Toxicity manifests as supranormal venous oxygen levels with a concurrent metabolic lactic acidosis that does not resolve with oxygen therapy. The patient displays many similar neurologic and cardiovascular symptoms as observed with CO poisoning, and in fact may require treatment for the toxic effects from both vapors. Treatment involves the administration of agents that scavenge intracellular cyanide and promote its conversion to nontoxic metabolites. Sodium thiosulfate donates a sulfur group to cyanide and increases its conversion rate to thiocyanate, which then undergoes renal elimination (Gracia and Shepard, 2004). Nitrites (e.g., amyl nitrite and sodium nitrite) induce methemoglobin, which then interacts with cyanide to release it from cytochrome-oxidase binding sites. Nitrites should be used with caution in children because concurrent methemoglobin and carboxyhemoglobinemias significantly reduce oxygen-carrying capacity (Fidkowski et al., 2009). Hydroxocobalamin combines with cyanide to form nontoxic cyanocobalamin (vitamin B₁₂), and this compound is excreted by the kidneys (Borron et al., 2007).

Additional Injury Mechanisms

Acute dermal necrosis from burn trauma is characterized by protein denaturation, loss of elasticity, and tense contractures of the dermal remnant. The rigid layer of eschar that accompanies circumferential full-thickness burns of the abdomen and thorax may severely restrict diaphragmatic movement and chest-wall expansion, quickly progressing to respiratory failure within the first hours after trauma (Quinby, 1972). Markedly elevated intraabdominal and intrathoracic pressures impair venous return, with subsequent reduction of cardiac output

(Demling, 1986). Compressive effects of circumferential burns involving the upper or lower extremities lead to neurovascular compromise and render the limbs nonviable. Abdominothoracic and extremity escharotomies are performed to relieve compartment syndromes and restore effective chest wall compliance and limb perfusion.

Cardiovascular Abnormalities

Pediatric burn patients experience profound changes in intravascular fluid dynamics and impairments of systemic organ perfusion. Hypotension is the result of volume deficits and low peripheral vascular resistance that lead to diminished measures of cardiac output, central venous pressure, and pulmonary artery occlusion pressure. Additionally, pediatric patients often experience varying degrees of the systemic inflammatory response syndrome (SIRS), a complex milieu of cytokines, chemokines, and proinflammatory mediators that alter capillary permeability, depress myocardial contractility, and impair the normal function of many other organ systems (Table 31-4).

The release of tumor necrosis factor- α (TNF α) from cardiac myocytes has been demonstrated to contribute to progressive cardiac contractile dysfunction in several models of trauma, thermal injury, and sepsis (Horton et al., 2004; Niederbichler et al., 2006). TNF α is a well-recognized inflammatory mediator that normally modulates the antimicrobial and metabolic response to tissue injury. In the context of burn trauma, this mediator recruits additional neurohumoral agents that exacerbate organ injury and initiate cellular apoptosis. Interleukins (IL-1 β , IL-6, and others) also possess negative inotropic effects and may act synergistically with TNF α to perpetuate postburn myocardial cardiac depression (Maass et al., 2002a, 2002b). Nuclear factor $\kappa\beta$ (NF $\kappa\beta$) is a transcription agent involved in the regulation of many of the cytokines and chemokines that contribute to the progression of SIRS. Burn trauma appears to activate myocardial NF $\kappa\beta$, which promotes the secretion of TNF α (Maass et al., 2002a). Prolonged hypotension that is resolved with volume replacement may result in reperfusion injury and the formation of oxidized free radicals and lipid peroxidation by-products. These agents exacerbate the tissue damage incurred during the low-flow state (Parihar et al., 2008). Free radical generation is accompanied by impaired antioxidant mechanisms and the up-regulation of inducible nitric oxide synthetase (iNOS). This cascade promotes peripheral vasodilation, enhanced NF $\kappa\beta$ release, and production of additional reactive tissue injury mediators such as peroxynitrite (Horton, 2003). Leukotrienes, platelet activation factor, thromboxane A₂, and complement are other factors that potentially modulate burn-induced inflammatory responses. Cellular oxidative stress is an important component of burn-mediated injury with a complex and extensive impact on organ function. Further studies are needed to fully describe the interactions of many neurohumoral mediators detected during the systemic burn response, and their appropriate manipulation may result in therapeutic benefits.

Burn shock is the clinical summation of intravascular fluid deficits and cellular ischemia that is initially characterized by decreased cardiac output, impaired contractility, and hypoperfusion of organ systems. Thermal injury also creates significant alterations in endothelial permeability, resulting in pronounced

TABLE 31-4. Systemic Effects of Thermal Injury

System	Early	Late
Cardiovascular	↓ CO caused by decreased circulating blood volume, myocardial depression (TNF α)	↑ CO caused by sepsis or hypermetabolism Hypertension

Modified from Szyfelbein SK, et al.: Burn injuries. In Coté CJ, et al., editors: *A practice of anesthesia for infants and children*, ed 2, Philadelphia, 1993, Saunders. TNF α , Tumor necrosis factor- α ; GFR, glomerular filtration rate; ICU, intensive care unit.

fluid translocation and generalized edema formation (Warden, 2002). Transcellular electrolyte shifts and the loss of circulating plasma proteins further impair tissue perfusion. Pediatric burn patients possess limited compensatory responses to systemic hypotension and vasoactive infusions (e.g., dopamine or norepinephrine) may be needed to supplement intravenous fluid administration to achieve adequate blood pressure and cardiac output. Resuscitation guidelines have evolved to become goal-oriented rather than formula-driven; current recommendations advocate periodic reassessment and adjustment of individual fluid requirements to restore organ perfusion and tissue oxygenation.

Survivors of the acute injury phase often develop a hyperdynamic circulation that is characterized by marked elevation of cardiac output and lowered peripheral vascular resistance. Hypertension has been observed with increased incidence in patients who have sustained more than 20% TBSA thermal injuries (Falkner et al., 1978). Elevations of plasma renin, aldosterone, and catecholamines have been noted. Untreated hypertension may manifest as seizures, encephalopathy, and ultimately, end-organ dysfunction in up to 7% of pediatric patients with severe burns (Popp et al., 1980). Although desirable, antihypertensive therapy may have adverse side effects

in this setting and should be guided by clinically relevant measures of systemic perfusion.

Renal Abnormalities

Acute renal dysfunction occurs in the context of hypoperfusion, intravascular depletion, myoglobin-induced tubular damage, and mechanical obstruction secondary to cast formation by the products of hemolysis (Aikawa et al., 1990). Hyperglycemia is a function of the stress response and may add to intravascular volume depletion by promoting an osmotic diuresis. Efforts to maintain urine output within a recommended range of 1 to 1.5 mL/kg per hour should be confirmed with serial urimeter measurements that demonstrate ongoing evidence of adequate fluid resuscitation. Tubular dysfunction in the form of altered responses to plasma renin and aldosterone may also contribute to renal derangements (Mariano et al., 2008).

Significant interpatient differences concerning the pharmacodynamics and pharmacokinetics of commonly used antibiotics have been reported (Weinbren, 1999; Kiser et al., 2006; Conil et al., 2007). Alterations of creatinine clearance and glomerular filtration rates impact drug-dosing schedules and

effective plasma concentrations, necessitating customized dosing regimens guided by serum plasma levels (Boucher et al., 1992). Antibiotics with nephrotoxic properties are likely to exacerbate renal dysfunction.

Perturbations of extracellular water and macromolecules affect electrolyte composition, and rapid changes of serum sodium, potassium, and calcium concentrations are associated with increased morbidity; serial monitoring and correction of these alterations is an essential component of acute burn management. Elevated levels of stress hormones (e.g., aldosterone, angiotensin, catecholamines, and plasma renin) also contribute to renal dysfunction observed in the early post-burn period. Patients with thermal injuries release elevated levels of atrial natriuretic peptide (ANP), which may mitigate the adverse effects of low-flow states by improving renal blood flow and urine output (Onuoha et al., 2000). Animal studies have shown intrarenal redistribution of blood flow with the preservation of inner cortical perfusion. Reductions in urinary chloride and sodium concentration reflect the increased perfusion of the juxtaglomerular nephrons that possess significant salt-retention capacity (Carter and Well, 1975).

Hepatic Abnormalities

Burn-related hepatic dysfunction is a significant contributor to morbidity and mortality. Hepatic blood flow is compromised in the early burn phase secondary to blood loss, large-volume fluid shifts, and compensatory vasoconstriction. The extent of hepatocellular derangement is also influenced by the onset of sepsis, toxic drug interactions, and the potential infectious risks of multiple blood product transfusions. Liver dysfunction is likely modulated by cytokines IL-1 β and TNF α , both of which are potent inflammatory mediators (Jeschke et al., 1999). Elevations of serum transaminases, reduced synthesis of constitutive proteins (e.g., albumin, transferrin, and retinol-binding protein), and focal hypertrophy are all clinical markers of evolving hepatic dysfunction (Jeschke et al., 2007a).

Restoration of hepatic blood flow precedes an extended phase of hypermetabolism and initiates a catabolic cascade with adverse systemic effects. Acute phase protein production occurs at the expense of albumin synthesis, and subsequent reductions of the protein binding capacity result in unpredictable drug plasma levels. The acute-phase process may continue for months, prolonging systemic organ dysfunction and delaying efforts to restore lean body mass (Jeschke et al., 2004). The duration and severity of hepatic dysfunction are variable and ultimately dependent on the ability to reconvert the patient's hepatic function to an anabolic state; this process requires successful wound closure, infection control, and adequate nutritional support.

Metabolic and Gastrointestinal Abnormalities

The severity of burn trauma correlates directly with the anticipated degree of inflammatory and hypermetabolic responses, and these physiologic derangements are associated with increased mortality for those patients who have experienced more than 60% TBSA burn (Jeschke et al., 2007b). Endogenous catecholamines and other stress hormones (e.g., glucagon and glucocorticoids) act synergistically to produce metabolic

changes that include a hyperdynamic circulation, sharply elevated basal energy expenditure, and the catabolism of skeletal muscle proteins. Additional clinical findings include refractory tachycardia, increased cardiac output and oxygen consumption, hyperpyrexia, and increased carbon dioxide production (Tredget and Yu, 1992).

The prolonged catabolic phase of thermal injury is also marked by accelerated gluconeogenesis, glucose intolerance, lipolysis, glycogen mobilization, and insulin resistance. Increased amino-acid oxidation causes urea formation and nitrogen loss. These processes manifest as delayed wound healing, muscle wasting, and long-term rehabilitative failure if they are not adequately treated. Recent experimental efforts have examined the pharmacologic attenuation of burn-related metabolic disturbances with the administration of exogenous β -adrenergic blockade, human growth hormone, insulin, synthetic testosterone analogues, and nutrient-specific enteral formulae to restore systemic anabolic balance (Herndon and Tompkins, 2004; Pereira and Herndon, 2005; Mayes et al., 2008; Jeschke et al., 2008).

Gastrointestinal ulceration is a common complication of extensive burns that can be prevented with the early administration of proton-pump inhibitors, H₂-receptor antagonists, and neutralizing agents such as sulcrafate. Acid prophylaxis is an important adjunctive therapy, because thermal injury is strongly associated with disruptions of the mucosal intestinal barrier. Severe burns induce enlargement of the mucosal gap junctions and are followed by bacterial translocation and systemic absorption of endotoxins; these two factors contribute to an increased risk of sepsis (Ziegler et al., 1988). Enteral feeding is superior to intravenous caloric administration as a means of preserving gastrointestinal motility and mucosal barrier integrity and reducing the incidence of enterogenic infection (Chen et al., 2007).

Hematologic Abnormalities

The immediate postburn period features a significant contraction of red blood cell mass secondary to destruction by heat-induced denaturation, lysis by circulating free radicals, and sequestration in the extravascular space. Hemoglobinuria (particularly after electrical injury) and the accumulation of cellular debris promote cast formation and impair renal function. Normal erythrocyte deformability may also be affected with a subsequent decrease in functional half-life and an increased risk of thrombosis (Schachar et al., 1974). During the acute phase, normal or supranormal hemoglobin measurements may represent hemoconcentration—an indirect indicator of inadequate resuscitation. After restoration of intravascular volume, anemia can persist despite elevated levels of erythropoietin; persistent bone marrow suppression is likely mediated by circulating inflammatory factors (Jelkmann et al., 1990). Repetitive excisional procedures, gastroduodenal ulceration, and phlebotomy are other important factors to consider during assessment of ongoing blood loss. Because of the limited circulating blood volumes of infants and small children, these may become disproportionately significant sources of anemia.

Platelet abnormalities initially manifest as thrombocytopenia secondary to platelet aggregation, microemboli consumption, and dilution secondary to large-volume fluid administration. A biphasic pattern is seen when thrombocytosis occurs 10 to

14 days postburn and continues for several months (Heideman, 1979). Qualitative platelet function may be altered after thermal injury, and clinical evidence of coagulopathy should be treated with platelet transfusions. Persistent thrombocytopenia in the immediate postburn period is associated with sepsis and is considered to be a poor prognostic indicator.

Elevations of factors V, VII, VIII, fibrinogen, and fibrinogen split products normally occur with burn trauma and indicate thrombotic and fibrinolytic pathway activity. Despite increased factor levels that may continue for months, there does not seem to be a higher incidence of hypercoagulable states (Simon et al., 1977). The response to extensive burn trauma may include disseminated intravascular coagulation (DIC); the clinical diagnosis is supported by thrombocytopenia, decreased fibrinogen, prothrombin time (PT)/partial thromboplastin time (PTT) prolongation, and elevated levels of fibrin split products. Underlying etiologies (e.g., sepsis, hypoxemia, and burn shock) need to be identified and aggressively treated using blood product transfusions as supportive therapy.

Neurologic Injury

Varying degrees of neurologic dysfunction may occur through multiple mechanisms, and the evaluation of these deficits remains particularly challenging in infants and young children. Direct nerve trauma from crush or electrical injuries and compartment syndromes often appear as peripheral neuropathies and profound sensorimotor loss. Neurologic dysfunction may also arise from the acute or delayed toxic effects of hypoxia, metabolic derangements, and potential drug interactions. Burn encephalopathy is a complex syndrome characterized by a variable course of delirium, hallucinations, seizure activity, coma, and behavioral changes that afflict as many as 1 in 7 pediatric burn patients (Antoon et al., 1972). One third of all pediatric burn patients are predisposed to acute stress disorders, and the incidence increases with burn severity (Stoddard et al., 2006). Additional neuropsychiatric disturbances may arise from the complex interactions of stress, anxiety, anticipated procedural pain, and generalized sleep deprivation that often occurs in the intensive care environment but remains underappreciated.

Children with severe burn injuries often become obtunded in the first hours after trauma as a result of rapid fluid shifts, side effects of analgesia, and stress-related exhaustion. CO intoxication must always be suspected and promptly treated; diagnostic delays may manifest as persistent neurologic deficits in the survivors (Meert et al., 1998). Occult brain trauma should be investigated with computerized axial tomography when the elicited patient history supports a mechanism of injury.

Increased intracranial pressure from cerebral edema may occur within 72 hours postinjury (Gueugniaud et al., 1997). Patients requiring massive volume resuscitation may be subject to electrolyte shifts that potentiate the risk of cerebral edema and subsequent seizure activity. Aggressive correction of iatrogenic hyponatremia results in central pontine demyelination (Cohen et al., 1991). Serial monitoring of electrolyte concentrations and correcting imbalances help avert undesirable consequences.

In addition to direct nerve trauma, metabolic derangements, and tissue hypoxia, peripheral neuropathies may evolve secondary to constrictive dressings complicated by progressive edema

(Dagum et al., 1993). Careful attention to patient positioning and periodic documentation of peripheral pulses by Doppler ultrasound helps detect vascular compromise.

The pediatric burn patient is exposed to varying degrees of polypharmacy during efforts to achieve clinically adequate sedation and analgesia, often through the use of supranormal doses of benzodiazepines, narcotics, and other drugs for extended periods. Burn-related derangements of hepatic and renal function alter the normal pharmacodynamics and kinetics of these agents and contribute to unpredictable plasma concentrations. The clinician should be aware that these agents may be associated with transient or sustained neurocognitive impairments observed in some pediatric burn patients. Several animal studies have identified the potential for premature apoptotic neurodegeneration with the use of drugs that interact with N-methyl-D-aspartate (NMDA) and γ -aminobutyric acid (GABA) receptors (Jevtovic-Todorovic et al., 2003; Young et al., 2005). Many of the anesthetic agents expected to be used throughout the conduct of pediatric burn procedures (e.g., midazolam and ketamine) act at one or both receptor sites and are implicated as potential sources for neuroapoptosis; there are data suggesting that some combinations of these agents may possess greater neurotoxic potency. No information is currently available to reliably identify the least harmful pharmacologic choice (Mellon et al., 2007) (see Chapter 7, Pharmacology).

Immunosuppression

The child with major burn trauma suffers from epithelial barrier loss and a dynamic proinflammatory cascade that creates a grossly immunocompromised state. Absence of the normal dermal functions is further complicated by the infectious potential of invasive monitoring devices and passive exposure to drug-resistant organisms (Weber et al., 1997). Bacterial translocation secondary to gastrointestinal-permeability changes increases the incidence of sepsis. Common inflammatory mediators have been demonstrated to impair neutrophil chemotaxis and cytotoxic activity (Church et al., 2006). Strict observance of sterile technique, early burn wound excision, restoration of dermal barriers, and targeted antibiotic administration are all important components to limit infectious complications.

PHARMACOLOGIC ALTERATIONS

Pediatric burn patients experience a spectrum of metabolic and organ-system derangements, with implications for the pharmacodynamics and kinetics of commonly-used anesthetic drugs. Significant interpatient variability observed with drug uptake and elimination necessitates the titration of all prescribed medications toward a desirable clinical endpoint, and each individual should be frequently reassessed for developing side effects. The more extensive the burn injury, the more pronounced this phenomenon (Martyn, 1986).

Intravascular depletion, transcompartmental fluid shifts, and blood-flow deficits in organs are factors that alter the distribution volume and clearance mechanisms of the drugs used throughout the acute burn admission. Major organ perfusion is preserved at the expense of blood flow to the gastrointestinal tract and extremity muscle groups and thereby renders oral and intramuscular administration routes of

uptake unreliable. Organ blood flow improves with the onset of the hypermetabolic phase, but it is not clear if there is a concurrent increase in the rate of drug metabolism (Wilmore et al., 1980; Aulick et al., 1981). Hepatic protein synthesis shifts from albumin to α_1 -acid glycoprotein during the hypermetabolic phase. Albumin binds acidic drugs (e.g., benzodiazepines), and a reduction of circulating protein levels increases the pharmacologically active fraction. Conversely, α_1 -acid glycoprotein provides competitive binding sites for basic drugs (e.g., muscle relaxants) and reduces muscle bioavailability (Martyn et al., 1984).

Neuromuscular Relaxants

Succinylcholine is normally an appropriate drug selection to facilitate rapid sequence inductions and establish a definitive airway; however, in the context of the acutely burned patient, the risk of a severe hyperkalemic response must be carefully considered (Tolmie et al., 1967; Gronert and Theye, 1975). Excessive succinylcholine-induced potassium efflux may be observed as early as 12 hours postinjury and can persist for up to 2 years (Gronert, 1999). It has been posited that extensive proliferation of acetylcholine receptors and multiple isoforms occur throughout the muscle membrane, even at sites distant from the original injury (Martyn et al., 2006). As large masses of extrajunctional tissues are depolarized, serum potassium levels rapidly increase to induce lethal cardiac arrhythmias. Some controversy remains concerning the onset and duration of receptor proliferation with the subsequent risk of hyperkalemic responses, but the availability of rapid-acting nondepolarizing alternatives (e.g., rocuronium) obviate the need for succinylcholine in acute burn management.

Resistance to a variety of nondepolarizing muscle relaxants (NDMRs) has been previously reported (Martyn et al., 1983a, 1983b; Mills and Martyn, 1989). Although there are notable distinctions concerning the pharmacokinetics and protein-binding capacities between patient cohorts with and without burns, these factors probably do not contribute significantly to observed clinical differences. Increases in receptor density are believed to be the predominant mechanism attributable to developing NDMR tolerance, and this effect correlates with burn severity (Martyn et al., 1982). Studies of vecuronium and rocuronium in adults with thermal injuries demonstrated the clinical effects of this resistance phenomenon; longer onset times and shorter recovery profiles were observed and attributed to decreased drug saturation of an enlarged receptor population (Fig. 31-6) (Mills and Martyn, 1989; Han et al., 2004). Burn patients generally require larger doses of NDMRs to produce clinically relevant responses for airway manipulation and surgical procedures (Table 31-5). The serum half-lives of the short- and intermediate-acting relaxants do not appear to be prolonged, and appropriate reversal of neuromuscular blockade is successful using the normal dosing ranges of neostigmine and glycopyrrolate (Martyn et al., 2006).

Analgesics

Effective pain management for pediatric burn patients is highly desirable but difficult to achieve consistently because of the varying intensities of pain associated with recurrent

débridement, dressing changes, and physical therapy occurring throughout treatment. Previously, insufficient analgesic administration was often because of unsupported but lingering reservations concerning the risk of addiction to potent narcotics (Perry and Heidrich, 1982). Additional confounders included patient- or family-held misconceptions concerning dependence and associated social stigma, clinicians' fear of potential litigation, and individual variations of nociception attributable to cultural differences. Frequent assessment with age-appropriate rating systems, education, and candid discussions about reasonable expectations for pain relief have largely eliminated opiate underuse.

In addition to their analgesic properties, opiates attenuate metabolic demands and help reduce the anxiety that is encountered during extended stays in an intensive care unit. Rapid-dose escalation is a consequence of thermal-injury-induced changes observed in protein binding, distribution volume, altered clearance, and hypermetabolism. Consequently, individual titration of opioid analgesic agents to appropriate clinical endpoints is a consistent and effective analgesic technique (as opposed to arbitrarily recommended dosing regimens) to making patients comfortable.

Morphine sulfate is widely used, and although its metabolism to active glucuronidated metabolites suggests a prolonged duration of action, this has not been substantiated (Furman et al., 1990; Perreault et al., 2001). Fentanyl is another common choice, and kinetics studies in adults have demonstrated increased distribution volumes and clearance; these changes have partially explained observed increases in opiate requirements (Han et al., 2007; Kaneda and Han, 2009). Agonist-antagonist drugs (e.g., nalbuphine) theoretically offer the advantage of analgesia without significant respiratory depression; when administered to adult patients for limited debridement procedures, results have compared favorably with morphine (Lee et al., 1989). Methadone has been used for patients who were unresponsive to other analgesics, but its duration of action may be variable in the context of burn-related drug kinetics (Concilus et al., 1989). Methadone also possesses weak NMDA antagonism and as such may be an appropriate drug selection to minimize opioid tolerance and pathologic hyperalgesia (the paradoxical sensitization to painful stimuli) (Callahan et al., 2004). With its ultrashort half-life (7 to 10 minutes), remifentanyl has no practical utility in the burn unit.

Tolerance develops in pediatric burn patients, but this fact should not preclude opioid administration. Addiction and the subsequent abuse of narcotics are rare when opiates are prescribed to achieve clinically appropriate endpoints (Porter and Jick, 1980; Goodman and McGrath, 1991). The supranormal dosing ranges commonly needed to provide effective analgesia in burn patients are the consequence of thermal-injury-induced quantitative and qualitative changes of receptor populations. After skin wound closure, opioid requirements rapidly decline. Undesirable withdrawal symptoms can be avoided by prescribing a gradual taper that parallels the decreasing frequency of procedures conducted during the acute injury phase (see Chapter 15, Pain Management).

Although opioid addiction has not been observed with regularity among the pediatric burn population, some animal studies cite potential adverse effects from exposure to high-dose narcotic regimens. Hyperalgesia has been observed in burn patients who have been the recipients of opiate-dose escalation, and this

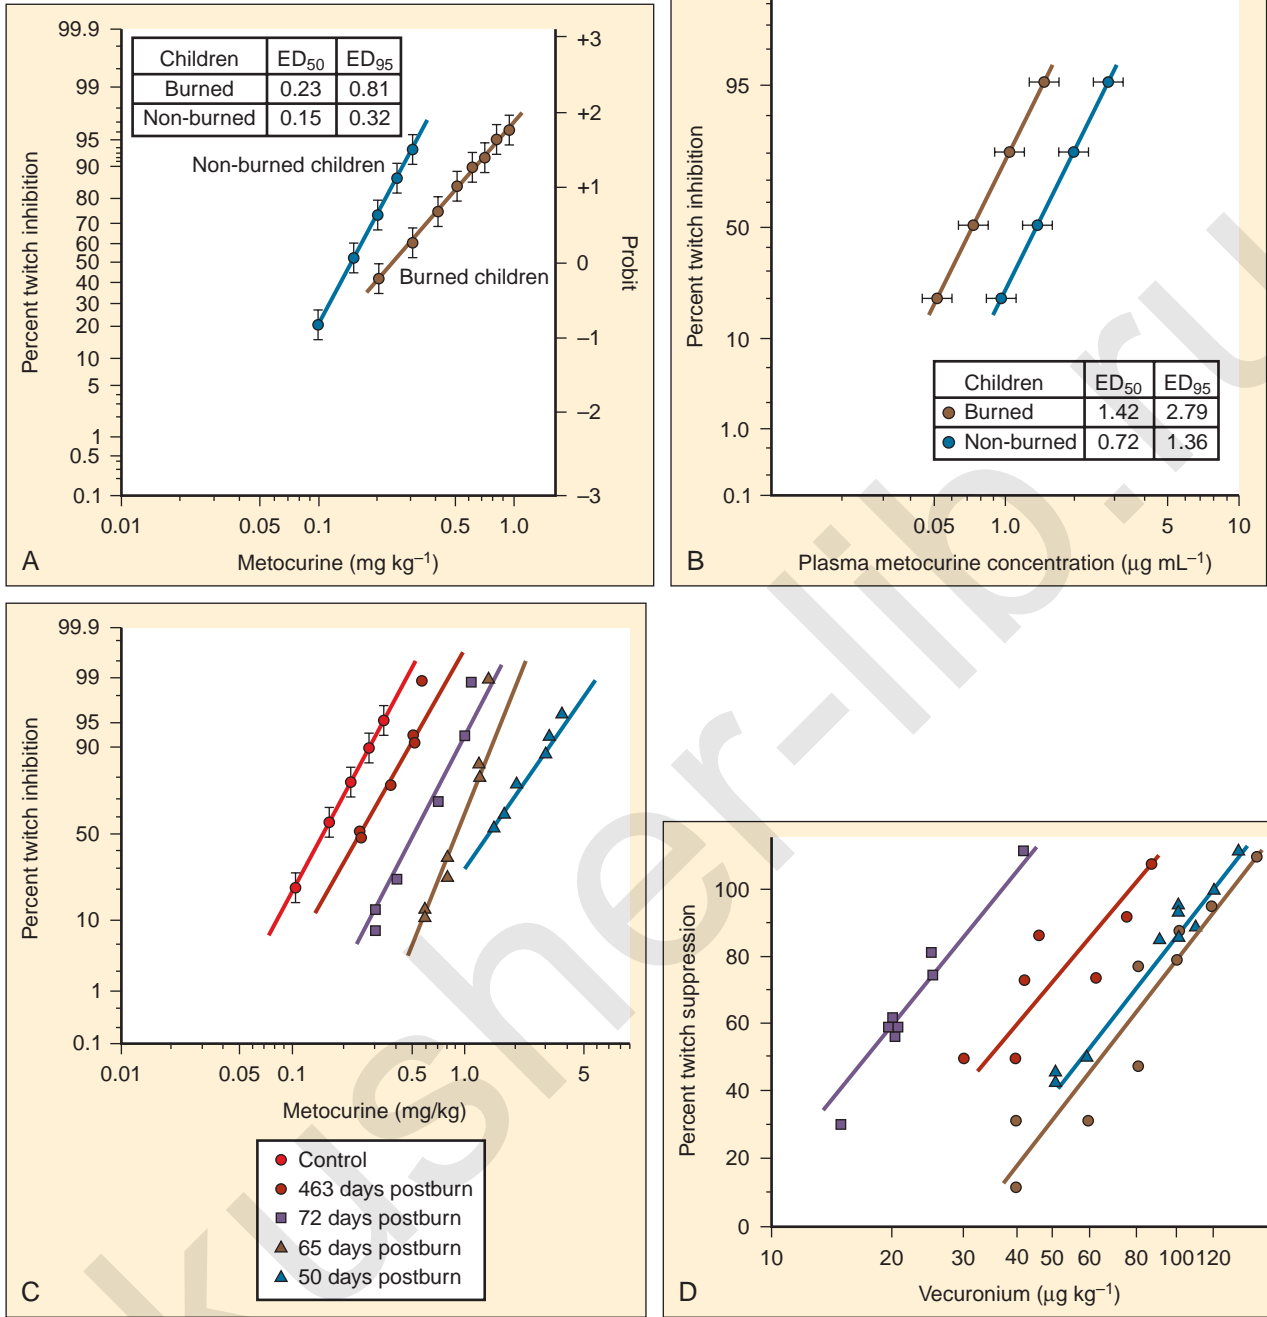

FIGURE 31-6. These four figures illustrate the neuromuscular effects of nondepolarizing agents in burn patients. Figures **A** and **B** show the increased dose requirement for metocurine on a mg/kg and plasma-concentration basis, respectively. Figure **C** demonstrates the effect of age of burn on neuromuscular blockade. Even after 1 year, patients with burns are still resistant to neuromuscular blocking agents. Figure **D** shows the effects of burn area on neuromuscular blockade resistance. Group 1 (purple square) is comprised of patients in a control group with burn injuries that occurred 3 years before the study. Group 2 (red circle) is made up of patients with less than 40% burn area. Group 3 (blue triangle) includes patients with 40% to 60% burn area, group 4 (brown circle) has patients with more than 60% burn area. (From Martyn JA, et al.: *Unprecedented resistance to neuromuscular locking effects of metocurine with persistence after complete recovery in a burned patient*, *Anesth Analg* 61:61, 1982; Martyn JA, et al.: *Metocurine requirements and plasma concentrations in burned paediatric patients*, *Br J Anaesth* 55:263, 1983; and Mills AK, Martyn JA: *Neuromuscular blockade with vecuronium in paediatric patients with burn injury*, *Br J Clin Pharmacol* 28:155, 1989.)

condition is thought to be secondary to neuroplastic changes in nociception pathways (Chu et al., 2008). Modulations of spinal receptors may produce hyperalgesic conditions secondary to inhibitory neuron apoptosis (Angst and Clark, 2006). Tolerance and opioid-induced hyperalgesia are clinically similar (both

show evidence of decreased analgesic efficacy) but the molecular mechanisms are distinct. Other studies have examined opioids and their contribution to postburn immunosuppression, possibly through cytokine modulation (Alexander et al., 2005; Schwacha et al., 2006).

TABLE 31-5. Emergency-Department Values of Vecuronium in Burn Patients and Control Patients

(% TBSA Burn)	Study Group	
	ED ₅₀ (mcg/kg)	ED ₉₅ (mcg/kg)
Controls	17.6 (15.4-19.9) [†]	35.3 (30.6-42.3)
<40	34.0* (29.3-38.7) [‡]	68.2* (59.8-79.9)
40-60	55.4* (48.1-62.1)	111.1* (99.8-126.2)
>60	64.5* (57.4-71.9)	129.4* (113.0-154.0)

Anxiolytics

Adequate sedation improves acceptance of prolonged mechanical ventilation, decreases narcotic requirements, and reduces anxiety associated with dressing changes or other bedside procedures. Benzodiazepine infusions are administered concurrently with opioids, and patient requirements are elevated in the presence of developing tolerance and altered pharmacokinetics. Daily background infusions up to 0.1 mg/kg per hour are typical for severely burned patients and may be titrated to desired clinical effect throughout the weaning period (Sheridan et al., 2001). Clinicians should be aware of potential side effects; in one pediatric study, neurocognitive and behavioral changes attributed to midazolam fully resolved with drug cessation (Sheridan et al., 1994).

Dexmedetomidine is an α_2 -agonist with analgesic, anxiolytic, and sedative properties that has been used successfully as a supplement for mechanically ventilated children with opiate and benzodiazepine resistance (Walker et al., 2006). It is insufficient for primary analgesia but offers minimal respiratory depression and reasonable hemodynamic stability. In contrast to other sedative agents, treatment with dexmedetomidine mimics a physiologic sleep state that may attenuate sleep-related disorders observed in the intensive-care environment. Hypotension and bradycardia are potential side-effects of dexmedetomidine, presumably mediated through unopposed vagal stimulation (Carroll et al., 2008).

Patients treated with protracted opiate and benzodiazepine infusions are required to metabolize several half-lives worth of drug. In this setting, it is often difficult to balance the need for clinically effective sedation with the desire for the prompt return of protective airway reflexes. Short-term infusions of propofol have been used in the hours preceding extubation, so that opiate and benzodiazepine administration may be adequately weaned (Sheridan et al., 2003). Extended infusions of propofol are not suitable for pediatric burn patients, because there is an ill-defined risk of refractory acidosis and myocardial depression specific to the lipid-based emulsion (Parke et al., 1992; Vasile et al., 2003). Additionally, bacterial contamination of a centrally-infused

sedative would be poorly tolerated in the setting of postburn immunosuppression (see Chapter 7, Pharmacology).

Ketamine

Some animal models that studied thermal injury have demonstrated an increase in NMDA receptors, which suggests that ketamine (a noncompetitive antagonist) may be a more effective analgesic than opioids for burn patients. Ketamine may also prove useful in reducing the incidence of opioid-induced hyperalgesia. Its analgesic potency is enhanced by several metabolites, the most active of which is norketamine (which possesses one third of the potency of ketamine). Used in combination with benzodiazepines, its half-life increases 20% to 30% (Reich and Silvay, 1980).

Ketamine produces a dose-dependent shift of the carbon dioxide response curve but unlike other hypnotic agents, does not alter the slope; hypercarbic respiratory drive remains intact at clinically relevant doses (Bourke et al., 1987). Preservation of spontaneous respiratory drive is complemented with a degree of hemodynamic stability secondary to centrally mediated sympathetic stimulation. However, in the hypovolemic burn patient who has exhausted the compensatory endogenous catecholamines, ketamine acts as a direct myocardial depressant (Owens et al., 2006). Dosing should be adjusted to avoid hemodynamic collapse in these patients or a vasoactive infusion (e.g., norepinephrine) can be used to provide a background level of sympathomimetic support.

Because concurrent benzodiazepine administration is so prevalent in burn patients, the unpleasant psychomimetic residua attributed to ketamine have not been clinically significant. Ketamine has been used as an adjunct for other drugs, and multiple delivery routes make it particularly suitable for those burn patients with behavioral difficulties or developmental delay (Allison and Smith, 1998; Heinrich et al., 2004; Tosun et al., 2008).

Volatile Agents

All of the common volatile agents have been successfully used for anesthetic maintenance in pediatric burn patients. Halothane is inexpensive and possesses some residual anesthetic effect, whereas sevoflurane promotes more rapid awakening and return of protective airway reflexes. Sevoflurane is an appropriate choice for inhalation induction, but its rapid taper may be associated with an increased incidence of emergence delirium (Kain et al., 2005). Patients with acute injuries and decompensated burn shock generally do not tolerate the vasodilation associated with potent volatile agents; concurrent vasoactive support may be needed. Pediatric burn patients with residual pulmonary injury and elevated metabolism demonstrate variable degrees of dead-space ventilation and elevated cardiac output that may alter the speed of inhalation inductions.

CONSIDERATIONS FOR INITIAL MANAGEMENT

After admission of the pediatric burn patient, there are three immediate goals that should be addressed simultaneously: the clinician should conduct a prompt airway assessment and

judge the perceived risk of impending compromise; the burn process should be arrested to prevent further tissue destruction; and burn shock and its treatment with volume resuscitation should be evaluated. A brief review of conditions at the scene and pertinent transport events is also prudent.

Airway

Supraglottic edema has the potential to evolve rapidly and severely reduce airway patency. Aspiration of scalding liquids or caustic agents may have a presentation similar to that of epiglottitis (Sheridan, 1996). A focused history should identify factors supporting possible inhalational injury; prolonged extrication from a confined space is consistent with increased risk (Box 31-2). Preexisting pulmonary disease and prior intubation attempts in the field by paramedic personnel should also be reviewed.

Fiberoptic bronchoscopy has been used to support the diagnosis of inhalation injury but should not supersede clinical judgment (Hunt et al., 1975). Arterial blood gas values and chest radiographs are often normal with initial presentation and may therefore provide false reassurance of patient stability. The absence of overt thermal injury does not preclude significant CO poisoning and 100% fraction of inspired oxygen (F_{iO_2}) should be empirically applied. Although it is not always possible to avoid the “lost airway scenario,” the clinician should be aware that the American Society of Anesthesiologists’ (ASA) difficult-airway algorithm has practical limitations when applied to pediatric burn patients. Fiberoptic intubation performed when the patient is awake is rarely feasible for injured children who are not profoundly sedated, and the presence of oropharyngeal debris or edema reduces the likelihood of success. See related video online at www.expertconsult.com. Small ketamine boluses titrated to maintain spontaneous ventilation provide a reasonable margin of safety over the protocolized administration of rapid-sequence hypnotics and muscle relaxants. Ketamine is thought to leave protective airway reflexes intact; however, this may not be the case depending on the level of sedation (Drummand, 1996; Peña and Krauss, 1999).

A semiselective surgical airway created early may be considered for facial burns, because ensuing edema alters anatomy and renders endotracheal tube stabilization difficult at best (Fig. 31-7) (Palmieri et al., 2002). Perceived advantages of early tracheostomy in the setting of prolonged mechanical ventilation remain controversial (Saffle et al., 2002). Laryngeal mask airways have been used as a bridging technique to definitive airway control, but direct injuries to the oral cavity and unpredictable

FIGURE 31-7. Full-thickness facial burn. The patient required autografts to produce biological wound closure. A tracheostomy provides improved safety during multiple surgical procedures and patient transports.

swelling may prevent an adequate seal and preclude delivery of sufficient tidal volumes. Progressive edema distorts facial and neck circumference, leading to inadvertent malposition or extubation; the endotracheal tube must be thoroughly stabilized (often using nonconventional methods such as dental anchoring with sutures or wire). Potentially catastrophic dislodgement may be minimized with frequent reassessments and secondary confirmation by chest radiographs.

Volume Resuscitation

Adequate intravenous access is problematic with extensive tissue destruction, and patients often require central venous catheters (femoral or subclavian) for extended periods. Intraosseous routes offer a safe and reliable alternative in the presence of severe injury and are suitable for large-volume infusions (Horton and Beamer, 2008) (see Chapter 30, Anesthesia for the Pediatric Trauma Patient). Bladder catheterization is performed to accurately quantitate urine output and continuously evaluate the efficacy of ongoing resuscitation.

Treatment of burn shock initially depends on weight-based calculations for crystalloid administration. There are several formulas in use, but none is ideal or suitable for every patient and should only provide guidelines; actual fluid volumes need to be based on the patient’s clinical response (Warden, 2002). The Parkland formula recommends 4mL/kg per percentage of burn over 24 hours, with half of the calculated volume delivered during the first 8 hours of treatment, followed by the projected balance over the remaining 16 hours. The Brooke formula uses a combination of crystalloid and colloid delivered over the same time period (Table 31-6). However, a recent adult study demonstrated that volume requirements based on accepted values of minimal hourly urine output were higher than those predicted by the either formula (Blumetti et al., 2008). The formulas are inadequate when calculating resuscitation requirements for children who weigh less than 10 kg. A suggested guideline for these patients is to administer the sum of normal hourly maintenance fluids and the volumes derived from the Parkland or Brooke formula over a 24-hour period (Graves et al., 1988).

Capillary permeability increases in patients with burns more than 20% TBSA, and the degree of change correlates with burn

Box 31-2 Indicators of Lower-Airway Injury*

Parkland	4.0	0	X% Burn
Brooke	1.5	0.45	X% Burn

Half of the calculated volume is administered in first 8 hours. The remainder is administered over the next 16 hours.

severity. Some centers advocate the use of colloids as the primary fluid choice during early resuscitation, because colloids offer improved intravascular retention and may decrease the total volume requirements while minimizing tissue edema (Sheridan, 2002). There has been no definitive demonstration of improved outcomes when isotonic crystalloid- and colloid-resuscitation regimens have been compared (Bowser-Wallace and Caldwell, 1986). Hypertonic saline has been proposed as an alternative choice for resuscitation fluids, but the outcomes data are unclear and there is a potential risk of iatrogenic hypernatremia (Huang et al., 1995; Junger et al., 1997). Normal vascular integrity is usually restored within 24 to 36 hours if resuscitation efforts are adequate.

Hypoglycemia may occur during the resuscitation of infants and children weighing less than 20 kg. Lactated Ringer's solution with 5% dextrose delivered at a maintenance rate helps preserve appropriate serum-glucose levels, but frequent monitoring is recommended during the first 24 hours after injury. Myoglobin and hemoglobin released from damaged tissues may impair renal function, and pigmented urine should be cleared with adequate intravenous fluids. Severely compromised individuals may require sodium bicarbonate or mannitol to avoid mechanical obstruction from cast formation.

Achieving clinometric targets consistent with normal organ perfusion (goal-oriented resuscitation) has proved superior to the fulfillment of rote volume algorithms, and this principle has been an important advance of modern burn care (Box 31-3). Urine output (1 to 1.5 mL/kg per hour) has been cited as an indicator of systemic normoperfusion, and the maintenance of target outputs often requires intravenous volumes that exceed the initial formulaic predictions (Yowler and Fratianne, 2000; Hoskins et al., 2006). Closed-loop and decision-assist algorithms have been introduced to manage infusion rates directed by desired levels of urinary flow and have the potential to reduce total volume requirements and minimize edema (Salinas et al., 2008). Despite these advances, there

is growing controversy concerning the suitability of accepted invasive monitors and clinical endpoints as valid indicators of adequate cellular perfusion (Ahrns, 2004). Further research is needed to refine monitoring strategies and identify physiologic markers that accurately reflect oxygen derangements and perfusion deficits.

Nutritional Supplementation

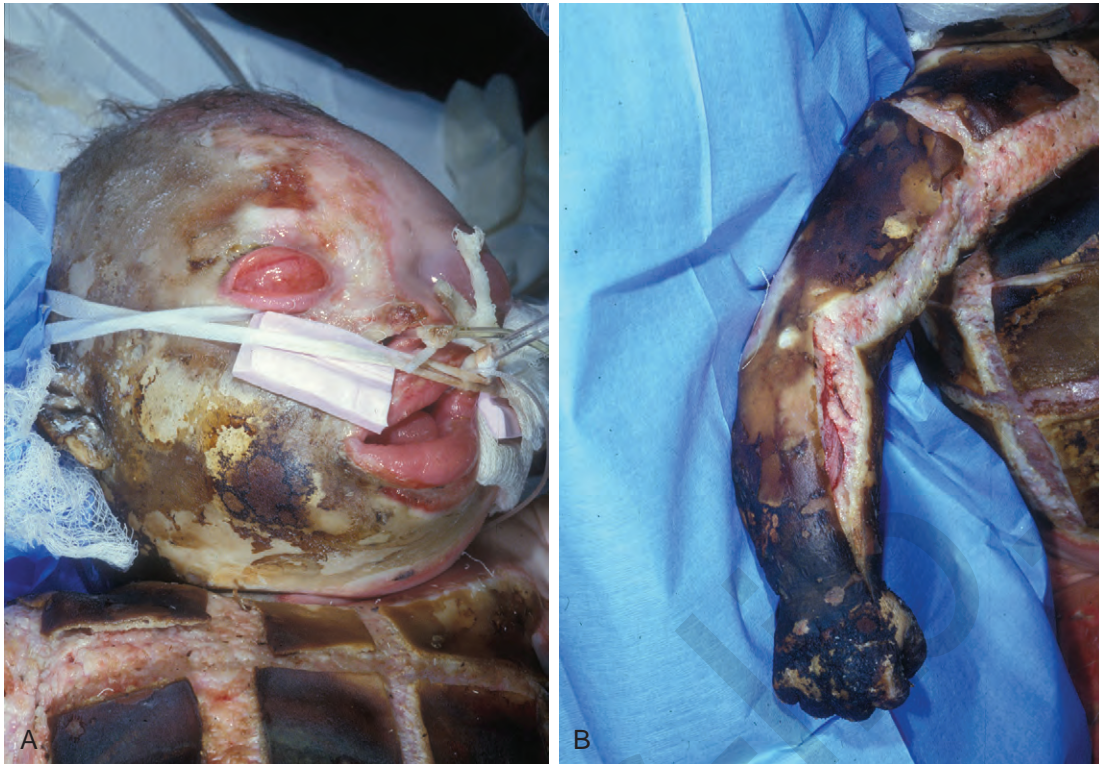

Early enteral feeding via a nasoduodenal tube provides caloric support and helps maintain the integrity of the intestinal mucosal barrier that restricts bacterial translocation (McDonald et al., 1991). These devices offer the opportunity for continuous feeding throughout surgical procedures without the risk of aspiration. Patients with extensive burns or inadequate volume replacement may not tolerate these feedings because of splanchnic hypoperfusion (Jenkins et al., 1994). Poor caloric replacement results in delayed wound healing, an increased risk of sepsis, and resistance to ventilator weaning from catabolic loss of lean body mass. Modulation of hormonal, adrenergic, and inflammatory mediators continues to be the focus of therapeutic research (Ipaktchi and Arbabi, 2006).

Surgical Excision

The goal of current surgical techniques is to remove necrotic debris and achieve biological wound closure. The early reestablishment of a physical barrier, which provides protection from bacteria, mechanical trauma, and insensible water loss, improves long-term outcomes even for those patients who have experienced significant thermal injury. Variable mesh sizes may expand harvested autograft coverage, but staged procedures are to be expected in patients with more than 50% TBSA as suitable donor sites are rapidly depleted. Split-thickness cadaveric allograft provides physiologic protection similar to native skin (Sheridan and Tompkins, 1999). A number of dermal analogs have been manufactured and used clinically. Integra (Integra Life Sciences; Plainboro, New Jersey) is a bovine-derived acellular dressing that promotes fibroblast migration and growth. Alloderm (LifeCell Corporation; The Woodlands, Texas) is an acellular collagen matrix procured from screened cadaveric donors. These dermal substitutes restore protective barriers and provide a structural framework for the rapid revascularization and fibroblast repopulation of the recipient sites (Sheridan, 2002). As wound healing progresses, temporary biological dressings are resurfaced with autograft. Physiologic closure is most advantageous when performed within the first 24 hours of injury to circumvent wound colonization and reduce the systemic inflammatory response.

Excisional procedures have been refined so that blood loss is minimized through the use of extremity tourniquets, subcutaneous deposition of diluted epinephrine, and controlled operative times. These operations are still associated with hemorrhage in the range of 3% to 5% of estimated blood volume for each 1% TBSA excised (Budny et al., 1993; Housinger et al., 1993). Intraoperative fluid selection and replacement should be guided by oxygen delivery needs and serial lab analysis.

Circumferential burns are notable for the inelastic eschar that can quickly induce neurovascular compromise, possibly leading to limb loss. Patients with thoracic-wall involvement

■ **FIGURE 31-8.** Escharotomies. The patient experienced more than 60% full-thickness burns and required escharotomies of the chest (**A**) and upper extremities (**B**) to relieve compartment syndrome and reduce neurovascular compromise.

develop a restrictive form of respiratory insufficiency. Extensive burns involving the trunk may be complicated by abdominal compartment syndrome, which has symptoms of diminished venous return, cardiac output, and urinary flow (Jensen et al., 2006). Escharotomies decompress these insults to restore perfusion (Fig. 31-8).

Concurrent Trauma

All pediatric patients should be evaluated as multitrauma victims because of the increased morbidity associated with missed injuries. Falling debris from destabilized structures and explosions associated with transmitted overpressure may complicate burn management with varying degrees of neurologic trauma, fractures, and internal hemorrhage. In older children and adolescents, there is also the possibility of alcohol or drug ingestion that adds further layers of complexity to treatment. A focused history and complete secondary survey help guide pertinent labwork, x-ray studies, and other diagnostics for treatment of concurrent injuries.

PERIOPERATIVE CONSIDERATIONS

After initial resuscitation efforts, the pediatric burn patient is likely to need repetitive excision and grafting procedures to achieve appropriate wound closure. Volume replacement continues throughout the conduct of serial operations and the usual physiologic insults associated with surgical trauma add to those resulting from thermal and traumatic injuries.

Preoperative Assessment

The clinician should assess the resuscitation efficacy by examining current trends of hemodynamics, urinary output, and use of vasoactive support. Airway evaluation includes the confirmation of endotracheal tube position and ventilator settings. Electrolyte balance, serial hematocrit, and arterial blood gas results should also be reviewed.

The proposed procedure is discussed with the burn surgeon to address anticipated blood and fluid requirements. Ideally, both the surgeon and anesthesiologist should agree on parameters for abbreviating the surgical plan if the patient's condition deteriorates unexpectedly. The parents also need to be briefed about potential surgical and anesthetic risks to establish informed consent.

Induction and Airway Management

The transfer of a patient to the operating room presents opportunities for inadvertent extubation, intravenous catheter displacement, hypothermia, and respiratory insufficiency after separation from the ventilator in the intensive care unit. Additional personnel need to be recruited for safely transporting multiple infusion sets, as well as providing assisted ventilation and uninterrupted hemodynamic monitoring. The patient must be kept warm, and it is advisable to continue adequate sedation during the transfer process.

Standard monitor application is often problematic with extensive burn injury and concurrent trauma. Noninvasive blood-pressure cuffs may not provide reliable data, necessitating

the placement of an arterial catheter. Oximetric signal degradation often occurs with poor peripheral perfusion; oximeters have been creatively applied to many locations (e.g., tongue, cheek wall, nose, and ear lobe) for improved signal capture. Redundant monitors in this setting are recommended, because surgical manipulation and patient repositioning further deteriorate signal transduction. Electrocardiogram pads may not adhere to burned tissue, and adequate lead contact may be accomplished with needle probes.

Performing the induction with the patient in the intensive-care bed is reasonable, because discomfort caused by transfer to the operating room table and positioning is common. Selection of the induction drug is based predominantly on hemodynamic status, and volume-repleted patients are likely to tolerate most intravenous induction agents. The suitability of ketamine for hemodynamically compromised individuals relates to its moderate sympathomimetic effect and preservation of cardiac output. Caution is warranted for select patients who already function at the limit of their sympathetic response; exogenous catecholamine support with epinephrine or norepinephrine may be required to avoid sudden cardiovascular decompensation.

Mechanical trauma and edema may sufficiently alter facial features to impair mask fit and assisted ventilation. Tight eschar restricts mandibular mobility and mouth opening despite effective muscle relaxation. Mask-seal maintenance may require the participation of a second anesthesia provider. In general, difficult airways should be anticipated for the first 24 to 48 hours, with alternative techniques and necessary equipment immediately available. The surgeon should be physically present to perform an emergent tracheostomy in the event of an unrecoverable airway. In rare circumstances, the use of extracorporeal membrane oxygenation has been used as the initial technique to maintain oxygenation in a patient who had surgery for delayed closure with gross neck deformity that was judged sufficient to preclude tracheostomy rescue (Sheridan et al., 2008). Primary tracheostomy might be considered in the presence of gross deformities of the face, neck or head, but there are risks of long-term sequelae (Palmieri et al., 2002).

Fiberoptic-assisted endotracheal intubation is the preferred method for securing a potentially difficult pediatric airway. Appropriate sedation and maintenance of spontaneous respirations may be accomplished by the judicious use of low-dose ketamine or dexmedetomidine infusion. Manual distraction of the tongue, jaw thrust, and antisialogue therapy improve conditions. The success of additional methods such as retrograde wire, light wand, and GlideScope video laryngoscopy (Verathon; Bothell, Washington) have been reported (Hsu et al., 2007, 2008). Some practitioners have advocated the use of laryngeal mask airways to avoid the potential trauma of repetitive intubations, but this method is impractical if an adequate seal cannot be maintained secondary to anatomic distortion (McCall et al., 1999). Laryngeal mask airways may also be used as an assist-device to facilitate fiberoptic intubation as previously described (see Chapter 12, Airway Management). All airway devices possess positive qualities and disadvantages, and the specific use of any technique should be guided by the anticipated needs of the patient and the clinician's experience.

Endotracheal tube stabilization is often difficult and must be tested repeatedly as the patient is repositioned throughout the procedure. Various tapes, staples, and wiring of the endotracheal tube to the teeth have all been successfully employed to

maintain a secure airway. If postoperative mechanical ventilation is anticipated, a nasotracheal tube offers stability, improved patient comfort, and the capacity to better deliver oral care.

Ventilator settings should mimic those delivered in the intensive care unit, with the stipulation that surgical manipulation and repositioning require repeated adjustment of ventilatory parameters. Noncompliant lung tissue and restricted thoracic-wall expansion dictate the delivery of elevated pressures and the application of positive end-expiratory pressure (PEEP) to provide adequate gas exchange. Cuffed endotracheal tubes, sometimes avoided in small children, ensure an effective subglottic seal for the transmission of adequate inspiratory pressures. As edema resolves, cuff inflation can be adjusted to maintain an appropriate air leak while preserving delivered tidal volumes. Periodic assessment of arterial blood gases is recommended, because the end-tidal carbon dioxide (EtCO₂) may not accurately reflect arterial carbon dioxide secondary to increased dead-space ventilation and shunt.

Maintenance of Anesthesia

Many techniques (e.g., nitrous oxide and oxygen [N₂O/O₂], total intravenous anesthesia [TIVA], volatile agents, and various combinations) have been used, and selection is often based on the patient's physiologic status and surgical procedure. Preoperative infusions should be continued in the operating theater, including caloric replacement delivered via nasoduodenal tube feeds. Opiate and benzodiazepine infusions can be supplemented with additional doses titrated to the level of clinical effect, and the provider should be aware of the generalized increase of these drug requirements. Antibiotic dosing schedules are often accelerated as a result of alterations of distribution volume and fluid loss. Resistance to NMDRs has been discussed previously; individual dosing regimens are adjusted according to monitored twitches.

The maintenance of normothermia is vital in the prevention of caloric wastage and coagulation defects during débridement. Increasing the ambient temperature and humidity is the most effective conservation method, although providers find prolonged exposure to these conditions to be personally uncomfortable. Wrapping exposed body segments in impermeable sleeves and other thermal barriers also reduces heat and evaporative losses, as does the incorporation of heated humidifier systems into the breathing circuit. All fluids and blood products should be delivered through heat-exchange devices. Forced-warm-air blankets have marginal utility because of the limited coverage of exposed body surfaces.

Hemostasis

Tangential excisions are invariably associated with hemorrhage, although the amount of blood loss during the procedure is difficult to quantitate, because blood is distributed among the drapes, table, and floor. Excisions of the face, neck, and head involve greater losses attributable to the increased vascularity of these areas. One study offered guidelines suggesting that 3% to 5% of estimated blood volume (EBV) will be lost for every 1% TBSA excised; increasing the precision of anticipated blood-volume loss may improve the efficiency of product ordering (Housinger et al., 1993). Where significant volume depletion

is expected, transfusion therapy should begin preoperatively to maintain adequate oxygen delivery. Despite the known inaccuracies involved with blood-loss estimates, some practical intraoperative recommendations have been forwarded; the surgical time should be limited to no more than 2 hours, with the planned excision restricted to 15% TBSA. The procedure should be aborted if blood loss exceeds 50% EBV (Engrav et al., 1983).

Transfusion volumes that exceed the calculated EBV often cause dilutional thrombocytopenia and coagulation factor loss. The avoidance of unnecessary blood-product administration is desirable for the pediatric burn patient and relates to issues of cost, infectious potential, and risks of transfusion complications. There is no substantiated “transfusion trigger” for the pediatric burn patient, but the maintenance of a hematocrit value of 27% to 30%, guided by periodic intraoperative measurement and hemodynamic trends, is likely to be prudent in the context of hypermetabolism and elevated oxygen consumption.

Multiple blood conservation techniques have been described and include the injection of a saline solution mixed with diluted epinephrine, epinephrine-soaked compressive wraps, topical sealants, extremity tourniquets, and preoperative acute normovolemic hemodilution (Gomez et al., 2001; Losee et al., 2005). The tumescent technique uses a solution (consisting of isotonic crystalloid with 1:100,000 epinephrine) that is subdermally injected to facilitate eschar débridement and donor-site harvest by creating a smooth, tense skin surface (Robertson et al., 2001). Blood loss from freshly debrided areas can be further reduced by the liberal application of fibrin sealants or thrombin sprays that promote hemostasis and graft adherence (Nervi et al., 2001; Foster, 2007). Few adverse affects have been noted.

Postoperative Pain Management

Significant pain is to be expected, and opiate and benzodiazepine infusions should be continued in the immediate postoperative period, with additional bolus doses of narcotics titrated to clinical response. Developing tolerance and elevated baseline drug requirements often confound pain assessments but need not delay monitored dose escalation (Abdi and Zhou, 2002). Pain tends to be most intense from freshly harvested donor sites. The tumescent solution may be supplemented with bupivacaine (2 to 2.5 mg/kg) or lidocaine (5 to 7 mg/kg) for locoregional analgesia (Jellish et al., 1999; Bussolin et al., 2003). Serum measurements of local anesthetic absorption have demonstrated that this technique is safe and effective. Intravenous lidocaine infusion has also been used to improve analgesia and may possibly modulate nociceptive pathways in burn patients (Cassuto and Tarnow, 2003). However, the experience with local anesthetic infusion is limited to case reports and has yet to be validated in well-designed clinical trials (Wasiak and Cleland, 2007).

CONSIDERATIONS FOR OTHER BURN INJURIES

Electrical Injury

Low voltage events (those less than or equal to 500 volts) typically occur in the residential setting and are associated with full-thickness burns at the point of contact (most commonly the hands and oral cavity of young children). The voltage is

■ **FIGURE 31-9.** Electrical burn. The patient experienced a contact burn with an exposed electrical wire across the dorsa of the toes.

insufficient to traverse large body segments, so that deep tissue damage is generally limited to the area demarcated by the contact burn (Fig. 31-9). These injuries can still present significant trauma and airway management challenges, such as when an unfortunate young child suffers bilateral oral commissure burns from biting into an electrical cord. New-onset cardiac conduction abnormalities have also been documented (Garcia et al., 1995). Low-voltage burns are treated using the same principles as previously described for the care of thermal injuries.

High-voltage events (of 1000 volts or more) are generally encountered in commercial or industrial environments and involve catastrophic neurovascular and skeletal muscle damage that follows the conductive path from its source to the ground. Several distinct forms of trauma occur with these events: plasma arcing and its associated flash create localized heat in excess of 2000° F that often ignites clothing; high-energy electrical transfer produces acute cardiac and neurologic injury; and loss of coordination and profound muscle spasm is associated with falls, potential fractures, or organ rupture. Energy that passes through the axis of the trunk and limbs affects muscle, nerves, and vasculature. Unlike the entrance and exit wounds that demarcate the path of current flow, these devastating internal injuries are not immediately apparent. Victims of high-voltage electrical exposure should therefore be evaluated as polytrauma patients because there can be such a variety of resulting systemic manifestations (Edlich et al., 2005).

Initial treatment is focused on airway support and the identification of cardiac conduction abnormalities. The risk of delayed and unpredictable cardiac arrhythmias increases when the presenting history supports transthoracic current propagation, tetany, loss of consciousness, and abnormal electrocardiography results from admission (Bailey et al., 2007). Early fasciotomy is often necessary to preserve the extremities, as myonecrosis causes severe edema with subsequent compartment syndrome. Myoglobin and hemoglobin are released in large quantities, and their precipitation as glomerular casts impairs renal function. Urine output should be maintained with fluids, sodium bicarbonate-induced alkalization, and osmotic diuretics. Global and focal neurologic dysfunction resulting from electrical exposure and its associated trauma is

variable and may continue to affect the patient throughout the rehabilitation course (Cherining, 2005).

Chemical Exposure

Caustic liquids continue to damage adjacent tissues until the offending agent is neutralized, and clinician safety may be compromised if these active residuals are not properly handled (Fig. 31-10). Before definitive treatment begins, decontamination requires the removal of the patient's clothing and copious irrigation of affected surfaces with warm water until the efficacy of rinsing is confirmed with litmus paper applied to the wound (Sheridan, 2002). Consultation with a poison-control center is warranted if there is a potential risk of systemic toxicity from chemical absorption. Many caustic agents are potent respiratory irritants, and concurrent inhalation injury should be considered and treated appropriately.

REHABILITATION AND RECONSTRUCTIVE PROCEDURES

The medical and technical advances of modern burn care have reduced mortality and improved expectations concerning long-term functional outcomes and cosmesis. Physical therapy is a key element in preventing debilitating contractures, which may begin to form in young patients within days after their injury. Passive range of motion, antideformity positioning, and the application of therapeutic splints are all necessary but uncomfortable techniques; an adequate level of sedation and analgesia is needed to facilitate patient and family participation.

Many pediatric burn patients return to the operating room over the course of several years to reduce hypertrophic scarring and reestablish function, particularly with injuries that encompass the major joints, hands, and face. Children may have contractures and scar distortions in anatomic locations that provide limited intravenous access options. Inhalation induction is commonly used to permit multiple intravenous

■ **FIGURE 31-10.** Chemical burn. The irregular, pitted appearance of this injury as a result of caustic lye exposure is characteristic of chemical burns. Early decontamination and treatment allow for limited injury progression.

attempts without discomfort, but intramuscular ketamine (and rectal methohexital for some small children) are also effective. Hypertrophic scarring of the face, neck, or head may present challenges to airway management and should be reviewed with the burn surgeon to plan appropriate alternatives in the event of sudden airway compromise.

Anxiety and fear are often problematic, because many children retain unpleasant memories of their admission and previous procedures. Parental participation during induction, the liberal use of comfort objects, and nontraditional methods of reducing patient anxiety (e.g., music and video games) have all been used to ease the transition from the holding area to the operating room. The choice of anesthetic is based on the patient's current physiologic status and residual cardiopulmonary dysfunction as well as procedural requirements. No single method is suitable for all circumstances, and the anesthesiologist needs to be sensitive to the patient's emotional and physical maturation, as well as to the patient's perception of the perioperative experience over time. Consideration of persistent psychosocial issues and the potential for increased analgesic requirements should be continued during emergence and recovery in the postanesthesia care unit.

SUMMARY

The applied principles of modern pediatric burn management have achieved an overall decline in morbidity and mortality accompanied by improvements in long-term functional outcomes and the assisted reintegration of the patient into their familial and social environments. However, treatment of the pediatric burn patient continues to test the skill set of the anesthesia provider and the multidisciplinary team. Initial management remains focused on targeted resuscitation, caloric replacement, and the delivery of effective anxiolysis and analgesia both in the intensive care unit and during a multitude of surgical excisions. There are continuing research efforts evaluating the pharmacologic mediation of the catabolic state and protracted inflammatory response. Although the acute burn phase requires an intense commitment to identify and address evolving physiologic derangements, the anesthesiologist is also challenged by the sequelae of the original injury as this unique patient population revisits the operating room over the course of several years.

ACKNOWLEDGMENTS

The author would like to thank Drs. John McCall and Carl Fischer for their previous contributions to this chapter. I would also like to express my gratitude to Sue Brogna of the Shriners Burn Hospital, Boston, for her patience and tireless assistance during the illustration-selection process for this edition.

Patient Spectrum	1030	Summary	1040

In light of the advances in health care, dental disease is still among the most prevalent of diseases, according to the Centers for Disease Control and Prevention (CDC). Although dental caries (tooth decay) is largely preventable, it remains the most common chronic disease of children aged 6 to 11 years, and of adolescents aged 12 to 19 years. Tooth decay is more common than many other common chronic diseases of childhood including asthma. It is four times more common than asthma among adolescents aged 14 to 17 years (CDC Division of Oral Health). Maternal nutritional and behavioral influences are very strong factors that propagate transmission of caries from the mother to her infant (American Academy of Pediatrics, 2003). The impact of caries is pervasive; poor nutrition may cause them or be the result of them. However, fluoridation of community water supplies, use of children's vitamins containing fluoride, and increased awareness of dental hygiene have produced a significant reduction in dental caries in the general population.

Despite advances in preventive dentistry, some conditions still require more than local anesthesia to facilitate dental treatment. General anesthesia may be required to treat children with severe systemic disease or disabling congenital anomalies, as well as infants and toddlers with milk-bottle caries who require partial or complete oral rehabilitation. General anesthesia may also be required for children and adolescents with severe developmental delay who require a safe and effective environment to render the necessary dental treatment. In addition, the fearful or combative child may require procedural sedation when behavior modification techniques have not succeeded. Proper care for these populations necessitates a care team approach, consisting of properly trained anesthesia and dental providers. A glossary of commonly used dental terms is shown in [Table 32-1](#).

HUMAN DENTITION

Dental Development

Initial calcification of the primary tooth buds may be seen in the fourth month of prenatal life. In general, by the end of the sixth prenatal month, all of the primary teeth have begun to develop. The newborn infant is edentulous, with the rare exception of a mandibular central incisor. This natal or neonatal tooth tends to be quite mobile, and in the past it was thought to require immediate extraction. Recent data suggest that by the end of the neonatal period, this mobile tooth becomes quite stable and capable of normal masticatory function. This is indeed fortunate for the infant, because these neonatal teeth are frequently the only primary teeth that develop in that position (King and Lee, 1989; Cunha et al., 2001).

The sequence of eruption of human teeth may critically affect infant feeding, behavioral, and masticatory skills. Major changes in the appearance of the dentition in the oral cavity probably alter important aspects of neurobehavioral development (Wright, 2000). As an example of eruption sequence alterations, premature infants and neonates requiring prolonged orotracheal intubation have significant defects in both oral and dental structures that may persist past age 5 years, even after removal of the orotracheal tube (Fadavi et al., 1992).

The order of appearance of the teeth in the oral cavity tends to follow generalized patterns ([Table 32-2](#)). Usually the teeth erupt in pairs. A mandibular right central incisor erupts at approximately the same time as the mandibular left central incisor, at approximately 6 to 7 months of age. The mandibular teeth usually precede their maxillary counterparts; the maxillary incisors erupt approximately 1 month later than the mandibular incisors. The eruption sequence continues and is usually complete

TABLE 32-1. Glossary of Common Dental Terms

Proper Name	Common Name or Definition
Abutment	Tooth or teeth on either side of an edentulous area supporting a bridge
Amalgam	Silver-coated restoration
Bicuspid	Premolar tooth (older term)
Bitewing	Dental radiograph that views several adjacent maxillary and mandibular teeth simultaneously; especially useful in evaluating dental caries
Bruxism	Involuntary tooth grinding
Burr	Drill bit used to prepare a tooth for caries restoration
Caries	Dental cavity or cavities
Composite	Tooth-colored restoration
Crown	Portion of the tooth seen in the mouth above the gum line; also, term used for the dental restoration of the same anatomic region; popularly known as a cap
Cuspid	Canine tooth (older term)
Diastemata	Separations between the teeth; commonly seen between the maxillary central incisors
Dry socket	Nonhealing extraction site
Endodontic therapy	Root canal therapy
Exfoliation	Spontaneous loss of a tooth
Exodontia	Dental extraction
Eye tooth	Canine tooth (familiar term)
Gingivitis	Inflammation of superficial aspects of the peridontium
Handpiece	Dental drill
Ludwig's angina	Dental infection of the floor of the mouth involving the submandibular, submaxillary, and submental spaces bilaterally
Milk tooth	Primary or baby tooth
Occlusion	Patient's "bite"
Oral prophylaxis	Dental cleaning
Overbite	Degree of vertical overlap of the maxillary teeth over the mandibular teeth
Overjet	Degree of horizontal projection of the maxillary teeth beyond the mandibular teeth
Periapical	Area surrounding the apex of the root; a periapical dental radiograph also includes the clinical crown of the tooth
Periodontium	Soft and hard tissues surrounding and supporting teeth
Pulpotomy	Therapeutic removal of the coronal portion of the dental pulp
Pyorrhea	Common name for periodontal inflammation, or gum disease; except for gingivitis, periodontal disease is rare in children
Rubber dam	Square latex or vinyl sheet used to isolate the teeth from the oral cavity during dental treatments

TABLE 32-2. Eruption Sequence of the Human Dentition

	Approximate Age Eruption Begins	Approximate Age Eruption Is Completed
Primary Dentition		
<i>Maxillary</i>		
Central incisor	7½ mo	1½ yr
Lateral incisor	9 mo	2 yr
Cuspid	18 mo	3¼ yr
First molar	14 mo	2½ yr
Second molar	24 mo	3 yr
<i>Mandibular</i>		
Central incisor	6 mo	1½ yr
Lateral incisor	7 mo	1½ yr
Cuspid	16 mo	3¼ yr
First molar	12 mo	2¼ yr
Second molar	20 mo	3 yr
Permanent Dentition		
<i>Maxillary</i>		
Central incisor	7–8 yr	10 yr
Lateral incisor	8–9 yr	11 yr
Cuspid	11–12 yr	13–15 yr
First bicuspid	10–11 yr	12–13 yr
Second bicuspid	10–12 yr	12–14 yr
First molar	6–7 yr	9–10 yr
Second molar	12–13 yr	14–16 yr
<i>Mandibular</i>		
Central incisor	6–7 yr	9 yr
Lateral incisor	7–8 yr	10 yr
Cuspid	9–10 yr	12–14 yr
First bicuspid	10–12 yr	12–13 yr
Second bicuspid	11–12 yr	13–14 yr
First molar	6–7 yr	9–10 yr
Second molar	11–13 yr	14–15 yr

From Schour I, Massler M: The development of the human dentition, *JADA* 28:1153, 1941. Reprinted by permission of ADA Publishing.

by age 2 to 2½ years. The last tooth to erupt is the deciduous second molar, called the 2-year molar because of its appearance at age 2 years.

When completed, the primary dentition totals 20 teeth (Wright, 2000). As the toddler's growth continues, the mandible and maxilla enlarge, causing separations, also known as diastemata, between the primary teeth (Zwemer, 1993). The diastemata increase as the primary teeth are beginning to exfoliate and the permanent or succedaneous teeth begin to erupt. The separations also permit sufficient room for the proper alignment of the permanent dentition.

The maintenance of the health and hygiene of the primary teeth is essential to avoid premature tooth loss. When

primary teeth are prematurely lost as a result of decay or trauma, the space needed for the permanent tooth eruption is also lost because the natural tendency of the tooth is to tip mesially (toward the midline) in the oral cavity. Subsequently, dental malocclusions tend to occur. Finally, the primary teeth may also function as the permanent teeth if the permanent analogous tooth fails to develop (Wright, 2000).

The transition period between exfoliation of the primary teeth and eruption of the permanent teeth is called the mixed-dentition phase. This phase continues until the last primary tooth is normally exfoliated or extracted. Unlike the primary teeth, the permanent teeth normally erupt so that there is tooth-to-tooth contact.

Development of the secondary, or permanent, dentition begins at birth with calcification of the buds of the permanent first molars. The permanent dentition begins its eruption pattern with the permanent first molar, usually at approximately 6 years of age. Like their primary counterparts, the mandibular teeth usually precede the maxillary teeth, with the permanent mandibular incisors beginning to appear at approximately age 6 to 7 years. Unlike the primary dentition, where there is usually a variability of several months in the timing of eruption, the permanent teeth may vary as much as 1 to 2 years in eruption sequence. After eruption of the permanent first molars, eruption of the remaining permanent teeth then occurs in this sequence: mandibular central incisors, maxillary central incisors, mandibular lateral incisors, maxillary lateral incisors, mandibular cuspids, maxillary and mandibular first premolars, maxillary and mandibular second premolars, maxillary cuspids, and mandibular and maxillary second molars (see Table 32-2). At the completion of the eruption sequence, the permanent dentition consists of 32 teeth (Wright, 2000).

The third molars, commonly known as wisdom teeth, have the least predictable eruption sequence of any of the human dentition. They may erupt as early as age 15 to 16 years, as late as age 25 years, or not at all. Quite commonly, the third molars fail to erupt because of dental germinal pattern alterations or impactions in the soft or hard tissues. Impactions usually occur because of insufficient bony growth of the maxilla or mandible in proportion to the individual's full dental complement.

In addition to the frequently absent third molars, two other permanent tooth forms are sometimes congenitally absent. The mandibular premolars and the maxillary lateral incisors may be congenitally absent, either singly or in symmetric pairs (Neville et al., 2002). Occasionally, a tooth that is thought to be congenitally absent is actually impacted in the soft tissues or alveolar bone.

Just as there are congenitally absent teeth, there are supernumerary or accessory teeth. The most common supernumerary tooth is the mesiodens, a conically shaped tooth consistently located in the midline between the maxillary central incisors. Other supernumerary teeth are the third premolars and fourth maxillary molars (Neville et al., 2002).

Identification of mobile primary versus transitional, or mixed, dentition can be of importance to anesthesia personnel. It is often recommended that mobile primary teeth be removed prior to airway instrumentation, as they may be at risk for dislodgment and airway obstruction. Likewise, it is important to note that newly erupted permanent teeth are often slightly mobile, with incomplete root formation. For this reason, extra care should be taken during laryngoscopy, oral airway

placement, or other jaw manipulation, as immature permanent teeth may be predisposed to luxation or avulsion trauma if too great a force is placed on them.

Dental Identification

There are two principal universal dental identification systems. In both systems, the primary teeth are designated by letters, and the permanent teeth are designated by numbers. These systems differ in the way that the dental arches (mandible and maxilla) are divided. The first system uses a sequential means for identification, with the primary maxillary right second molar designated as tooth A and followed sequentially around the contralateral side of the maxilla to the left second molar, which is tooth J. The primary mandibular left second molar is tooth K, and the sequence is completed on reaching the mandibular right second molar, tooth T. Similarly, the numbering system for the permanent dentition starts with the maxillary right third molar as tooth 1 and continues to the maxillary left third molar, tooth 16. The sequence continues with the mandibular left third molar, tooth 17, and is completed with the mandibular right third molar, tooth 32 (Herlich, 1990). Both pediatric and general dentists commonly use this system of tooth identification.

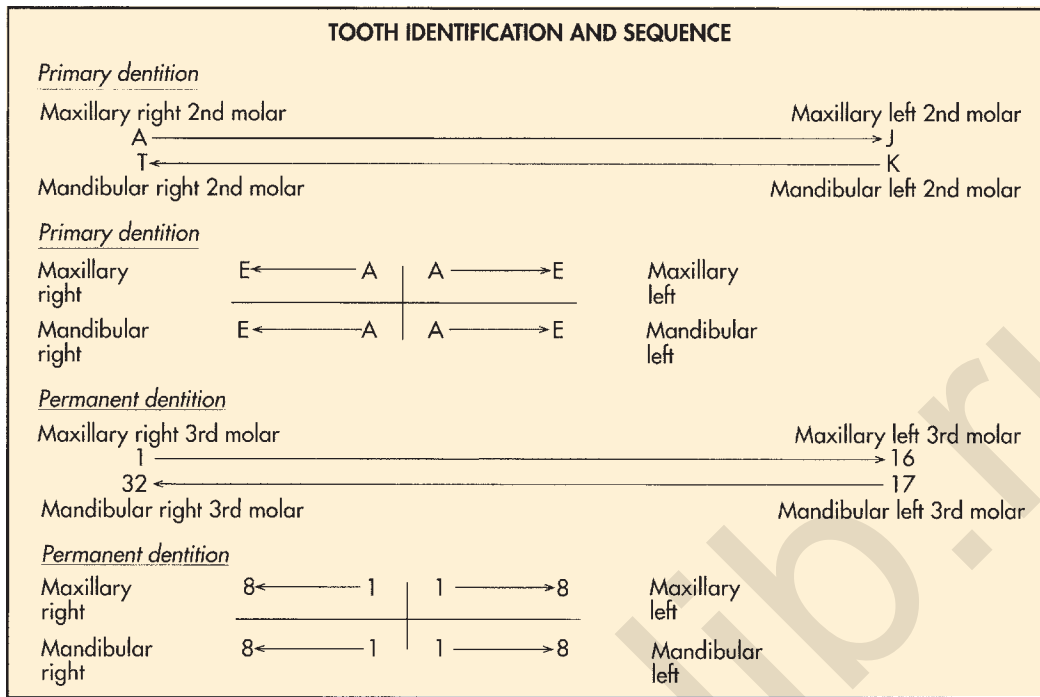

The second designation system divides the dental arch into quadrants. All primary central incisors are tooth A and follow distally or posteriorly, so that all primary second molars are tooth E. To make the designation more specific, the quadrant is also named. For example, the primary maxillary right lateral incisor is designated maxillary right B. Similarly, the permanent dentition is divided into quadrants. All central incisors are tooth 1 and continue posteriorly, so that all third molars are tooth 8. This system is most commonly used by orthodontists (Fig. 32-1).

Dental Anatomy and Physiology

The tooth is composed of a crown, which is usually visible for clinical examination, and a root, which is not seen during routine clinical examination. They are separated by the cemento-enamel junction or cervical region of the tooth (Fig. 32-2). The cemento-enamel junctions are seen more commonly in adult dentition if gingival ("gum") recession occurs. The crown is responsible for the slicing, ripping, and grinding of foodstuffs (incisors, canines, and molars, respectively). The root structure imparts stability to the tooth in its surrounding tissues. The anterior teeth, the incisors and the canines, are single rooted with a conical shape. The posterior teeth, the premolars and molars, are multirooted and impart most of their stability by both the number of roots and the subtly divergent directions in which the roots may grow.

Surrounding the root structure of the tooth is the periodontium, which is composed of three structures as follows:

- The most external portion is a combination of the gingival and alveolar mucosa, which constitute the soft tissue covering for the remainder of the periodontal structures.
- The periodontal ligament attaches the external surface of the root to the alveolar bone, acting as a shock absorber and anchor during masticatory function.

A

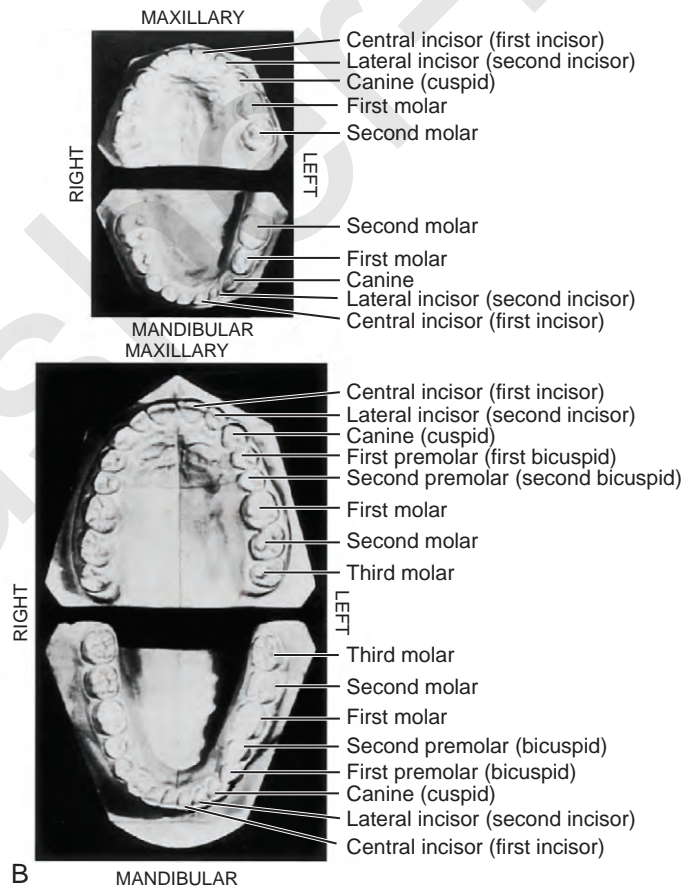

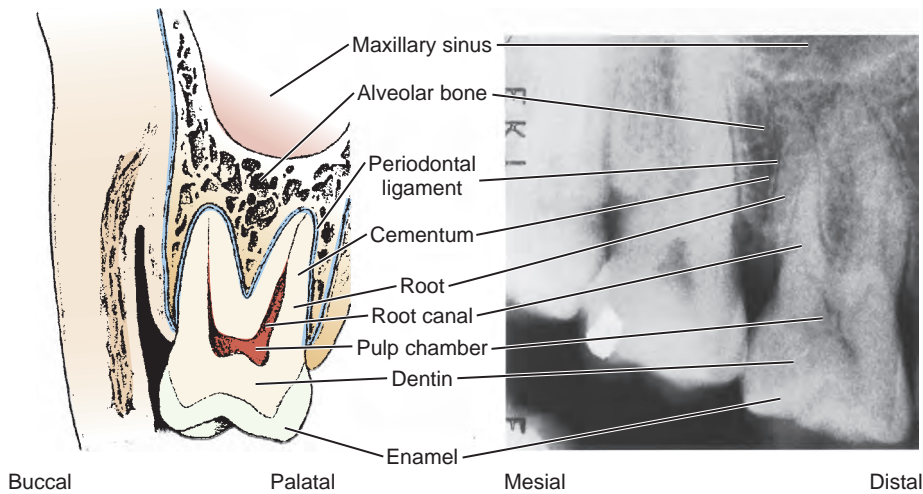

FIGURE 32-1. A, Tooth identification and sequence. **B,** Cast models of the primary dentition (upper) and permanent dentition (lower). (A, From Herlich A: *Dental complications of anesthesia*, Prog Anesthesiol 11:250, 1990. ■ **FIGURE 32-2.** Schematic (left) and radiographic (right) views of a right maxillary molar. (Modified with permission from Ash MM Jr, editor: Wheeler's dental anatomy, physiology, and occlusion, ed 7, Philadelphia, 1993, Saunders, p 6.)

- The bony component is called the alveolar bone or tooth socket. Beneath the alveolar bone rests the supporting basal or skeletal bone. Basal bone, the part seen in edentulous patients, forms the skeletal support for full or partial dentures. When the tooth structure is lost, alveolar bone is also lost and is not naturally regenerated.

The individual teeth are composed of enamel, dentin, dental pulp, and cementum (Wright, 2000) (see Fig. 32-2). The enamel covers the external surface of the dental crown. It is the hardest substance in the human body and, unlike bone, has no living cells. When intact, enamel functions as a thermal insulator and an impervious barrier to chemicals and microorganisms.

On the internal surface of the enamel lies the dentin. It is composed of microtubules and has living cells in the dentinal structure. When tooth decay is advanced, noxious stimuli are readily transmitted via the dentinal tubules to the underlying dental pulp. The neurovascular supply of the individual teeth is contained in the dental pulp. Pain is easily elicited by many different stimuli—thermal, tactile, or liquid. The pain is transmitted from the dental pulp through the root apices to the alveolar bone and subsequently to the body's pain receptors.

The final portion of the tooth structure is the dental cementum, which covers the external surface of the roots. Because it is not nearly as hard and impervious to the surroundings as is enamel, noxious stimuli are perceived when the cementum is exposed. The cementum is similar to the dentin of the tooth. Patients who enjoy good dental health usually do not have exposed cementum. However, with gingival and alveolar recession, root structure and its investing cementum may be exposed to the external environment.

Some morphologic differences exist between deciduous and succedaneous teeth. The most obvious difference exists in the size of the teeth in general. The deciduous teeth are significantly smaller than their permanent counterparts. With respect to the molars, the buccal-lingual dimensions are proportionately narrower. In contrast, the mesial-distal dimensions are proportionately larger.

Another difference between the sets of dentition rests in the color of the enamel. The primary teeth are milky white, or opalescent; hence, the name *milk teeth*. The permanent teeth, on the other hand, are significantly less “milky” because pigment absorption has occurred during their development or has been

acquired during the intraoral lifetime of the tooth (Wright, 2000). Two examples are tetracycline staining (developmental) and caffeine staining (acquired).

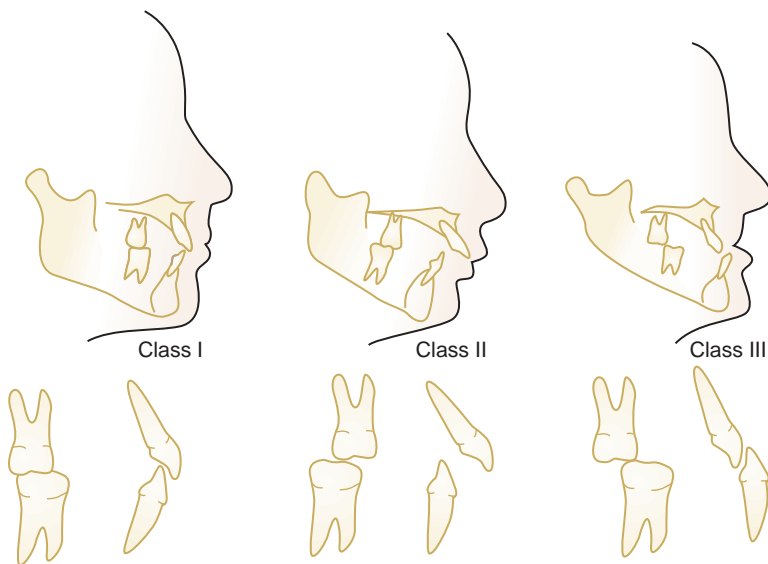

The pulp chambers of the primary teeth are larger than the permanent teeth because of the relative thinness of the deciduous enamel and dentin (Wright, 2000). Less than meticulous dental restorations or large carious lesions may predispose the primary teeth to pulpal or endodontic therapy earlier than their permanent counterparts.

The root structures of the primary molars are more saber shaped and extend laterally beyond the crown width. This unique root structure allows adequate room for the permanent tooth bud to develop and mature until the exfoliative process is completed for the primary tooth (Wright, 2000).

DENTAL PATHOPHYSIOLOGY

Despite declines in the overall caries rate of the general population, dental caries remains a common chronic disease of childhood. The high incidence is related to several risk factors, including consumption of fermentable carbohydrates (sugar-containing beverages), lack of adequate oral hygiene practices and fluoride exposure, and socioeconomic status. *Early childhood caries* specifically refers to severe caries involving multiple teeth in the preschool age group.

In the presence of fermentable carbohydrate, the metabolic by-products of microorganisms (particularly *Streptococcus mutans*) result in the acidic demineralization of enamel of the teeth. If the body's capacity for remineralization of the affected tooth is overwhelmed, a microscopic cavity will form in the surface of the enamel. Topical fluoride exposure in toothpaste is an important resource for remineralization of these initial lesions. If remineralization capacity is inadequate, the carious lesion will progress through the enamel into the dentin, or the inner layer of tooth structure. Further progression will involve the neurovascular bundle or pulp in the tooth. Bacterial contamination of the pulp will result in pulpal inflammation (toothache) or outright necrosis. An acute or chronic dental abscess may then develop. Localized signs of dental abscess include gingival edema, and pain during mastication or palpation. Treatment of dental abscess is accomplished with either endodontic therapy (root canal) or extraction of the tooth.

■ **FIGURE 32-3.** Angle classification system for malocclusion.

Treatment of dental caries is surgical. Using a burr, the carious portion of the tooth structure is removed. The tooth is then restored to form and function using an appropriate dental restorative material, such as amalgam (traditional silver filling material), composite resin (mixture of plastic and silicate particles), or stainless steel (for crowns).

Orthodontic Pathology

Teeth erupt into the alveolar processes of the maxilla and mandible and are held into bone by the periodontal membrane and gingival fibers. Together, the teeth and the jaws provide structure to the lower third of the face. In a normal bite, the maxilla and maxillary teeth are larger, which allows the maxillary arch to overlap the mandibular arch. *Occlusion* describes how maxillary and mandibular teeth fit together during chewing or at rest.

Malocclusion is the improper alignment of the teeth and jaws or bad bite. A skeletal malocclusion describes a malalignment between the jaws. A dental malocclusion describes the inter-arch relationship between the upper and lower teeth. A malocclusion may be caused by both hereditary and environmental factors. Crowding, spacing, supernumerary teeth, hypodontia, and asymmetric jaw growth are determined mostly by inheritance. Environmental factors such as thumb sucking, dental caries, premature loss of primary teeth, and trauma also can contribute to malocclusion (Mossey, 1999). An untreated malocclusion can lead to tooth decay, periodontal disease, abnormal wear of teeth, difficulty in chewing and speaking, and poor self-image.

Edward H. Angle, who is regarded as the father of orthodontics, developed a classification system for malocclusion based on the sagittal (anteroposterior) relationship of the teeth and jaws (Angle, 1899). Angle believed the upper first molars were critical to occlusion, and that the upper and lower molars should meet so that the mesiobuccal cusp of the upper molar contacts in the buccal groove of the lower molar. If this molar relationship existed and the teeth were arranged on a smoothly curving line of occlusion, then

normal occlusion would result (Fig. 32-3). Angle's classification system is as follows:

Class I: Malocclusion, in which jaws are aligned well, but teeth are crowded, rotated, or missing.

Class II: Overbite, in which the maxilla may be too large and protrude, or the lower jaw may be too small and retruded. The maxillary molar is anterior to the mandibular molar.

Class III: Underbite, in which the upper jaw is too small or the lower jaw is too large and protrudes. The maxillary molar is posterior to the mandibular molar.

Discrepancies in the vertical or transverse dimension can also contribute to a malocclusion. An openbite or deepbite describe how teeth fit together in the vertical dimension.

Whether orthodontic treatment should occur in one or two phases of treatment is a source of controversy. Phase I, or early orthodontic treatment, may correct a problem when the patient still has primary teeth or has a combination of primary and permanent teeth. Some practitioners believe it may keep more serious problems from developing, and it may make treatment at a later age shorter or less complicated. Typically, early treatment involves the use of materials and techniques to guide or modify growth as adult teeth are erupting (Kluemper et al., 2000)

Appliances used in early treatment may be removable or fixed (cemented). They may be made of metal, ceramic, or acrylic. Examples of appliances used to address transverse discrepancies include palatal expanders, quad helixes, and transpalatal arches (Fig. 32-4). Headgear therapy may be used to treat anteroposterior discrepancies (class II or class III malocclusions) and are composed of a removable and fixed component. A lower lingual holding arch is a banded appliance used to maintain space for the eruption of permanent teeth in the mandibular arch (Fig. 32-5). Functional appliances change the position of the lower jaw to produce movement of teeth and modification of growth. Examples of functional appliances include the Twin block, Herbst appliance (Fig. 32-6), and Bionator.

Phase II or active treatment involves placement of fixed appliances (braces) or Invisalign in the permanent dentition

■ **FIGURE 32-4.** Appliances used to address transverse discrepancies include bonded palatal expander (A), banded palatal expander (B), quad helix (C), and transpalatal arch (D).

■ **FIGURE 32-5.** A lower lingual holding arch.

■ **FIGURE 32-6.** Herbst appliance, used to change the position of the lower jaw.

(Boyd, 2008). Treatment times vary with several factors, including the severity of the problem being corrected, patient response to treatment, and patient compliance. Temporary anchorage devices (Fig. 32-7) are implants used to provide absolute anchorage and help move teeth (Cope, 2005). Patients use retainers to keep teeth in their new positions after treatment.

■ **FIGURE 32-7.** Temporary orthodontic anchorage devices.

■ **FIGURE 32-8.** Nasopalveolar molding.

Combined surgical orthodontic treatment is used to treat patients with severe malocclusions or craniofacial anomalies. Presurgical orthodontic treatment is used to prepare patients for surgery by removing dental compensations and upright teeth over basal bone (Proffit and Miguel, 1995). In a traditional orthognathic procedure, a surgical splint may be fabricated and wired to the patient's teeth. This splint may help the surgeon determine the final position of the jaws.

Nasopalveolar molding (NAM) is a presurgical orthopedic technique used to reduce the severity of the cleft deformity in infant patients with complete unilateral or bilateral cleft lip and palate (Grayson et al., 1999). The appliance is composed of a removable acrylic plate fabricated from an intraoral impression, and a nasal stent (Fig. 32-8). The amount of acrylic is sequentially reduced to decrease the separation between the greater and lesser alveolar segments. Once the gap between the alveolar segments is 5 mm or less, the nasal stent is added to mold the nasal cartilage. Lip or nasal repair occurs at 4 to 6 months of age. Patients with NAM can present for cleft lip surgery or ear, nose, and throat procedures such as myringotomy and tubes. The NAM appliance can be left in place during inhalation induction and mask ventilation, or it can be removed before the

beginning of induction. The device should be removed before airway instrumentation for a laryngeal mask airway (LMA) or endotracheal tube.

Facial Cellulitis

Bacterial abscess can spread from the apex of the root of the primary or permanent tooth into the surrounding alveolar bone and periosteum into deep tissue planes of the face or neck, resulting in an odontogenic facial cellulitis. Fever, dysphagia, leukocytosis, trismus, and dehydration are common physical findings. The lateral pharyngeal, retropharyngeal, masticator, buccal, submandibular, and submental spaces may be involved. Appropriate antibiotic therapy and prompt surgical drainage and extraction of the infected tooth are critical components of care.

Careful preoperative airway evaluation is critical in patients with facial cellulitis. Involvement of the masticator space or other anatomic spaces of the neck may threaten the airway. Ludwig's angina, with bilateral involvement of the submandibular space and with associated superior displacement of the tongue base can cause airway compromise.

PATIENT SPECTRUM

The population base of the pediatric dentist or pedodontist is generally composed of healthy children who are able to comprehend and follow simple directions by the pedodontists and their staff. However, pediatric dentists are trained (2 years or longer) to treat the following patient groups:

- Physically handicapped adolescents and adults
- Neonates, young infants, and toddlers too young to cooperate with routine dental care
- Fearful, unmanageable, or psychologically challenged children
- The entire spectrum of medically compromised children
- Children with dental problems in a hospital critical care unit
- Children with orofacial trauma
- Children requiring interceptive or minor orthodontic care

The physically handicapped patient most likely to appear for pedodontal treatment has athetoid cerebral palsy, postencephalitis syndrome, profound mental retardation, or autistic behavior (Dougherty et al., 2001; Shenkin et al., 2001; Waldman and Perlman, 2001). For example, patients with cerebral palsy may be wheelchair bound and have significant difficulty in controlling athetoid motion. The use of nitrous oxide, which depresses involuntary movement, may ensure a higher success rate in dental treatments for patients with cerebral palsy (Kaufman et al., 1991). The pedodontist is specially trained to deal with these problems in the kindest and most expedient methods available regardless of the clinical setting (Rosenstein, 1978; Pope and Curzon, 1991).

The pedodontist may be called on to fabricate a presurgical appliance for cleft lip and cleft palate in newborn infants. These presurgical appliances facilitate surgical closure of the palate. They also improve sucking and feeding in the cleft lip and palate patient. Toddlers who have circumoral burns from child abuse or domestic accidents may need an acrylic prosthesis to protect their circumoral tissues from shrinkage.

Emotionally impaired children or those who are too fearful to undergo routine treatment by a general dentist are frequently referred to the pediatric dentist who is both familiar with and comfortable in the treatment of such patients.

The pediatric dentist is routinely called on to treat the medically compromised child or adolescent when the general practitioner is reluctant to get involved in treatment. For example, the pediatric dentist primarily treats the child with congenital heart disease, the insulin-dependent diabetic, the patient with craniofacial anomalies, or the child with oncologic diseases in conjunction with the pediatrician or primary care physician. Both fear and lack of training may cause the general dentist to feel quite uncomfortable in treating the compromised child or adolescent. In addition, the general dental practitioner frequently lacks the physical resources, such as specialized equipment, to care for these patients. The pediatric dentist is usually quite comfortable in recommending and prescribing antibiotic prophylaxis for subacute bacterial endocarditis (SBE), for example, and keeps current with appropriate timing in dosage, effectiveness, and relative risks (Wahl, 1994; Hayes and Fasules, 2001; American Academy of Pediatric Dentistry, 2002e).

A few unfortunate children develop such severe illnesses or injuries that they require prolonged admissions in critical care units. These children also need dental care, which takes place at the bedside. For example, the child who has sustained significant head injuries may develop neuropathic chewing, which damages dental tissues (wearing down of teeth via grinding action) or soft tissues (tongue or cheek maceration). The pedodontist can fabricate an intraoral acrylic appliance to prevent further damage to oral tissues.

Finally, the pediatric dentist may be called to the emergency department of a hospital to treat orofacial trauma. This situation is more common in pediatric hospitals, where pediatric dental house officers are on 24-hour call with attending supervision. In general, in hospitals without specific pediatric dental services, the oral and maxillofacial surgeon handles pediatric dental trauma.

DENTIST'S NEEDS AND TECHNIQUES

The pediatric dental patient requiring anesthesiology services usually needs many dental procedures during a single anesthetic administration. The quality of dental restorations is probably improved under general anesthesia (Tate et al., 2002; Al-Eheideb and Herman, 2003). In addition, the parents of children who have had general anesthesia for pediatric dental care have greater satisfaction than parents of children who did not have general anesthesia (Acs et al., 2001). After induction of general anesthesia and protection of the airway, the anesthesiologist, the anesthesia machine, and the anesthesia equipment cart are positioned at either the patient's head or side.

The dentist's first step is to obtain necessary intraoral radiographs of the teeth (periapical, bitewing, and occlusal radiographs). The dentist then performs a clinical examination. After placement of a pharyngeal pack (which should be noted on the anesthesia record), dental impressions may be taken if future orthodontic treatment is anticipated. Also, the dentist usually places a rubber dam around the dental arch to be treated. Despite its name, the rubber dam is not usually latex. Nevertheless, if the patient is latex sensitive, care must be taken to ensure that

nonlatex products are being used. The rubber dam is held in place by a metal clamp that grasps the dental crown. A substantial length of dental floss or umbilical tape is tied around the clamp before its placement, to prevent inadvertent loss in the aerodigestive tract. Except for extractions and oral prophylaxis, the remainder of the treatment is performed with the rubber dam in place. Caries removal and tooth restoration take place with silver amalgam, tooth-colored composite, or preformed crowns. The rubber dam affords the dentist a dry environment in which the dental materials can cure optimally and achieve their greatest compressive and tensile strength. The rubber dam is also a barrier to protect the patient from iatrogenic dental trauma, including the accidental loss of dental materials or broken instruments and their possible entrance into the aerodigestive tract. The application of topical fluorides takes place after all of the restorative dentistry is completed with the rubber dam still in place (Mathewson and Primosch, 1995).

When severe malocclusion, facial skeleton dysmorphism, or tooth loss prevents rubber dam placement, the dentist still needs to maintain a dry intraoral environment. Injection of glycopyrrolate (0.005 to 0.01 mg/kg) or atropine (0.01 to 0.02 mg/kg) immediately after the placement of the intravenous cannula affords satisfactory intraoral conditions. The pedodontist places cotton rolls along the buccal and lingual or facial and palatal margins of the adjacent soft tissues to assist in the achievement of a dry oral cavity.

Pediatric dentistry may also encompass the need for oral and maxillofacial surgery. Oral and maxillofacial surgeons frequently perform these procedures after extensive training. Many oral and maxillofacial surgeons have dual dental and medical training, as well as fellowship training in head and neck surgery or plastic and reconstructive surgery. Because children may have craniofacial anomalies, including orofacial clefts, orthognathic problems, tumors, and blunt or penetrating trauma, such surgical management requires the ability to combine cosmesis, restoration of normal occlusion, and the promotion of normal growth and development of the entire facial skeleton (Kaban, 1993; Vig and Fields, 2000; Ord et al., 2002; Oza et al., 2002; Zeltser et al., 2003).

Clinical Settings for Pediatric Dentists

Most pediatric dental treatment occurs in the dental office without the need for psychological or pharmacologic intervention to address the child's fear and anxiety. The hallmark of dental pain management is a kind practitioner and staff and the responsible use of adequate local or topical anesthesia, or both. For some patients, simple behavior modification techniques improve the level of cooperation in the dental chair. These techniques include the tell-show-do method and voice control for the fearful, hostile, or disruptive child. The tell-show-do technique involves explaining before the procedure, demonstrating the procedure outside of the child's mouth, and then actually performing the procedure on the patient. This technique removes the fear of the unknown from the procedure (Lenchner and Wright, 1975). Voice control involves modulation of both the volume and tone of the dentist's voice to achieve positive behavioral results (Wilson, 1994; American Academy of Pediatric Dentistry, 2008). When behavior modification is deemed necessary for a preschool child, it should be scheduled during the morning, because the child's longest

attention span and optimal level of cooperation are early in the day. Additional techniques include positive reinforcement, distraction, and parental presence (American Academy of Pediatric Dentistry, 2008). Additional behavior modification techniques have been used by the dentist to physically restrain frightened children. This *protective stabilization* is the restriction of the patients' freedom of movement, with or without their permission, to decrease the risk of injury and to allow the safe completion of the treatment. Included in these techniques are passive physical restraint with a rigid board (papoose board), and active physical restraint by dental personnel. These techniques are controversial because of their potential psychological trauma and legal implications (Nathan, 1989; Wilson, 1994; Wright, 1994). Continuous monitoring of the patient is essential during protective stabilization.

Most analgesia for pediatric dental procedures is achieved by local anesthetic block. Most blocks are local infiltration in the maxillary region, or mandibular nerve blocks in the mandible. Adverse reactions to local anesthetics seldom occur when they are administered alone. Most commonly, they are related to a relative overdose or lapse in technique. However, even a low dosage, inappropriately injected, can cause palpitations, diaphoresis, or even dizziness (Kaufman et al., 2000). Rarely does vasomotor collapse occur. True allergic reactions, including allergy to metabisulfite or other preservatives of local anesthetics (e.g., paraaminobenzoic acid), are probably the smallest proportion of untoward reactions (Campbell et al., 2001).

Behavior modification may include such novel approaches as hypnosis or music therapy. Highly motivated, intelligent, attentive, or anxious children may have a good emotional and analgesic response to hypnosis when other forms of behavior modification, including pharmacologic forms, are precluded (Kleinhauz and Eli, 1993). Children as young as 3 to 4 years may be successfully hypnotized in the dental office (Lampshire, 1975). Music did not diminish pain, anxiety, or disruptive behavior in a recent study (Aitken et al., 2002), despite anecdotal beliefs of pediatric dentists and parents. Nevertheless, in this study, the patients enjoyed listening to the music and chose to listen to music in subsequent visits.

Electroanesthesia (transcutaneous electronic nerve stimulation [TENS]) has been used successfully for children in the dental office setting. TENS is reported to be effective based on several interrelated theories. These pain control theories include gate control, endorphin release, and serotonin release. For dental procedures, disposable electrode pads are placed bilaterally in the treated dental arch after drying the buccal mucosa. Using a dentally specific TENS device, a pulse rate of 110 Hz, and a pulse width of 225 microseconds in the normal mode, amplitude is slowly increased until the desired response is obtained. Twitching of the lower lip is the amplitude end point in the mandibular arch, and twitching of the orbicularis oculi is the amplitude end point in the maxillary arch. Children are instructed to raise a hand if the amplitude is too uncomfortable, and it is then diminished (te Duits et al., 1993). This technique works best in the area of restorative dentistry in the teeth that have relatively shallow lesions with respect to the dentoenamel junction (Quarnstrom, 1992; te Duits et al., 1993).

The spectrum of use of sedation is illustrated by the fact that medication, including nitrous oxide, is being used less than in previous years and studies. A study by Houpt (2002) suggests that, although more sedation is being used, it is being used by fewer practitioners on more patients in the United States.

A retrospective review of pediatric sedation management suggests that at one U.S. dental school pediatric dental clinic, nonpharmacologic behavioral management is favored more frequently because of its greater success (Eid, 2002). One British study estimated that more than 300,000 general anesthetics are still being administered for dentistry each year in Great Britain, mostly for children. The authors suggest that fewer general anesthetics are available for dentistry now than in the 1970s (Blayney et al., 1999). It is implied that most general anesthetics in Great Britain, however, as opposed to in the United States, are provided in a hospital setting.

Most pediatric dentists and those treating handicapped patients are experienced in the use of nitrous oxide and oral premedication when necessary in the dental office. The reported advantages of nitrous oxide delivered via a Goldman nasal mask include analgesia and sedation (Nathan et al., 1988). The incidence of diffusion hypoxia is minimal after the use of nitrous oxide and oxygen alone, as opposed to nitrous oxide supplementation to parenteral or oral sedatives (Quarnstrom et al., 1991; Dunn-Russell et al., 1993). Hypoxemia may occur when 30% to 50% nitrous oxide is added to chloral hydrate sedation (Litman et al., 1998b). In a recent study, nasal midazolam and nitrous oxide resulted in satisfactory sedation in 96% of the pediatric patients without any clinically relevant oxygen desaturation (Wood, 2010). However, in children with enlarged tonsils, oral midazolam (0.5 mg/kg) and 50% nitrous oxide resulted in significant upper airway obstruction and implied hypoxia (Litman et al., 1998a).

Patients classified by the American Society of Anesthesiologists (ASA) as having physical status I or II are appropriate candidates for treatment with pharmacologic adjuncts in the dental office setting. If a child's physical status is III or beyond, the hospital setting is probably a wiser choice. It must be emphasized that the pediatric dentist should use local anesthesia to optimize analgesia and anesthesia for the patient. Local anesthesia may add to the potential complications of polypharmacy if attention is not paid to dosages that are age and weight appropriate. This is especially true in the pediatric age group. The pediatric dentist rarely uses intramuscular or intravenous sedation while serving as both the operator and the practitioner administering the sedation.

The reports of severe adverse outcomes include hypoxic brain damage and occasional deaths, with the use of nitrous oxide, local anesthesia, and other premedicants. Anesthesiologists should have an active role in the training of pediatric dentists in techniques of anxiolysis and moderate sedation. Adverse outcomes will likely be diminished under these circumstances (Herlich, 2010; Costa et al., 2010). Invariably, these adverse outcomes result from relative or absolute overdosage of one or a combination of nitrous oxide, local anesthetic, and parenteral medication (Goodson and Moore, 1983; Doyle and Goepferd, 1989; Coté et al., 2000a). Because of the widely publicized adverse outcomes of dental office sedation and general anesthesia, the trend in this type of care has been to move away from the dental office unless guidelines for deep sedation and anesthesia by the American Academy of Pediatric Dentistry are followed. These guidelines were promulgated in 1985 and restated in 2006 to promote and ensure that the public is aware and the pediatric patient is protected. The guidelines describe that the anesthesia care provider must be a separate individual with appropriate licensing, credentialing, and training to perform deep sedation and general anesthesia.

In the United Kingdom, a group of investigators performed several retrospective analyses during the 1970s and 1980s.

Retrospective data obtained from a national data bank indicated that dental office deaths were infrequent, and the number decreased substantially in the second survey. The decreases in deaths probably result from two factors. First, fewer general anesthetics were being administered in the dental office. Second, the practice of the single individual being both dental practitioner and anesthetist is becoming less frequent because of warnings and suggestions from the General Dental Council of Great Britain. The anesthetist and dental practitioner are more commonly two individuals, each of whose attention is directed toward a single task. Also, the British survey indicated that the person providing anesthesia is more commonly a physician (Coplans and Curson, 1982, 1993). In the United States, closed claims morbidity and mortality involving oral surgeons show that during the period of 1988 to 1999, there were 22 deaths in the office and 136 anesthesia-related claims in total. It was calculated that the death rate was 1 in every 747,732 (0.013 in 10,000) administrations of anesthesia in the dental office (Deegan, 2001). D'Eramo and colleagues (2008) in a survey of oral maxillofacial surgeons in Massachusetts found the adult death rate to be 1 in 1,733,055 from office-based anesthesia. Data from the Pediatric Sedation Research Consortium indicated no mortality in over 49,000 propofol sedations, of which 307 were for dental procedures (Cravero et al., 2009).

In the United States, opposing forces create difficulties for the pediatric dental patient. Economic issues tend to restrict hospital-based procedures, including payment for the dental service only, without payment for the anesthesia service; payment for the anesthesia service only, without payment for the dental service; and frequently no payment or only partial payment for the hospital service. Frequently, the patient's family is faced with a significant out-of-pocket expense, which many cannot afford. On the other hand, the litigious nature of our society has prevented the rational expansion of anesthesia services in the office environment beyond sedation. Mandated equipment and monitors and the cost of liability insurance may be prohibitive for the office practitioner.

Another issue with significant economic ramifications is the cost of multiple treatments in the dental office with procedural sedation as opposed to a single session in the operating room of the hospital under general anesthesia. In studying healthy patients aged 24 to 60 months, Lee and colleagues (2001) found that a patient who required more than three treatment visits with procedural sedation had more cost-effective treatment when all of the treatments were provided in a single visit under general anesthesia.

A reasonable compromise may be a well-equipped hospital or surgicenter dental clinic with standard monitoring devices and resuscitation equipment. Pediatric patients with ASA status I or II may be suitable candidates. With the use of proper equipment and appropriately trained personnel, a large diversity of patients may be safely and satisfactorily treated on an outpatient basis. If the clinic is rationally designed, including recovery areas equipped with oxygen, suction apparatus, and essential monitoring devices, the anesthesiologist can safely administer the anesthetic outside of the traditional operating room setting. It allows more efficient use of time and space as well as reduced cost. From the perspective of the parent and child, outpatient treatment permits a more rapid return to familiar surroundings and activities of daily living (Zuckerberg, 1994). Only the patients with disease or physical conditions that preclude off-site clinical practice need to be treated in the operating room in

today's environment. Some examples of the patients who may need the traditional operating room setting include those with difficult airways, those with coagulopathies, and those with complex anomalies or cardiovascular disease for whom more than standard monitoring is necessary.

SEDATION AND ANESTHESIA FOR DENTAL PROCEDURES

The key to success in anesthetic management is a good patient history and physical examination. The parent or caregiver of the child should be able to relate relevant data such as previous anesthetic successes and failures. These anesthetic experiences should also be related for any family members. Birth history, growth, and development, including psychological issues and the child's emotional status, may be helpful in conducting a safe and pleasant dental experience. If the child has significant fears or behavioral problems that warrant premedication, the historical background permits the anesthesiologist to select an appropriate premedication agent.

The physical examination of the child must include the airway. Despite plans for nasotracheal intubation, the oral cavity must also be examined, because nasotracheal intubation may not be successful. Loose teeth, enlarged tonsils and adenoids, or herpes labialis all affect the anesthesiologist's management of the airway. Issues of nasal obstruction or sinus disease also have a great impact on the decision-making process for airway management. Cardiac murmurs should be investigated as to their relative seriousness. Most cardiac murmurs are in fact innocent flow murmurs; however, reasonable percentages are pathologic conditions and warrant prophylaxis for endocarditis. Other factors, such as coagulation status, neurologic history, and recent viral syndromes, may also affect the anesthesiologist's decision-making process.

Procedural Sedation

In 1985, The American Academy of Pediatric Dentistry established goals for sedation of the pediatric dental patient. These goals were updated in 2006 and are as follows:

1. To guard the patient's safety and welfare
2. To minimize physical discomfort and pain
3. To control anxiety, minimize psychological trauma, and maximize the potential for amnesia
4. To control behavior and/or movement so as to allow the safe completion of the procedure
5. To return the patient to a state in which safe discharge from medical supervision, as determined by recognized criteria, is possible

With these goals in mind, procedural sedation of the pediatric dental patient may be considered. The foundations of pharmacologic sedation for the pediatric dental patient are monitoring standards to which all practitioners should adhere (Wilson, 2000). Minimum or moderate procedural sedation intended in the sensitive patient may become deep sedation or general anesthesia if vigilance is not applied. These standards have been promulgated by several organizations, including the ASA (2002), The American Academy of Pediatric Dentistry and American Academy of Pediatrics (McGuire, 2007), and the American Academy of Pediatric Dentistry (2002d) (Consensus

Conference, National Institutes of Health, 1985; Rosenberg and Campbell, 1991; Council on Scientific Affairs, AMA, 1993). The American Academy of Pediatric Dentistry guidelines suggest that children who are status ASA III or IV should have treatment that necessitates sedation performed in a hospital environment.

The use of precordial/pulse oximetry for nitrous patients is not supported for nitrous oxide alone in the 2009 American Academy of Pediatric Dentistry Guidelines (American Academy of Pediatrics and American Academy of Pediatric Dentistry, 2006). Additionally, a full E-cylinder of oxygen and a self-inflating bag and mask capable of delivering 15 L/min of oxygen must be available in the care facility. An important monitor is a trained individual whose sole duty is to pay attention to the electronic and mechanical monitors in place and who is prepared to act on untoward events. As mentioned, the treating dentist should not be the person administering the anesthetic.

Before any sedation is administered, including nitrous oxide with oxygen, appropriate fasting guidelines must be given to the parents or guardians of the patient. Data suggest that prolonged fasts meant to reduce the likelihood of vomiting and aspiration are somewhat deleterious to patient outcome. Guidelines for fasting from solid foods, milk, and milk products remain at a minimum of 8 hours. However, clear liquids, including pulpless juices, plain gelatin, and ice popsicles, are encouraged and acceptable until 2 hours before the anticipated arrival in the care facility. The pediatric patient is more cooperative and the parents are more satisfied as a result of these suggested guidelines (Schreiner, 1994). All of these guidelines are predicated on normal gastrointestinal function. If the patient has abnormal gastrointestinal function, more conservative fasting orders must be considered.

Oral, intranasal or transoral, parenteral, and rectal routes for administration of sedative medications are used during procedural sedation. Pediatric dentists have traditionally and preferentially used the oral route to administer premedication (Primosch and Bender, 2001). The old practice of having the parents administer a prescribed oral medication at home has been fraught with danger to the toddler and young child. Airway obstruction and emesis with aspiration were real complications of that practice. For reasons of safety, the practice has changed. Children are now brought to the treatment facility or dental office 1 hour ahead of the scheduled procedure time, and the oral premedication is administered under the guidance of the pediatric dentist. Two of the most popular agents have been hydroxyzine (1 to 2 mg/kg) and chloral hydrate (50 to 75 mg/kg; maximal dosage, 2 g). These agents have had a good success rate and a reasonable margin of safety. In addition, nitrous oxide may be given in conjunction with the usual administration of local anesthetic blocks (Moore et al., 1984; Shapira et al., 1992). More potent oral agents, such as ketamine, diazepam, and midazolam, are also given in the treatment facility or dental office. The practitioner must allow a reasonable time for onset of action before dental treatment (Sullivan et al., 2001). Oral midazolam has gained widespread popularity because of its reasonable margin of safety in addition to its rapid onset for either premedication before general anesthesia or as the main agent for procedural sedation (Kupietzky and Houpt, 1993; Levine et al., 1993). These agents may be given alone or with another agent (Dallman et al., 2001; Bui et al., 2002; Nathan and Vargas, 2002).

Mild oxygen desaturation has been noted and is easily treated with supplemental oxygen and repositioning of the patient's

airway. In some cases, when nitrous oxide was added to the oral premedication, the degree of hypoxemia increased (Litman et al., 1998a). The use of traditional monitors such as clinical observation, blood pressure, and pulse was clearly insufficient to assess the degree of hypoxemia. Pulse oximetry, capnography, and precordial stethoscopes have become necessary to adequately assess and prevent poor outcomes despite limitations in the pediatric dental environment (Anderson and Vann, 1988; Poiset et al., 1990; Wilson, 1990; Dunn-Russell et al., 1993). The use of supplemental oxygen also helps to reduce hypoxemia. Novel means of improving oxygenation include the delivery of supplemental oxygen via the saliva injector and the use of external nasal dilators (Milnes, 2002; Moses and Lieberman, 2003).

Intranasal or transoral administration of water-soluble agents such as ketamine, midazolam, or sufentanil produces effective sedation and premedication for procedural sedation. However, sufentanil produces a significantly high incidence of respiratory depression, even in relatively small dosages (1.0 mcg/kg) and is not recommended (Abrams et al., 1993). Midazolam (0.5 mg/kg orally, or 0.2 to 0.3 mg/kg intranasally) is ideal for creating a milieu in which the child is easily separated from the parent. It also transforms a disruptive child into a quiescent child in the dental chair with minimal desaturation (Abrams et al., 1993; Levine et al., 1993). However, once the handpiece (dental drill) was activated, the noise distracted the child sufficiently that the pediatric dentist could not efficiently treat the child (Theroux et al., 1994). Despite the popularity of oral sedation, one group of investigators found that there was no relationship between oral sedation and behavior of the children in the dental office on subsequent visits (McComb et al., 2002).

The rectal route of administration for procedural sedation and premedication has enjoyed popularity with only a small number of practitioners. Midazolam (1.0 mg/kg or even higher dosages) has been used for procedural sedation and for premedication. Onset of action usually occurs within 15 to 30 minutes (Roelofse and Van der Bijl, 1991). The main drawback to rectal administration of these agents is the risk of expulsion of the sedative and the unreliable uptake from the distal colonic mucosa.

Many drugs have been used as parenteral agents for procedural sedation in pediatric dentistry. Opioids, benzodiazepines, antihistamines, ultra-short-acting barbiturates, and dissociatives have been used successfully. All have had some negative features as well. Short-acting agents with acceptable margins of safety in dental sedation include methohexital, meperidine, ketamine, diazepam, and midazolam. Respiratory depression and concomitant hypoxia have been the recurrent theme in parenteral sedation by pediatric dentists (Allen, 1992; Coté et al., 2000a, 2000b). As previously mentioned, clinical observation was insufficient and the airway was subsequently lost. Because of the fine line between moderate procedural sedation, deep sedation, and general anesthesia, the dentist and assistant who administer procedural sedation must be experienced in recognizing and handling cardiorespiratory depression. Electrocardiography, pulse oximetry, blood pressure, capnography, and precordial stethoscope are essential monitors (American Academy of Pediatrics and American Academy of Pediatric Dentistry, 2006).

Other drawbacks to intravenous sedation in pediatric dentistry have been the potential for inflicted pain to achieve intravenous access and the lack of familiarity with drug combinations on the part of the practitioner. The child's fear of

pain from a needle puncture has been successfully addressed by inhalation of nitrous oxide in oxygen or the transmucosal administration of midazolam. Use of EMLA (eutectic mixture of local anesthetics, 2.5% lidocaine, and 2.5% prilocaine) cream or topical (ELA-Max) lidocaine cream before venipuncture has been successful in reducing or eliminating needle puncture pain (Nilsson et al., 1994; Koh et al., 2004). Also, EMLA- and lidocaine-impregnated patches have been used intraorally with varying success before local anesthetic blocks and local procedures before the insertion of rubber dam clamps (Stecker et al., 2002). The main disadvantage of the use of the transdermal local anesthetics in EMLA cream is that it requires application at least 45 minutes to 1 hour before a painful procedure. ELA-Max is faster and requires approximately 30 minutes to take effect (Koh et al., 2004).

General Anesthesia

The American Academy of Pediatric Dentistry (2002d) has issued guidelines for the indications for general anesthesia for children having dental procedures (Box 32-1). Nunn et al. (1995) also described the indications for general anesthesia in 265 pediatric patients. These indications include extensive treatment needs, behavior management issues, medically compromised children, extreme anxiety, and physical disabilities. The most common indication, accounting for 30.6% of the anesthetics, was intellectual impairment and autism. Dental phobia accounted for 21.4% of the patients.

Behavioral issues are a very common indication for sedation or general anesthesia in children. The behavioral issues may stem from fear and anxiety or an abnormality in development such as autism, autism spectrum disorders, cerebral palsy with mental retardation, and Down syndrome.

Fear of dental procedures affects all ages. For some it may be so strong that dental visits are avoided altogether. In children, anxiety prior to a surgical or dental procedure centers on the fear of pain, loss of control, and separation from the parent or guardian. Preoperative anxiety and its risk factors are discussed in Chapter 8, Psychological Aspects of Pediatric Anesthesia, and Chapter 9, Preoperative Preparation. Children most at risk

Box 32-1 American Academy of Pediatric Dentistry Guidelines for the Elective Use of Sedation and General Anesthesia

- Patients who are unable to cooperate due to a lack of psychological or emotional maturity and/or mental, physical, or medical disability
- Patients who are extremely fearful, anxious, or non-communicative or in instances where it may protect the developing psyche.
- Patients who require significant surgical intervention or in instances where local anesthetic may be ineffective like an acute infection, anatomic variation, or allergy or patients needing immediate comprehensive care.

From the American Academy of Pediatric Dentistry: Guidelines for the elective use of conscious sedation, deep sedation and general anesthesia in pediatric dental patients, *Pediatr Dent* 24:74, 2002.

for heightened anxiety are between 1 and 5 years old and have divorced parents, previous negative medical experiences, and heightened emotionality (Kain et al, 2007).

Autism is an abnormality in neurodevelopment that results in abnormal social interactions and recurrent repetitive behavior. The diagnostic criteria include age of onset of less than 3 years old, severe abnormality of social reciprocity, severe abnormality of communication development, and restrictive, repetitive patterns of behavior and imagination (Klein and Nowak, 1998). The incidence of autism is increasing and is now estimated to be 1 to 2 per 1000 (Newschaffer et al., 2007). Autism spectrum disorders are a heterogeneous group of disorders that include autism, Asperger's syndrome, Rett syndrome, and Pervasive Developmental Disorder-Not Otherwise Specified (PDD-NOS). Children with autism and autism spectrum disorders can be uncooperative and often require behavioral interventions, sedation, or general anesthesia to complete a dental examination or procedure.

The child with significant medical disorders may require the assistance of an anesthesiologist during dental care. Some of these medical disorders may include the child with a known difficult airway, congenital cardiac disease, or multiple coexisting disorders. Children with cyanotic congenital heart disease may require SBE prophylaxis (Box 32-2). The appropriate antibiotic selection is summarized in Table 32-3. Patients with one of the cardiac conditions in Box 32-2 having dental procedures that manipulate the gingival tissue or periapical region of the teeth or perforate the oral mucosa require SBE prophylaxis. Procedures that do not require prophylaxis include routine anesthetic injections through noninfected tissue, taking dental radiographs, placement of removable prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth, and bleeding from trauma to the lips (Wilson et al., 2007).

Premedication

Patients presenting for general anesthesia often require a premedication to reduce anxiety and enhance cooperation.

Box 32-2 Indications for the Use of Subacute Bacterial Endocarditis Prophylaxis

- Presence of a prosthetic cardiac valve or prosthetic material for cardiac valve repair
- Previous infective endocarditis
- Congenital heart disease (CHD), including the following:
 - Unrepaired cyanotic CHD, including palliative shunts and conduits
 - Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure
 - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop cardiac valvulopathy

Adapted from the AHA SBE guidelines, 2007.

TABLE 32-3. Antibiotic for Subacute Bacterial Endocarditis (SBE) Prophylaxis

Indication	Agent	Single Dose 30 to 60 min before Procedure	
		Adults	Children
No contraindications	Amoxicillin (oral)	2 g	50 mg/kg
Unable to take oral medication	Ampicillin (IM or IV)	2 g	50 mg/kg
	OR cefazolin or ceftriaxone (IM or IV)	1 g	50 mg/kg
Allergic to penicillins or ampicillin	Cephalexin (oral)	2 g	50 mg/kg
	OR clindamycin (oral)	600 mg	20 mg/kg
	OR azithromycin or clarithromycin (oral)	500 mg	15 mg/kg
	Cefazolin or ceftriaxone (IM or IV)	1 g	50 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medication	OR clindamycin (IM or IV)	600 mg	20 mg/kg
	OR clindamycin (IM or IV)	600 mg	20 mg/kg

Adapted from the AHA SBE guidelines 2007, Table 4.
IM, Intramuscular; IV, intravenous.

Benzodiazepines are a very effective anxiolytic. Adults or adolescents can be given diazepam. In one study, patients with autism were sedated more effectively with midazolam (0.5 mg/kg) than with diazepam (0.3 mg/kg) (Pisalchaiyong et al., 2005). In younger children, midazolam can be administered orally in a commercially flavored liquid or the concentrated intravenous solution can be given intranasally. The recommended dosage for midazolam is 0.5 mg/kg and 0.2 mg/kg for oral and nasal administration, respectively (Davis et al, 1995; Kain et al, 2000). Buccal midazolam (0.2 mg/kg) was described for dental procedures but found not to be effective (Hosey et al., 2009). Ketamine can also be administered alone or in combination with midazolam. This combination is effective and provides both anxiolysis and analgesia. The dosage of oral ketamine is 3 to 10 mg/kg. When combined with oral midazolam, the dosage is typically 3 to 6 mg/kg. This combination has been described to be very effective in patients with developmental delay. In this case report, the authors suggest using a flavored soda such as Dr. Pepper to mask the bitter flavor of the medication (Shah et al., 2009).

Clonidine has also been described as a premedicant for anxiolysis for children prior to surgical procedures. There are some significant advantages. It has no bitter taste, it may provide some analgesia, and it may decrease the incidence of emergence agitation, and it may decrease postoperative nausea and vomiting. A significant disadvantage is its slow onset time (30 to 45 minutes) (Almenrader et al., 2007; Dahmani et al., 2010). α_2 -Agonists have been used in patients with autism, autism spectrum disorders, and attention deficit hyperactivity disorder (ADHD) and have been shown to have some benefit (Ming et al., 2008; Scahill, 2009). Clonidine may be an effective premedication for these patients when they present for dental procedures. The dosage of oral clonidine for sedation is 4 mcg/kg.

Induction and Maintenance

There is no standard anesthetic for children having dental procedures. Patients that require a general anesthetic require

medications that will allow them to remain motionless during repeated painful stimuli without feeling pain or having recall. This can be achieved with intravenous or inhalational anesthetics. The principles that guide the selection of anesthetics depend on the underlying medical disorders and the procedure being performed. In the United States, the traditional induction technique for general anesthesia in the pediatric age group has been inhalational anesthesia. The anesthesia mask is coated with a pleasant scent such as a fruit-scented lip balm. Sevoflurane, nitrous oxide, and oxygen is administered using high flows and concentrations while the anesthesiologist tells a story or employs another distraction technique. Intravenous induction techniques may include the use of a transdermal local anesthetic (ELA-Max), followed by the insertion of an intravenous cannula and subsequent administration of an appropriate intravenous agent, most commonly propofol or thiopental (Zuckerberg, 1994). Propofol can be mixed with lidocaine (1 mL of 1% lidocaine added to 9 mL of 1% propofol) to minimize local irritation and pain (see Chapter 13, Induction, Maintenance, and Recovery). Other, less commonly used techniques for the induction of general anesthesia include rectal administration of methohexital, thiopental, ketamine, or midazolam (Martone et al., 1991; Roelofse and Van der Bijl, 1991; Zuckerberg, 1994). The nasal or oral transmucosal administration of water-soluble agents such as ketamine or midazolam has also been used (Levine et al., 1993).

When all other attempts have been futile for a child with intellectual or emotional handicaps, an intramuscular injection of ketamine and glycopyrrolate with or without midazolam is used. These techniques should be attempted only with appropriate monitoring and when oxygen, self-inflating resuscitation bag, and suction are available.

Once general anesthesia is induced, intravenous access and the airway are secured. All monitors may be placed before or after induction of anesthesia, depending on the cooperation of the patient. When possible, the first monitors that are placed, regardless of the timing of their placement, should be pulse oximetry and a precordial stethoscope. Careful positioning, padding, and application of thermal conservation devices must be accomplished before beginning dental treatment (see Chapter 13, Induction, Maintenance, and Recovery).

Maintenance of anesthesia for the pediatric patient having dental surgery can be accomplished with either an inhalation technique or an intravenous technique. Sevoflurane is used very commonly as an inhaled anesthetic for outpatient anesthesia. Its use has been described in children having dental procedures. Desflurane is also commonly used for outpatient procedures because of its relatively low blood gas solubility. There does not appear to be a significant advantage of either of these agents over the other for ambulatory anesthesia in terms of clinically significant discharge times. A potential concern for desflurane is its effect on airway reactivity. Patients recovering from desflurane may experience more coughing than those receiving sevoflurane (White et al., 2009). This occurs because, unlike sevoflurane, desflurane increases airway resistance in children having anesthesia. Patients with bronchial hyperreactivity (asthma, upper respiratory tract infections, and bronchopulmonary dysplasia) may be particularly prone to the bronchospastic effects of desflurane and should probably avoid this agent (von Ungern-Sternberg et al., 2008). If an intravenous agent is chosen for maintenance, an ideal agent may be propofol. It has the advantage of a short duration

of action along with its antiemetic benefits (Coté, 1994). Remifentanyl is also an appropriate choice.

Studies have not demonstrated benefit of one anesthetic technique over another for dental procedures. König et al. (2009), in a double-blind study, compared a sevoflurane-based anesthetic with a propofol-based anesthetic and found no difference in emergence delirium or postoperative pain. However, there was significantly less postoperative nausea and vomiting in the propofol group. Children with autism may have increased propofol requirements when compared with other children with intellectual impairments. In a retrospective study, Asahi and others (2009) found that an increased amount of propofol was required to achieve adequate sedation in children with autism.

Postoperative pain management for children having dental surgery is best accomplished with a multimodal technique. Intraoperatively, the dentist can place dental nerve blocks prior to dental extractions. Nonsteroidal antiinflammatory agents such as ketorolac are very effective for dental pain. The pharmacology of ketorolac has been established in infants and children. A dosage of 0.5 mg/kg provides adequate analgesic plasma levels, and it is cleared at a faster rate in infants, even in those less than 6 months old, than in adults (Lynn et al., 2007; Zuppa et al., 2009). Analgesia may also be supplemented with morphine (0.05 to 0.10 mg/kg), or fentanyl (1 to 4 mcg/kg).

Airway Management

Management of the airway during general anesthesia for dentistry begins with mask ventilation. If the patient has a NAM device in place, it can be removed before initiating mask ventilation. If the device does not interfere with mask ventilation, it can be left in place until the airway is instrumented. Intubation for dental procedures is typically performed nasally to keep the mouth clear for the dentist or oral surgeon. During the preoperative examination, a history of epistaxis should be elicited, and the nares should be inspected for evidence or recent nosebleeds. A child who is old enough may be able to breath through the nares individually to determine which one is more patent. Despite these preoperative tests, epistaxis may still be a significant issue.

Preparation of the nasal cavity is essential to minimize the risk of bleeding and to optimize the laryngoscopic or fiberoptic view. Once the child has been anesthetized, a mucosal vasoconstrictor such as oxymetazoline (Afrin) is applied to the nasal mucosa in both nares. The dosage for the child between 2 to 5 years of age is 2 to 3 drops of a 0.025% solution in each nostril (Mcgee et al., 2009). Oxymetazoline can be administered as drops or it can be applied via nasal cottonoids. There is controversy regarding the use of topical vasoconstrictors. Some pediatric anesthesiologists choose not to use topical vasoconstrictors (phenylephrine or oxymetazoline) because of concern about cardiac complications (e.g., pulmonary edema and cardiac arrest) (Thrush, 1995; Groudine et al., 2000). Systemic absorption of the vasoconstrictor can result in profound systemic vasoconstriction and hypertension. Pulmonary edema occurs secondary to β -blockade treatment of the hypertension.

Before introduction of the nasal endotracheal tube, each naris should be assessed to determine which is the most patent. A lubricated nasal pharyngeal airway can be passed into each naris to accomplish this. The most effective way to determine the best anatomic route for nasal intubation is to fiberoptically

inspect each nares. Previously unidentified anatomic abnormalities are most likely to be found with this technique (Smith and Reid, 1999).

Other techniques to minimize bleeding during nasotracheal intubation in children include reducing the size of the endotracheal tube (ETT) by a half to a full size, warming it in warmed saline, and telescoping its end into a rubber catheter (Elwood et al., 2002; Watt et al., 2007). The incidence of bleeding appears to be reduced when the ETT is warmed in saline. The reduction in bleeding is even more pronounced when its tip is covered with a rubber catheter prior to introduction into the nares. In Watt's study, 56% of children who had a room temperature ETT placed had clinically significant bleeding. This was reduced to 39% if the ETT was exposed to warm saline, and it was reduced even further (to 5%) when the tube was telescoped with a rubber catheter. A final technique is to use an obturator, which can be an esophageal stethoscope (Seo et al., 2007), a suction catheter (Herlich et al., 1996), or a fiberoptic scope. Beside bleeding, complications of nasotracheal intubation include bacteremia, dislodgment of adenoidal tissue, and laceration of aerodigestive mucosa with subsequent false passage. Turbinate ulceration may also occur. Fiberoptic guidance of nasotracheal intubation may reduce some of the attendant comorbidities that the anesthesiologist may face (Herlich, 1991). Once the tip of the ETT is positioned in the posterior pharynx, it can be guided into the larynx with direct laryngoscopy or with a flexible fiberoptic scope.

Nasotracheal tubes need to be secured in a way that avoids alar pressure (Fig. 32-9). Prolonged alar pressure can result in tissue ischemia and loss. In addition, the eyes must be protected and the forehead padded.

Fiberoptic intubation may become the rule rather than the exception in patients with facial trauma (Kaban, 1993), mandibulofacial dysostosis (Treacher Collins syndrome), and other congenital craniofacial anomalies (Pierre Robin sequence, Goldenhar's syndrome). These patients frequently have palatal clefts and severe dental problems that require dental therapy and possibly orthognathic surgery (Gendelman and Herlich, 1993).

Patients with a history of recurrent epistaxis, recent nasal trauma, or recent head trauma should potentially not have a nasal intubation performed. In these patients, a straight ETT

■ **FIGURE 32-9.** One method of taping a nasotracheal tube. Note there is no alar pressure.

or an oral RAE tube can be used. A preformed orotracheal tube, such as the oral RAE tube, may be disadvantageous because it is designed to be a midline tube. Moving the preformed tube to either side of the mouth may cause an eccentric positioning in the trachea. An endobronchial intubation may create difficulties in ventilation. If orotracheal intubation is needed, a conventional ETT easily moves to either side of the mouth and oropharynx with the compensatory eccentric tracheal position of the tube. Another concern with moving an oral ETT from side to side is the increased risk of unintentional extubation. An oral tube also decreases the ability of the dental operator to place a rubber dam and complete the dental treatment efficiently. Suboptimal position and placement of dental instruments may also occur when an orotracheal tube is in place. A pharyngeal pack reduces the likelihood that blood and debris are introduced into the aerodigestive tract. Noting the times of insertion and pack removal from the pharynx on the anesthesia record reduces the risk of airway embarrassment postoperatively.

The armored version of the LMA, or flexible LMA, may be indicated for some pediatric dental patients who need dental care under general anesthesia. The advantages of the LMA are its ease of placement and tolerance in the spontaneously ventilating patient. Like an orotracheal tube, it has disadvantages, including its presence in the oral cavity, the interference with rubber dam placement, and its larger size in comparison with a standard orotracheal tube. With a skilled pediatric dentist performing restorative dentistry or surgical procedures, minimal hemorrhage may be seen on the LMA at the end of the procedure (Alexander, 1990; Webster et al., 1993).

Despite meticulous technique on the part of the pediatric dentist who is placing a rubber dam, dental materials may lodge in the oropharynx and subsequently enter the laryngotracheobronchial tree. Hence, a gentle but thorough cleaning and suctioning of the oropharynx before extubation are mandatory.

POSTOPERATIVE PROBLEMS

Most postoperative problems related to pediatric dentistry are common to many other surgical procedures. Postoperative pain, prolonged emergence difficulties with voiding and ambulation, and nausea and vomiting are all seen in pediatric dental patients. However, even after brief general anesthetics for dental procedures, significant hypoxemia may be encountered that is not relieved by administering supplemental oxygen alone. A British study demonstrated that experienced postanesthesia nursing after dental procedures was the most effective means of preventing and treating hypoxemia (Lanigan, 1992).

Postoperative pain may be obviated by the early intraoperative administration of analgesics such as morphine (0.05 to 0.1 mg/kg) or fentanyl (1 to 2 mcg/kg). In addition, an acetaminophen suppository (30 to 40 mg/kg), given shortly before the end of the procedure, confers additional analgesia with minimal side effects. Oral acetaminophen (10 to 15 mg/kg) may be even more effective if given preoperatively (Yaster et al., 1994).

Postoperative nausea and vomiting have numerous causes in the pediatric dental population. A common cause is swallowed blood. Once intraoral bleeding has ceased, the nausea and vomiting from this cause usually abate. Opioid use and abdominal distention caused by bag-mask ventilation with upper airway obstruction or with excessive pressure may also produce postoperative nausea and vomiting. Nitrous oxide is a controversial

cause of postoperative nausea and vomiting. A cause of emesis or nausea unique to dentistry is the inadvertent ingestion of intraoperatively administered topical fluorides to reduce dental caries (Mathewson and Primosch, 1995).

With prolonged postoperative nausea and vomiting, increased hydration and antiemetics may be administered with their attendant caveats, including bladder distention, extrapyramidal effects, and prolonged sedation (Herlich et al., 1996). Ondansetron (100 to 150 mcg/kg) is effective at lessening the severity of postoperative nausea and vomiting when administered prophylactically. Dexamethasone (0.1 to 0.2 mg/kg, up to a maximum of 10 mg) is another highly effective medication for the prevention and treatment of postoperative nausea and vomiting, especially in conjunction with ondansetron (see Chapter 13, Induction, Maintenance, and Recovery). Moderate dose metoclopramide (0.5 mg/kg) has been described prophylactically in children having tonsillectomies, but it is less effective than ondansetron (0.1 mg/kg) (Bolton et al., 2007). If the emesis is severe enough to warrant admission to the hospital for control and rehydration, the pediatric dentist requires the services of a primary care physician (presumably a pediatrician) to assume the overall management of the pediatric dental patient. Fluid and electrolyte management, as well as general patient welfare issues, may be beyond the scope and comfort level of the pediatric dentist. Patients with refractory vomiting requiring admission should have their serum sodium measured to look for hyponatremia.

Some postoperative problems appear more frequently among patients who have had dental rehabilitation, surgical removal of impacted teeth, or other surgical lesions. Postoperative hyperpyrexia seems to occur with greater frequency in patients in whom intraoral dental procedures have been performed. One group investigated preschool-age children to ascertain the etiology of such febrile states. In a randomized fashion, some children were given oral antibiotics 1 hour before their procedure. All children received general anesthesia with nasotracheal intubation and subsequent packing of the oropharynx to reduce the incidence of aspiration of gastric contents and blood. Ventilation was controlled to reduce the likelihood of atelectasis as a cause of postoperative temperature elevation. Intravenous fluid therapy was administered to both groups to reduce the contribution of dehydration as a cause of postoperative temperature elevation. The two groups were found to have equal rates of significant postoperative temperature elevation. The authors suggested that other perioperative etiologies should be investigated, including anesthetic effects on temperature regulation during dental procedures (Holan et al., 1993). There may be certain dentally induced pyrogens, or an antibiotic with a broader spectrum may be needed to cover the organism causing the hyperpyrexia.

Nasotracheal intubation, as previously described, is the preferred method of airway protection. However, transient postoperative epistaxis is not uncommon in patients with boggy turbinates, traumatic intubation or extubation, or relatively stenotic nares (Herlich et al., 1996). Usually, direct pressure adequately treats the problem. Rarely, vasoconstrictors and intranasal packing are needed to treat the epistaxis.

Other sequelae of traumatic intubations or extubations, such as croup or generalized laryngeal edema, may need to be treated with intravenous dexamethasone (0.4 mg/kg) immediately after a traumatic or oversized intubation, and possible vasoconstrictors such as racemic epinephrine may be used after extubation.

Postobstruction or negative pressure pulmonary edema may be seen in children with large muscle mass or obesity. The patients are usually adolescents, but this can occur in children as young as 5 years (Van Kooy and Gargiulo, 2000; Ciavarrro and Kelly, 2002).

Postoperative oral bleeding should be treated with direct intraoral pressure if a site can be located. Generalized oozing of blood may be treated with gauze dental packs that have large extraoral tails for retrieval. The oral packs act as compression dressings, which should be left in place for 2 hours and not be replaced unless there is significant ongoing hemorrhage. Premature removal or replacement dislodges clots that have not sufficiently matured and retracted into the dental socket. Persistent, minor oral hemorrhage after extraction may also be created. Dislodgment of recently cemented crowns or appliances, inadvertent movement of dental packs, or avulsion of loose teeth not previously extracted may require the presence of the dentist in the postanesthesia care unit to treat the problem.

Dental Complications of Anesthesia

The dental complications of anesthetic care are varied, usually minor, but a frequent source of malpractice claims. Most minor injuries are settled without going through malpractice litigation. The incidence of perioperative dental injury is based on retrospective data and varies from 0.02% to 0.05% (Lockhart et al., 1986; Warner et al., 1999; Newland et al., 2007). In one study of a large tertiary medical center, the frequency of perianesthetic dental trauma requiring repair, stabilization, or removal of the tooth was approximately 1 in 4500 cases (Warner et al., 1999). Nevertheless, the anesthesiologist must be aware of the potential pitfalls and take appropriate safeguards. If a dental complication of anesthesia does occur, a dental consultation should be obtained as soon as possible. Also, the chief of the anesthesia department, the hospital's risk manager, and the patient's family should be notified. Patients old enough to understand what has transpired should also be informed.

The neonate is not immune from the dental complications of anesthesia. Laryngoscopy of the neonatal oral cavity may result in excoriation or laceration of the gum pads. Unilateral right- or left-sided hypoplastic enamel defects may be seen in the primary maxillary incisors as a result of laryngoscopy during the neonatal period (Angelos et al., 1989). Oropharyngeal airways, as well as suction devices, may also cause lacerations or excoriation of the intraoral soft tissues. Prophylactic use of water-soluble lubricants or saline solution applied to any of these devices before their placement reduces the likelihood of intraoral trauma.

Many children and their parents are aware of loose primary teeth during the preoperative visit. However, a careful examination, including a mobility check of each primary tooth before induction of general anesthesia, is appropriate (Maxwell et al., 1994).

If an excessively loose primary tooth is noted during the exfoliative phase, the parents should be informed, and it may be safely removed by the anesthesiologist once general anesthesia has been induced. In this increasingly litigious society, a separate, written consent may be necessary for removal of the loose primary tooth by the anesthesiologist. A gauze barrier is placed lingually to prevent inadvertent introduction of the

tooth into more distal locations in the respiratory or gastrointestinal tract. Subsequently, a second gauze is wrapped around the loose tooth to be extracted. With a twisting and snapping action, the tooth is easily removed. The tooth is usually missing most or all of its root structure. The reason for the root structure loss is the natural resorptive processes that occur from the underlying permanent tooth that is beginning to erupt. If some of the root structure remains in the extraction site, no attempt should be made to retrieve it. The retrieval process may cause damage to the erupting permanent tooth bud. Also, the remaining root fragment naturally and harmlessly sequesters into the oral cavity (Herlich et al., 1996).

Conditions that may predispose the pediatric patient to dental avulsions under general anesthetic conditions include the scissors-like action of the anesthesiologist's fingers in the mouth opening before laryngoscopy. If this maneuver is accomplished using the incisors, the likelihood of inadvertent avulsion is increased. The mouth-opening maneuvers should be accomplished by using the molars whenever possible to take advantage of their inherent dental stability as well as to effect the largest opening possible. The use of oropharyngeal airways in the pediatric or adult patient as a bite block should be avoided for similar reasons. The anterior teeth are single rooted. If the patient closes the mouth with excessive force, the force transmitted by the tooth is essentially perpendicular to the airway and leads to increased risk of avulsion or fracture. The ideal technique uses gauze bite blocks with a long retrieval tag placed along the molar teeth. The forces are now directed toward softer material and the multirrooted molar teeth, which are more likely to sustain and evenly disperse the vertical, shear forces (Herlich, 1990; Herlich et al., 1996).

The inadvertent avulsion of loose primary teeth may nevertheless be unavoidable during airway manipulations. If a primary tooth is avulsed, it is imperative that it be retrieved. The tooth is usually found elsewhere in the mouth or outside of the oral cavity. It may also be found on the patient's gown or bed sheets or on the floor. If it cannot be located in these likely places, anteroposterior and lateral thoracoabdominal radiographs are necessary to locate the tooth. If the tooth is found in the digestive tract, it should pass without incident within several days. If the tooth is found in the tracheobronchial tree, however, it must be retrieved by whatever means necessary, including thoracotomy. The sequelae of leaving a foreign body in the tracheobronchial tree are extremely dangerous (Herlich, 1990; Herlich et al., 1996).

If a primary tooth was lost and then retrieved, it should not be reimplanted. Such attempts are usually futile because of its advanced root resorption before exfoliation. Reimplantation of a primary tooth may also cause significant damage to the underlying permanent tooth bud. However, if the avulsed tooth is a permanent tooth and morphologically intact, attempts should be made to reimplant it as soon as possible. The success of dental reimplantation depends on early reimplantation. Because the periodontal ligament has remnants attached to the tooth that are crucial to the success of reimplantation, the avulsed tooth should not be scrubbed with any material. Ideal preparation consists of gentle rinsing of the tooth in cool physiologic saline solution to remove crude debris and gross clots. Then the tooth should be placed in a cool saline-soaked gauze pad until a dentist can reimplant it, either in the operating room or as early as possible during the postoperative period.

Reimplantation also includes splinting of the tooth to one or two adjacent teeth on each side of the reimplanted tooth to confer stability. Despite early reimplantation, failures exist and may necessitate root canal therapy or extraction at an unspecified later date. The time course of reimplantation failure is unpredictable (Herlich, 1990), but if reimplantation occurs within 30 minutes, success may be as high as 90% (Kainuma et al., 1996).

Pediatric dentistry has made many advances to conserve tooth structure and space if deciduous teeth are lost prematurely. Various polymer and metal crown structures may be bonded or cemented in place. Normal intraoral forces or untoward unnatural forces may cause these prosthetic devices to be loosened or avulsed during airway manipulations. For the most part, they may be easily recemented or bonded postoperatively. Most hospital dental consultants are able to rebond or recement these prostheses in place without difficulty.

Interceptive orthodontic appliances, such as mandibular lingual arch wires or maxillary segmental orthodontic wires, or both, are bonded by brackets to the teeth. These appliances may become loosened or avulsed during airway maneuvers. Like other prosthetic devices, they may also be recemented or bonded postoperatively with little harm to the patient or dentition (Herlich, 1990).

In general, a thorough preoperative history and examination and prudent warnings to the parent reduce dissatisfaction when inadvertent dental complications do occur. Congenital craniofacial anomalies, such as palatal clefts, mandibulofacial dysostosis (Treacher Collins syndrome), Pierre Robin sequence, and hemifacial microsomia, may indeed increase the likelihood of dental complications because of intubation difficulties. Congenital dental anomalies, such as amelogenesis imperfecta or dentinogenesis imperfecta, may subject the patient to dental fracture with even the most trivial airway manipulations.

Acquired dental problems, such as milk-bottle caries syndrome, occur on the lingual surfaces of teeth in children who are regularly put to bed with a bottle of milk, formula, or glucose water. These carious lesions tend to require extensive pediatric dental rehabilitation in very young patients for whom prolonged dental visits are not feasible. As mentioned, those lesions may also be subject to the dental complications of anesthesia.

Pharmacologic agents such as oncologic chemotherapy, chronic inhaled or systemic steroids, diphenylhydantoin, and nifedipine may also cause intraoral or dental damage. A child with a blood dyscrasia or one who has had head and neck radiotherapy may also be subject to dental complications of anesthesia. Blood dyscrasias predispose the child to increased intraoral hemorrhage even during daily oral hygiene activities such as tooth brushing.

Head and neck radiation result in significant xerostomia (dry mouth) because of the destruction of the salivary glands. Because normal salivary flow has been eliminated, these children are at a very high risk for cervical (gumline) caries and possible dental complications during anesthesia. Regardless of the severity or nature of the injury, any head, neck, and oral trauma may predispose a patient to dental complications of anesthesia. With proper planning and care, the patient will have fewer and less severe dental complications (Herlich et al., 1996).

SUMMARY

A diverse and potentially challenging pediatric population requires dental care. For the most part, the dental needs of children are largely unappreciated by physicians, short of their personal experience in the dental chair. This chapter addresses dental issues from the viewpoint of anatomy, physiology, and dental growth and development. The dentist's needs and technical refinements are elaborated to prepare the anesthesiologist to deal with the spectrum of dental procedures. Particular attention is paid to the behavioral and physiologic needs of the pediatric dental population. Nonpharmacologic, pharmacologic, and practical technical strategies are suggested for both the dental operator and the operating room settings. The pitfalls and complications of each anesthetic technique are given

to reduce the learning curve and the anesthesiologist's anxiety when problems do arise, as well as to provide a background for future clinical research. Gentleness and understanding of the pediatric dental patient are required to meet the challenges facing the anesthesiologist and to ultimately improve patient care.

Advances in imaging and endoscopic technology requests from medical colleagues for support during prolonged or high-risk procedures and concern about liability exposure have led to increasing demands for anesthesiologists' professional services outside the operating room. In the 14 years since the first publication of this chapter, anesthesia services outside the operating room have increased more than sixfold at Children's Hospital Boston to over 7000 anesthetic procedures annually. As the demand for sedation services has increased nationally, so also have nonanesthesiologists expressed an interest in providing these services and are often using anesthesia billing codes. Indeed, pediatric radiologists, oncologists, dentists, gastroenterologists, pulmonologists, pediatricians, hospitalists, and intensivists are all able to supervise and deliver sedation. Monitoring techniques, sedative choices, and sedation guidelines vary between specialty organizations. Although the American Academy of Pediatrics (AAP) recently updated its guidelines, the recommendations of the American College of Gastroenterology and the American College of Emergency Physicians differ from those of the AAP (AAP et al., 2008).

Anesthesia departments may be reluctant or unable to commit limited financial resources to providing state-of-the-art anesthesia equipment and monitors to extramural locations with limited caseloads. Historically, anesthesia equipment and monitors designed for the outfield environment—small, portable, or safe for use with magnetic resonance imaging (MRI)—are at least double the costs of their operating-room counterparts. In addition, insurance reimbursement may be dif-

ficult, because insurers do not always understand the need for an anesthesiologist. Nonsurgical colleagues and support personnel may have little experience with anesthesia care, delivery, and needs, particularly in urgent situations. Even anesthesiologists are challenged, as few are familiar with the specific requirements associated with interventional, endoscopic, or radiologic procedures. Conflicts may inevitably arise between physicians, administrative personnel, and insurers, particularly because each group has different priorities and expectations. This chapter explores the requirements for anesthetic administration outside the operating room, the available anesthetic techniques, and some specialty-specific considerations. It concludes with current and important safety issues.

REQUIREMENTS FOR EXTRAMURAL LOCATIONS

Organization and Administration

A collaborative relationship between extramural and anesthesiology departments is critical to providing safe patient care. At a minimum, safe patient care requires appropriate anesthesia equipment and monitors, adequate space, and experienced ancillary providers who are knowledgeable in anesthesia and facile in providing assistance if needed. Each off-site area has its own needs, goals, and guidelines. It is ideal to designate a team of anesthesiologists committed to providing extramural anesthesia care and troubleshooting the logistical challenges in the

various locations. Each member should rotate regularly through the different extramural sites in order to maintain familiarity with the procedures, to foster a relationship with the physicians and ancillary personnel, to understand the anesthesia demands unique to each site, and sharing information about ongoing advances. Technological advances are particularly expanding in the field of radiology, and complicated imaging studies challenge the anesthesiologist to have an understanding of the unique conditions that each study requires. Understanding these requirements will guide the anesthesiologist in developing a management plan (Lee et al, 2008).

In the past, extramural locations were not designed with the anesthesiologist in mind. The need for anesthesia had not been anticipated when off-site locations were planned. It is only within the past decade that the demand for anesthesia services in these sites has burgeoned. Thus, most off-site locations have not been configured to support the capabilities for anesthesia. Ideally, anesthesiologists should be involved in the early stages of site design to ensure that minimum standards for anesthesia delivery are met and to troubleshoot engineering issues and advocate for adequate space for anesthetic induction and emergence (Committee on Drugs, 1992; American Academy of Pediatrics Section on Anesthesiology, 1999). Physical plant considerations for MRI-site planning have been previously described (Koskinen, 1985). When anesthesia services are requested, these sites may not meet minimum standards and may require reengineering to meet minimum requirements of the American Society of Anesthesiologists (ASA) (House et al., 1994). The anesthesia machine should be equipped with back-up supplies of E cylinders filled with oxygen and nitrous oxide. If pipeline oxygen is not available, then oxygen should be supplied from H cylinders (6600 L) rather than the smaller E tanks (659 L).

Scavenging systems should be carefully evaluated in the extramural location. Unlike the operating room, passive scavenging systems may not always be possible. A safe means of active scavenging may be provided by the vacuum at the wall or wall suction canisters. A scavenging system should be dedicated solely to waste gases. Many MRI scanners do not have wall suction because MRI-compatible wall suction is not widely available. If the suction is located outside the MRI suite, then a mouse-sized hole may be created in the suite's wall to allow suction tubing to be passed inside (Koskinen, 1985).

Electrical circuitry and lighting in extramural locations may not be up to operating room standards, even if the outlets are grounded and up to hospital grade. Although some extramural locations carry minimal risk of electrical shock or electrocution, these sites do not have line-isolation monitors (LIMs) and therefore do not warn of excess leakage of current. Supplemental lighting for recordkeeping, label verification, establishment of intravenous (IV) access, and visualization of the patient is critical. Even under the best circumstances, for example, lighting is dim in the MRI scanner, and monitoring by simple clinical observation can be limited. Anesthesia personnel may not always remain in the imaging suite, particularly during ionizing radiation imaging, computerized tomography (CT) scanning, and radiation therapy. Monitoring capabilities via remote television or hardwiring through reinforced walls can allow video display of the patient and the physiologic monitors within.

A storage area large enough to stock anesthesia equipment and supplies must be easily and quickly accessible. This area should be routinely checked, restocked, and kept locked when anesthesia services are not required. The need for redun-

dancy of nondisposable supplies is a matter of philosophy. Are two laryngoscopes enough, or should there be a third? Is one electrocardiograph (ECG) monitor enough, or should there be a battery-operated monitor for back-up and transport? Drugs should be checked according to the usual operating-room routine, and expired medications should be replaced. Gas-cylinder supplies must be reliable, especially in areas without piped oxygen. A code cart should be conveniently located in an area known to all physicians and ancillary personnel. This cart should be routinely checked and restocked. With larger volumes of patients necessitating significantly sized critical care areas, strong consideration should be given to having a difficult-airway cart available at extramural locations.

Finally, extramural anesthetizing locations are often distant from the operating room. Patients may need to remain anesthetized during transport to or from the extramural location. For these circumstances, assured elevator access with key-controlled emergency overrides is a must. All anesthesiologists who deliver extramural services should be familiar with their surroundings. Checklists are invaluable to guarantee consistent patient care, anesthesia monitoring, equipment, documentation, and back-up assistance.

Personnel, Support, and Logistics

Support and medical personnel in nonsurgical areas may not be familiar with the requirements of an anesthesiologist, thus providing an important educational and training opportunity. Proper training facilitates teamwork and minimizes chaos in critical situations. A standard anesthesia cart at each anesthetizing location should be fully stocked with essential medications, necessary additional equipment, a spare self-inflating bag, endotracheal tubes, laryngeal mask airways (LMAs), suction catheters, IV supplies, laryngoscope handles and blades, and a variety of oral and nasopharyngeal airways.

Leadership is crucial; a director of anesthesia services at an extramural location can orchestrate, facilitate, and coordinate anesthesia services. This director can also serve as a consultant for the other medical and nursing staff. By being available to answer questions, do on-site consultations, examine patients, and provide back-up support or emergency-airway expertise, the anesthesiologist can also support a nurse-administered sedation program. Nurses who provide sedation under the supervision of the ordering extramural physician (e.g., gastrointestinal, radiologic, or dental) should have Pediatric Advanced Life Support (PALS) and Basic Life Support (BLS) certifications. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) (2009) requires that individuals who administer sedation are able to rescue patients from whatever level of sedation or anesthesia is achieved, whether intentional or unintentional. All children scheduled for nursing sedation during a scan should receive a prescreening telephone call from a radiology nurse the day before the scheduled scan. Often, these telephone calls are made after business hours to ensure that a parent is home. The nurse reviews the medical history, relays fasting instructions, and reminds the parent to administer the child's routine medications with a sip of clear fluid. The supervising physician must give final approval for sedation after reviewing the child's medical history and current medical status and before ordering the medications. To minimize the chance of drug-delivery error or miscalculation, it is helpful to have preprinted order sheets or a computerized order-entry template.

It is crucial to know whom to call for assistance if a problem arises. A speed-dial system should be available from all extramural anesthetizing location sites in order to immediately request emergency back-up help.

PERIPROCEDURAL PATIENT CARE: STANDARDS OF PRACTICE AND QUALITY ASSURANCE

The practice standards adopted by the American Society of Anesthesiologists (ASA) in 1986 for basic intraoperative monitoring apply to extramural locations as well. Practice standards and guidelines promulgated by the AAP are exceeded by established practice standards in anesthesiology (Committee on Drugs, 1992; Anesthesiology and Pediatrics, 1999). Significant variances may exist when practitioners who are not anesthesiologists administer sedation (Keeter et al., 1990). Practice Standards for Non-Anesthetizing Locations were adopted by the ASA in 1994 (ASA House of Delegates, 1994).

As recommended by the JCAHO, sedation-related policies and procedures should be part of a quality-assurance initiative that should accompany all sedation programs. Ideally, adverse events such as failed or prolonged sedations, paradoxical reactions, hypoxia, emesis, unscheduled admissions, or cardiac and respiratory events should be identified and entered into a computerized database. In addition, the extramural nurse should call all patients and families within 24 hours in order to follow-up care on patient outcome and identify any delayed adverse events.

Scheduling and Preparation of Patients

Appropriate planning for an anesthetic begins with a familiarity with the procedure. The requesting service orders the procedure and then leaves the logistics of scheduling to the extramural service. Radiologists recognize that involvement with anesthesia lengthens their total time commitment to a patient and potentially limits the number of procedures accomplished in a day (Winter, 1978; Cremin, 1990). A well-coordinated system to screen patients on the day of the procedure is important. Experienced personnel, ideally a certified pediatric nurse practitioner (CPNP), should be designated to take initial vital signs, review recent medical history, begin IV lines if necessary, and familiarize the family with the upcoming procedure, including anesthesia.

Screening patients for extramural procedures may be challenging and time consuming. Many children are chronically ill, nutritionally impaired, and have complicated medical conditions. These issues must be carefully addressed through attention to the patient's history, physical examination, old medical records, outside consultations, and close communication with other medical colleagues. Several consultants may need to confer in order to fully understand the patient's current state of health. Not every procedure is elective. Urgent procedures may be required despite an upper respiratory tract infection (URI), ongoing pneumonia, deteriorating physical status, untreated gastroesophageal reflux, sepsis, or hemodynamic instability. In these situations, consultation between the anesthesiologist, the requesting physician, and the radiologist should confirm urgency. Anesthesia plans should be adjusted to accommodate the requirements of the procedure (e.g., holding breath for a CT scan of the chest) and the patient's medical condition.

It is not always possible for an anesthesiologist to provide sedation and anesthesia for all children when there is a large volume of cases. A structured nursing sedation program can provide safe and effective sedation. In many hospitals, the extramural department (gastroenterology, radiology, cardiology) outsources responsibility for sedation to another department, which could include pediatrics, hospital medicine, anesthesiology, intensive care, or emergency medicine. After screening the patient, an appropriate referral for either general anesthesia or procedural sedation is the usual result. Because MRI is a unique environment, it is more efficient to have the MRI nurses screen patients before and on the day of the procedure. To ensure consistent decision making, the anesthesiology and radiology departments should develop a set of guidelines and easily identifiable "red flags" to help in this triaging process (Table 33-1). If any questions arise, additional medical history needs to be clarified, or additional studies need to be performed, the nurse and anesthesiologist confer before making the final decision regarding general anesthesia or procedural sedation. In addition, chronically ill children often have electrolyte disturbances, coagulation and hematologic abnormalities, and hemodynamic instability. A consent for the administration of general anesthesia or procedural sedation must be obtained in parity with policies established for anesthesia in the operating room.

Because gastroesophageal regurgitation is common in infants, a detailed clinical history should be taken with regard to the incidence and timing of the regurgitation. If the reflux is predictable (i.e., only associated with mealtimes or soon thereafter) infants are usually approved for procedural sedation. Fasting guidelines are adjusted to minimize the risk of reflux. For example, if the infant has refluxes within 2 hours of eating solid food but never after 3 hours, the fasting guidelines for this infant may be extended to 6 hours for solids.

TABLE 33-1. Red Flags for Sedation

Red Flag	Indications
Apnea	Documented by sleep study, strong clinical history, or on an apnea monitor
Unstable cardiac disease	Cyanotic, depressed myocardial function, or significant stenotic or regurgitation lesions
Respiratory compromise	Recent (<8 weeks) pneumonia, bronchitis, asthma, or respiratory infection
Craniofacial defect	Potential for difficult airway
History of a difficult airway	
Active gastroesophageal reflux or vomiting	In poor control, with or without medical or surgical treatment
Hypotonia and lack of head control	Patient may not be able to maintain own airway without assistance
Allergies to barbiturates	Usually the mainstay of a sedation protocol; also allergies to other sedatives to be administered
Prior failed sedation	Unable to be sedated or unsuccessful imaging study because of excessive movement
Tremors	Unlikely to be ablated with sedation

Selection of Agents and Techniques

The selection of an anesthetic technique in an extramural location depends on the patient's underlying medical condition, age, drug tolerance, and anticipated procedure. The airway management may be influenced by the procedure itself, anticipated postprocedure course (e.g., intensive care unit [ICU] or postprocedure intubation) and past anesthetic course (e.g., difficult intubation). The assistance of an anesthesiologist is often sought when sedation administered by the radiologist has failed in the past; it is important to be aware that parents and radiologists may have the expectation that anesthesia will provide ideal conditions and guarantee successful completion of the procedure (Hubbard et al., 1992).

Premedication has many purposes: the relief of anxiety, easy separation from parents, sedation, analgesia, amnesia, reduction of salivary and gastric secretions, elevation of gastric pH, and decreased cardiac vagal activity. Medications should be adjusted to the psychological and physiologic condition of the patient and family. Parent-present inductions may be offered when the presence of a parent has a calming effect on the child. In the event of potentially detrimental parent anxiety, premedication may be preferable to a parent-present induction (Kain et al., 2001).

Barbiturates may be useful as the sole method of providing sedation. Pentobarbital, for example, has the advantage of providing sedation, causes minimal respiratory and circulatory depression, and is rarely associated with adverse events (Karian et al., 2002). Barbiturates have no analgesic properties. They can produce paradoxical reactions, especially in children. No antagonist to barbiturates is available, thus dosing should be carefully titrated. IV pentobarbital by titration has been used successfully by radiologists while monitoring oral and nasal air flow, oxygen saturation with a pulse oximeter (SpO_2), end-tidal carbon dioxide, and cardiac rate and rhythm, with transient decreases in SpO_2 in up to 7.5% of patients; interventions have included stimulation and head repositioning (Strain et al., 1988; Rooks et al., 2003).

Other studies have described the use of pentobarbital both in the oral and IV forms (Chung et al., 2000; Mason et al., 2001a). For infants younger than 1 year of age, oral pentobarbital is more successful and carries a lower rate of adverse events compared with chloral hydrate (Rooks et al., 2003). The long half-life of pentobarbital (approximately 24 hours) requires careful and conservative recovery and discharge guidelines. The dosage of oral pentobarbital is 2 to 6 mg/kg and up to 9 mg/kg in patients who are receiving barbiturate therapy.

Sodium thiopental in a mean induction dose of 6 mg/kg and a mean total dose of 8.5 ± 3 mg/kg has been used successfully as the sole anesthetic for CT and MRI in 200 children from 1 month to 12 years of age (Spear et al., 1993). Methohexital has a shorter recovery time than thiopental and is more effective than oral chloral hydrate (Manuli and Davies, 1993). Methohexital-induced seizures in patients with temporal lobe epilepsy have been reported. Thiopental or pentobarbital are alternatives for these patients (Rockoff and Goudsouzian, 1981). For patients taking barbiturate-containing anticonvulsant medications, a higher dose limit is generally more successful. Methohexital has also been used intramuscularly (IM) for radiotherapy in doses of 8 to 10 mg/kg. The onset time via this route is often twofold to threefold longer than rectally administered methohexital (Jeffries, 1988).

Although propofol does not have a labeled indication for children younger than 3 years of age, propofol has been used extensively in this age group as a means of providing sedation or anesthesia. Propofol sedation by bolus or continuous infusion for MRI scans of the brain can provide successful imaging conditions but with the risk of need for airway intervention and respiratory compromise (Vangerven et al., 1992; Cravero et al., 2009). Fatal metabolic acidosis and myocardial failure associated with lipemic serum have been reported in five children who were admitted to the ICU for respiratory support for upper respiratory tract infections while being sedated with continuous infusion propofol (Parke et al., 1992). Bloomfield and others (1993) have suggested a continuous infusion beginning at a rate of 99 mL/hr until the patients fall asleep (usually over 1 to 3 minutes) and then a decreasing rate during treatment, a strategy that works very well. Patients were typically awake, alert, and taking clear liquids 20 minutes later (Bloomfield et al., 1993).

Opiates reduce anesthetic, preprocedure, and postprocedure analgesic requirements. They are reversible with naloxone. Whereas narcotics may be unnecessary for diagnostic procedures that are not painful, they may be very useful for therapeutic interventions, especially for patients with postprocedural pain. They are also useful after anthracycline chemotherapy, with documented impaired myocardial function (Burrows et al., 1985). Because narcotics depress the ventilatory response to carbon dioxide (CO_2), this respiratory depression may be of particular concern for children with increased intracranial pressure. Narcotics may also worsen preexisting nausea and vomiting.

Benzodiazepines have the advantage of anxiolysis with minimal vomiting and cardiorespiratory depression. Diazepam is painful during IV injection and may lead to thrombophlebitis; midazolam is water soluble and therefore may be more suitable intravenously or intramuscularly. The elimination half-life of midazolam averages 2.5 hours, compared with 20 to 70 hours for diazepam (Greenblatt et al., 1981; Reves et al., 1985). Young patients or patients with significant liver disease may have prolonged duration and exaggerated effect of the benzodiazepines.

Preparation of the stomach and aspiration prophylaxis are of particular concern for urgently scheduled cases (outside of fasting guidelines) or when the medical history suggests aspiration risk. If using H_2 -receptor antagonists, bronchospasm may occur in patients with asthma because of the relative increased availability of H_1 -receptors. H_2 -blockers may also inhibit metabolism of other concurrently administered medications. Metoclopramide accelerates gastric emptying and increases tone in the lower esophageal sphincter, but it is associated with a significant incidence of extrapyramidal side effects in children (Sledge et al., 1992). Ondansetron works synergistically with other agents through its vagal blocking actions in the gastrointestinal tract, as well as through its inhibition of the chemoreceptor trigger zone via serotonin receptor antagonism, particularly for patients undergoing radiation therapy with pulses of chemotherapy (Burnette and Perkins, 1992; Figg et al., 1993).

Ketamine has enjoyed great popularity during the past 30 years for sedation, analgesia, or anesthesia outside the operating room because of its support of the cardiovascular and respiratory systems. Ketamine-induced nightmares, hallucinations, delusions, and agitation are rare in children (Sussman, 1974; Hostetler and Davis, 2002). Karian and others (2002)

have reported on a ketamine-sedation program for use in interventional radiology. In this program, IV or IM ketamine was administered in the interventional radiology suite by credentialed nurses and radiologists to patients undergoing select procedures. This protocol has allowed painful procedures to be tolerated by patients who previously would have required general anesthesia (Karian et al., 2002).

Dexmedetomidine, although not approved by the Food and Drug Administration (FDA) for pediatric use, obtained approval in October 2008 for adult procedural sedation in areas outside of the ICU. Particularly for pediatric sedation for radiologic imaging studies, dexmedetomidine alone in high dosages can achieve immobility for MRI and CT examinations (Mason et al., 2006, 2008a, 2008b). Its use for procedural sedation has still to be explored further, because its clinical application has been examined only in small studies and often in combination with ketamine (Barton et al., 2008).

Some patients require general anesthesia because of previous sedation failures, the need for a secure airway, or procedural logistics. Newer, less-soluble anesthetic agents such as sevoflurane and desflurane have pharmacokinetic profiles that compare favorably with propofol in adults; there seems little reason to think that this would not be the case with children, although pediatric anesthesiologists often avoid using desflurane because of its pungency and associated airway irritability (Van Hemelrijck et al., 1991). Since its introduction to clinical practice in the mid-1990s, sevoflurane has become the volatile anesthetic of choice in children. Its lack of airway irritability as a side effect and its ability to provide children with stable hemodynamic function, together with its rapid onset and offset make sevoflurane a useful agent for children (Furst et al., 1996).

Regional anesthesia, rarely administered outside the pediatric operating room, nevertheless remains a valid choice in some circumstances. Intercostal nerve blocks may be useful for lung or rib biopsies, chest tubes, biliary or subphrenic drainage procedures, and insertion of biliary stents. Nerve block of the brachial plexus by the axillary, interscalene, or supraclavicular route has been reported for the brachial approach to catheterization and neuraxial block of the lower extremities for femoral catheterizations and percutaneous approaches to the kidneys (Eggers et al., 1967; Ross, 1970; Lind and Mushlin, 1987). Spinal anesthesia in conjunction with regional hyperthermia and limb exsanguination has been successfully used for repeated painful radiotherapy on lower extremities (Spencer and Barnes, 1980).

Indwelling central catheters are implanted in the majority of radiotherapy patients and can be used for induction and maintenance of anesthesia, blood draws, IV fluid administration, and chemotherapy. Dressing changes are often accomplished in conjunction with the sedation or anesthesia. Antiseptic preparation of all injection sites with povidone-iodine and alcohol is critical. At the end of the session the catheter should be carefully flushed with heparinized saline. An alternative to central catheters is the use of a heparin-lock peripheral IV port, changed weekly, with careful parental instruction. Smoothness of emergence is particularly important after angiographic procedures because of the risk of a dislodged clot or bleeding at the puncture site. Some patients have been heparinized without protamine reversal. Unlike adults, sand bags and weights are not routinely applied to angiographic cannulation sites of children.

Occasionally, the loss of self-control with sedation results in dysphoria, and some patients fare better when they are completely awake. Minimal medication may be preferable in patients with complicated and unstable medical conditions who may not tolerate the anesthesia or sedation. Some procedures (e.g., unilateral carotid barbiturate injection or the Wada test) may require conversation, interaction, and responsiveness of the patient. In these situations, no sedation may be the best alternative.

POSTANESTHESIA CARE

Recovery criteria and the postanesthesia care unit (PACU) environment in an extramural location must be no different than the postanesthesia care delivered to children after an operative procedure. Each site must have sources of supplemental oxygen, the ability to deliver positive pressure ventilation, the availability of suction and monitoring equipment, and a nursing staff trained in postanesthesia care. Discharge criteria should be established by an anesthesiologist in conjunction with the extramural service and its nursing staff.

Postprocedure analgesic requirements are extremely variable. Whereas a groin puncture may be only mildly annoying for adults, the inability to move about and the ache of blood dissecting subcutaneously causes considerable discomfort in children. All children who have undergone angiography require a minimum PACU stay of 4 hours to ensure that the puncture site does not bleed or develop a hematoma. Ideally, a patient should be free of pain and resting supine and motionless in order to minimize the risk of a groin-puncture bleed or hematoma. An experienced member of the nursing staff should be able to recognize and manage unexpected agitation, delirium, or an unanticipated or undesired change in mental status and know to call for extra help.

The anesthesiologist may be asked to participate in the perioperative care of patients who have had embolization procedures. These patients often experience pain or swelling after the procedure, with the severity of discomfort depending on the extent of embolization, the agent used for embolization, postembolic swelling, and the amount of tissue necrosis. A variety of analgesic techniques are available, and the use of steroids perioperatively, although they do not directly decrease pain, may be of benefit in reducing edema and postembolic neuritis. Postembolic swelling influences perioperative airway management for procedures in the head and neck. Pediatric patients may need to remain intubated after such procedures, particularly when visible edema in the floor of the mouth, tongue, hypopharynx, oropharynx, or anterior neck could compromise the airway.

Nausea or vomiting may increase venous blood pressure because of the Valsalva maneuver, which can aggravate bleeding and swelling in puncture sites or after head and neck procedures. Hypothermia is a risk at some extramural locations because the MRI, CT, and interventional radiology equipment require a cool environment. Heating lamps and forced air heaters may be used when it is safe and appropriate to do so. Finally, with the use of iodine-containing radiocontrast media, as well as sclerosing and embolizing agents, consideration must be given to adequate volume resuscitation, the risk of a contrast reaction, and bladder catheterization for detection of oliguria, polyuria, or hematuria.

RESUSCITATION

Each extramural anesthetizing location is unique with regard to conducting resuscitation. Redundancy of monitoring devices and equipment is important; a provider should not be limited to a single item that could malfunction at the time of resuscitation. Patients with multiple allergies, shellfish allergies, or atopic disease are at increased risk of exhibiting anaphylaxis to iodine-containing contrast. These patients may benefit from pretreatment with steroids and antihistamines. Areas with restricted access (MRI in particular) should have designated adjacent locations to perform full resuscitation. These areas should be equipped with wall oxygen, suction, and full monitoring and resuscitation capability. A self-inflating silicone bag (no ferromagnetic working parts) or nonferrous Jackson-Rees circuit should always be kept inside the MRI suite.

The physicians, nurses, anesthesiologists, technologists, and support personnel must know the location of a readily accessible code cart. In addition, a hard board to be placed under the patient during resuscitation should be available. Mock codes should be performed regularly to ensure adequate flow, teamwork, and delineation of responsibilities in the event of an emergency. The MRI scanner poses a special problem. Codes should never be conducted in the scanner because as support personnel rush inside to assist, ferrous materials that are not removed will become projectile and create an even more hazardous situation. Quenching a magnet should not be an alternative, because it requires a minimum of 3 minutes to eliminate the magnetic field. In addition, inadequate exhaust during a quench has been known to produce hypoxic conditions in the scanner and has resulted in patient death. A “black quench” could melt the MRI coils and require replacement of the scanner, a costly and time-consuming undertaking. Defibrillators are not compatible with MRI and may not function properly when they are exposed to the magnetic field (Snowdon, 1989). In an emergency, a patient should be removed from the scanner to an area outside of the magnetic field. This designated area is a safe place for resuscitation and should have not only a wall oxygen source for a self-inflating bag but also access to appropriate monitors.

SPECIFIC EXTRAMURAL SITES

Radiology

Computerized Tomography Scan

CT differentiates between high-density (e.g., calcium, iron, bone, and contrast-enhanced vascular and cerebrospinal fluid [CSF] spaces) and low-density (e.g., oxygen, nitrogen, carbon in air, fat, CSF, muscle, white matter, gray matter, and water-containing lesions) structures. Because the scan time is quick, CT may be preferable for patients who are medically unstable and in need of rapid diagnosis—for example, with the child being evaluated for abuse, an intracranial hemorrhage, or abdominal or thoracic mass. Other indications for emergency CT scans may include encephalopathy and a change in neurologic status. In these situations, the issues of a full stomach and increased intracranial pressure usually necessitate a rapid-sequence induction with tracheal intubation. A CT scan of the head is often the preferred study in emergency situations where head trauma is involved (Blankenberg et al., 2000).

The actual scanning sequences are short and can range from 10 to 40 seconds. These short scan times enable many children to complete a CT scan without any sedation, especially with parental presence and distraction techniques. When an anesthesiologist is involved, it is often for airway or failed-sedation issues or for a medically complicated patient. An important aspect of some CT scans is to visualize the sinuses, ears, inner auditory canal, and temporomandibular bones and to evaluate for choanal atresia or craniofacial abnormalities. These scans may require direct coronal imaging with extreme head extension (off the end of the table at an angle between 40 and 70 degrees) or absolute immobility for three-dimensional reconstruction, so it is critical for the treatment team to have a thorough understanding of the specifics of the study. Three-dimensional airway and cardiac studies have evolved and have unique anesthetic requirements. The airway studies require breath holding on inspiration and expiration in order to allow visualization of areas with airway collapse (Lee et al., 2008). The cardiac studies are often done in collaboration with cardiologists and radiologists who are able to make structural and functional assessments of the heart. These scans can also be challenging, because adenosine is often requested in order to briefly pause heart function so that image quality is maximized (Woodard et al., 2006).

Any patient who is at risk for cervical instability should be properly screened before neck extension. Children with Down syndrome are at risk for atlantoaxial instability. The incidence of instability varies from 12% to 32% (Blankenberg et al., 2000). Many children with Down syndrome require cervical spine radiographs before entering grade school or participating in Special Olympics. Usually, the parents are well aware of the radiologic findings. The cervical spine films, however, do not indicate whether or not a child is at risk for dislocation (Davidson, 1988). Rather, those children who exhibit neurologic signs or symptoms such as abnormal gait, increased clumsiness, fatigue with ambulation, or a new preference for sitting games are at risk. In infants, developmental milestones (e.g., crawling, sitting up, and reaching for objects) should be verified. Physical signs of Down syndrome may include clonus, hyperreflexia, quadriparesis, neurogenic bladder, hemiparesis, ataxia, and sensory loss. The asymptomatic Down syndrome child with radiologic evidence of instability may be approved for procedural sedation; however, unnecessary neck movement should be avoided. Any child who displays neurologic signs or symptoms should not be sedated until a neurosurgical or orthopedic consultation is obtained.

Radiologists employ Gastrografin when evaluating abdominal masses. Gastrografin diluted to a concentration of 1.5% is usually considered a clear liquid. The volume that is administered orally is significant; newborns younger than 1 month of age receive 60 to 90 mL, infants between 1 month and 1 year of age may receive up to 240 mL, and children between the ages of 1 and 5 years receive between 240 and 360 mL. Because sedation or anesthesia should usually be accomplished within a window of 1 to 2 hours after ingestion of the contrast, most “elective” fasting guidelines would be violated; however, the scan must be completed while the Gastrografin is still in the gastrointestinal tract. There are no published data to guide optimal induction or sedation techniques as they relate to aspiration risk in these circumstances. Full strength (3%) Gastrografin is hyperosmolar and hypertonic. All Gastrografin should be diluted to an isosmolar and isotonic 1.5% concentration of neutral pH. There is

one case report of 1.5% Gastrografin aspiration in a child with no adverse sequelae; therefore, the risk of using a 1.5% concentration of Gastrografin seems low (Friedman et al., 1986; Wells et al., 1991).

Embolization Procedures

Interventional techniques include nonvascular and vascular interventions (Towbin and Ball, 1988). In vascular interventions, embolization and sclerotherapy have become important techniques for treating vascular malformations, aneurysms, fistulas, and hemorrhage; for accomplishing renal ablation; and for presurgical embolization of hypervascular masses. Percutaneous transluminal angioplasty and fibrinolytic therapy are increasing in pediatric institutions; great success is being reported, even in the smallest infants, and the important contribution that adequate sedation and analgesia can make to ultimate outcome has been recognized (Diament et al., 1985).

Vascular malformations are congenital aberrant connections between blood vessels and may be composed of lymphatic, arterial, and venous connections. These lesions, although present at birth, are often discrete and not clearly visible. As the child grows, the vascular malformation may expand rapidly, growing with the child. This rapid proliferative phase may occur in response to hormonal changes (e.g., pregnancy or puberty), trauma, or other stimuli (Jackson et al., 1993). Vascular malformations may be high-flow or low-flow lesions, depending on which vessels are involved. High-flow lesions include arteriovenous fistulas, some large hemangiomas, and arteriovenous malformations. Particularly with large lesions, high-output cardiac failure and congestive heart failure with the potential for pulmonary edema should be anticipated and sought out in the medical history and physical examination. Low-flow lesions consist of venous, intramuscular venous, and lymphatic malformations. Surgical resection of symptomatic vascular malformations may be hazardous as well as unsuccessful—any vascular element not resected may enlarge and cause further problems.

Because vascular malformations enlarge over time, even asymptomatic lesions may require intervention. Patients with symptoms may suffer from pain, tissue ulceration, disfigurement, airway or cardiovascular compromise, impairment of limb function, coagulopathy, claudication, hemorrhage, and progressive nerve degeneration or palsy. Because large vascular lesions require multiple embolizations, parents and patients are often comforted by seeing familiar anesthesiologists, another benefit of having a core group of anesthesiologists in the radiology suite. Vascular embolization is also used as a bridge to surgical resection. Successful embolization and sclerotherapy decrease the size of the malformation and reduce blood flow to the lesion, thereby decreasing surgical risks.

When embolizing vascular malformations, radiologists often aim to cut off not only the feeding vessels but also the central confluence (nidus) where much of the arterial shunting occurs. Embolic agents include stainless-steel minicoils, absorbable gelatin pledgets and powder, detachable silicone balloons, polyvinyl alcohol foam, cyanoacrylate glue, and ethanol. The choice of agent depends on the clinical situation and the size of the blood vessel. When permanent occlusion is the goal, polyvinyl alcohol foam and ethanol are often employed. Both occlude at the level of the arterioles and capillaries. Medium to small-sized arteries may be occluded with coils, the equivalent of surgical ligation. Particularly in trauma situations, when only tempo-

rary occlusion (days) is the goal, absorbable gelatin pledgets or powder are used (Coldwell et al., 1994).

Large hemangiomas may be associated with the coagulopathy of Kasabach-Merritt syndrome. In this condition, the hemangioma traps and destroys platelets and other coagulation factors, resulting in thrombocytopenia and an increased risk of bleeding. As the hemangioma involutes, the coagulation status improves (Mulliken and Young, 1988). A condition described as systemic intravascular coagulation (SIC) can occur after the embolization of extensive vascular malformations. This condition is marked by an elevated prothrombin time (PT) with a decrease in coagulation factors and platelets.

Absolute (99.9%) ethanol is injected in vascular malformations to promote sclerosis. Ethanol may produce a coagulum of blood and cause endothelial necrosis (Becker et al., 1984). Sclerotherapy or embolization with absolute ethanol increases the risk of developing a postprocedure coagulopathy marked by positive D-dimers, elevated PT, and decreased platelets (Mason et al., 2001b). Ethanol causes thrombosis, because it injures the vascular endothelium. Ethanol also denatures blood proteins. Extensive ethanol injections can cause hematuria, and urinary catheters should be inserted to monitor urine output, diuresis, and hematuria. Especially with children scheduled for outpatient surgery, liberal fluid replacement ensures that the hematuria clears before discharge. Ethanol can cause neuropathy and tissue necrosis if it is not injected selectively. Using selective catheterization and direct percutaneous puncture, care is taken not to expose normal blood vessels to the ethanol. In addition to the risk of hematuria, ethanol also can produce significant serum alcohol levels. Mason and others (2000) note that up to 1 mL/kg of ethanol can be administered and that serum ethanol levels have been greater than the intoxication level of .008 mg/dL (Fig. 33-1). Patients with high serum-ethanol levels may be either sedated or extremely agitated, depending on their particular response to intoxication.

Embolization or balloon occlusion of arterial venous malformations, vascular tumors, intracranial aneurysms, and fistulae carries considerable risk of catastrophic results. Risks include a sudden intracranial hemorrhage, acute cerebral ischemia, or catheter or balloon migration. If sedated, the patient may require urgent airway management. Long cases require a urinary catheter, especially if contrast material is used.

■ **FIGURE 33-1.** Relationship between ethanol administered (mL/kg) and serum ethanol level (mg/dL).

Cerebral angiography requires motionlessness as well as exquisite control of ventilation. Anesthetic technique, in choice of agent as well as in control of arterial CO₂ tension, may affect cerebral blood flow and hence the quality of the scan. Cerebral angiography may be performed in children for the diagnosis or follow-up study of Moyamoya disease, and these children should have anesthetic techniques that minimize the risk of transient ischemic attacks (TIAs) and stroke during the procedure (Soriano et al., 1993). Other considerations include controlled hypercarbia to promote vasodilation and facilitate access and visualization of the vasculature for the radiologist. In the event of vasospasm or difficult access of small, torturous vessels, locally administered (through the catheter) nitroglycerin in small doses (25 to 50 mcg) may facilitate visualization and access. Occlusion of the venous portion of the arteriovenous malformation (AVM) without complete occlusion of the arterial inflow vessels could result in acute swelling and bleeding. Vascularity reduction through occlusion of major feeder vessels is the goal of embolizing large AVMs before planned surgical excision. This may be accomplished as a staged procedure over several days, involving repeated anesthetics or sedation sessions.

Angiographic imaging may be enhanced through the use of glucagon. Glucagon is efficacious for digital subtraction angiography, visceral angiography, and selective arterial injection in the viscera. When needed, glucagon is administered intravenously in divided doses of 0.25 mg to a maximum of 1 mg. Risks include glucagon-induced hyperglycemia, vomiting (particularly when given rapidly), gastric hypotonia, and provocation signs of pheochromocytoma (McLoughlin et al., 1981; Chernish et al., 1990; Jehenson, 1991). Children who receive glucagon should routinely receive prophylactic antiemetics.

The ability to intermittently assess neurologic function and mental status is invaluable during embolization procedures, but it may not be practical in children because of fear, pain, and movement. General anesthesia permits easier control of blood pressure and ventilation and eliminates the concern about patient movement. For children, general anesthesia is often preferred when performing high-risk procedures that require immobility and periods of breath-holding. Preprocedural assessment should include any history of seizures, bleeding, treatment with anticonvulsants or anticoagulants, neurologic symptoms, and evaluation of intracranial-pressure status. It is important to determine whether the patient has had any TIAs or has evidence of cerebrovascular occlusion. Vasodilator agents (calcium channel blockers) or nitrate derivatives may need to be administered after embolization. Because many patients are anticoagulated during the procedure, a preoperative coagulation profile should be obtained. A variety of anticoagulants may have to be on hand as well to prophylaxis for thrombosis (Bidabe et al., 1990).

Morbidity associated with embolization is not negligible. Arteriovenous malformations (AVMs) involving the head and neck often require cannulation of the external carotid artery branches and the thyrocervical trunk. All patients scheduled for embolization should be typed and cross-matched for blood. Those patients who undergo embolizations of AVMs of the head and neck are at risk for stroke, cranial nerve palsies, skin necrosis, blindness, infection, and pulmonary embolism (Riles et al., 1993). It is important to assess and document full return of neurologic status after the patient is extubated.

Ultrasound-Directed Procedures

Needle biopsies and drainage procedures are directed with ultrasound guidance for diagnostic examination (e.g., of the kidneys, liver, lungs, muscle, unknown mass, or unknown fluid). Percutaneous drainage of abscesses, cysts, pancreatic pseudocysts, and other fluid-containing structures can often be accomplished with ultrasound guidance. Ultrasound is useful for placement of difficult central venous-line (CVL) catheters and peripherally inserted central catheters (PICCs). The requirement for general anesthesia vs. sedation for ultrasound-guided procedures depends in part on the duration of the procedure, the location involved, the risks associated with the procedure, and any procedural requirements. The need for controlled ventilation with breath holding may require an endotracheal tube and general anesthesia. Associated secondary effects of the end-organ disease must be kept in mind in the overall anesthetic care plan.

Magnetic Resonance Imaging

Atoms with an odd number of protons or neutrons are capable of acting as magnets. When they are aligned in a static magnetic field, they can be subjected to radiofrequency energy that alters their original orientation. With removal of the radiofrequency pulse, the nuclei rotate back to their original alignment (relaxation), and the energy released can be detected and transformed into an image. Hydrogen is the atom most often used for imaging, because it is present in most tissues as water and long-chain triglycerides.

MRI is employed for the evaluation of neoplasms, trauma, skeletal abnormalities, and vascular anatomy (Barnes, 1992). MRIs of the brain are often performed to evaluate developmental delay, behavioral disorders, seizures, failure to thrive, apnea and cyanosis, hypotonia, and mitochondrial or metabolic disorders. Magnetic resonance angiography and venography (MRA and MRV) are especially helpful in evaluating vascular flow and can sometimes replace invasive catheterization studies for follow-up or initial evaluations of vascular malformations, interventional treatment, or radiotherapy (Edelman and Warach, 1993). Functional MRI (fMRI) is an evolving technology that measures the hemodynamic or even metabolic response related to neural activity in the brain or spinal cord. fMRI is often able to localize sites of brain activation and is now dominating brain-mapping techniques because of its low invasiveness and lack of radiation exposure. Some fMRI studies require cognitive facility and are typically interactive with a conscious and responsive patient. fMRI studies on children who are unable to respond appropriately either because of age or cognitive compromise are challenging—how that will evolve in pediatric anesthesiology practice is not yet clear.

Historically, the anesthetic management of children in the MRI suite has been highly dependent and somewhat limited by MRI-compatible monitors and anesthesia gas machines. (Karlik et al., 1988; Menon et al., 1992; Tobin et al., 1992). The American College of Radiology (ACR) established guidelines to minimize the risk of MRI-related mishaps but did not address the needs of the anesthesiologist (Kanal et al., 2007). These guidelines were written in response to fatalities that had occurred when loose, nonferrous oxygen cylinders became projectiles when brought inadvertently into the MRI suite with a patient in the bore of the magnet (Chaljub et al., 2001). In 2008 the ASA assembled a

task force composed of anesthesiologists and a radiologist with MRI expertise. This Task Force on Anesthetic Care for Magnetic Resonance Imaging created a document entitled the *Practice Advisory on Anesthetic Care for Magnetic Resonance Imaging* (ASA Task Force on Anesthetic Care for MRI, 2009). This document establishes important recommendations for safe practice as well as consistency of anesthesia care in the MRI environment. Most important, the Practice Advisory includes all sedation, including monitored anesthesia care, general anesthesia, critical care, and ventilatory support. Conditions of high-risk imaging were defined as imaging in patients with medical or health-related risks or as equipment-related, procedure-related, or surgery-related risks. MRI-guided interventions, cardiac imaging, and airway imaging were all identified as high-risk procedures. The Task Force was designed to promote patient and health care provider safety, prevent MRI mishaps, recognize limitations in physiologic monitoring, optimize patient management, and identify potential equipment and health risks (ASA Task Force on Anesthetic Care for MRI, 2009).

Anesthetic management also depends on the availability of support personnel, equipment and monitors; the personal style and comfort level of the anesthesiologist; and the patient's particular medical history. Requiring a general anesthetic solely to ensure motionless conditions for a radiologic imaging study is often a frightening concept for parents. Parents often equate pain and surgical interventions with the need for anesthesia and are reluctant to expose their child to a general anesthetic for the sake of an MRI study. Children under the age of 5 years most commonly require moderate or deep sedation or an anesthetic to ensure motionless conditions. Ketamine, narcotics, or benzodiazepines are generally unsuccessful. Pentobarbital, propofol, and dexmedetomidine offer successful alternatives to inhalation anesthesia (Mason et al., 2001a, 2004, 2008a, 2008b; Guenther et al., 2003; Yamamoto, 2008). One technique for general anesthesia is to perform an inhalation induction followed by placement of an LMA. During the scan, the patient maintains spontaneous ventilation. Lidocaine gel (2%) on the LMA cuff is a useful adjunct, because it decreases the incidence of sore throat and retching (Chan and Tham, 1995; Keller et al., 1997). A retrospective study of 200 patients demonstrated the usefulness of this approach (Brimacombe et al., 1995). In children with upper respiratory infections, there was a lower incidence of mild bronchospasm, laryngospasm, breath-holding, and major oxygen desaturation (less than 90%) in the group with LMAs compared with the group that received endotracheal anesthesia (Tait et al., 1998). Temperature monitoring can be accomplished by liquid crystal display (skin temperature). There is still no means of monitoring core temperature, because any temperature probe would risk heat generation and thermal burns to the patient.

Anesthesiologists must be aware of many personal items taken for granted—clipboards, pens, watches, scissors, clamps, credit cards, eyeglasses, and paper clips that should not be in the MRI field (Karlik et al., 1988; Menon et al., 1992; Tobin et al., 1992). Conventional ECG monitoring is not possible, because as the lead wires traverse the magnetic fields, image degradation occurs and, most importantly, the ECG leads heat and cause burns on the patient. Fiberoptic ECG monitoring is necessary to minimize the risk of patient burn. Even with fiberoptic cables, it is important to recognize that the connections between the ECG pads and the telemetry box are still hardwired, and careful attention must be paid to prevent frays,

overlap, exposed wires, and knots in the cables (Shellock, 1989). In order to prevent injury to the patient, care must be used to avoid creating a conductive loop between the patient and a conductor (e.g., ECG monitoring and gating leads, plethysmographic gating wire, and fingertip attachments). During the scan, no exposed wires or conductors can touch the patient's skin, and no imaging coil can be left unconnected to the magnet. Pulse oximeters are also not conventional to the operating room environment; rather they are fiberoptic. Failure to remove the conventional pulse oximeter probes and adhesives has resulted in second- and third-degree burns (Shellock, 1989; Brow et al., 1993).

Current advances in physiologic monitoring and anesthesia machines for the MRI environment have optimized the ability of the anesthesia care provider to provide safe care in the MRI suite. The Dräger Fabius MRI (Dräger Medical AG; Lübeck, Germany) was designed for MRI and approved by the FDA in 2008 for use within both a 1.5-Tesla (T) and 3-T magnetic field up to a field strength of 400 gauss. The Dräger Fabius MRI, equipped with two vaporizers, is an electronically controlled ventilator and the first one able to deliver multiple modes of ventilation in the MRI suite. Advances in physiologic monitoring now offer the ability to monitor ECG and pulse oximetry in a 1.5-T and 3-T MRI scanner via wireless, fiberoptic communication (Invivo Precise, Invivo; Orlando, Florida).

Average noise levels of 95 dB have been measured in a 1.5-T MRI scanner; this level of noise is comparable with the noise level of very heavy traffic (92 dB) or light road work (90 to 110 dB). Exposure to this level of noise has not been considered hazardous if it is limited to less than 2 hours per day (Gangarosa et al., 1987). There are case reports, however, of both temporary and permanent hearing loss after an MRI scan (Brummett et al., 1988; Kanal et al., 1990). Three-Tesla magnets offer the advantage of less image degradation and improved neuroskeletal and musculoskeletal imaging. As the field strength increases, so does the noise (Hattori et al., 2007). In fact, the peak sound-pressure level of a 3-T magnet exceeds 99 dB, the level approved by the International Electrotechnical Commission. Noise reduction did not differ between earplugs and headphones, although the combination of both was more effective at reducing sound (Hattori et al., 2007). Earplugs or MRI-compatible headphones should be offered to all pediatric patients and are required for all patients imaged in the 3-T MRI scanner. fMRI provides additional challenges in the 3-T environment; the noise of the 3 T can interfere with the acoustic stimulation generated for purposes of obtaining the fMRI (Ravicz et al., 2000; Menendez-Colino et al., 2007). Video goggles compatible with the 1.5-T and 3-T environments (Resonance Technology; Los Angeles, California) may be worn by the patient during MR imaging to provide a three-dimensional virtual reality system complete with audio integration. The introduction of this integrated audio-video headset has revolutionized the ability to offer distraction to patients, many of whom are able to tolerate imaging without adjuvant sedation or anesthesia.

Although studies in mice and dogs suggest that exposure to magnetic fields may increase body temperature, it is unlikely that static magnetic fields up to 1.5 T have any effect on core body temperature in adult humans (Sperber et al., 1984; Shellock et al., 1986; Shuman et al., 1988). However, this may be of greater concern in infants and small children, especially in cases like cardiac MRI studies that require a long scan time. The specific absorption rate (SAR) is measured in watts per

kilogram and is used to follow the effects of radiofrequency heating. The FDA allows an SAR of 0.4 W/kg averaged over the whole body (Department of Health and Human Services, FDA, 1982). Ex vivo exposure of large metal prostheses to fields over six times that experienced in MRI have not revealed any appreciable heating (Davis et al., 1981). To date, there has been no conclusive evidence that radiofrequency is a significant clinical issue in magnets up to 3 T.

The biological effect of MRI should be considered when offering parent-present induction; however, there are no reports implicating MRI-caused chromosomal aberrations. Studies in amphibians demonstrate that exposure to a 4-T magnetic field does not cause any defects in embryologic development (Prasad et al., 1990). Most hospital's MRI machines are 1.5 T. Despite these studies, pregnant patients or family members are not usually allowed into the MRI scanner. MRI scans during pregnancy are discouraged by the ACR during the first and second trimesters unless fetal imaging is required or the MRI is necessary for emergent medical care (Woodard et al., 2006).

Additional safety issues for MRI include implanted objects (i.e., cardiac pacemakers), ferromagnetic attraction that causes objects to become projectile, noise, biological effects of the magnetic field, thermal effects, equipment issues, and claustrophobia. Some stainless steel may contain ferritic, austenitic, and martensitic components (Dujovny et al., 1985; Persson et al., 1985). Martensitic alloys contain fractions of a crystal phase known as martensite, which has a body-centered cubic structure, is prone to stress corrosion failure, and is ferromagnetic. Austenite is formed in the hardening process of low carbon and alloyed steels and has ferromagnetic properties. Iron, nickel, and cobalt are also ferromagnetic. For this reason, the components of any implanted device should be carefully researched before entering the magnet. Stainless steel or surgical stainless objects interacting with an external magnetic field may produce translational (attractive) and rotational (torque) forces. Intracranial aneurysm clips, cochlear and stapedial implants, shrapnel, intraorbital metallic bodies, and prosthetic limbs may move and potentially dislodge. Special precaution should be taken with cochlear implants in the 3-T environment, because unremovable magnets may suffer demagnetization in the scanner. These patients should only undergo imaging in the 3-T scanner after special precautions are taken (Majdani et al., 2008). Some eye makeup and tattoos may contain metallic dyes and therefore cause ocular, periorbital, and skin irritation (Scherzinger and Hendee, 1985; Prasad et al., 1990). Some tissue expanders employed in reconstructive surgery have a magnetic port to help identify the location for intermittent injections of saline (Liang et al., 1989). Bivona tracheostomy tubes usually contain ferrous material (although it is not specified in the package insert) and should be replaced with Shiley tracheostomy tubes before patients enter the MRI environment.

Cardiac pacemakers present a special hazard in and around the MRI scanner, especially in patients who are dependent on pacemakers. Most pacemakers have a reed relay switch that can be activated when they are exposed to a magnet of sufficient strength (Pavlicek et al., 1983). This activation could convert the pacemaker to the asynchronous mode. There are at least two known cases of patients with pacemakers who died from cardiac arrest while in an MRI scanner. The autopsy of one patient determined that the death was the result of an interruption of the pacemaker in the magnetic environment (Center for Disease and Radiological Health, 1989).

In addition to the risk of pacemaker malfunction, there is also the chance that torque on the pacer or pacing leads may create a disconnect or microshock (Erlebacher et al., 1986). Recent studies demonstrate that with careful preparation, select patients with permanent pacemakers and implantable cardioverter defibrillators may safely undergo imaging in the 1.5-T environment without any inhibition or activation of their device (Nazarian et al., 2006). The ACR formed a Blue Ribbon Panel on MRI Safety in 2001 to review existing MRI safety practices and issue new guidelines. The *ACR Guidance Documents for Safe MR Practices* was published in 2002 and updated in 2004 and again in 2007 (Kanal et al., 2007). Safety concerns related to pediatric MRI were specifically addressed in the 2007 document, with specific emphasis on patient screening, sedation, and monitoring issues. Implanted cardiac pacemakers or implantable cardioverter defibrillators were considered a relative contraindication to MRI and only scanned in locations staffed with radiologists and cardiologists of appropriate expertise. The recommendation was for radiology and cardiology personnel, along with a fully stocked crash cart, to be readily available, as well as a programmer to adjust the device if necessary. After the MRI, a cardiologist should confirm function of the device and recheck it within 1 to 6 weeks. In general, heart valves are not ferromagnetic and are not a contraindication to MRI. It is critical that everyone entering the vicinity of the MRI scanner fills out a screening form that specifically lists every possible implantable device, alerting the MRI staff to any potential hazards.

The magnetic field may affect the electrocardiogram. The changes in the T wave are not the results of biological effects of the magnetic field but rather to superimposed induced voltages. This effect of the magnetic field on the T wave is not related to cardiac depolarization, because no changes to the P, Q, R, or S waves have ever been observed in patients exposed to fields up to 2 T. There are no reports of MRI affecting heart rate, ECG recordings, cardiac contractility, or blood pressure (Beischer, 1969; Tenforde et al., 1983; McRobbie and Foster, 1985; Gulch and Lutz, 1986). One study, however, found that humans exposed to a 2-T magnet for 10 minutes developed a 17% increase in the cardiac cycle length (CCL). The CCL represented the duration of the RR interval. The CCL reverted to preexposure length within 10 minutes of removing the patient from the magnetic field (Jehenson et al., 1988). The implications of this finding are unclear. This change in CCL in patients with normal hearts may be of no consequence. The implications of this finding for patients with fragile dysrhythmias or sick sinus syndrome, however, have yet to be determined.

In the presence of an external magnetic field, a ferromagnetic object can develop its own magnetic field and become a projectile object. The attractive forces that are created between the intrinsic and extrinsic magnetic fields can propel the ferromagnetic object toward the MRI scanner. Special note should be made of the magnet's strength. Over the past few years, 1.5-T magnets have been supplanted by 3-T magnets. The field strength and magnetic force generated by a 3-T MRI scanner are unforgiving to the careless or inadvertent introduction of a ferrous object into the environment. Placing a magnet outside the MRI scanner can be a helpful but crude and sometimes inaccurate way to test any objects. If the object is not attracted to the magnet, this is not an absolute indication that there is no ferrous material present. A positive attraction, however, provides critical information to the anesthesiologist. Some unusual

objects that have found their way into the MRI suite only to become projectile objects include a metal fan, a pulse oximeter, shrapnel, a wheelchair, a cigarette lighter, a stethoscope, a pager, a hearing aid, a vacuum cleaner, a calculator, a hair pin, an oxygen tank, a prosthetic limb, a pencil, an insulin infusion pump, keys, watches, and steel-tipped or heeled shoes (Kanal, 1992). Small objects can usually be easily removed from the magnet, but large objects may have so much attractive force to the MRI scanner that it is impossible to remove them by manual force. In these circumstances, quenching the magnet may be the only way to release the object once it is attached to the scanner. Quenching the magnet eliminates the magnetic field over a matter of minutes. This process is not without substantial risk; as helium gas is vented, condensation and considerable noise fill the suite. All personnel are required to vacate the suite during a quench, because there is a risk of hypoxic conditions if the helium should inadvertently enter the room.

In 2008, the JCAHO recognized the potential and existent hazards of the MRI environment when they published the *Sentinel Event Alert* (The Joint Commission, 2009). This alert identified 5 MRI-related cases of injury and 4 MRI-related deaths—one from a projectile and three cardiac events. The alert was designed to prevent accidents and injuries in the MRI suite, specifically identifying eight types of possible injuries (Box 33-1).

Special attention has recently been devoted to the topic of the IV gadolinium contrast that is used to enhance MR images. Gadolinium (in the form of gadopentetate dimeglumine) was approved by the FDA in 1998 as a contrast agent for MRI. With an elimination half-life of between 1.3 and 1.6 hours, gadolinium is excreted via the kidneys after forming a complex with chelating agents (Baker et al., 2004). Adults and children have similar elimination half-lives of gadolinium, with 95% excreted within 72 hours (Weinmann et al., 1984; Van Wagoner et al., 1990). Because gadolinium does not contain iodine, it does not produce an osmotic load and is generally considered safer and less allergenic than iodine (Brasch, 1993; Murphy et al., 1996; Dorta et al., 1997). Important warnings from the FDA suggest that patients with advanced kidney failure are at risk of developing nephrogenic systemic fibrosis or nephrogenic fibrosing dermopathy after gadolinium-based MR contrast agents. The FDA first notified health care professionals and the public about this risk in June 2006. There are currently five gadolinium-based contrast agents approved for use in the United States: Magnevist (gadopentetate dimeglumine), Ominiscan (gadodiamide); OptiMARK (gadoversetamide); MultiHance (gadobenate dimeglumine); and Prohance (gadoteridol). To date there are no reports of nephrogenic systemic fibrosis in those with normal kidney function or those with mild-to-moderate kidney insufficiency. The FDA suggests that gadolinium only be used when absolutely necessary in those with advanced kidney failure and that these patients undergo dialysis after vascular studies that require a large amount of gadolinium contrast.

Some patients experience claustrophobia and have difficulty cooperating during the study. Anxiety reactions are estimated to occur in 4% to 30% of patients (Granet and Gelber, 1990; Melendez and McCrank, 1993). As already discussed, new advances in technology now offer patients with anxiety or claustrophobia distraction with MRI-safe video goggles (Resonance Technology; Los Angeles, California). Patients with extreme skeletal abnormalities such as advanced scoliosis or flexion contractures, although motivated, may be unable to lie motionless

Box 33-1 The Joint Commission Sentinel Event Alert

PREVENTING ACCIDENTS AND INJURIES IN THE MRI SUITE

- “Missile effect” or “projectile” injury in which ferromagnetic objects (those having magnetic properties) such as ink pens, wheelchairs, and oxygen canisters are pulled into the MRI scanner at rapid velocity.
- Injury related to dislodged ferromagnetic implants such as aneurysm clips, pins in joints, and drug infusion devices.
- Burns from objects that may heat during the MRI process, such as wires (including lead wires for both implants and external devices) and surgical staples, or from the patient’s body touching the inside walls (the bore) of the MRI scanner during the scan.
- Injury or complication related to equipment or device malfunction or failure caused by the magnetic field. For example, battery-powered devices (laryngoscopes, microinfusion pumps, monitors, etc.) can suddenly fail to operate; some programmable infusion pumps may perform erratically; and pacemakers and implantable defibrillators may not behave as programmed.
- Injury or complication because of failure to attend to patient support systems during the MRI. This is especially true for patient sedation or anesthesia in MRI arenas. For example, oxygen canisters or infusion pumps run out and staff must either leave the MRI area to retrieve a replacement or move the patient to an area where a replacement can be found.
- Acoustic injury from the loud knocking noise that the MRI scanner makes.
- Adverse events related to the administration of MRI contrast agents.
- Adverse events related to cryogen handling, storage, or inadvertent release in superconducting MR imaging system sites.

or supine on the solid, uncushioned MRI table for the extended duration of a spinal MRI. These patients may require general anesthesia for positioning and comfort or may need adjunctive pain medication.

Nuclear Medicine

Nuclear medicine is one of the oldest functional imaging disciplines. Scans obtained through nuclear medicine are useful for identification of epileptic foci in refractory epilepsy, evaluation of cerebrovascular disease (e.g., Moyamoya disease), and the evaluation of cognitive and behavioral disorders (O’Tuama and Treves, 1993). Anesthesiologists become involved when the child’s medical history suggests that procedural sedation would not be appropriate. In order to complete these scans, the child must remain motionless for at least 1 hour.

The two most common nuclear medicine studies that require the administration of an anesthetic are single-photon emission computed tomography (SPECT) scans and positron emission

tomography (PET) scans. SPECT scans use single-photon gamma-emitting radioisotopes and rotating gamma cameras to produce three-dimensional brain images. SPECT scans involve the use of radiolabeled technetium-99 (half-life, 6 hours), which has a high rate of first-pass extraction as well as intracellular trapping in proportion to regional cerebral blood flow (Chiron et al., 1989). SPECT scans are ideal when seeking seizure foci, and they often precede surgical resection of an identified focus. The technetium radionuclide is ideal because it remains intracellular and can be visualized on scan hours after a seizure has occurred. Ideally, the child should be scanned within 1 to 6 hours of the seizure. The radionuclides are physiologically harmless and not allergenic. Caregivers should, however, wear gloves to minimize contact with radiation-containing secretions.

PET scans use positron emission tomography and radionuclide tracers of metabolic activity, such as oxygen or glucose metabolism (Chugani, 1993; Griffeth et al., 1993). Unlike SPECT scans, PET scans should be performed during the seizure itself. Because of the short half-life of the glucose tracer (110 minutes), the scan is best completed during the seizure or within 1 hour thereafter.

Radiation Oncology

Pediatric radiation oncologists use ionizing photons to destroy lymphomas, acute leukemias, Wilms tumor, retinoblastomas, and tumors of the central nervous system. Multiple sessions are typical, requiring reliable motionlessness in order to precisely aim the beam at malignant cells while sparing healthy cells. A planning session in a simulator is often scheduled before the initiation of radiation therapy so that fields to be irradiated can be plotted and marked.

Radiation therapy is usually brief, nonpainful, and may be approached with a variety of plans for rendering the patient temporarily motionless. The key issue is the anesthesiologist's limited access to the patient. Remote video monitoring, as well as ECG and pulse oximeter use, are crucial. Two, or in some locations three, video cameras are used to look at the monitors, the chest, and the face of the patient. A central venous catheter in young children undergoing a long course of radiation therapy helps immensely. It is important to remember that infants undergoing radiation therapy after a prolonged fast are at risk for hypoglycemia; delayed awakening, or tremulousness, any of which should prompt a glucose determination.

Fractionated radiation therapy is the strategy of dividing the total radiation therapy course into discrete daily sessions, allowing normal tissue repair between sessions while the tumor burden is lessened or destroyed. Hyperfractionated, or multiple-session daily radiation therapy, is a modality reported primarily in adults for head and neck cancers. The rationale for twice-daily fractionation in children is that fractionation to growing bone in rats reduces the growth deficit by 25% to 30%; the hope is that other normal tissues may be similarly spared during growth (Eifel, 1988; Eifel et al., 1990). Whereas one successful approach has been to give infants an initial formula feeding 6 hours before their first treatment and keep them fasting until recovery from their second anesthetic (6 hours after the first), with the current liberalization of fasting guidelines it is preferable to give children clear liquids during their recovery from the first anesthetic and keep them fasting thereafter for 4 hours before the second anesthetic (Menache et al., 1990).

Stereotactic radiosurgery (with a Gamma Knife) is a major advance in the treatment of select intracranial arteriovenous malformations and tumors in children (Loeffler et al., 1990). Stereotactic radiosurgery differs from external-beam radiotherapy in several important ways. A focused, single, large fraction of radiation is used instead of smaller, daily fractions. Stereotactic radiosurgery uses gamma rays of relatively weak intensity that are produced by 201 cobalt-60 sources that intersect at a single point where all 201 beams converge to destroy tumors, vascular malformations, or abnormal tissue sites within the brain. Normal brain tissue surrounding the abnormality is therefore relatively protected from radiation effects. In pediatrics as well as in adults, most radiosurgery originally concentrated on treatment of small, histologically benign lesions such as vascular malformations, acoustic neuromas, and pituitary adenomas. This has more recently been expanded to include malignant tumors such as solitary metastases, ependymomas, glioblastomas, and several other tissue types. For optimal results, the tumor's volume should be small (14 cm³) (Coffey et al., 1992).

Stereotactic radiosurgery requires coordination between departments of radiology, radiation therapy, neurosurgery, and anesthesiology. The stereotactic procedure begins either during the CT or MRI scan. The child is placed in a stereotactic head frame that is screwed into the cranium. Most adults are able to tolerate this entire procedure with local anesthesia or sedation. The neurosurgeon infiltrates the skin with a local anesthetic before applying the head frame. Adults and older children who tolerate this procedure with sedation alone may vomit as a result of anxiety, headache, or the location of the tumor itself. Because the head frame is heavy and cumbersome, it is difficult for the vomiting patient to turn his or her head in order to protect his or her airway. Pediatric patients (including most adolescents) typically require a general anesthetic. General anesthesia with tracheal intubation is induced before placement of the head frame. The key for removal of the head frame is taped to the frame itself. A nasogastric tube is placed for the day's anesthetic.

Calculations for dose and the three-dimensional coordinates for the beam may take several hours to compute after the initial radiologic study and head-frame placement. Some patients do well with sedation and spontaneous breathing; however, younger patients are usually mechanically ventilated. An initial CT scan is followed by computer calculations. Once the calculations are complete, the patient is transferred to the radiosurgery suite. After the irradiation, the patient is allowed to emerge from the anesthetic (Loeffler et al., 1990). The most common perioperative problem is nausea and vomiting, probably because of radiation sensitivity of the chemoreceptor trigger zone.

Stereotactic radiation therapy is a more precise localization of the fractionated radiation dose over the same duration of time as conventional radiation therapy, with the adjunctive use of a head frame. Considerations for the head frame include ease of application, reliability, ability to deliver supplemental oxygen and support the airway with a face mask if needed, and rapid removal of the facial restraint should it become necessary.

Total body irradiation (TBI) is generally performed twice a day over a 6-week period. It is usually in preparation for a bone-marrow transplant. For those patients who require anesthesia, the commitment is large—not only for the twice daily anesthetic but also for the coincident fasting status required. As these patients progress with their TBI treatment and become more immunocompromised, there is an increased risk of

acquiring an illness during the course of treatment. Vomiting, respiratory illness, poor nutrition, or hypovolemia are all possible. Cancelling a TBI treatment because of an associated illness is discouraged, because it disrupts the course of treatment and could compromise the patient's overall prognosis. Although anesthesiologists are wary of the risks of aspiration, both sedation and general endotracheal anesthesia have been found to decrease the incidence of vomiting with TBI (Westbrook et al., 1987; Whitwam et al., 1978).

Clinic and Office Procedures

Endoscopic Procedures

Gastrointestinal endoscopy has become a routine part of patient care, and as such it constitutes the bulk of procedures performed by a pediatric gastroenterologist (Fox, 1998). Depending on the patient and the type of procedure contemplated (therapeutic vs. diagnostic), children may require no sedation, minimal to moderately deep sedation, or general anesthesia. Minimal sedation may impair cognitive function and coordination while ventilatory and cardiovascular functions are relatively unaffected. However, pediatric patients often are uncooperative and do not tolerate endoscopic procedures with minimal or moderate sedation, necessitating deeper sedation or general anesthesia to successfully accomplish the procedure (American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists, 2002). Over the past 15 years, the volume of endoscopic procedures has increased by twofold to fourfold in the adult community, and has most likely increased at a similar rate in children (Cohen et al., 2006).

The inability to independently maintain ventilatory function and to respond purposefully increases the risk involved with deep sedation. Although some recommend that deep sedation be limited to anesthesiologist delivery only, gastroenterologists have demonstrated that they too are able to safely administer sedation (Saint-Maurice and Hamza, 1992; Wolfe and Rao, 1992; Hassall, 1993, 1994; Dillon et al., 1998; Bouchut et al., 2001; Koh et al., 2001; Paspatis et al., 2006). Propofol, considered by the ASA to be within the scope of anesthesia practice only, is considered by the American Society for Gastrointestinal Endoscopy (ASGE) to be an acceptable sedative for gastroenterologist administration (ASGE, 2002; Walker et al., 2003; Rex et al., 2005; Perera et al., 2006; Rex, 2006; Abu-Shahwan and Mack, 2007). Propofol is an important sedative for gastroenterologists, and it is estimated that one quarter of all adult endoscopies are performed with propofol sedation (Cohen et al., 2006). Children with more complex medical problems, anticipated airway difficulties, morbid obesity, or behavioral problems can undergo their procedures in the operating room. Regardless of the site of the procedure, all patients scheduled for endoscopy should be evaluated in advance to confirm that they are appropriate candidates. In addition, the anesthetic technique depends on the procedure, the patient, and the skill of the endoscopist, as well as the limitations and capabilities of the endoscopy suite. There is a wide range of sedation agents for children as well as adults, and there is no optimal sedation regimen for either age group (Lightdale et al., 2007).

Procedural sedation is readily achieved with an IV anesthetic combining a sedative (e.g., midazolam), opioid (e.g., fentanyl, alfentanil, remifentanyl, or dexmedetomidine), and a hypnotic

(e.g., propofol). Spontaneous ventilation without the patient's airway being intubated has been shown to be a safe and effective technique (Bouchut et al., 2001; Koh et al., 2001; Koroglu et al., 2006). The majority of complications are respiratory and usually occur during an esophagogastroduodenoscopy (EGD). These complications include apnea, laryngospasm, bronchospasm, and airway obstruction. Bradycardia has been observed with dexmedetomidine use in children. Most problems resolve after withdrawal of the endoscope and positive pressure ventilation with a tightly-fitting mask; however, some patients may require endotracheal intubation to secure an airway and safely complete the procedure.

Esophagogastroduodenoscopy

Access to the airway is obviously limited once a transoral endoscope is in place. It is important to maintain spontaneous ventilation during deep sedation, because any airway intervention needed typically requires the removal of the endoscope. The two most stimulating portions of the EGD are transoral and transpyloric passage of the endoscope. A smooth endoscope insertion can be aided by topical spray of local anesthesia to the oropharynx to help eliminate coughing and gagging.

A majority of the respiratory complications noted previously occur during EGD when compared with colonoscopy, especially in infants and younger children. It has been suggested that this results from a combination of factors, including the large size of the endoscope and partial airway obstruction resulting in hypoxemia. Abdominal distention as a result of air introduced into the stomach may impair diaphragmatic excursion, leading to hypoventilation. This has led several groups to select 6 months of age, as a result of the higher respiratory complication rate in this age group, as the time before which general anesthesia with endotracheal intubation is required for the procedure (Wolfe and Rao, 1992; Koh et al., 2001).

Colonoscopy

Access to the airway is unimpeded during a colonoscopy. Deep sedation can be achieved more readily, and if respiratory problems occur, airway interventions are straightforward to manage. Patients undergoing colonoscopy also experience increased stimulation during certain parts of the procedure, such as when traversing the colon to the cecum. Also, at times, abdominal pressure is applied to help guide the colonoscope. The depth of the anesthetic should be adjusted accordingly.

Endoscopic Retrograde Cannulation of the Pancreas

Although many institutions report success of procedural sedation in pediatric patients undergoing endoscopic retrograde cannulation of the pancreas, general anesthesia with endotracheal intubation may make the procedure easier to perform, especially if the procedure is of long duration, the patient has significant comorbid diseases, or the procedure is performed with the patient in the prone position (Teng et al., 2000; Prasil et al., 2001).

Psychiatric Interviews

IV sodium amobarbital has a long history as an adjunct to psychotherapy, having found its peak use during World War II

and immediately thereafter in helping soldiers deal with the stresses and trauma of combat (Zonana, 1979). Although this technique has enjoyed a resurgence for diagnostic and therapeutic interventions in adults, pediatric reports are rare. Weller et al. (1985) described the successful use of sodium Amytal in psychiatric interviews in prepubescent children. The induction of a tranquil state and sedation (e.g., slurred speech, a sense of fatigue, difficulty counting backwards, and basal vital signs) is similar to the anxiolysis achieved during monitored anesthesia care. A bispectral index (BIS) monitor may prove to be a useful adjunct as well (Palmer et al., 2001). The psychiatric interview process under these conditions is fascinating to participate in, if only as an observer. Memory retrieval, for instance the uncovering of relationships between current psychopathology and earlier traumatic life events, or symptom removal via therapeutic suggestions, are examples of interventions facilitated by the pharmacologically induced relaxed state made possible by the anesthesiologist during the interview.

SAFETY ISSUES FOR PATIENTS AND THEIR ANESTHESIOLOGISTS

As anesthesiologists find themselves participating in the care of patients who require increasingly sophisticated imaging technology, it is appropriate to examine the risks for patients and staff exposed to the types of high energies and contrast agents used.

Use of Intravascular Contrast Media

In a comprehensive review, Goldberg (1984) noted that approximately 5% of radiologic examinations with radiocontrast media (RCM) are complicated by adverse reactions, with one third of these being severe and requiring immediate treatment. Reactions occur most commonly in patients between 20 and 50 years of age and are relatively rare in children. The male/female ratio is about 2.5:1, not dissimilar to the gender distribution of other allergies such as latex, aspirin, and neuromuscular blocking agents. With a history of atopy or allergy, the risk of a reaction is increased from 1.5- to 10-fold. Reactions vary from mild, subjective sensations of restlessness, nausea, and vomiting to a rapidly evolving, angioedema-like picture accompanied by respiratory distress, bronchospasm, arrhythmias, and cardiac arrest. Because of the high osmolar concentrations of these agents (often higher than 1000 mOsm, and sometimes more than 2000 mOsm), caution should be exercised with patients who have a limited cardiovascular reserve (such as patients in congestive heart failure or those with cardiomyopathy). In addition, volume-depleted young children who have been kept fasting for prolonged intervals or who have had bowel preparations should be prehydrated before RCM administration. Those patients who are dependent on a full intravascular volume status (e.g., patients with sickle cell disease or restricted pulmonary circuit volume with cyanotic congenital heart disease and patients with arteriovenous shunts) should be monitored carefully for an initial rise in filling pressures and intravascular volume and subsequent diuresis after an osmolar load. Patients with impaired excretory mechanisms, such as those in renal failure, must be monitored closely after high osmolar loads. Low-osmolar RCM administrations are relatively safe with regard to life-threatening reactions, but moderate non-life-threatening

reactions requiring some treatment occur 0.2% to 0.4% of the time, and a severe life-threatening reaction can occur in 0.04% of patients (Thomsen and Bush, 1998).

RCM contains iodine, because iodine's high density and low toxicity make it an ideal agent for visualization and differentiation. The iodine is filtered through the glomeruli and is not reabsorbed by the glomeruli or the tubules. Because the contrast agent is hypertonic relative to plasma, an initial hypertensive response is usually followed by a hyperosmotic diuresis with the potential for hypotension. Equilibration with the extracellular fluid compartment occurs within 10 minutes, heralded by the onset of diuresis. Special attention should be paid when administering RCM with iodine to any child with a history of congestive heart failure. Patients with hepatic or renal dysfunction should be observed closely for signs of impaired excretion of the RCM. In sickle cell disease, the increase in blood osmolarity may precipitate shrinkage, clumping, and ultimately sickling of erythrocytes and vascular occlusion. Sickled cells are known to align with external magnetic fields to which they are exposed; it is unknown how this theoretic concern compares, for example, with the normal forces of deformation imposed on red cells of patients with sickle cell disease in their normal course through the vascular tree (Kanal et al., 1990).

Gadolinium diethylenetriaminepentaacetic acid (DTPA) is a low osmolar ionic contrast medium used for MRI, with a slower clearance in neonates and young infants than adults, yielding longer windows for imaging (Elster, 1990). Free gadolinium has a biological half-life of several weeks, with uptake and excretion taking place in the kidneys and liver. Unfortunately, free gadolinium is quite toxic and is therefore chelated to another structure that restricts the ion and decreases its toxicity. The most common adverse reactions are nausea, vomiting, hives, and headache. Local injection site symptoms include irritation, focal burning, or a cool sensation. Transient elevations in serum bilirubin (3% to 4% of patients) have been reported, and a transient elevation in iron for Magnevist and Omniscan (15% to 30% of patients) occurs, which tends to reverse spontaneously within 24 to 48 hours (Van Wagoner and Worah, 1993). Anaphylactoid reactions occur on the order of 1:100,000 to 1:500,000 and are more rare (< 1:100,000 doses) in children.

The older literature states that patients who have had anaphylactic reactions to shellfish are at increased risk of anaphylactoid reaction to RCM. The irony of the statement is that it may be correct, but not for obvious reasons. The original rationale was that shellfish contain high quantities of iodine, and therefore it was assumed that there would be a risk of cross-reactivity. However, neither shellfish allergy nor RCM reactions are caused by iodine. Atopy is a risk factor; therefore, the association between atopy, anaphylactic reactions to shellfish, and a possible predisposition to a RCM reaction may indeed be valid.

The treatment of severe allergic reactions, whether anaphylactoid or anaphylactic, is no different than for any other allergic reaction. Epinephrine, aminophylline, atropine, diphenhydramine, and steroids have all been employed in order to control varying degrees of adverse reactions. A patient who requires RCM administration and who has had a previous reaction to RCM has an increased (35% to 60%) risk for a reaction on reexposure. Pretreatment of these high-risk patients with prednisone and diphenhydramine 1 hour before RCM administration reduces the risk of reactions to 9%; the addition of ephedrine 1 hour before RCM administration further reduces the rate to 3.1% (Kelly et al., 1978; Greenberger, 1984).

In 2007, the ACR updated their practice guidelines for the use of intravascular contrast media that they published in the *Manual on Contrast Media* (ACR, 2008). Iodinated low-osmolality contrast media have a lower incidence of adverse effects as compared with ionic high-osmolality contrast media. The management of acute reactions in children is clearly outlined by the ACR (Box 33-2).

Allergic reactions rarely occur with oral agents. The incidence of severe anaphylactoid reactions to gastrointestinally administered agents is approximately 1:2,500,000, and the causes remain unknown. There are no pretreatment protocols established for these types of reactions and no well-defined risk factors. Gastrointestinal complications include nausea, vomiting, and diarrhea. One of the factors that may protect against having an allergic reaction is the poor absorption of oral iodinated contrast agents. Indeed, disruption of the GI mucosa is recognized as causing an increase in absorption of oral contrast, and the urinary excretion of contrast in a gastrointestinal study is a well-recognized sign. However, these signs are rarely associated with bronchospasm, flushing, periorbital edema, pruritis, rash, rhinitis or urticaria.

Ionizing Radiation

Radiation exposure is directly proportional to the duration of the procedure and inversely proportional to the square of the

distance from the source. Henderson et al. (1991) monitored the radiation exposure of 16 pediatric anesthesia fellows during a 1-month period. Fellows assigned to the cardiac catheterization laboratory had a fluoroscopy exposure time of 14 to 85 minutes per case, typically for two to three cases per day. For these anesthesiologists, badge readings ranged from 20 to 180 mrem/month. All noncardiac anesthesia fellows had undetectable (<10 mrem/month) levels. All fellows wore lead aprons, 50% wore a thyroid shield, and one stepped at least 10 feet away from the source during every exposure; this latter fellow had a reading of 30 mrem, despite having spent 26 hours in the catheterization laboratory. The annual maximum permissible dose (MPD) for nonradiation workers (including anesthesiologists) is 100 mrem or 1 mSv (mSv, Systeme Internationale Units). For comparison, the MPD for radiation workers is 50 mSv annually and 10 mSv times age cumulatively. MPD during pregnancy for radiation workers (per gestation) is 5 mSv. Limits of exposure and comparative sources of exposure are listed in Table 33-2.

High-Intensity Magnetic Fields

MRI exposes the patient (and the health care workers surrounding the patient) to a static magnetic field, a rapidly switched spatial-gradient magnetic field, and radiofrequency magnetic fields. The static magnetic field, which causes alignment

Box 33-2 Management of Acute Reactions in Children

URTICARIA

No treatment needed in most cases
Give H₁-receptor blocker: diphenhydramine PO, IM, or IV 1 to 2 mg/kg, up to 50 mg.
If severe or widely disseminated: give α -agonist, epinephrine SC (1:1000) 0.01 mL/kg.

FACIAL EDEMA

Give O₂ 6 to 10 L/min (via mask, face tent, or blow-by stream). Monitor electrocardiogram, O₂ saturation (pulse oximeter), and blood pressure.
Give α -agonist: epinephrine SC or IM (1:1000) 0.01 mL/kg, up to 0.3 mL/dose. Repeat in 15 to 30 minutes as needed.
Give H₁-receptor blocker: diphenhydramine IM or IV 1 to 2 mg/kg, up to 50 mg.
If not responsive to therapy, seek appropriate assistance (e.g., cardiopulmonary arrest response team).

LARYNGEAL EDEMA OR BRONCHOSPASM

Give O₂ 6 to 10 L/min (via mask, face tent, or blow-by stream). Monitor electrocardiogram, O₂ saturation (pulse oximeter), and blood pressure.
Give β -agonist inhalers: bronchiolar dilators, such as metaproterenol, terbutaline, or albuterol, 2 to 3 puffs. Repeat as necessary.
Give epinephrine SC or IM (1:1000) 0.01 mL/kg, maximum 0.3 mL/dose or IV epinephrine (1:10,000) 0.1 mL/kg, maximum 3 mL/dose. Repeat in 3 to 5 minutes as needed.
Call for assistance (e.g., cardiopulmonary arrest response team) for severe bronchospasm or if O₂ saturation <88% persists.

PULMONARY EDEMA

Give O₂ 6 to 10 L/min (via mask, face tent, or blow-by stream). Monitor electrocardiogram, O₂ saturation (pulse oximeter), and blood pressure.

Give diuretic: furosemide IV 1 to 2 mg/kg.
Call for assistance (e.g., cardiopulmonary arrest response team).

HYPOTENSION WITH TACHYCARDIA

Give O₂ 6 to 10 L/min (via mask). Monitor electrocardiogram, O₂ saturation (pulse oximeter), and blood pressure.
Legs elevated 60 degrees or more (preferred) or Trendelenburg position.
Keep patient warm.
Give IV or IO normal saline or lactated Ringer's solution 20 mL/kg over 5 to 10 minutes. Bolus infusion over 10 to 20 minutes in patients with myocardial dysfunction.
Seek appropriate assistance (e.g., cardiopulmonary arrest response team).

HYPOTENSION WITH BRADYCARDIA (VAGAL REACTION)

Give O₂ 6 to 10 L/min (via mask). Monitor electrocardiogram, O₂ saturation (pulse oximeter), and blood pressure.
Legs elevated 60 degrees or more (preferred) or Trendelenburg position.
Keep patient warm.
Give IV or IO normal saline or lactated Ringer's solution 20 mL/kg over 5 to 10 minutes. Give infusion over 10 to 20 minutes in patients with myocardial dysfunction.
Give atropine IV 0.02 mg/kg if patient does not respond quickly to steps 2, 3, and 4. Minimum initial dose of 0.1 mg. Maximum initial dose of 0.5 mg (infant/child), 1 mg (adolescent). Atropine dose may be doubled for second administration.
Seek appropriate assistance (e.g., cardiopulmonary arrest response team).

From American College of Radiology 2008 "Manual on Contrast Media." Version 6. Reston, Va, p 75-76.

IM, Intramuscular; IO, intraosseous; IV, intravenous; SC, subcutaneous; PO, orally.

TABLE 33-2. Limits and Sources of Radiation Exposure

Limits for Exposures	Exposure	Range
Occupational dose limit (U.S. NRC)	5000 mrem/year	
Occupational exposure limits for minors	500 mrem/year	
Occupational exposure limits for fetus	500 mrem	
Source of exposure		
Average dose to U.S. public from all sources	630 mrem/year	
Average dose to U.S. public from natural sources	330 mrem/year	
Average dose to U.S. public from medial sources	53 mrem/year	
Chest x-ray	8 mrem	5-20 mrem
Extremities x-rays	1 mrem	
Dental x-ray	10 mrem	
Head/neck x-ray	20 mrem	
Cervical spine x-ray	22 mrem	
Lumbar spinal x-rays	130 mrem	
Pelvis x-ray	44 mrem	
Hip x-ray	83 mrem	
Upper GI series	245 mrem	
Lower GI series	405 mrem	
CT (head and body)	1100 mrem	
Expected 50% death without medical attention	400,000 mrad	300,000-500,000 mrem
Doubling dose for genetic effects	100,000 mrad	
Doubling dose for cancer	500,000 mrad	(8% per mSv, natural level at 20%)
Dose for increase cancer risk 1:1,000	1250 mrem	(8% per mSv)
Consideration of therapeutic abortion threshold (dose in utero)	10,000 mrem	

1 mrem = 10 mSv; 1 rad is the amount of radiation to deposit 0.01 joules of energy per kilogram.

of unpaired tissue protons, may cause movement of ferromagnetic devices such as vascular clips, ventricular shunt connectors, casings for pacemakers, and control devices for pacemakers. Metallic devices in other areas, particularly when invested with fibrous tissue, are less problematic (Shellock and Crues, 1988; Shellock, 1989). As mentioned previously, tissue expanders may have magnetic ports to facilitate identification of the injection site. Despite their low mass, such ports have a potential for torque and movement in the presence of a strong magnetic field; therefore, the specific type of tissue expander should be identified before patient evaluation in an MRI (Liang

et al., 1989). Assessment of risk in patients with implants or other possibly ferromagnetic devices or objects consists of a careful history including penetrating wounds, physical examination to look for scars, and possibly a plain radiograph of the region in question (Pohost et al., 1992). Other concerns have been increased blood pressure, cardiac arrhythmias, and impaired mental function. Although described or theorized on an experimental basis, little clinical documentation is available.

The magnetic field generates an electrical current two to three orders of magnitude less than a defibrillator (10 mA/M², compared with, 000 to 10,000 mA/M²). This current strength may nevertheless reprogram a programmable pacemaker and interfere with its function (Erlebacher et al., 1986). Exposure to a strong external magnetic or electromagnetic field can lead to conversion of a demand pulse generator from synchronous to asynchronous mode, damage to the reed switch (that activates the fixed-rate pulse generator), reprogramming of pacemaker parameters, induction of currents in the electrode wires, or displacement of the generator itself. Indeed, it is the sensitivity of some reed switches that has determined the safety boundary of MRI devices as being 5 Gauss (5×10^{-4} T). Patients with implantable defibrillators or cardioverters, implantable infusion pumps (e.g., for insulin), cochlear implants, and neurostimulators are all at risk for having the implant device reprogrammed on exposure to the magnetic field. Defibrillator failure has been reported in the MRI environment (Snowdon, 1989).

Radiofrequency pulses cause heat production in metallic implants and coiled wires such as ECG cables or pulse oximeter cables if they are looped and laying on the patient's skin. Patients with compromised thermoregulatory abilities, such as those with cardiac problems, fever, or taking certain drugs, may be at particular risk. Included in this group are infants, whose SAR is greater than that of adults because of the greater ratio of body surface area to body mass, and whose thermoregulatory abilities may be interfered with during a general anesthetic (Kussman et al., 2004). SAR refers to the energy absorption (e.g., increasing body temperature) with an increase in the total amount of radiofrequent energy absorbed (Fitzsimmons, 1992).

Increased reports of vertigo, nausea, and a metallic taste have been found in a study on human exposure to the 4-T magnetic field of a whole-body scanner (Schenck et al., 1992). Fertilized frog embryos exposed to a 4-T magnetic field did not demonstrate any adverse effects on early development (Prasad et al., 1990). An increase in CCL of 17% was found in healthy volunteers in a 2-T environment after 10 minutes of exposure, causing speculation about the effect of the 2-T environment on the sinus node (Jehenson et al., 1988). This may be of particular concern in patients with a preexisting arrhythmia history. Of more significant concern in pediatric patients is the potential for hypothermia, because of the air flow directed through the scanner cavity and the inability to control room temperature or use radiant warmers. The use of warm IV fluid bags, thermal packs, and blankets can decrease heat loss. Excellent reviews of monitoring considerations and equipment choices in the MRI environment, as well as patient safety principles are available, and the ACR (with a representative from the ASA) has published a recent white paper on MRI safety (Kanal et al., 1990, 2007; International Non-Ionizing Radiation Committee of the International Radiation Protection Association, 1991; Fitzsimmons, 1992; Menon et al., 1992; Patteson and Chesney, 1992; Pohost et al., 1992).

MRI and spectroscopy do not employ ionizing radiation. However, secondary harmful effects, such as magnetic objects becoming projectiles within the magnetic field as they approach the bore of the magnet and potentially causing injury, are a consideration (Chu and Sangster, 1986; Chaljub et al., 2001). Patients (and anesthesiologists) with metallic implants such as vascular clamps, hemostatic clips, dental devices, heart valve prostheses, intravascular coils, filters and stents, ocular implants, orthopedic implants, otologic implants, shrapnel, penile implants, and vascular access ports must be individually evaluated for their risk in the MRI environment (Cahalan et al., 1987; Shellock and Curtis, 1991).

As with individual precautions, equipment precautions should be taken for all ferromagnetic objects such as IV stands, oxygen, and nitrous oxide cylinders, and monitoring equipment. The anesthesia machine, if used in the scanning room, should be outfitted with aluminum gas cylinders and kept in the corner of the room. Anesthesia machines especially designed to be MRI-compatible are now readily available.

DIFFICULT-AIRWAY MANAGEMENT IN THE RADIOLOGY SUITE

If a child with a known difficult airway requires endotracheal intubation in order for the scheduled procedure to be completed, it is wise to perform the anesthetic induction in the operating room, an area where access to difficult-airway equipment is readily available. Regardless of an anesthesiologist's comfort level and familiarity with extramural environments, the same depth of back-up coverage is simply not available.

The unrecognized difficult airway is problematic in a remote location; therefore, it is important to have LMAs stocked in all extramural anesthesia carts. If a child cannot be intubated or ventilated with a mask, LMAs can provide a successful alternative. Case reports describe the successful use of LMAs in children with difficult craniofacial anomalies, such as Goldenhar's syndrome and even Pierre Robin sequence (Fan et al., 1995; Hansen et al., 1995; Haxby and Liban, 1995). Similarly, a light wand may facilitate endotracheal intubation in the child with a difficult airway (Holzman et al., 1988). Recently introduced rigid laryngoscopes with video in infant through pediatric sizes (e.g., Glidescope), should be strongly considered for availability in offsite locations.

It is important to recognize that an airway that was not difficult on induction may become difficult on emergence after sclerotherapy with alcohol and subsequent tissue edema, particularly at the base of the tongue, neck, or the mediastinum (Furst et al., 1996; Ohlms et al., 1996; Fishman, 1999). These patients often require several days of airway support and ongoing evaluation in the ICU until airway swelling is no longer a concern.

BLOOD-LOSS MANAGEMENT OUTSIDE OF THE OPERATING ROOM

Transfusion requirements are rare in extramural locations, yet preprocedural anemia, accidental perforation of vascular structures, or medical transfusion requirements such as sickle cell disease or prematurity may require transfusion therapy. Equipment familiar to the anesthesiologist and identical to that available in the operating room is a welcome sight in a life-threatening emergency. Calling for additional help, establishing additional vascular access, and coordinating with the blood bank is crucial. Having a runner available may be critical when there is no equivalent to a circulating nurse. In an emergency, it may become necessary to involve a surgeon and transport the patient to the operating room, in which case it would be optimal for another anesthesia team to set up the operating room while the patient is being prepared for transport.

SUMMARY

The demand for anesthesia and sedation services in sites distant to the operating room is continuing to increase. Providing patient services in locations remote to the operating room can be challenging and poses risks that may not exist in the operating-room setting. Although the incidence of adverse outcomes for anesthesia and sedation in these remote areas has never been prospectively studied, we can look at office-based and ambulatory surgery centers to extrapolate the risk. Comparative outcomes analysis in Florida reveals that the incidence of adverse events is higher in the office-based setting when compared with outpatient surgical centers (Vila et al., 2003). Although these outcomes cannot be directly compared, it raises the question of added risk in the off-site anesthetizing location. Sedation, monitored anesthesia care, and general anesthesia are all choices that carry risks. Historically, an avoidance of a general anesthesia has been thought to minimize the risk of adverse outcome. Closed-claims analysis has shown, however, that monitored anesthesia care poses an equal risk to general anesthesia with respect to severity of injury, death, and permanent brain damage. Furthermore, 24% of all monitored anesthesia care claims involve oversedation and respiratory depression (Bhananker et al., 2006). In summary, anesthesia care providers must recognize that as the demand for off-site services increases, so also should their ability to understand the environment and do careful risk analysis when selecting patients and formulating a plan of care.

		Summary	1076

O utpatient procedures continue to account for the majority of anesthetics given to children in the United States. It is estimated that more than 60% of anesthetics in children are performed on outpatients, and this number is considerably higher in some practice settings. Although the practice of outpatient anesthesia and surgery for children is not new—reports in the medical literature have documented the practice for over 100 years—advances in drugs and techniques are transforming the care given to day-surgery patients. Procedures that previously required overnight stays can often be performed on a same-day basis. It is possible to reduce the incidence of troubling side effects of anesthetics that may have prevented the discharge of patients in the past, and better postoperative analgesic regimens may allow for earlier discharge. Changes in facility designs have improved our ability to provide outpatient care in an efficient and cost-effective manner, while simultaneously enhancing and simplifying the perioperative experience for patients and their families. Nevertheless, along with these advances have come new challenges. The envelope of

what patient and procedure is appropriate for same-day surgery has continued to stretch, whereas resources may be shrinking. The pressure to increase performance and throughput places greater stresses on the perioperative system, and great care must be taken to avoid cutting corners for the illusionary benefits of efficiency and cost-containment alone.

Historical reports of outpatient surgery date back to the early twentieth century, when Nicholl reported nearly 9000 operations on ambulatory children at Glasgow's Royal Hospital for Sick Children (Nicholl, 1909). Other early reports from the United States soon followed, but it was not until the 1970s that studies looking at same-day surgery from a systems perspective were published. In addition to examining the patient population, complication rates and surgical procedures, these reports began to look at issues such as cost and delivery of care, as well as the optimization of the nursing and support staff, organization, and physical plant for outpatient surgery. Attention to these details continues to play a central role in the increased use and success of outpatient surgery. In the current economic

climate of health care in the United States, there is and will continue to be a major emphasis on cost savings. In addition to the economic advantages of savings on hospital resources, a primary driving force in the popularity of outpatient surgery is satisfaction of the patient's parents. There are obvious advantages for many parents and children to avoid overnight hospitalization and to have the child back in a familiar home environment on the same day. The decisions that are made in planning the outpatient system will have a major impact on how parents perceive ease of use and quality of care of the entire system, and, as a result, its success. Factors that are not medical at all (e.g., ease of parking, efficiency of check-in procedures, waiting time, parental presence during induction of anesthesia, and early admission to the postanesthetic recovery unit [PACU]) may make impressions on the parent that are equal to the obvious medical issues, such as complication rates, management of postoperative analgesia, postoperative nausea and vomiting (PONV), and rapid return to the preoperative mental state.

PROCEDURES AND PATIENTS AMENABLE TO OUTPATIENT SURGERY AND ANESTHESIA

Many operative procedures are well suited to be performed on pediatric outpatients and all share several common characteristics. They all are peripheral procedures that do not involve major violation of a body cavity. They all have limited duration, generally lasting less than 2 hours, and have minimal or moderate amounts of postoperative pain that can easily be managed after discharge from the PACU with oral analgesics, or by either a single-injection regional block placed at the time of surgery or continuous regional analgesia at home. They do not result in major physiologic perturbations or blood loss, nor do they disturb the ability to take oral fluids and nutrition in the immediate postoperative period. They do not require postoperative monitoring beyond the capability of the parents and home. Commonly performed outpatient procedures are listed and categorized in [Table 34-1](#).

CONTRAINDICATIONS FOR OUTPATIENT ANESTHESIA

There are few firm contraindications to outpatient surgery for amenable procedures, but there are some patients who have medical issues that make it advisable to consider an overnight ("23-hour") admission rather than discharge on the day of surgery. In the majority of these cases, monitoring is required because of anesthetic-related risks or because of exceptional risks related to the operative procedure or postoperative care in susceptible individuals.

Expremeure Infants and Apnea

The risk of postanesthetic apnea in former premature infants has been well described since the early 1980s, when Liu et al. (1983) published the first prospective study of premature infants anesthetized between 41 and 46 weeks' postconceptional age (postconceptional age equals the gestational age at birth plus an infant's current age in weeks). The authors compared a group of premature infants with a control group of term infants of similar

TABLE 34-1. Operations Commonly Performed as Outpatient Surgical Procedures by Specialty

Specialty	Procedures
Otolaryngology	Myringotomy and ventilating tubes, adenoidectomy (see text), tonsillectomy (see text), frenulectomy, branchial cleft cysts, endoscopic sinus surgery, examination under anesthesia including some bronchoscopy
Ophthalmology	Examination under anesthesia, strabismus repair, nasolacrimal duct probe, intraocular lens implantation, trabeculectomy
General pediatric surgery and urology	Herniorrhaphy and hydrocelectomy, orchiopexy, uncomplicated hypospadias, cystoscopy and cystoscopic surgery, circumcision, esophagoscopy, lumps and bumps
Gastroenterology	Endoscopy
Plastic surgery	Cleft lip and some cleft palate repair, placement of tissue expanders, scar revision, minor reconstructive procedures (otoplasty, septorhinoplasty, etc.)
Orthopedics	Hardware removal, casting, percutaneous tenotomy, arthrograms Percutaneous pinning and simple OFIF
Radiology	Imaging studies, radiation therapy
Dentistry	Extractions, restorations, examinations Nerve treatments, crowns, sealants, and fillings

ages. The incidence of apnea, defined as pauses in breathing lasting greater than 15 seconds, was 20%. Subsequent studies have approximated this incidence, although some have placed the at-risk period as far out as 60 weeks' postconceptional age (Welborn et al., 1986; Kurth et al., 1987; Warner et al., 1992). It is now established that infants born before 36 weeks' gestational age are at some risk of apnea after general anesthesia. It appears that this risk is because of immaturity in the brainstem's control of breathing after exposure to general anesthetics, and there may be similar risks after exposure to sedative-hypnotic agents and neuroleptic agents such as ketamine. Numerous studies have tried to define the period of susceptibility in the at-risk population. Several investigators have stratified the risk according to postconceptional age and gestational age at birth, and a meta-analysis of eight studies has reported that the postconceptional age required to reduce the risk to less than 1% with 95% confidence was 54 weeks in infants born at 35 weeks' gestational age and 56 weeks in those born before 32 weeks' gestation (Malviya et al., 1993; Coté et al., 1995). In this meta-analysis, anemia was also associated with increased apnea risk, particularly in infants older than 42 weeks' postconceptional age. The patients in the numerous studies that were included in this meta-analysis may not have all been comparable in terms of underlying state of health, so these data (as in all meta-analyses) must be approached with some caution. Several investigators have suggested that the use of regional anesthesia may eliminate the risk, and a few even advocate discharge of these patients on the day of surgery if no other agents have been administered (Veverka et al., 1991; Webster et al., 1991; Sartorelli et al., 1992; Krane et al., 1995). However, uncontrolled case reports of apnea after spinal anesthesia have been published (Watcha et al., 1989; Tobias et al., 1998). Because these are case reports and there

were no control pneumograms, it is unknown if the apnea was related to the anesthetic or not, but these reports have still prompted most clinicians and consultants to continue to recommend admission and monitoring of these patients for 24 hours after any anesthetic. Krane et al. (1995), in a prospective randomized controlled study, compared former premature infants receiving general or spinal anesthesia with preoperative and postoperative impedance respirometry, oxygen saturation, and electrocardiography (ECG). In this small sample of 18 patients, no central apnea differences were detected, but the group receiving spinal anesthesia had fewer desaturations and bradycardic events than those receiving general anesthesia. Caffeine, which has a long history of effective use in apnea of prematurity, has also been suggested to increase central respiratory drive after anesthesia in these patients, although it is still not commonly used (Welborn et al., 1988, 1989).

Obstructive Sleep Apnea

One of the most common indications for tonsillectomy is upper-airway obstruction during sleep. In many centers, obstructive sleep apnea (OSA) accounts for 50% or more of all children who come for tonsillectomy and adenoidectomy (Messner, 2003). These children may have abnormal ventilatory responses to both hypoxia and hypercarbia as a result of the chronic exposure to hypoxic and hypercarbic conditions during sleep (Strauss et al., 1999; Kerbl et al., 2001). These responses can take up to several weeks to revert to normal after resolution of the obstruction. There are concerns, therefore, about the ability to maintain adequate ventilation and oxygenation in the period immediately after the exposure to general anesthetics and to opioids given for postoperative analgesia. A study of 15 otherwise healthy children, ages 1 to 18, with mild OSA used preoperative and postoperative pneumograms to assess respiratory status on the night after adenotonsillectomy. Nine of these children received a halothane-based anesthetic, and six received a fentanyl-based technique. The number of obstructive events decreased, and the nadir of oxygen saturation improved from 78% to 92%. The authors concluded that in cases of mild OSA without other underlying disorders, intensive postoperative monitoring is not necessary (Helfaer et al., 1996). In another group of 134 children selected for outpatient tonsillectomy, 83% of whom carried the diagnosis and indication for surgery for OSA, 11 (8.2%) were admitted for inpatient observation after experiencing respiratory problems in the post-anesthetic care unit (Lalakea et al., 1999). These patients as a group were significantly younger than those discharged home (an average age of 4 vs. 6.3 years). Preoperative evaluation and assessment of OSA was not described. Most otolaryngologists consider significant (as opposed to mild or moderate) OSA to be a relative contraindication to outpatient management of adenotonsillectomy, especially in children younger than 3 years of age, although in one small study the postoperative complications in these younger children were not related to obstructive events (Slovik et al., 2003). Those investigators suggested that the severity of OSA, rather than a patient's age, may be a more predictive factor, but this is in conflict with other reports that recommend that an age younger than 3 years should be considered an independent discriminator (Shott et al., 1987; Biavati et al., 1997). One large retrospective analysis of 2315 patients younger than 6 years of age undergoing adenotonsillectomy for

OSA found a higher rate of respiratory complications in those younger than 3 years (9.8% vs. 4.9%) (Statham et al., 2006). The only criterion that appears to be unequivocally accurate in the diagnosis and stratification of severity in OSA is polysomnography; neither the history nor pulse oximetry alone is specific or sensitive enough (American Thoracic Society 1996; Schechter, 2002; Subcommittee on Obstructive Sleep Apnea, American Academy of Pediatrics, 2002). In the absence of objective data, it is worthwhile to elicit a history of significant snoring or sleep-disordered breathing during the preoperative interview with the parent. Even though such historical data may not be accurate in all cases, it serves to alert the anesthesiologist to the potential for problems (Sinha et al., 2008).

Recent data on opioids in the patient with chronic hypoxemia are particularly relevant to the child with OSA, whether the child is to undergo tonsillectomy or another surgical procedure. In an animal model, rats exposed to chronic hypoxic conditions had greater respiratory sensitivity to opioids, exhibiting diminished respiratory drive (Moss et al., 2006). Confirming these animal data, children who experienced significant hypoxia during sleep had lower opioid requirements to achieve analgesia after tonsillectomy (Brown et al., 2006). In this prospective study of 22 children with OSA undergoing tonsillectomy, the opioid dose required to achieve equal analgesic scores on a behavioral pain scale was directly correlated with the nadir of their oxygen saturation on the preoperative polysomnogram. Those with the lowest saturations required the least opioid, demonstrating that chronic recurrent hypoxemia during sleep was associated with increased analgesic sensitivity to morphine. The key implication is that not only are ventilatory responses to hypoxia and hypercarbia with opioids blunted, but actual analgesic requirements are less, and lowering opioid and other sedative medication doses still results in adequate analgesia while potentially reducing the risk of untoward effects.

PREOPERATIVE EVALUATION AND PLANNING

The evaluation of outpatients for surgical procedures presents a significant organizational challenge to the anesthesiologist. Because one of the primary goals of outpatient surgery is both efficiency and rapid throughput, there is a great disincentive to require preoperative visits before the day of surgery itself. At the same time, an efficient system demands an absolute minimum of cancellations on the day of surgery. Such pressures put both the anesthesiologist and the system as a whole at significant risk of proceeding with cases in which the patient may not be optimally prepared for surgery and anesthesia. There is also the stress of "production pressure"—the urgency to move patients rapidly through the preoperative queue and into the operating room on schedule. This, too, is in competition with the need to provide the best and most complete evaluation and care of the patient. In order to avoid these situations, a system of preoperative screening must be instituted that provides the most accurate, up to date, and complete information so the anesthesiologist may make well-informed decisions about patient management. Fortunately, both technological and nontechnological aids exist to streamline this process.

The implications of cancellation, particularly on the day of surgery, go far beyond the efficiency of the operating room. A survey by Tait et al. (1997) found that nearly half of parents whose

children's operations were cancelled on the day of scheduled surgery missed a day of work, and about half of these went unpaid as a result. Many drove long distances to get to the hospital, and nearly 25% were frustrated or angry as a result of the cancellation. A small number of dissatisfied or angry parents can have an adverse impact on the success of an outpatient surgery program well out of proportion to their numbers, and great attention must be paid to minimizing these events by using systems that work effectively.

In many cases, a preoperative visit to the anesthesiologist is neither practical nor necessary. Because the majority of children who come for same-day surgery are relatively healthy, screening tools that employ methods such as telephone interviews and self-reporting can often be employed. Coordination with the surgeon's office may reduce both redundancy in paperwork and repeated questioning of the patient's family. The efficiency in combining surgical, anesthetic, and nursing evaluations can be greatly enhanced if a computerized record is used. With these systems, which are finally beginning to reach maturity after years of development, data from one evaluation can automatically populate another linked database; however, at times implementation of these systems still remains limited, and lack of universal interoperability and poor interface and database design remain major impediments to their acceptance. Nevertheless, at the start of the second decade of the 2000s, progress is being made and it can be expected that increased use of electronic medical records will greatly streamline the evaluation process. Even in the majority of institutions, where paper records still remain the standard, systems using secure e-mail, facsimile, or even common forms can be designed to eliminate redundancy. The elimination of needless paperwork or data entry can be a great aid in increasing patient throughput, as well as reducing the frustration of staff and parents alike.

The initial step in preoperative planning and evaluation begins when the surgeon books the case. This is the first opportunity for the system to alert the anesthesiologist of any unusual conditions or underlying illnesses that the patient may have. A short list of check-boxes on the booking form suffices and need not have any great detail. This information can be reviewed by an anesthesiologist (or, in an electronic system, automatically trigger an alert to a consulting anesthesiologist) to detect any cases that might benefit from especially extensive consultation or planning before the day of surgery.

The surgeon's office, because it is the initial contact point of the patient's family with the perioperative system, also provides an excellent opportunity to present the parents with introductory information about the anesthetic. A pamphlet describing generalities such as the role of the pediatric anesthesiologist in caring for the child, fasting instructions, contact numbers, and other information specific to the hospital or outpatient surgical center can be a useful reference for the family. Having a written reference for fasting guidelines is especially helpful, because lack of adherence to these instructions is a common cause of case delay or cancellation. The language should be clear and uncomplicated, and a place for the actual times that the child in question should cease eating and drinking should be provided to eliminate confusion and misinterpretation. It is advisable to set the fasting time based not on the scheduled time of operation but rather on the time of arrival at the preoperative unit. This permits the case to go forward early if the operating

room runs ahead of schedule. Parents should be given a number to call both for questions about the anesthetic that they feel cannot wait until the preoperative assessment, and for consultation with an anesthesiologist should an intercurrent illness develop between the time of the visit to the surgeon and the day of surgery.

A preoperative visit to the surgeon alone, however, will not optimize the preoperative evaluation process for the anesthesiologist or for the same-day surgery process as a whole. A case-control study of pediatric outpatient cancellations found that 10% of all day surgery patients at a children's hospital were cancelled on the day of surgery, and half of those were for preventable reasons. Cancelled patients who had inadequate preoperative preparation were more likely to have been seen only in the surgeon's office and not in the hospital's preoperative program (Macarthur et al., 1995). It is clear that further screening is optimal to address general medical and anesthetic concerns.

Background

A short telephone interview with the patient's parent before scheduled surgery, whether conducted by the anesthesiologist, a physician's assistant, or a nurse practitioner, can be not only a source of clinical information about the patient and about the parent's concerns, but can also forestall unanticipated problems that can cause delays, cancellations, or complications on the day of surgery. Knowing in advance, for example, that a child with asthma had a mild upper respiratory infection (URI) the week before surgery, can allow the anesthesiologist to prescribe a short preoperative course of steroids with ample time for the drug to take effect. The child who has sickle cell disease with an active URI, on the other hand, might have surgery postponed, thus saving the parents a trip to the hospital and allowing the schedule to be rearranged before the day begins. A well-organized system for conducting these calls should be established, so patients are not missed and communications with the anesthesiologist scheduled to care for a particular patient can be easily accomplished. It is important to organize the system so that calls are most effective. A study of over 5000 patients conducted at National Children's Hospital in 1992 found that calls made during the evening were far more likely to successfully reach the parents—not an unexpected finding (Patel and Hannallah, 1992). In Great Britain and in some hospitals in the United States, preoperative clinics rather than telephone screening are used, but this may necessitate an additional visit by the family. The inconvenience may outweigh the advantages of a face-to-face visit for some families, and success may be predicated on ease of use of the system. Preoperative screening and evaluation can also improve throughput on the day of surgery, particularly if there is a long list of short cases, such as myringotomy and ventilation-tube placement. The duration of those cases is so short that the time it takes to do a preoperative evaluation may be longer than the operative time. Saving even 10 or 15 minutes per hour might allow the team to perform an additional operative procedure each hour.

Other methods of communication, including secure websites and e-mail, have been used for similar purposes. The ability for a family to access a secure server and enter preoperative interview information will likely become increasingly attractive in coming

years. Although the personal interaction with a knowledgeable professional can never be replaced, certain “boilerplate” data can be entered with great efficiency in this manner, permitting rapid and efficient review by the anesthesiologist. Intranet-based kiosks at the hospital, where patients’ families can use either keyboard or touch-screen technology to enter information that is now entered on paper questionnaires at the time of admission, will become increasingly important modalities as hospitals move from paper-based records to digital ones.

It is particularly important that reports of previous operative procedures or consultations by specialists be made available to the anesthesiologist during the preoperative assessment. A computerized repository of this information is the best solution, because it allows immediate access from any location. However, many institutions have not yet migrated to completely digital medical records, and legacy data from the paper chart must be entered into the electronic chart as scanned documents. Unless all electronic documents are properly tagged or archived in appropriate folders, they may be difficult to locate. Knowledgeable database professionals, in consultation with the anesthesiology department, must carefully determine a scheme for labeling and retrieving archived documents in advance. If an electronic medical record is not in place, a day-surgery coordinator should have the responsibility of ensuring that necessary outside and internal records are readily available the day before surgery in order to avoid delays. Such information must be immediately accessible to the anesthesiologist on the day of surgery as well.

In some locations, it is common for a child’s pediatrician to be responsible for “clearing” the child for surgery. This can be a considerable help, because the pediatrician often has the best knowledge of the child’s underlying illnesses and conditions. The pediatrician, however, often has little understanding of the issues that are of greatest concern to the anesthesiologist and may actually miss or ignore problems that can impact anesthetic management, to the detriment of the preoperative evaluation process. The anesthetic implications and preoperative optimization of airway anatomy and function, gastroesophageal reflux, upper respiratory illness, and asthma, as well as of syndromes and chronic conditions such as Trisomy 21 and the former premature infant, all may be underappreciated by pediatricians who do not work in the operating room or administer anesthetics and have usually had little or no training in perioperative medicine (Fisher, 1991). Several recent reviews (written by pediatric anesthesiologists) in the pediatric literature have discussed the preoperative screening process and what the pediatrician needs to know about preparing the child for anesthesia (Fisher, 1991; Fisher et al., 1994; Maxwell et al., 1994; Section on Anesthesiology, 1996). If a hospital or surgery center relies on pediatricians as a major link in the preoperative assessment chain, pediatricians must be familiar with this literature and should have ongoing communication with their anesthesiology colleagues. Collaborative efforts, such as continuing medical education conferences and residency training about these topics, can reap significant rewards.

Policies on preoperative testing have been completely reassessed in recent years, and abandonment of the routine use of tests has become the norm. This is driven by both the growing number of studies that demonstrated little or no value in such testing, as well as by economic concerns that mandate the elimination of unnecessary expenditures.

Urinalysis

A 1990 study of nearly 500 children scheduled for elective surgery found abnormalities in 15% of children; however, more than 80% of those were historically known, clinically insignificant, or false positives. The authors concluded that preoperative urinalysis should not be routinely performed on healthy children for preoperative assessment (O’Conner and Drasner, 1990).

Hematocrit and Complete Blood Count

Unless a surgery is expected to result in significant blood loss (highly unlikely for outpatient surgery), the complete blood count (CBC) screening has little or no value (Roy et al., 1990, 1991; Hackmann et al., 1991). Several studies have demonstrated that the presence of mild to moderate anemia has little to no effect on the conduction of anesthesia or outcome in children undergoing same-day surgical procedures. The presence of anemia in former premature infants of fewer than 54 weeks’ postconceptual age has been found to correlate with an increased risk of postanesthetic apnea, and screening for anemia in this population may detect those at increased risk (Welborn et al., 1991). It is not known, however, if the anemia is the cause of increased apnea or only an associated finding. There are no data to determine whether correction of anemia in these patients reduces the risk of apnea. All former premature infants who are at risk should be admitted for postoperative monitoring in any case, thus screening may not alter clinical practice. Children with sickle cell disease (not trait) need to have their hemoglobin level measured, because both management and outcomes of these patients are dependent on an adequate level of hemoglobin A or F (see the following section).

Sickle Cell Testing

In many states, newborns in at-risk populations are screened for sickle cell disease, thus the sickle cell status of all infants and children in those locations is known. In locations where such newborn screening is not universal, it is prudent to obtain sickle cell testing in any infant or child under the age of 3 years of at-risk ethnicity whose status is unknown. Children older than this are likely to have had symptoms if they are affected. In children who do have sickle cell disease, a preoperative hemoglobin level is mandated to determine the need for preoperative transfusion. A large multicenter trial found that simple transfusion, if the hemoglobin was less than 10g/dL, is as effective as exchange transfusion in these patients (Vichinsky et al., 1995) (see Chapter 36, Systemic Disorders). One study has reported that minor surgical procedures like those usually performed on outpatients could be safely performed in patients with sickle cell disease without preoperative transfusion; complication rates were significantly higher in children undergoing abdominal, thoracic, or airway procedures (Griffin and Buchanan, 1993). However, sickle cell trait, which usually does not cause any symptoms or illness, has rarely been associated with the complications of surgery and anesthesia, and hemoglobin determination in these patients is unnecessary (Konotey-Ahulu, 1969; McGarry and Duncan, 1973; Atlas, 1974; Gibson and Love, 1974).

Heart Murmurs and Cardiology Consultation

At least 25% of healthy children have an audible heart murmur at some time during childhood, and the question of when to refer a child to a pediatric cardiologist for the evaluation of a new murmur is often raised during the preoperative evaluation. The vast majority of these are functional (“innocent”) murmurs, not associated with any structural heart disease. Innocent murmurs are soft (less than grade 3), blowing, and loudest along the left sternal border. They tend to decrease or disappear during inspiration. Most congenital heart lesions appear before the first several months of life, so an asymptomatic murmur in an older child is less likely—but not entirely impossible—to be significant. Exceptions include atrial septal defects, small ventricular septal defects, coarctation of the aorta, some valvular lesions that have no hemodynamic symptoms during normal activity, and in rare instances, other lesions. The ability of a pediatric cardiologist to distinguish between a functional murmur and one caused by a structural heart lesion by examination alone was evaluated and found to be high, so more extensive (and expensive) evaluation, such as echocardiography, is rarely necessary (Newburger et al., 1983). If the child is older than 6 months of age, without any symptoms referable to the cardiac system, most skilled clinicians should be able to evaluate these murmurs and rule out hemodynamically significant congenital heart disease. Cardiomyopathy can also bring on a new murmur, so a previously undetected murmur accompanied by symptoms suggestive of impaired myocardial performance or irritability, such as dysrhythmias, especially if it follows a viral illness, should be evaluated by a cardiologist.

Children with some congenital heart lesions require antibiotic prophylaxis for the prevention of endocarditis when undergoing operations during which they will be at risk. In 2007 there was a major revision in the recommendations for antibiotic prophylaxis of congenital heart disease that significantly reduced the number of conditions that require treatment (Box 34-1). The current American Heart Association recommendations are available online at <http://circ.ahajournals.org/cgi/reprint/CIRCULATIONAHA.106.183095>. It should be noted that for optimal treatment, the intravenous (IV) antibiotic should be administered 30 minutes before the procedure’s

start, which can pose a considerable problem in day surgery when an IV port is not present before induction. Antibiotic prophylaxis is no longer recommended for routine procedures of the gastrointestinal (GI) or genitourinary (GU) tract, but it is still advisable for dental and oral procedures during which there is manipulation of the gingivae and periapical region of the teeth or perforation of the oral mucosa, procedures of the respiratory tract, and procedures on infected skin or musculoskeletal tissues. For these procedures, oral antibiotics can be given 1 hour before the procedure, thereby eliminating the problem of timing. When IV antibiotics are desired, our current practice is to begin their administration as soon as IV access is obtained.

UNDERLYING ILLNESSES AND COMPLICATING FACTORS

There are numerous underlying conditions that exist commonly in relatively healthy children that do not preclude outpatient surgery but have implications regarding the preoperative preparation and anesthetic management.

Upper Respiratory Tract Infections

Probably the most common problem to confront the anesthesiologist caring for children in outpatient surgery is the child with a URI. Viral respiratory tract illness is virtually ubiquitous in children, particularly during the winter months when close indoor contact in schools and daycare facilities with other children with colds is impossible to avoid. The average preschool child contracts between 6 and 8 URIs per year. Both upper and lower respiratory tract viral infections can increase airway inflammation, irritability, and respiratory tract secretions by mechanisms as diverse as increased production and decreased degradation of tachykinins and other neuropeptides, viral induced damage to M2 muscarinic receptors in the airways leading to vagal-mediated hyperreactivity, and increased volume and viscosity of airway secretions causing subsegmental atelectasis (Empey et al., 1976; Dusser et al., 1989; Williams et al., 1992). Increased airway reactivity and hyperresponsiveness occur in the lower airways even in patients with respiratory viral illness clinically limited to the upper airway and even in those with no history of asthma (de Kluijver et al., 2002). After the apparent resolution of the URI, increased airway hyperresponsiveness and irritability may persist for as long as 8 weeks (Empey et al., 1976; Empey, 1983). In children with underlying respiratory disease, such as asthma, bronchopulmonary dysplasia, or other chronic lung diseases, these responses may be further exaggerated. Other risk factors that may be associated with more serious or common complications are age younger than 1 year and sickle cell disease (Cohen and Cameron, 1991). In what is perhaps one of the most comprehensive investigations of URI and anesthesia, 1078 infants and children were prospectively studied (Tait et al., 2001). Independent risk factors for respiratory complications were endotracheal intubation, history of prematurity, reactive airways disease, parental smoking, airway surgery and nasal congestion, and the presence of copious secretions. Of interest is that a history of prematurity was a risk factor even in children who were several years old and no longer had ongoing problems referable to their premature birth.

Box 34-1 AHA Recommendations for Antibiotic Prophylaxis for Endocarditis: Cardiac Conditions Associated with a High Risk of Adverse Outcome

Prosthetic cardiac valve
 Previous history of infectious endocarditis
 Unrepaired cyanotic congenital heart disease, including palliative shunts or conduits
 Completely repaired congenital heart disease with prosthetic material or devices, whether placed surgically or by catheter intervention, during the first 6 months after the procedure
 Repaired congenital heart disease with residual defects or shunts at the site or adjacent to the site of a prosthetic patch or prosthetic device (that inhibit endothelialization)
 Cardiac transplant recipients who develop cardiac valvulopathy

Adapted from Wilson et al.: Prevention of infective endocarditis: guidelines from the American Heart Association, *Circulation* 115:1736–1754, 2007.

Numerous studies have documented that children who either have URIs or who have recently recovered from one have more minor airway complications during or after anesthesia compared with healthy children. Mild oxygen desaturation and coughing, as well as more potentially serious complications such as bronchospasm, laryngospasm, and respiratory failure are particularly likely to occur if the airway is stimulated. Tait and Knight (1987) prospectively studied a large cohort of children undergoing myringotomy and ventilating-tube placement for chronic or recurrent otitis media under general mask anesthesia with halothane. The group that had URIs had no difference in the incidence of respiratory problems, no increase in the severity of respiratory illness, and no increase in the duration of URI symptoms. When compared with matched unanesthetized controls, URI symptoms actually decreased in the group receiving halothane anesthesia. These beneficial results may have been influenced by the effects of myringotomy on the course of the infection, but there is also some laboratory evidence that halothane has viricidal properties in tissue-culture preparations. It is not known if the newer volatile anesthetics have similar effects.

Coté et al., in their investigation of the utility of capnometry and pulse oximetry in detecting adverse events during anesthesia and in a subsequent paper further analyzing these data, found that children with URIs commonly had mild oxygen desaturation both during surgery and in recovery (Coté et al., 1991; Rolf and Coté, 1992). Others have noted that postoperative oxygen requirements in these children are commonly transiently increased (Levy et al., 1992). It is possible that the cause is related to subsegmental atelectasis from increased quantity and viscosity of secretions, and that with deep breathing and coughing after emergence, reexpansion of these segments occurs. In the prospective study previously cited, patients with current or recent URIs had a greater incidence of respiratory complications, including breath-holding and desaturation less than 90%, although none of the complications was associated with long-term sequelae. Both the authors and an accompanying editorial concluded that most children with URIs who were not overtly ill and had no other complicating medical issues could, with judicious attention to anesthetic technique, be safely anesthetized with increased risk for only mild transient sequelae (Coté, 2001; Tait et al., 2001).

Although most children with clinically mild URIs can undergo anesthesia safely, the potential for more serious complications in children with URIs should not be overlooked. A prospective study of over 15,000 children found that children who developed laryngospasm were twice as likely to have a URI (Schreiner et al., 1996). The investigators found that the incidence of laryngospasm was most clearly related to the parent's subjective assessment of a URI, and that younger age and surgeries involving the airway were additive risk factors. A prospective case-controlled study of 1283 children with URI who underwent general anesthesia found a two- to sevenfold increase in respiratory complications during the perioperative course when compared with their counterparts without URIs (Cohen and Cameron, 1991). The incidence was 11-fold higher if the patient was intubated. A very small minority of children with URIs who do not appear to be ill during the preoperative examination may develop acute respiratory failure after the induction of anesthesia or some time during the anesthetic course. Severe hypoxia, bronchospasm, ventilatory insufficiency, and reduced compliance may occur and may even require postoperative ventilation and critical-care management. Some of these children have an unrecognized underlying lower

tract disease, such as pneumonia, and others may experience shunt and ventilation-perfusion mismatching from atelectasis and pulmonary collapse as a result of inspissation of secretions and mucus plugging (Campbell, 1990; Williams et al., 1992). In rare instances, cardiomyopathy may follow viral illness. There are several reports of cardiac dysrhythmias or collapse occurring after induction of general anesthesia that were attributed to post-viral myocarditis. The onset of abnormal rhythms on the ECG tracing or sudden deterioration of blood pressure or perfusion should alert the anesthesiologist to this possibility (Brampton and Jago, 1990; Terasaki et al., 1990).

It should be kept in mind that all of the ill patients who are included in these studies had mild to moderate URIs—children who were more severely ill had their surgery cancelled by the clinicians responsible for their care and were never enrolled in the study. Thus, clinical judgment remains crucial in deciding whether or not to cancel a case. Firm criteria for when to proceed and when to cancel are hard to discern, but the most current data suggest that there are several guidelines that can be applied:

- Laboratory tests are usually not useful; clinical impression is more reliable, such as noting the presence of toxicity, fever, purulent nasal discharge, productive cough, or wheezing. If physical examination suggests pneumonia, a chest radiograph may be confirmatory.
- There should be a lower threshold for postponing surgery in patients at increased risk, such as former premature infants, children with underlying pulmonary disease (e.g., asthma or bronchopulmonary dysplasia), infants younger than 1 year of age, and children with sickle cell disease.
- Patients who are to undergo surgery involving the airway should be considered at increased risk.
- If endotracheal intubation can be avoided, it is likely to decrease the risk of complications. Data suggest that the risk of airway complications in children with URIs is least with a conventional face mask, intermediate with a laryngeal mask airway (LMA), and greatest with an endotracheal tube (Tait et al., 1998, 2001). A logistic regression based on retrospective data did not identify any specific clinical factors that were associated with a higher incidence of adverse respiratory events during anesthesia in children with URIs, it but did find an association with endotracheal intubation and to a lesser degree with the use of an LMA, as compared with mask anesthesia (Rachel Homer et al., 2007).
- If a child is deemed too ill for anesthesia and surgery to proceed, it is best to wait 3 to 4 weeks from the resolution of the URI to reschedule the operation to allow for resolution of airway hyperresponsiveness. The aforementioned logistic regression found an increased incidence of adverse airway events if the peak symptoms of the URI had occurred within 4 weeks of the anesthetic (Rachel Homer et al., 2007).
- One should anticipate that the child with a URI might have a modest prolongation in PACU stay because of transient oxygen requirements or other mild respiratory symptoms that can delay discharge.

Asthma

The prevalence and severity of asthma, especially in children, remains a significant health problem in the United States. As of 1998, 6.4% of the U.S. population carried the diagnosis; two thirds of those were children. A more recent assessment of

prevalence rates from 1980 to 2007 found that the prevalence plateaued in 1997, but that 9.1% (or 6.7 million) of American children carried the diagnosis (Akinbami et al., 2009). Nearly one-half million patients are hospitalized yearly with exacerbations of asthma, and almost half of those are children. The prevalence has increased by about 60% in the past 20 years before leveling off in the past 10 years. The death rate, although small, more than doubled from 1975 to 1995, but it appears to have stabilized in the past decade. Children with asthma can be safely and effectively anesthetized for same-day surgery, but careful preoperative preparation and evaluation, as well as intraoperative management, are crucial to avoid exacerbations and complications. Although it was previously common to think of asthma in terms of bronchospasm, current definitions of the disease emphasize the role of airway inflammation in pathogenesis, progression, and management. Recent consensus conferences of the National Institutes of Health (NIH) National Heart, Lung, and Blood Institute have defined asthma as a chronic inflammatory disorder of the airways that comprises many cells beyond those structural elements of the airways themselves, including mast cells, eosinophils, and T lymphocytes. The inflammatory processes that are involved in both the pathogenesis of the disorder, as well as in the progression of disease, are now addressed much more effectively in therapy for all patients with asthma and not only those with severe disease. The mainstay of therapy in the past was the chronic use of bronchodilator therapy, with antiinflammatory drugs reserved for the more severe cases; current thinking is that the first line of treatment should target inflammation with drugs such as inhaled steroids and newer drugs targeting inflammatory mediators (see Chapter 36, Systemic Disorders).

Anesthetizing the child with asthma for outpatient surgery involves the same general principles as for inpatient procedures (Pradal et al., 1995). It is critical for the asthmatic patient to closely adhere to their medication regimen before surgery. Inhaled steroids and agents like leukotriene inhibitors and cromolyn all require regular use for efficacy. The patient must use these medicines regularly and faithfully in the days (and weeks) before undergoing anesthesia. For those who have required systemic steroids in the past, a short course of steroids, beginning 24 hours before induction of anesthesia, may be advisable, particularly if intubation of the trachea will be required. Preoperative treatment with a short acting β -agonist such as albuterol may be helpful as well, even if the patient is not symptomatic, because events may occur during surgery that are likely to provoke airway irritability, especially intubation (Maslow et al., 2000). Much like the child with a URI, avoidance of intubation and airway stimulation, if possible, reduces the potential for exacerbation of airway irritability.

Volatile anesthetics, which have bronchodilatory properties, have obvious advantages in the child with asthma. Propofol, which has been shown to relax tracheal smooth muscle *in vitro* and to decrease airway resistance in subjects with and without asthma during induction of anesthesia, is an excellent choice when an IV induction is used (Pizov et al., 1995; Eames et al., 1996). This effect on airway smooth muscle has been shown to be even greater than that of ketamine and was also demonstrated during maintenance when an infusion was continued during the anesthetic (Pedersen et al., 1993). A propofol-based anesthetic, combined with either regional anesthesia or a non-histamine-releasing opioid, is a good alternative to volatile anesthesia when a total IV technique is indicated or desired. Some

caution must be taken with the sulfite-containing preparation of propofol, as one study in adults has demonstrated a significant increase in airway resistance with this formulation compared with the non-sulfite-containing drug, although adverse clinical events have not been often reported despite widespread use (Rieschke et al., 2003).

Emergence from anesthesia is perhaps the most vulnerable period that is faced during the case. Although the stimulation of intubation at induction is unquestionably a time of increased risk, the ability to treat bronchospasm by deepening the anesthetic in response to airway hyperreactivity is not present at emergence. There is, therefore, a significant advantage to deep extubation when a volatile technique is used, because the patient can awaken without the endotracheal tube (a highly potent stimulus to the airway) in place. Judicious timing of extubation during emergence from total IV anesthesia can accomplish the same goal.

The risk from anesthesia in a child with an active exacerbation of asthma is certainly increased, and careful attention must be given to postponing procedures in these patients until baseline control of the disease is regained. The child with severe asthma who is never fully “clear” can still be a suitable candidate for outpatient surgery if the clinical management is optimized; there is aggressive preoperative treatment, such as a short course of systemic steroids, increased bronchodilator therapy, and strict avoidance of airway irritants like tobacco smoke is instituted; and contingency plans for admission are made in the event of an exacerbation.

Diabetes

Type I diabetes in children is relatively common, occurring in approximately 1 in 500 school-aged children, but data on the optimal intraoperative management of children with this disease are scant. Although there are no prospective investigations published in the English language literature on the subject, there are two recent reviews and consensus guidelines on the perioperative management of insulin-dependent diabetes in children that offer excellent and well-reasoned guidance on their care (Rhodes et al., 2005; Betts et al., 2007). Although many of the problems in anesthetizing adults relate to the late complications of this condition (e.g., damage to many end-organ systems and autonomic dysfunction), these problems are less prevalent in children, and the most common issue is that of glucose control. Children with diabetes can be safely anesthetized as outpatients if great care is taken to maintain good glucose homeostasis. The child should observe the usual fasting guidelines for elective surgery and should be scheduled for surgery early in the day. If the child is receiving a split-dose insulin regimen with short- and intermediate-acting insulins, the child may receive half of the usual intermediate- or long-acting insulin dose on the morning of surgery and omit any short-acting insulin (McAnulty et al., 2000; McAnulty and Hall, 2003). For children receiving a basal insulin regimen, there should be no short-acting insulin administered at all on the morning of surgery, but they should be given the usual dose of insulin glargine, an insulin for basal control with no true peak and a very long duration of action of about 24 hours (Chase et al., 2008; Hirsch, 2005). In all cases, the blood glucose level should be checked upon awakening and again 2 to 3 hours later. Intravenous infusions containing 5% glucose have often been

recommended for intraoperative fluid management, but it has generally been found easier to use a non-glucose-containing IV fluid into which a glucose-containing IV is “piggybacked.” In this manner, the patient’s fluid requirements and glucose requirements can be independently regulated. Because the most potentially catastrophic complication of diabetes during surgery is unrecognized hypoglycemia, and symptoms of hypoglycemia may be undetectable during anesthesia, blood glucose levels should be checked every 30 to 60 minutes during the procedure. Hypoglycemia should be treated promptly by reducing or stopping any insulin administration and increasing the IV glucose rate, and hyperglycemia (blood glucose levels over 250 mg/dL) should be treated with a continuous insulin infusion titrated to effect, usually beginning at a rate of 0.05 units/kg per hour. The very short duration of action of IV regular insulin (about 5 minutes) makes glucose control much easier with this method (Barnett et al., 1980). The same management scheme is continued in the PACU until the patient is awake and taking oral fluids without difficulty. At that time, a dose of subcutaneous regular insulin can be administered and an oral diet begun. The patient should check blood glucose levels often during the postoperative day, because the stress of surgery often alters insulin requirements. The dose should be adjusted accordingly. The usual insulin regimen can often be restarted on the day after surgery.

Malignant Hyperthermia

The advent of improved and short-acting IV anesthetics has made the management of patients with malignant hyperthermia (MH) considerably simpler. Current recommendations for the care of patients with MH no longer includes prophylactic therapy with dantrolene, and the use of nontriggering techniques coupled with proper preparation of the anesthesia machine can assure that these patients are not exposed to triggering agents. A 10-year review of 303 patients with the diagnosis of MH who underwent trigger-free anesthesia found that none developed fever in the perioperative period that was attributable to an MH crisis, and none required treatment with dantrolene (Yentis et al., 1992). The authors concluded that patients with MH are suitable candidates for outpatient anesthesia (see Chapter 37, Malignant Hyperthermia).

Sickle Cell Anemia

Children with sickle cell disease have increased risks in the perioperative period; however, they can usually undergo anesthesia and surgery as outpatients. Preoperative testing and management of transfusion was discussed above. The major risk factors for inducing a crisis in the perioperative period are dehydration, hypoxia, diminished perfusion, and acidosis. If close attention is paid to avoiding these risk factors, most patients with sickle cell disease can be managed as outpatients for suitable operations. In particular, good hydration and analgesia are important for stable recovery. Caregivers must be more strict than usual in ensuring that the child can take oral fluids without difficulty before discharge to home. The use of surgical tourniquets for orthopedic surgery in patients with sickle cell disease is controversial, but they should probably be avoided in outpatient surgery where postoperative acid-base status, perfusion, and the development of late-onset complications cannot be closely

monitored (Adu-Gyamfi et al., 1993). Tonsillectomy and adenoidectomy in patients with sickle cell disease and OSA appear to entail increased risks and probably should not be performed on an outpatient basis (Sidman and Fry, 1988; Derkay et al., 1991; Halvorson et al., 1997) (see Chapter 36, Systemic Disorders).

PREOPERATIVE PREPARATION OF THE CHILD AND FAMILY

Family-Centered Care

There has been increasing emphasis in pediatric medicine on the care of the child within the context of the family. This is in part behind the current vogue for including the parents of the patient in the experience of induction of anesthesia and early admission to the PACU. When one considers outpatient surgery, however, this concept is extended even further, because the family is more intimately involved in the postoperative care of the child than ever before. The parent or primary caregiver becomes the surrogate nurse once the child is discharged home and therefore must be involved to a greater degree in the postoperative experience even before discharge from the day-surgery unit. It has become the norm in most pediatric institutions and general hospitals that have sizable pediatric surgical programs for parental involvement to include preoperative tours of the operating room and PACU, parental presence during induction of anesthesia, and admission of the parents to the PACU very soon after the child’s arrival and emergence from anesthesia. In most cases, experience with these programs have found them to ease, not complicate, the care of the child, and disruptive parents are the rare exception (Schofield and White, 1989).

Preoperative Teaching and Parental Presence

Outpatient surgery is an intense experience for both parents and children. Many things happen within a short time span, and the emphasis on efficiency and throughput can limit the time that staff can spend in preparing each parent and child for all that will happen. Preoperative teaching programs have become common methods of education to help families understand what to expect on the day of surgery. These programs include preoperative tours of the outpatient surgery center, preoperative telephone calls, written brochures, and videotapes (Karl et al., 1990; Kleinfeldt, 1990; O’Byrne et al., 1997; Cassady et al., 1999; Bellew et al., 2002; Koinig, 2002). Whereas the explicit goals of these programs are education and the efficient transmission of information, an implicit goal is reduction of anxiety and undesirable behavioral consequences of the stress of the perioperative experience (Margolis et al., 1998). The first objective can be met by many, if not all of these programs, but the more far-reaching ones may be more difficult to attain. A study of 143 2- to 6-year-old children who were randomized to receive either an interactive teaching book or no intervention found more, not less, preoperative anxiety in the children who had received the book, but less aggression during induction and fewer behavioral changes 2 weeks after surgery (Margolis et al., 1998). A well-controlled and designed study found that preoperative teaching programs of various modalities had an effect of anxiolysis only in the holding area on the day of surgery; that

effect did not extend effectively to the induction period itself (Kain et al., 1998b). Although parental satisfaction was clearly increased by parental presence during induction, and highly anxious children benefited from presence of a parent during induction, children's anxiety and behavior were more effectively modulated by the use of premedication (Kain et al., 1996; Kain et al. 1998a). Although these data might suggest that the expense and effort of elaborate teaching programs, when examined in a critical and rigorous manner, may not be as cost-effective as more modest programs combined with premedication, one must recognize that limited benefits have value as well. For the parent and child who are waiting for an hour in the preoperative area, a reduction in stress for that period alone is meaningful. Furthermore, the norm in many communities is that such programs are welcomed and expected by many parents; they can also serve as opportunities to educate and improve compliance with preoperative procedures and thereby reduce the incidence of case cancellation.

Part of the art of pediatric anesthesia, of course, is the ability to rapidly establish effective and reassuring communication with the parent and child. The rapport and trust that the anesthesiologist creates during the preoperative interview is also an important and effective method of reassurance and anxiolysis that can enhance the transition to the operating room. In the outpatient setting, where time is more constrained, the value of a quick game, magic trick, kind word, or even brief induction of hypnotic suggestion should not be underestimated. Bringing a security item, such as a blanket or favorite toy into the operating room, can provide additional comfort to the child. Having this item immediately available at the time of emergence may also be helpful (see Chapter 8, Psychological Aspects of Pediatric Anesthesia).

Premedication

As was noted above, the use of sedative premedication has been shown to be the most effective means of reducing preoperative anxiety, postoperative recall, and maladaptive behavior in children undergoing outpatient surgery. Oral midazolam has become the most commonly used premedicant in the United States since 2000 (Kain et al., 2004). Significant reduction in postoperative recall and establishment of anterograde amnesia has been demonstrated with 0.5 mg/kg of midazolam administered orally as little as 10 minutes before induction (Kain et al., 2000). Oral doses as low as 0.25 mg/kg have been demonstrated to be as effective as larger doses with only a slightly slower time of onset (Coté et al., 2002). Of particular concern in the outpatient setting, however, is the problem of delayed emergence. Several studies using 0.5 mg/kg of oral midazolam have found that the drug delayed recovery, but the actual time of discharge from the hospital was not prolonged (Bevan et al., 1997; Viitanen et al., 1999a, 1999b). In institutions where the PACU is divided into phase I (initial recovery from the operating room until the child has reached an awake state with stable vital signs and is ready to take oral fluids) and phase II (less intensive observation and readying for discharge to home) areas, this translates to a longer stay in phase I recovery only. Such delays have the potential to affect throughput and cause bottlenecks for patients arriving from the operating room, but they do not effect total hospital time. The use of lower doses may reduce this problem, but data are not yet available. Young children who return to the operating room for repeated procedures (e.g.,

those with recurrent laryngeal papillomas) may especially benefit from premedication, even with relatively low doses. In this population the benefits largely outweigh any disadvantage of delayed emergence.

The benefits of oral administration, fairly rapid onset, and reliability of effect give midazolam considerable advantage over other agents. It does have several disadvantages, however, that must be considered. Midazolam has an extremely bitter, unpleasant taste. Although both the commercially available oral product and products compounded by the hospital mask the flavor to some degree, acceptance by some children remains poor. Alternative nonparenteral routes of administration have been studied, including nasal (0.2 to 0.3 mg/kg), transmucosal (0.2 mg/kg), and rectal (0.3 mg/kg), but each of these also has disadvantages, so that the oral administration remains the most commonly used and best-tolerated method for the majority of children (Saint-Maurice et al., 1986; Karl et al., 1993; Pandit et al., 2001).

Other agents and routes of administration, although less commonly used, have a place in the armamentarium. Other medications have been used in conjunction with midazolam, notably ketamine (Funk et al., 2000). Its advantage over a single-drug regimen appears to be in the child who is exceptionally uncooperative and requires a deeper level of sedation resulting from a dissociative state. Oral and transmucosal fentanyl has been used with success as well. Both the oral administration of the IV preparation and the commercially available oral transmucosal fentanyl "lollipop" have been shown to be effective; however, postoperative nausea may be increased compared with other agents, limiting its usefulness in the outpatient setting (Howell et al., 2002; Tamura et al., 2003). Similar results have been seen with nasally administered sufentanil, which also may cause nasal burning and chest wall rigidity. This agent appears to be less useful than others for these reasons and has largely fallen out of favor with most pediatric anesthesiologists. Intramuscular administration of premedication is uncommonly used in children for obvious reasons—children have an intense dislike and fear of needles. In some cases, however, when a child is exceedingly uncooperative and unmanageable, there may be no better alternative, and it is safer and more humane to administer a quick intramuscular injection with a small needle than to force the anesthesia mask on the face of an awake struggling child for what will surely appear to be a very long 60 seconds. Ketamine, often in combination with midazolam and glycopyrrolate, is the most commonly used agent. The usual doses range from 3 to 5 mg/kg; the lower doses are administered in combination with 0.1 mg/kg of midazolam. A high concentration (100 mg/mL) of ketamine should be used to minimize the injected volume. The anterior thigh is the most common site of administration (see Chapter 9, Preoperative Preparation).

ANESTHETIC TECHNIQUES

The operative procedure and underlying condition of the patient remain the primary decisive factors when choosing an anesthetic plan, but the disposition of the patient (i.e., discharge on the day of surgery) is an important consideration as well. An outpatient anesthetic has, in addition to all of the other usual goals, the additional priorities of rapid return to baseline function with minimal untoward effects and effective postoperative analgesia that can be sustained after leaving the hospital. It is only by achieving all of these objectives that patients can be effectively discharged home in a timely fashion.

Induction

Although clinical indications may on occasion dictate the safest induction technique, in many instances the older child may be given a choice, usually between inhalation and IV induction. Although the great majority of children seem to prefer an inhalation induction, there are a few who find the mask intolerable and prefer to have an IV line with local anesthetic, sometimes while breathing nitrous oxide. In cooperative school-aged children this can often be accomplished without difficulty, and it may be offered to appropriate children as an option. IV cannulation is often best accomplished in the operating room itself, where in the event of difficulty the plan can be easily and seamlessly changed.

The vast majority of children in the United States have an inhalation induction of anesthesia for outpatient procedures. The advantages are obvious—relatively rapid induction without any painful stimulus. Most children are needle-phobic, and are quite relieved when informed that they need not have anything painful done to them while they are conscious. The technique of inhalation induction is described in detail in Chapter 13, Induction, Maintenance, and Recovery. If the child uses a pacifier, it may be kept in the mouth until consciousness is lost, and the face mask may be placed over it. Scented lip gloss, such as bubble gum or fruit flavors, may be added to the facemask to disguise the odor of the volatile agent. The room should be otherwise quiet and free from conversation or other disruptions; the anesthesiologist should maintain continuous verbal contact with the child, telling a story in a soft, soothing modulated voice until the child falls asleep. Distracting modalities, such as movies or cartoons projected on the operating room's video monitors or on hand-held video devices can be used to good effect as well.

Sevoflurane has replaced halothane, which is no longer available in the United States, as the agent of choice for inhalation induction. Induction is rapid, and because sevoflurane is nonpungent, it causes very little airway irritation and coughing. It is possible to quickly increase the inspired concentration or even begin with the vaporizer set at 8% and still avoid coughing. Sevoflurane does have a mildly unpleasant odor, but it is still relatively easy to breathe. Sevoflurane, however, causes some interference with ventilatory drive and respiratory muscle function, reducing the effectiveness of spontaneous ventilation (Brown et al., 1998). In many cases, even if a total IV anesthetic is planned, an inhalation induction with sevoflurane is performed until IV access can be established.

Intravenous induction is a less commonly used technique. Propofol (3.5 to 5 mg/kg) has many attributes that make it an ideal IV induction agent for outpatient anesthesia. Not only does it have a very rapid onset of action, but its termination of action is similarly fast, with a characteristic rapid return to baseline function. The drug also has antiemetic properties, a highly desirable asset in outpatient anesthesia. Its only drawback is pain on injection. Although this may be moderated with lidocaine (1 to 2 mg/kg), injected before or mixed with the propofol, it can be quite painful, especially if it is injected into a small vein.

Rectal induction with a barbiturate such as methohexital, thiopental, or thiamylal has largely fallen out of favor, despite its advantage of being able to be performed in the parent's presence in an induction area outside of the operating room. Rectal induction and barbiturates in general have a significant disadvantage in outpatient anesthesia—a very prolonged elimination half-life—and for this reason they are not recommended.

Airway Management

There are numerous options for management of the airway in outpatient anesthesia. In many cases, an anesthesia mask alone is used—for example, during myringotomy and tube placement. This minimizes the risk of airway irritation but requires at least one of the anesthesiologist's hands be occupied. It is contraindicated in the event of a full stomach and may be problematic in patients who easily obstruct their airways, such as those with adenotonsillar hypertrophy.

The endotracheal tube remains the gold standard for the secured airway. Most pediatric anesthesiologists intubate their patients “deep,” or without the use of neuromuscular relaxants. This eliminates the need for reversal or for concerns of residual neuromuscular blockade, but mandates skillful judgment of anesthetic depth to avoid cord injury or laryngospasm. Just as in any anesthetic, one must choose the tube's size carefully so as to avoid producing injury or irritation to the vocal cords and trachea. This is especially critical in a patient who is going to be discharged home the same day. Supraglottic airway devices, although useful, have not supplanted the need to intubate a patient for many outpatient surgery cases that may still benefit from the placement of an endotracheal tube. Intracavitary operations, including laparoscopic operations, are generally best performed with an endotracheal tube, although brief laparoscopic examinations, such as laparoscopic examination of the contralateral side during herniorrhaphy, can be effectively performed with a supraglottic airway device. Surgery in or near the airway (including tonsillectomy, adenoidectomy, and upper GI endoscopy) can be performed with a LMA, but this remains somewhat controversial.

Supraglottic airway devices may cause less laryngeal irritation than endotracheal tubes and can be placed without visualization of the airway (Brimacombe, 1995). The LMA, developed by Dr. Brain, is the first of these devices and is available in multiple pediatric sizes. Several competitors, including the COBRA Perilaryngeal Airway and the COPA Oropharyngeal Airway, are now marketed (Figs. 34-1 and 34-2). All of these devices offer a less stimulating means of maintaining the airway while freeing the hands of the anesthesiologist for other tasks. As was mentioned above, a number of studies have demonstrated that the ability to maintain a stable airway without stimulating the larynx and trachea can decrease the incidence of adverse respiratory events in children with active or recent URIs (Tait et al., 1998). The same might be true for patients with asthma, where the airway is also hyperirritable, although there are no data in children at this time. Airway pressure and resistance in anesthetized adults without lung disease have been shown to be lower with the LMA compared with an endotracheal tube, and it has been shown to induce less bronchoconstriction (Berry et al., 1999). Although the LMA may diminish lower respiratory tract stimulation, it does not appear to decrease the incidence of postoperative sore throat (Splinter et al., 1994). The findings by Tait et al. that endotracheal tubes are more stimulating than LMAs, which are in turn more stimulating than a face mask, may serve to guide the decision of how to manage the airway if all other factors are equal.

Infants appear to have a greater incidence of problems with supraglottic airway devices than older children. There is a high incidence of infolding of the epiglottis and malposition in children under 10 kg and a significantly higher incidence of airway complications such as laryngospasm, breath-holding, obstruction, and coughing when compared with a conventional mask with oral airway (Harnett et al., 2000; Bagshaw, 2002; Polaner et al., 2006).

Anesthetic Maintenance

The ideal maintenance regimen for outpatient anesthesia would have three defining characteristics: ease of titration, rapid off-set, and minimal residual side effects. Although it can be argued that several techniques or contemporary agents fit this definition, none is entirely free of all side effects, or are ideal agents in every situation.

Inhalation anesthesia is still the most commonly used maintenance technique and has numerous advantages to commend it. No organ or enzymatic metabolism is necessary for its elimination—it is simply breathed away. Volatile agents are easily titrated to effect, and anesthetic depth can be adjusted with relative rapidity. They are relatively economical, especially when low fresh gas flows are used, and they have beneficial effects on reactive airways, a common problem in children. There are several disadvantages, however, that may temper the claim for

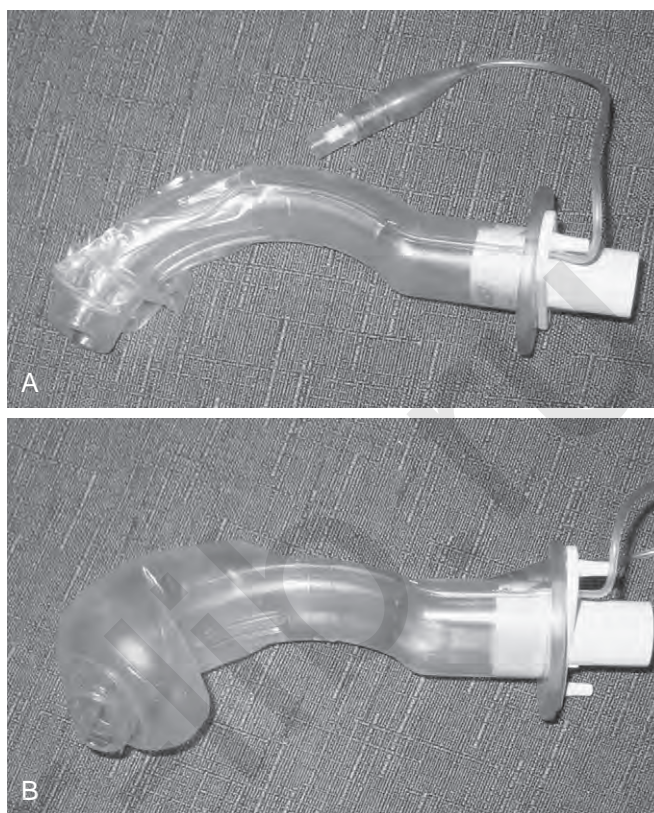

FIGURE 34-2. Cuffed COPA Oropharyngeal Airway. The device is sized and inserted like a conventional oropharyngeal airway with the cuff deflated (**A**) and the cuff inflated (**B**). The end of the device has a standard 15-mm connector to attach to the breathing circuit.

volatile agents as the ideal agents for outpatient anesthesia in all circumstances. Total IV anesthesia, as will be discussed, has numerous benefits for outpatients in many instances as well.

Halothane is no longer available in the United States and has been replaced by sevoflurane as the primary volatile anesthetic for inhalation induction. It has been argued that sevoflurane's lower blood-gas solubility and blood:gas partition coefficient give it significant advantage over older, more soluble agents such as isoflurane for emergence, where a more rapid return to consciousness is desired in the outpatient setting. Whereas return to wakefulness may indeed be quicker with sevoflurane (and is even more rapid with desflurane), for short cases the speed to awakening with isoflurane can approach that of the less soluble agents if the isoflurane is turned off sooner. Perhaps more importantly, time to awakening has no relationship to time to discharge from the hospital (Lerman et al., 1996; Sury et al., 1996; Welborn et al., 1996). The latter is the metric that reflects both day-surgery unit efficiency and cost savings, and anesthesia with sevoflurane has not been shown to produce shorter discharge times, which is generally related not to speed of emergence but more to other factors, including premedication, complications of recovery such as postoperative nausea and vomiting, emergence agitation, and analgesic needs (Bacher et al., 1997).

Sevoflurane has one additional characteristic that limits its effectiveness as a maintenance agent in outpatient anesthesia—the problem of emergence agitation. Several investigators have studied this problem, which can be exceedingly

disruptive and disturbing for PACU caregivers and parents. With the increased use of sevoflurane, it became apparent that there was an increase in emergence agitation or delirium in the PACU, and the majority of studies, including a recent meta-analysis (see Chapter 13, Induction, Maintenance, and Recovery, Figure 13-4), support this clinical impression (Mayer et al., 2006; Rieger et al., 1996; Beskow and Westrin, 1999; Cravero et al., 2000; Kuratani and Oi, 2008; Bortone et al., 2006). However, there are a few studies that have not found an increased incidence compared with isoflurane (Meyer et al., 2007; Voepel et al., 2003). The child with emergence agitation appears wild and incoherent; he is inconsolable and does not appear to recognize familiar people. This phenomenon has clearly been distinguished from inadequate analgesia. Cravero et al. (2000) compared emergence characteristics of sevoflurane to halothane anesthesia in children undergoing magnetic resonance imaging. This prospective randomized study design effectively eliminated pain or dysphoria of neural blockade as potential confounding variables, leaving only the choice of volatile agent as a factor (Cravero et al., 2000). Using either low- or high-threshold criteria to define agitation and delirium, the investigators found much higher rates (33% vs. 0% with high-threshold criteria and 88% vs. 12% applying low-threshold criteria) with sevoflurane as compared with halothane. Any time advantage gained by more rapid emergence was eliminated by the difficulty in caring for the agitated child in the PACU, and hospital discharge times were not different. Another study of sevoflurane in 100 children undergoing myringotomy and tube placement found that even with very short times under anesthesia, the incidence of emergence agitation was unacceptably high (Lapin et al., 1999). Although discharge times in this study were faster in the sevoflurane group, 67% demonstrated emergence agitation, leading them to conclude that sevoflurane was unsuitable for use as a sole agent for this procedure. They found that the addition of midazolam reduced this problem while lengthening recovery but not discharge times. Other investigators have found that midazolam does not prevent emergence agitation, and have found better responses to opioids, dexmedetomidine, low-dose ketamine, and propofol and ketorolac (Guler et al., 2005; Hung et al., 2005; Aouad et al., 2007; Breschan et al., 2007; Tsai et al., 2008; Davis et al., 1999). It is possible that the cause is related to the different effects of these agents on brain function that has been noted on electroencephalogram; speed of emergence does not seem to be a cause (Constant et al., 1999; Cohen et al., 2003; Oh et al., 2005).

Desflurane is another new volatile agent with rapid onset and offset characteristics caused by an exceptionally low blood:gas partition coefficient and solubility. It, too, appears to have a higher incidence of emergence agitation than older agents, although less than has been reported with sevoflurane (Mayer et al., 2006; Davis et al., 1994; Welborn et al., 1996; Valley et al., 2003). Emergence is significantly faster than with sevoflurane, however. This is because of its low solubility in tissues such as muscle and brain as compared with sevoflurane. Because sevoflurane is similar to halothane in its solubility in vessel-rich tissue groups, after discontinuance of the agent, significant blood concentrations are maintained as the agent returns from these depot storage sites to the bloodstream along its concentration gradient. This does not occur to a significant degree with desflurane because of its low tissue solubility, thereby speeding

emergence time. Desflurane has also been found to decrease the ability to maintain spontaneous ventilation at concentrations greater than 1 MAC (Behforouz et al., 1998). Although desflurane is a potent airway irritant and is contraindicated for inhalation induction because of a very high incidence of severe laryngospasm, it does not appear to cause problems with deep extubation, although the incidence of coughing and other symptoms of airway irritability appear to be somewhat higher with desflurane (Zwass et al., 1992; Sneyd et al., 1998; Valley et al., 2003).

Nitrous oxide continues to be used as an adjunctive agent for outpatient anesthesia in combination with both volatile and IV agents. It is useful as a sedative when placing IV cannulae in situations where a pure IV technique is used, and it can ease the introduction of the pungent volatile agents when performing inhalation induction. Its utility as an agent for maintenance, however, is limited by its capacity to increase the incidence of postoperative nausea and vomiting. For this reason, its use in the outpatient setting should be constrained (Divatia et al., 1996).

The development of propofol heralded a new era in the maintenance of anesthesia in outpatients. It is not hyperbole to suggest that it thrust total IV anesthesia (TIVA) into the mainstream of anesthetic techniques, allowing rapid titration of anesthetic depth and prompt emergence without the use of volatile agents. Propofol is a potent antiemetic and can reduce the incidence of nausea and vomiting when used in combination with both other anesthetic agents and other antiemetics (Sneyd et al., 1998; Barst et al., 1999). Despite its rapid emergence characteristics when used for anesthetics of short or moderate duration, the incidence of delirium and agitation is very low when compared with sevoflurane or desflurane (Nakayama et al., 2007). Propofol's major limitation is its lack of analgesic properties, and it must be used with an opioid or regional technique to provide adequate depth of anesthesia for most stimulating procedures. It is an excellent (and perhaps the ideal) agent for use in imaging, radiation treatment, or interventional radiologic procedures where there is a minimum or absence of stimulation (Aldridge and Gordon, 1992; Martin et al., 1992; Vangerven et al., 1992; Frankville et al., 1993). It is particularly attractive for anesthesia for radiation therapy, where children require daily repeated general anesthetics for up to 6 consecutive weeks. In this situation, children are able to be ready for discharge to home within 20 minutes of the end of the treatment session, and in contrast to other agents such as barbiturates, children receiving propofol have no evidence of either drug accumulation or development of tolerance and dose escalation (Glauber and Audenaert, 1987; Mills and Lord, 1992; Fassoulaki et al., 1994).

Remifentanyl is a unique IV opioid with rapid onset and elimination. In contrast to other opioids, its degradation is independent of organ metabolism, instead relying on hydrolysis by plasma esterases. The drug permits the anesthesiologist to provide intense intraoperative levels of opioid analgesia with no residual respiratory depression after emergence (Roulleau et al., 2003). Other postoperative side effects usually associated with opioids, such as nausea and vomiting, excessive sedation, and respiratory depression are absent or extremely rare (Pinsker and Carroll, 1999; Eltzschig et al., 2002). Intraoperative conditions are notable for hemodynamic stability, although both bradycardia and hypotension can occur at higher infusion rates. The most significant caveat to the use of remifentanyl is that its rapid degradation provides no postoperative analgesia whatsoever (Davis et al., 2000). It is essential, therefore, to use another agent or technique for this purpose, such as a long-acting opioid,

a regional block, or a nonsteroidal such as ketorolac, and to administer it with adequate time for action before the patient's emergence and the dissipation of remifentanyl's effect.

Perhaps the most effective manner in which to use remifentanyl is to combine it with propofol. The combination of the two agents provides a balanced anesthetic that is easily titratable and results in significant reductions in the dose of both (Grundmann et al., 1998; Keidan et al., 2001). The two drugs can be mixed in the same syringe and administered via syringe pump. Because remifentanyl degrades in propofol over time, aliquots small enough to be infused within 1 hour should be used (Stewart et al., 2000). For procedures of mild to moderate stimulation, 10 mcg of remifentanyl per 1 mL (10 mg) of propofol is used, with infusion rates beginning at 100 mcg/kg per minute of propofol (0.1 mcg/kg per minute of remifentanyl). This concentration permits the maintenance of spontaneous ventilation in most patients (Peacock et al., 1998; Reyle-Hahn et al., 2000). In particular, spontaneous ventilation is well maintained in children younger than 3 years old, even at higher infusion rates and even though remifentanyl requirements to block the somatic response to skin incision are close to twofold higher in children than in adults (0.15 vs. 0.08 mcg/kg) (Barker et al., 2007; Munoz et al., 2007). For more stimulating procedures, the remifentanyl concentration is doubled to 20 mcg/mL of propofol, and the infusion begins at the same rate of 100 mcg/kg per minute of propofol (0.2 mcg/kg per minute of remifentanyl). Many patients breathe spontaneously with this concentration as well, although slow respiratory rates are common, and clinicians must be vigilant to avoid hypoventilation. This technique provides a stable intraoperative course, combined with an exceptionally smooth emergence and rapid return to baseline function, especially for patients undergoing procedures such as bone marrow aspirations, lumbar punctures, interventional radiology, upper and lower GI endoscopies, and incision and drainage of abscesses (Glaisyer and Sury, 2005).

Regional anesthesia (usually in combination with a general anesthetic) can be used to great advantage in outpatients. Although the prime advantage and reason for its use is the provision of postoperative analgesia (as is later discussed in more detail), the modest reduction in the depth of general anesthesia can speed recovery and reduce the incidence of opioid-related untoward effects. Motor blockade is, in most cases, not a contraindication to discharge to home and can be reduced or eliminated by the use of low concentration local anesthetics. Most children have their motor block resolved before discharge from the PACU, although this may not be the case for longer-acting peripheral nerve blocks (Burns et al., 1990). For those who are discharged with residual blockade, clear and explicit instructions to the parents as to how to guard the limb and good follow-up inquiry via telephone are critical. Other reported advantages of regional blockade include decreased intraoperative blood loss and improved operating conditions during hypospadias repair (Gunter et al., 1990). For operations shorter than 1 hour in duration, preoperative blockade did not affect the duration of postoperative analgesia compared with blockade administered at the end of the case (Rice et al., 1990).

Nearly all regional anesthetics in children in the United States are administered after the induction of general anesthesia, although Marhofer and others (2004) reports the extensive use of regional anesthesia with sedation in Austria. See Chapter 16, Regional Anesthesia, for details on performing the various regional blocks. In most cases, regional blockade for ambulatory

surgery is performed with local anesthetics only, omitting opioids and adjunctive agents, although there is growing experience with caudal clonidine (2 mcg/kg or less) in outpatient anesthesia in children over 6 months of age. The risks of respiratory depression that can occur with those additives must always be considered, an important safety factor in the patient who will not be monitored after discharge from the PACU.

Neuromuscular Blockade

In most outpatient procedures in infants and children, neuromuscular blockade is not necessary. The majority of surgical procedures that are done in this setting can be performed without it, and intubation can most commonly be achieved with inhalation anesthesia, sometimes combined with a single dose of propofol in older children. Alternatively, a single dose of remifentanyl can be administered in combination with propofol for intubation and has been shown to facilitate rapid sequence induction without muscle relaxants (Batra et al., 2004). When muscle relaxants are employed, it is best to avoid any of the longer-acting nondepolarizers and rely on intermediate acting drugs such as atracurium or cisatracurium, rocuronium or vecuronium. These agents are discussed in detail in Chapter 7, Pharmacology of Pediatric Anesthesia. When a muscle relaxant is used, adequacy of reversal must be assured. A recent investigation in adults found that incomplete reversal and mild degrees of residual neuromuscular blockade were common (Debaene et al., 2003). At least with some agents, children are less prone to inadequate spontaneous reversal. In children receiving mivacurium (no longer available in the United States), residual weakness was not observed, whereas the finding was present in the adults (Bevan et al., 1996). Stringent criteria for adequacy of spontaneous reversal must be sought, and reversal agents administered if necessary (Baurain et al., 1998; Ali, 2003).

Fluids

As fasting times become shorter, the consequences of preoperative fasting are less problematic, but there remain occasional patients who come to surgery with varying degrees of dehydration (Coté, 1990; Cook-Sather et al., 2003). Additionally, the patient who is to be discharged home may not be interested in drinking large amounts of fluids in the hours immediately after surgery. It is useful, therefore, to provide adequate hydration not only to correct the fluid deficit but also to provide a cushion for the postoperative period. This is particularly the case for operations that may disrupt the ability to drink easily, such as tonsillectomy. Isotonic fluids should be administered, and the IV catheter may be kept in place until just before discharge. It is rarely necessary to provide glucose supplementation in the IV fluids in children outside the neonatal period (Sandstrom et al., 1993). The deficit plus current maintenance requirements should be repleted within 2 to 3 hours. In some cases, children are discharged home before that, but those are generally the ones at least risk for inadequate intake.

Emergence

The management of emergence from anesthesia in the outpatient is largely a question about the intubated child, and whether the endotracheal tube should be removed when the

patient is deep or awake. Certainly the contraindications to deep extubation (e.g., full stomach, difficult airway, and blood in the pharynx) are no different in outpatients or inpatients. Those who argue for awake extubation are primarily concerned about the loss of airway and of the development of laryngospasm. These concerns are magnified if the PACU staff is not adept and experienced at dealing with the patient who has been extubated deep. The advantages of deep extubation are numerous. The patient awakens from anesthesia in the PACU without the noxious stimulus of an endotracheal tube in place and may have a smoother emergence. The child with reactive airways disease does not have the airway stimulation that may precipitate a potentially severe episode of bronchospasm. Operating-room efficiency is enhanced, because the patient is able to leave within a minute of the end of the surgery, and room turnover can proceed at a more rapid pace. Several practices, in addition to the contraindications mentioned above, are crucial to increase the safety of this practice. The tube should not be withdrawn unless the patient is breathing spontaneously and has been demonstrated to have no alteration in breathing pattern with stimulation of the trachea (usually accomplished by gently moving the endotracheal tube). This may require at least a 2-MAC value of inhaled anesthetic; however, the concomitant administration of an opioid or propofol or topicalization of the vocal cords significantly reduces this value. The patient should be placed on the side after extubation and once airway patency is confirmed to prevent oropharyngeal secretions from collecting in the hypopharynx and either stimulating the larynx or causing aspiration and to promote the forward prolapse of the tongue, which improves airway patency and helps prevent the tongue from falling back to the palate and obstructing the airway. Supplemental oxygen and close attention to airway patency are necessary during transport to the PACU.

POSTOPERATIVE ANALGESIA

If there is any issue that has the potential to completely sabotage the success of an outpatient surgery it is inadequate postoperative analgesia. No child can be discharged to home if the parents cannot adequately manage their pain using simple interventions. Inadequate analgesia has been identified in several studies as one of the most common causes for unanticipated admission to the hospital after surgery (Grenier et al., 1998). In another study, postoperative pain was identified by parents as the major problem they encountered after discharge to home (Kokinsky et al., 1999). Only 28% of the patients in that study had received regional blocks, however.

Regional and Local Anesthesia

Regional and local anesthesia has become one of the key modalities for postoperative analgesia for amenable procedures. Among the commonly performed operations in pediatric outpatient surgery that are associated with significant postoperative pain, only adenotonsillectomy and tympanostomy tube placement are not suitable for local or regional anesthesia. A prospective randomized study of glossopharyngeal nerve block, previously reported as an effective technique in adults, was stopped before its completion because of a 50% incidence of upper airway obstruction in the treatment group. The authors

terminated the study and concluded that glossopharyngeal block is dangerous in children after tonsillectomy because of the common occurrence of inadvertent blockade of the vagus and recurrent laryngeal nerves (Bean-Lijewski, 1997).

Strict attention to the limits of local anesthetic dose must be observed with any regional block, and aspiration should precede any injection. When large volumes of local anesthetic are injected for any regional block, both a test dose and incremental injection technique should be employed to minimize the risk of intravascular injection. A maximum of 2.5 mg/kg of bupivacaine can be administered to children over 6 months of age; younger infants should have the dose reduced by 30% (1.8 mg/kg) because of decreased levels of plasma binding proteins (Lerman et al., 1989; Luz et al., 1998). In addition, there appears to be an increased toxicity risk during general anesthesia with volatile agents (Badgwell et al., 1990). In these younger infants an additional margin of safety may be gained by the use of ropivacaine or levobupivacaine (no longer available in the United States), which appear to have less toxic potential (Bardsley et al., 1998; Kohane et al., 1998; Gunter et al., 1999; Morrison et al., 2000).

Although usually performed by the surgeon rather than the anesthesiologist, the value of wound infiltration with local anesthetic should not be underestimated. There are numerous limited procedures for which a regional nerve block would be more intervention than necessary, such as simple hardware removals in orthopedics or excisional biopsies of small lesions, where infiltration of the wound can be used to great advantage. Local anesthetic blood levels with this technique have been found to be low when dose limits are adhered to (Mobley et al., 1991). When a peripheral nerve or regional block can be performed, however, those techniques may offer superior analgesia. A study of caudal analgesia compared with wound infiltration for analgesia after inguinal herniorrhaphy found better analgesia and quicker emergence times, fewer pain-related behaviors, and earlier hospital discharge times with the caudal block. Less supplementation with systemic analgesics was required (Conroy et al., 1993).

Caudal anesthesia is probably the most commonly performed block in pediatric anesthesia practice. It is usually easy to administer, has an acceptably low incidence of complications, and is highly effective for surgical procedures below the level of the umbilicus (Dalens and Hasnaoui, 1989). The duration of effective analgesia is considerably longer than one would expect based on the usual length of action of the local anesthetic alone. A study that compared 0.25% bupivacaine with and without epinephrine found that the addition of epinephrine markedly prolonged the analgesia, and that prolonged duration of analgesia was correlated with both younger age and lower surgical site (penoscrotal vs. inguinal) (Warner et al., 1987). Duration of analgesia ranged from as short as 5 hours (inguinal surgery in patients older than 11 years of age) to as long as 23 hours (penoscrotal operation in patients 1 to 5 years of age) as judged by the time to first requirement for supplemental analgesia. In a study of caudal blockade for analgesia after club foot repair, analgesia lasted at least 8 hours (Foult et al., 1995). The addition of clonidine to the local anesthetic has been found by some, but not all, investigators to prolong the duration of caudal analgesia (Constant et al., 1998; Ansermino et al., 2003; Tripi et al., 2005; Wheeler et al., 2005). Controversy remains, however, regarding the safety of this drug for outpatient use, particularly in smaller infants and

at higher doses because of the risk of oversedation (Hansen and Henneberg, 2004). It appears prudent to limit the dose to less than 2 mcg/kg if caudal clonidine is used in a patient who will be discharged home and to avoid it altogether in infants younger than 6 months of age.

Side effects of caudal blockade in children are unusual. Multiple studies have confirmed that urinary retention does not occur after caudal block using local anesthetic without central neuraxis opioids (Warner et al., 1987; Fisher et al., 1993). No differences in side effects were seen between caudal blockade and ilioinguinal-iliohypogastric nerve block; PACU stays were longer by less than 5 minutes and hospital stays by less than 10 minutes with the caudal block (Splinter et al., 1995). Motor function is not significantly impaired at the time of discharge and does not preclude or delay discharge (Burns et al., 1990).

Although one study found that placing the block at the end of the case resulted in better analgesia, other well-controlled studies have shown that there is no decrement in the duration of analgesia with blocks administered at the beginning or end of surgery for procedures lasting less than 1 hour (Rice et al., 1990; Holthusen et al., 1994). A study of 0.5 mL/kg vs. 1 mL/kg of 0.125% bupivacaine with epinephrine for penile and scrotal surgery found no difference in the duration of analgesia up to 8 hours postoperatively (Malviya et al., 1992).

Peripheral nerve blocks can be used with considerable efficacy for outpatient surgery in children and can be administered either by the anesthesiologist or by the surgeon on the operative field. Ilioinguinal-iliohypogastric nerve block combined with wound infiltration showed similar efficacy to a caudal block for analgesia after inguinal herniorrhaphy in two randomized studies (Schindler et al., 1991; Splinter et al., 1995). Paraumbilical block was shown to provide excellent analgesia for umbilical herniorrhaphy, although the duration of analgesia was less than 8 hours in three of 11 subjects (Courreges et al., 1997). The transverse abdominis plane block, which can be reliably placed under ultrasound guidance, has been shown to be effective for prolonged analgesia after abdominal operations, including herniorrhaphy (Suresh and Chan, 2009). Fascia iliaca block is an effective and easy to place block for surgery of the leg above the level of the knee (Dalens et al., 1989). Ophthalmic surgery is often associated with considerable postoperative pain. Placement of a peribulbar block or a subconjunctival injection has been shown to provide long-lasting analgesia with a minimum of side effects in pediatric patients (Ates et al., 1998; Coppens et al., 2002; Subramaniam et al., 2003). Penile nerve blocks are often used in older patients undergoing distal hypospadias repairs or for circumcision. The dorsal nerve block has been shown to result in better postoperative analgesia than a penile ring block (Holder et al., 1997). Greater auricular nerve block has been shown to be efficacious after tympanomastoid surgery (Suresh et al., 2002). Many peripheral blocks of the extremities are very useful for analgesia after ambulatory surgery because of their long duration of action (Marhofer et al., 2004). If children have residual motor blockade at the time of discharge, follow-up care is necessary until the block has completely resolved.

An emerging practice in regional anesthesia is the use of continuous ambulatory peripheral nerve blocks and field blocks for postoperative analgesia (Ganesh et al., 2007). This has been facilitated by two technological innovations: the increased use of ultrasound to accurately place peripheral nerve or plexus cannulae, and the development of elastomeric infusion devices that permit delivery of local anesthetic at a controlled rate without

■ FIGURE 34-3. Elastomeric infusion device.

the use of high-cost pumps. These devices contain a reservoir of local anesthetic large enough to last several days. The reservoir is surrounded by a balloon-like bulb that when filled with air compresses the reservoir and infuses the drug. A flow limiter in the tubing controls the infusion rate (Fig. 34-3). Children can be sent home, and with daily telephone follow-up conversations, can receive either a long-acting nerve block or the infusion of the local anesthetic into their wound for several days. The parent can easily remove the catheter when the infusion is complete.

The development of parenterally administered nonsteroidal antiinflammatory drugs, principally ketorolac, has allowed the anesthesiologist to administer long-acting nonopioid analgesics so that they have taken effect by the time the patient awakens. There is a sizable literature on the use of ketorolac in pediatric patients over the age of 1 year, but no randomized studies to date of COX-2 type drugs in pediatrics. Many of these studies have specifically examined the role of ketorolac in outpatient surgery. Ketorolac has been shown to have several advantages over opioid analgesics for postoperative analgesia in pediatric outpatients. There is a significant reduction in nausea and vomiting in patients receiving ketorolac as compared with morphine, fentanyl, or other opioids (Mendel et al., 1995; Purday et al., 1996). The duration of a single dose of ketorolac is longer (6 hours) than most of the commonly used opioid analgesics (Dside et al., 2002). Lack of respiratory depression, of course, is one ketorolac's major advantages over opioids. Ketorolac's major problem for use in outpatient analgesia is that it causes reversible dysfunction of platelet adhesion, and bleeding problems have been noted to be more common in children undergoing adenotonsillectomy (Gallagher et al., 1995; Judkins et al., 1996; Splinter et al., 1996; Splinter and Roberts, 1996). Bleeding problems have not been reported in other types of surgery, but caution should be used when administering ketorolac after other oral surgical procedures. Ketorolac appears to offer significant benefits to the pediatric outpatient after select operations.

Opioids remain the gold standard for postoperative analgesia for moderate to severe pain, and they are still commonly prescribed for pediatric outpatients, both parenterally during anesthesia and by oral, transmucosal, and other routes for postoperative analgesia. Their principal disadvantages are the side effects of nausea and respiratory depression; at the doses prescribed for outpatients, ileus is rarely a problem. Even a single dose of morphine administered for postoperative analgesia after inguinal hernia surgery has been reported to increase the incidence of PONV (Weinstein et al., 1994). Adjunctive nonopioid analgesics such as acetaminophen have an opioid-sparing effect and can reduce the amount of opioid necessary to achieve analgesia, thereby reducing the risk of side effects.

Intranasal fentanyl (2 mcg/kg, administered intraoperatively) has been used primarily for analgesia after myringotomy and tube surgery. Because these procedures are commonly performed without obtaining IV access, this provides an easy route for the administration of a potent analgesic. In a study comparing intranasal fentanyl to placebo, postoperative conditions were superior with fentanyl (Henderson et al., 1988). Children who received intranasal fentanyl were not only more comfortable and less agitated, but they did not have an increase in PONV, a problem that has been noted with intranasal sufentanil (Henderson et al., 1988; Galinkin et al., 2000).

Numerous oral opioid analgesics are used for postoperative analgesia in children. The surgeon and not the anesthesiologist often prescribes these drugs, but the anesthesiologist's expertise in the use of analgesics should be sought or offered when protocols are devised. Commonly used agents include oxycodone, hydrocodone, and tramadol (Table 34-2). All of these agents can be given in combination with acetaminophen and nonsteroidal antiinflammatory drugs for added efficacy. These agents are generally administered for 1 to 3 days; operations that result in more severe pain are less commonly performed on outpatients and require analgesic inpatient management. Codeine is still commonly prescribed for pain, but its use should be discouraged. Codeine is actually a prodrug—methyldorphine—that must be demethylated to its active form. Bioavailability varies widely depending on genetic variants of demethylation ability. Because of these pharmacogenetic differences, some patients achieve no analgesia at all as a result of an inability to demethylate the drug, whereas some suffer from increased side effects or even achieve potentially toxic drug levels because of more extensive demethylation (Quiding et al., 1992; Fagerlund and Braaten, 2001; El-Tahtawy et al., 2006) (see Chapter 15, Pain Management).

PACU, RECOVERY, AND DISCHARGE ISSUES

Nausea and Vomiting

PONV is perhaps the most common complication after anesthesia, although the reported incidence varies widely from approximately 8% to 50% (Heyland et al., 1997; Villeret et al., 2002). The

TABLE 34-2. Outpatient Analgesic Agents

Oxycodone	0.1-0.2 mg/kg	PO q3-4 hours
Hydrocodone	0.5 mg/kg	PO q3-4 hours
Tramadol	1-2 mg/kg	PO q4-6 hours

TABLE 34-3. Common Causes of Postoperative Nausea and Vomiting in Outpatients

Surgical Factors	Anesthetic Factors	Patient Factors
Adenotonsillectomy	Use of volatile agents	Prior history of PONV
Middle ear surgery	Use of nitrous oxide	History of motion sickness
Testicular surgery	Use of opioids	Age over 2 years
Laparoscopic surgery	Insufflation of the stomach (difficult mask ventilation)	Girls > boys
Insufflation of the bowel (endoscopy)	Reversal of neuromuscular blockade (cholinergics)	
	Unrelieved pain	

PONV, Postoperative nausea and vomiting.

variance is most likely because of study methodology and definitions. It is usually not an intractable problem, but it certainly is the cause of considerable distress, and if not well controlled may be a cause of unanticipated admission (Patel et al., 1997; Rose and Watcha, 1999). Numerous factors have been identified as increasing the risk of postoperative vomiting, some related to the surgical procedure, some to the anesthetic agents and some to the patient (Eberhart et al., 2004; Gan et al., 2007; Kranke et al., 2007). The most common of these are listed in Table 34-3. Eberhart et al. (2004) noted the following risk factors for pediatric PONV: surgery lasting longer than 30 minutes, age older than 3 years, family or patient history of PONV, and strabismus surgery. The incidence of postoperative vomiting was 9%, 10%, 30%, 55%, and 70% if zero, one, two, three, or four risk factors were present. Because discharge to home is so dependent on the child returning to a baseline condition that allows the intake of fluids and nutrients, it is essential that nausea and vomiting be kept to a minimum for outpatient surgeries.

Anesthetic technique has been correlated with the incidence of PONV, with propofol-based techniques having the lowest incidence (Sneyd et al., 1998; Barst et al., 1999; Gurkan et al., 1999). The use of volatile agents, opioids, nitrous oxide, and cholinergic drugs for the reversal of neuromuscular blockade all increase the risk, although one study found that desflurane had less PONV than reported with other volatile anesthetics (Mendel et al., 1995; Divatia et al., 1996; Kuhn et al., 1999). Remifentanyl, in contrast with other opioids, does not appear to increase PONV (Pinsker and Carroll, 1999).

There have been studies of both treatment and prophylaxis of PONV in children undergoing outpatient surgery and anesthesia. One of the drugs commonly studied, droperidol, is no longer in common use because of a rare association with prolonged QT interval, so it will not be discussed here. The most commonly used drugs for treatment and prophylaxis are currently the HT_3 -antagonists (ondansetron and granisetron), dexamethasone, and metaclopramide. All have been shown to be effective for both prophylaxis and treatment.

Dose-response studies of ondansetron suggest that for maximal efficacy, prophylactic doses of 0.1 to 0.15 mg/kg up to 4 mg should be administered (Rose et al., 1996; Patel et al., 1997; Sadhasivam et al., 2000). Lower doses were either not as effective, or were no more effective than placebo. Timing

the dose before or after manipulation of the extraocular muscles in strabismus surgery (one of the most emetogenic operations) did not appear to make a difference, although the best effect has been reported when the drug is given at the end of the procedure (Madan et al., 2000). Another HT₃-antagonist, granisetron, was effective when 0.2 mg/kg was administered orally before induction of anesthesia (Munro et al., 1999). When a single dose was not adequate, controversy exists as to whether a second dose is efficacious (Rose and Martin, 1996; Kovac et al., 1999). Dexamethasone is effective at preventing PONV, and has the additional advantage of costing substantially less than the 5-HT₃-antagonists (Splinter and Roberts, 1996; Subramaniam et al., 2001). Dosing recommendations vary widely, but two-dose ranging studies found no additional benefits to using more than 0.25 mg/kg for decreasing postoperative nausea and vomiting; higher doses may be justified after tonsillectomy for the additional benefit of improving the ability to take oral fluids (Madan et al., 2005; Kim et al., 2007; Karaman et al., 2009). Despite a recent controversial study that found an increased incidence of bleeding after a single dose of dexamethasone, a Cochrane Database meta-analysis found benefit with no adverse effects of this therapy (Steward et al., 2003; Czarnetzki et al., 2008).

Metaclopramide is thought to act by increasing gastric emptying. Although it appears to be effective, several investigators have found it to be less so than ondansetron; in a recent meta-analysis, metaclopramide was found to be less effective than either the 5-HT blocking agents or dexamethasone (Broadman et al., 1990; Furst and Rodarte, 1994; Bolton et al., 2006). It has a higher incidence of side effects, primarily sleepiness and occasional extrapyramidal effects, than either of the other agents; therefore, it should be viewed as a second-line therapy. Cisapride, which also is a prokinetic agent, was found to be ineffective at treating PONV (Cook-Sather et al., 2002).

Several investigators recommend the use of multiple agents in combination for those at greatest risk of PONV. It appears that combining multiple drugs with different mechanisms of action yield the best results (Rose and Watcha, 1999; Gan et al., 2007). A factorial analysis comparing the use ondansetron, metaclopramide, and dexamethasone alone and in combination found that although each of the drugs decreased the odds of vomiting, and the addition of dexamethasone to ondansetron further decreased the odds of postoperative emesis, the combination of metaclopramide and ondansetron actually had a negative effect, and the authors therefore recommend against that particular combination (Gunter et al., 2006). Similarly, the use of a low-risk anesthetic, especially propofol, which appears to have antiemetic properties of its own, in combination with prophylaxis, may result in the lowest incidence of all (Barst et al., 1999). Low infusion rates of propofol as an anesthetic adjunct have been shown to have similar effects (Erdem et al., 2008).

An additional factor that has been found to promote PONV is the insistence on oral intake in the PACU before discharge. Although it appears sensible to want to demonstrate that a child is able to take and retain oral intake before discharge to home, investigators found that insistence on oral intake before discharge increased the incidence of PONV and lengthened hospital stay (Schreiner et al., 1992; Schreiner and Nicolson, 1995). This common practice probably deserves a critical reexamination.

Inadequate Analgesia

One of the most common reasons for unanticipated admission, acceptable levels of analgesia are a necessity before discharge. No child can leave the hospital unless one is sure that the caregivers at home will be able to manage postoperative pain. More potent oral analgesics are often adequate to enable discharge, but in the event that it is not the case, admission and parenteral agents may be necessary. When the level of pain seems out of proportion to either the procedure performed or the experience of the clinicians, causes other than the obvious ones should be sought, although it must also be remembered that pain is a subjective experience and pain thresholds can vary widely.

Excessive Somnolence

This is rarely a cause for admission, but may be a cause for a prolonged PACU stay. Common reasons include excessive narcosis, sedative, or opioid drug errors (unintentional or patient sensitivity), unusual sensitivity to inhaled anesthetics, and drug interactions.

COMPLICATIONS AND UNANTICIPATED ADMISSION

Even when all care issues have been optimized, there inevitably are patients who develop complications that prevent discharge to home and require hospitalization. Inadequate analgesia, inability to take adequate oral fluids, PONV, excessive somnolence, respiratory deterioration in children with URI or occult lower tract disease, or surgical complications all occur at some point. What is most important is that there is a system in place to streamline these admissions. In some institutions, this is overnight admission to a short-stay unit, which may be on the ward, in the PACU, or in the emergency room. In others, it means a bed on the regular ward. In all cases, it is essential that adequate follow-up care be maintained by both the surgical and anesthetic teams so that the issues that mandated admission are properly and adequately addressed.

FACILITY DESIGN AND PATIENT THROUGHPUT

Because such a large percentage of children undergoing surgery are cared for as outpatients, it is common that their surgery takes place not in a separate outpatient facility but in the main operating room. Even though these facilities are not usually designed with outpatients in mind, there are still numerous changes in organization and structure that can reap benefits both in parent and patient satisfaction and in efficiency and throughput.

Many hospitals care for a very large volume of outpatients in their main operating suites and have modified older designs or planned new facilities to enhance the simultaneous throughput of inpatients, same-day admissions, and outpatients. In addition to the obvious efficiencies this produces, it also permits surgeons to operate on a mix of patients without changing operating rooms. Inpatients, outpatients, and same-day admissions can share a common preoperative area with different "regions" where intake and preparation for surgery are done; all patients are then brought postoperatively to a common phase I PACU. Whereas inpatients and same-day admissions are discharged from phase I directly to the floor, outpatient-surgery patients

are routed to a phase II recovery area immediately adjacent to the PACU, where they are able to complete their recovery in preparation for discharge to home. This enables “fast tracking” and more rapid discharge of these patients. The same concept is used for anesthesia in procedure and imaging centers, where ideally a satellite preoperative area and PACU should be established so that those patients may have their preoperative preparation done directly on site and tailored for their specific case flow and then may be discharged directly to home without having to relocate to the main PACU. Focusing on these system issues can enable more patients to be cared for in a smoother, more professional manner.

To complement the large volume of outpatients who are cared for in the main hospital, many large children’s hospitals have opened satellite outpatient-surgery centers in suburban areas. These facilities are staffed by anesthesiologists and nurses who meet the same standards of care as the main facility. Although satellite outpatient-surgery centers offer advantages in efficiency and costs, transfer protocols and arrangements must be established to cover the rare emergency or complication that may develop. In addition, an anesthesiologist must remain in the outpatient center until the last child is discharged home from the PACU and leaves the facility.

SUMMARY

The number of children in the United States undergoing outpatient anesthesia has surpassed the number of inpatient cases. Many of the considerations for the care of these patients are identical to that of inpatients, but there are unique issues that must be addressed to enable children to go home on the day of surgery and anesthesia. Careful case selection, both on the basis of the child's underlying condition and for the planned surgical procedure, is critical in ensuring the success of an outpatient program. Whether these procedures are performed in the day surgery unit of a hospital or in a freestanding surgical center, the same level of same-day perioperative services for children should be available. One must have a well-designed systematic approach to organization, throughout, and clinical care to achieve both efficiency and safety.

“A pediatrician’s dream of the ideal world would be to have individuals knowledgeable about the special needs of infants and children assembled wherever children are to be treated” (Avery, 1975). Little did Dr. Avery know back in 1975, as she wrote these words in the journal *Anesthesiology* as a guest editor introducing a symposium on pediatric anesthesia, to what extent and in what places children were to be anesthetized and by whom. The prophetic nature of her question, “Where will pediatric surgery be done in the future?” and her statement, “Surely the anesthetist should contribute to the definition of what can be done in what setting,” is astounding when considering how rapidly the surgical and anesthetic care of children has progressed from the hospital to the ambulatory surgery center to the office-based setting since Dr. Avery’s remarks (1975).

The concept of office-based anesthesia and surgery is not a novel one, because dentists, oral surgeons, and plastic surgeons have been using office-based procedures for decades. In fact, dentists and oral surgeons have been at the forefront of office anesthesia and surgery dating back to one of the first office-based anesthetics, involving Colton and Wells in 1844, for an extraction of a wisdom tooth (Jacobsohn, 1995; Yagiela, 1999).

Surgical practice has now come full circle, because before the early 1900s many surgical procedures were performed in offices. Subsequently, because surgical procedures became more complex, the hospital became the major site for surgery (Yagiela, 1999). Despite this shift, the development of ambulatory anesthesia continued throughout the twentieth century with the development of the first free-standing surgical center in 1916, by Waters, and ultimately with the first ambulatory surgery center established by Reed and Ford in the late 1960s (White, 1997).

Over the past several years, the concept of office-based anesthesia and surgery has become well publicized. In addition to the increasing number of clinical reports, professional society publications, review articles and texts looking at the efficacy or regarding the subject of office-based anesthesia, there are unfortunately numerous reports of significant morbidity and mortality, as well as near misses both in the medical and dental literature and in the lay press (LaMendola, 1998; Laurito, 1998; Schulte and Bergal, 1998; de Jong, 1999; Neergaard, 1999; Rao et al., 1999; Tang et al., 1999; Arens, 2000; Morrell, 2000; Stoelting, 2000; Vogt, 2000; Hilton, 2001; Joshi, 2003; Gooden, 2006; Kaushal et al., 2006; Hussain, 2006; Hausman and Frost, 2007; Shapiro, 2007; ASA, 2008a, 2008b, 2008c; Coldiron et al., 2008; Heard et al., 2009; Sherry, 2009). The initial reports of mortality in the office-based setting have been highlighted by the unexpected death of the mother of music celebrity Kanye West and consequent legislation in California (Carter, 2007; McGreevy, 2009).

Resident training in office-based anesthesia has also recently been advocated by some within the field of anesthesia. This information, along with the fact that there is an ongoing closed-claim analysis of office-based anesthesia and surgery within the American Society of Anesthesiologists (ASA) (lending itself to the knowledge that this entity does exist and that improvements to existing procedures have been started), must be compelling evidence for the anesthesiologist to realize that office-based surgery and anesthesia are here to stay (Domino, 2001; Hausman et al., 2006; Hausman, 2008; Posner, personal communication, January 2009).

Interest in office-based anesthesia is also manifesting in the increasing number of societies—specifically, the Society for Ambulatory Anesthesia (SAMBA), and the Anesthesia Patient Safety Foundation (APSF)—that promulgate educational and

*Not a complete list, as other professional societies may also have related guidelines.

[†]These guidelines specify surgery by facility class (A, B, C) depending on the invasiveness of the surgery and type of anesthesia used.

[‡]Joint statement with the American Academy of Pediatric Dentistry.

[§]Practice advisory only.

[¶]In this practice advisory, the ASPS recommends that in the event that sedation or analgesia is used, the surgeon follow the ASA Guidelines for Sedation and Analgesia by Non-Anesthesiologists.

safety-related literature in this relatively new arena for anesthesiologists. Also, the ASA, as well as other groups including, but not limited to, The American College of Surgeons and various surgical subspecialty societies, the American Dental Association, the American Academy of Pediatric Dentistry, and the American Association of Nurse Anesthetists, have published guidelines specifically addressing office-based anesthesia or surgery or both (Table 35-1). Furthermore, the ASA Committee on Ambulatory Surgical Care and SAMBA have published a “how-to” manual for setting up a safe office environment (ASA, 2008d).

In an effort to establish consistency in the safe administration of sedation and anesthesia to children, some societies have established joint guidelines or updated guidelines outlining the use of anesthesia personnel to its membership (American Academy of Pediatrics, 2006; American Academy of Pediatric Dentistry, 2009). All of these societies have developed their guidelines or policies in response to the overwhelming interest

and growing participation by their memberships in this area, as well as an overall common concern for patient safety.

Also significant, and perhaps legitimizing the presence of office-based anesthesia and surgery in present-day medicine, is the ever-increasing number of states developing legislation that specifically address this area. Consequent to this dynamic period of law making and law revision is that the ASA Office of Legal Affairs continues to compile information pertinent to the states that have developed and those that are developing legislation regulating office-based anesthesia and surgery.

Simply stated, office-based anesthesia is the practice of anesthesia in the free-standing physician's office and is defined as the provision of anesthesia service in an operating area or a procedure room that is not licensed as an ambulatory surgery center. The most important distinctions are that it occurs within the four walls of a physician's office where surgery is offered as a secondary service, and only physicians who are members of the

practice perform procedures in this space. It is the most “liberated” form of anesthesia practice and is at the most extreme end of the spectrum of “out-of-the-operating-room” or “off-site” anesthesia. In a sense, it is anesthesia for the most remote location (except, perhaps, for those individuals delivering anesthesia care in isolated areas of Third World countries).

Traditionally, office-based anesthesia has been the realm of various specialists, including but not limited to dentists, oral surgeons, plastic surgeons, podiatrists, certified registered nurse anesthetists (CRNAs), and in some instances, gastroenterologists. Until recently, few anesthesiologists dared to venture out of their conventional roles as hospital-based or ambulatory surgery-based physicians.

To what extent is the office-based surgical volume increasing that it requires or necessitates the continued evolution of this new “subspecialty” of ambulatory anesthesia?

Estimates of the actual number of surgical cases completed, pediatric or otherwise, in an office setting, are difficult to ascertain. It is estimated that there were 10 million office-based surgical procedures performed in 2005, consistent with one marketing study from several years ago, that estimated that by 2006 the total number of outpatient procedures performed would be approximately 40 million, with 11 million of these being office-based procedures (Fig. 35-1) (SMG Marketing-Verispan, L.L.C., 2002; Twersky, 2008). In 2009, these numbers are holding steady; however, the dynamic nature of the reimbursement environment and the development of minimally invasive surgical technologies may make the number of office-based procedures skyrocket over the next several years.

According to a 2009 report from the National Center for Health Statistics, in 2006 there were approximately 35 million

ambulatory surgery visits in the United States, with most of these being in hospital-based facilities vs. free-standing facilities (Cullen et al., 2009). Just over 7% of these reported ambulatory surgery visits were by children younger than 15 years of age. Although the total number of ambulatory surgery visits for this age group went up in 2006, the percentage decreased from the 8.5% reported for 1996 (Hall and Lawrence, 1998). As is suggested, without mandatory reporting of all ambulatory surgery procedures requiring anesthesia to a central agency, office-based anesthesia data will remain obscure (Perrott, 2008).

Although many different types of surgical procedures, including otolaryngologic, urologic, cosmetic, ophthalmologic, and radiologic (including single-photon emission computed tomography [SPECT]) scanning are performed on children in the office-based setting, the majority of procedures requiring anesthesia or sedation in the office setting for children are dental procedures (Cartwright et al., 1996; Goldblum et al., 1996; Grevelink et al., 1997; Yagiela, 1999; Siegel et al., 2000; Smith and Smith, 2000; Garin et al., 2001; Friedman et al., 2002; Ross and Eck, 2002; Barinholtz, 2009; Gravningsbraten et al., 2009).

The most common reason for children to require dental procedures is related to early childhood caries (ECC), with an incidence in primary teeth of 41% in children between ages 2 and 11 years (Beltrán-Aguilar et al., 2005). Furthermore, a majority of ECC in the United States occurs in children from low-income households. (Vargas et al., 1998; Nunn et al., 2009). Yagiela (1999) reports that a survey by the American Academy of Pediatric Dentistry estimated in 1995 that the number of children who received anesthesia for dental procedures was close to 200,000. Presently, the actual number of dental procedures performed with patients under general anesthesia is

■ **FIGURE 35-1.** This graph represents past and future trends in surgical volumes in specific patient-care sites. Notice the increasing surgical volumes in the free-standing outpatient surgery center (FOSC) and physician office-based surgery (POBS) center. (Courtesy SMG Marketing-Verispan, LLC., 2002, Chicago, Ill.)

difficult to determine because of underreporting, and because estimates are generated from Medicaid-provided information of hospital-based care (Casamassimo et al., 2009). The actual number of children requiring anesthesia for these procedures may be significantly greater than this, with the discrepancy being because of a paucity of access to the appropriate care secondary to a lack of primary-care access and as important, a lack of insurance coverage. Significantly, this access to care can be positively impacted by state legislation. White and others (2008) report that non-Medicaid and Medicaid dental visits increased by approximately 60% and 30% ($p < .05$), respectively after the State of North Carolina introduced general-anesthesia legislation for preschool-aged children.

In a 2006 survey of Illinois dentists licensed to give some form of sedation or anesthesia, close to 116,000 cases were performed with some form of sedation and general anesthesia (Flick et al., 2007). Most of these sedation and anesthesia cases (90%) were performed by oral and maxillofacial surgeons (63% of survey respondents); however, general dentist and pediatric dentist respondents (29%) accounted for most of the remaining sedation and anesthesia. The number of pediatric patients cared for, however, was not specified.

WHY OFFICE-BASED SURGERY AND ANESTHESIA?

As one can see from the information presented in [Figure 35-1](#), there is a compelling need to be able to provide quality surgical and anesthesia services in the office-based setting. The actual reasons as to why this boom has occurred and continues to evolve and why anesthesiologists are more aggressively entering this arena are several-fold.

Ostensibly, the most persuasive argument for a paradigm shift to the office-based setting is financial. Potential and realized limitations and reductions in reimbursement because of health care reform and economic constraints are causing physicians to become more creative in facilitating cost-effective approaches to surgery. Costs can be reduced by reducing or eliminating facility fees that ordinarily accompany the cost-sharing charges at hospital-based and ambulatory surgery-based centers. Much of office-based surgery, especially cosmetic surgery, is performed on a cash-payment, fee-for-service basis, and therefore cost containment by limiting facility-fee overhead becomes crucial to patient affordability. This affordability is critical in the case of pediatric dental procedures, where in many instances, neither dental nor medical insurance covers out-of-office dental procedures and anesthesia costs (Ross and Eck, 2002).

Although the lack of a facility fee is ideal and helps provide the surgeon with a cheaper alternative for the patient, the reality of the situation is that surgeons often include a facility fee in their global fee to the patient to offset the overhead required to run an office-based practice (e.g., personnel and supplies). In some instances, insurance companies may reimburse physicians a facility fee, but the cost to the third-party payers may still be less than if the procedure is performed in a hospital- or surgery center-based setting. Consequently, the procedure becomes financially advantageous for the surgeon, the anesthesiologist, the insurance company, and the patient.

One surgical study from the United States as early as 1994 compares the cost of performing an inguinal herniorrhaphy in the hospital with that of the cost in an office setting. This study finds the latter a more cost-effective alternative with a reduction

in cost of a laparoscopic approach or an open approach of approximately 70% and 60%, respectively when compared with the hospital outpatient setting (Schultz, 1994). In one pediatric study, Lalwani and others (2007) show a per-patient savings of close to \$5000 when patients with special health care needs who require anesthesia or sedation undergo dental rehabilitation procedures in an office-based setting when compared with those receiving care in a hospital operating room.

Operating in the office affords the surgeon not only financial but also logistic advantages. Office-based surgical practice virtually eliminates the lost time caused by turnover delays, bumping cases secondary to emergencies, overscheduled cases, and travel times between facilities. In the office-based setting, whatever turnover delays do occur can be quickly remedied by the surgeon, because he or she has total control over the personnel and the facility.

The ability of the surgeon to schedule on-site clinic visits between surgical cases allows for the efficient use of time. This eliminates the usual routine of having to rush back to the office between procedures or having office hours at the conclusion of a long and busy day at the hospital or surgery center.

Another advantage of office-based procedures is the more private, less stressful, and more familiar environment. For the anesthesiologist, office-based anesthesia may allow for an enhanced income, a better work environment (working with a limited number of surgeons or, in some instances, the same surgeon), and in most practices, the lack of a nighttime call schedule. Furthermore, this type of practice provides the anesthesiologist with the opportunity to have complete control over all aspects of practice for which he or she is ultimately responsible. Whether these potential advantages of establishing or taking part in an office-based practice prevail over the relative disadvantages of working in an extremely remote environment, routinely providing anesthesia care for cases of decreased complexity (compared with those cases in a hospital setting, but this may be changing), providing anesthesia services under itinerant conditions, and perpetually competing with other anesthesiologists and anesthesia providers for business, become individual decisions.

SAFETY AND OUTCOME

With the government, medical community, third-party payers, and the consumers (patients) pushing for more expeditious and cost-effective (and hence potentially more profitable) ways in which to provide surgical and anesthesia services, the anesthesia services provided are moving further away from the hospital safety net. Dr. Ervin Moss (1998), the impetus behind tighter regulation of office-based anesthesia and surgery in the state of New Jersey and perhaps beyond, stated, "Some say the major difference between the office-based and hospital-based anesthesiologist is that the former must be more courageous or foolhardy."

Whether or not Dr. Moss's characterization of the office-based anesthesiologist holds true, the fact remains that anesthesia care must be provided safely, if not more vigilantly, than hospital-based or surgery center-based anesthesia. Although some have questioned whether the convenience of office-based surgery and anesthesia is worth the risk, consensus opinion, as this specialty area continues to develop, is that it must be done correctly and consistently (Arens, 2000; Bridenbaugh, 2005).

Although anesthesia-related mortality risk continues to be difficult to assess, perhaps because of methodologic issues, it has nevertheless decreased over the past several decades (Lagasse,

2009). Anesthesia-related mortality risk in the United States has recently been quoted to range from 0.1: 10,000 to approximately 0.8:10,000 procedures performed (Biboulet et al., 2001; Lagasse, 2002, 2009; Newland et al., 2002; Li et al., 2009). These numbers appear slightly lower than the rate published outside the United States, at 1.12:10,000 cases (Braz et al., 2006).

In children, the incidence of cardiac arrest from anesthesia is reported to range from 1.4:10,000 to 4.6:10,000 with the incidence of anesthesia-related mortality being reported by some as between 1.2:10,000 and 7.7:10,000 cases in ASA Physical Status (PS) I-II and ASA PS III-IV, respectively (Murray et al., 2000). This disparity seen between patients of lower and higher ASA PS is consistent with morbidity statistics presented by Murat and others (2004) in a report of over 24,000 anesthesia cases over 2½ years and by Kakavouli and others (2009) in a study comparing adverse events for patients receiving anesthesia in the operating room (2.5%) with those outside the operating room (3.5%). Respiratory events were the leading cause in both studies, 1.7% and 1.9%, respectively (Zuercher and Ummenhofer, 2008; Bharti et al., 2009).

Interestingly, the number of pediatric arrests related to medications decreased almost 20% from 1994 to 1997 (37%) and from 1998 to 2004 (18%) as reported in an update on the pediatric perioperative cardiac arrest (POCA) registry (Bhananker et al., 2007). The authors suggest that this may be because of the decreased use of halothane in pediatric anesthesia. This is important in that the relatively newer, faster onset and offset (desirable characteristics in the office-based setting) volatile agents, sevoflurane and to a lesser extent desflurane, may confer a larger therapeutic index in the office-based setting. Furthermore, these authors report that airway causes for pediatric arrest still occur with a high incidence (27%), reemphasizing the importance of having superior airway management skills in pediatric anesthesia regardless of location.

Despite this information, an accurate assessment of the safety profile of office-based anesthesia and surgery relative to the pediatric population is difficult secondary to the paucity of site-specific information. Until across-the-board mandatory reporting for morbidity and mortality related to office procedures exists, in order to make an assessment of the relative safety of office-based anesthesia and surgery, it is imperative to continue to analyze data reviewing the safety of pediatric ambulatory and in-patient surgery, pediatric dental office surgery, and pediatric sedation and analgesia, as well as the adult literature that reviews this topic.

Many of the cases brought to the attention of the medical, dental, and lay community involve children undergoing dental procedures (Morell, 2000; Hussain, 2006; Sherry, 2009). This information is not only tied intimately to the present topic but also is the point of origin for much of the controversy over the safety and efficacy of office-based anesthesia for children.

In two reports from the United States, Coté and others (2000a, 2000b) retrospectively analyzed information obtained from the Food and Drug Administration, the United States Pharmacopoeia, and a survey of pediatric specialists to report on contributing factors to critical incidents and medications used in sedation as they relate to adverse sedation events in children undergoing diagnostic and therapeutic procedures.

In the first report, Coté and others (2000a) reported on 95 incidents. Over half of these incidents resulted in death ($n = 51$) or permanent neurologic injury ($n = 9$). The remaining patients either had prolonged hospitalization without injury ($n = 21$) or sustained no harm as a result of the adverse event ($n = 14$). Of note

was that those children who were cared for in non-hospital-based facilities (older and healthier) had a much higher rate of death and permanent neurologic injury (93%) than did those cared for in hospital-based facilities (37%). The authors also reported that inadequate resuscitation was a major factor in the non-hospital-based facilities (57%) compared with the hospital-based setting (2.5%) and that patients cared for in the nonhospital setting were more likely to sustain a cardiac arrest as the second or third event compared with those in the hospital setting ($p < .001$).

In the second report, Coté and others (2000b) used the same 95 incidents to determine whether there was a relationship between medications and adverse events. Although the authors noted no relationship between the class of drug used, the route of administration, and the incidence of death and permanent neurologic injury, they did note that adverse outcomes were associated with the administration of drug overdoses and administration of three or more sedating medications. Furthermore, 11 of 12 patients (all younger than 6 years of age) sustained adverse outcomes either at home or in a car. Two of the 12 patients, who had received sedative medication at home before their procedure, sustained an adverse event at home before the scheduled procedure.

Of note was that over one third of the reported events occurred during sedation for dental procedures ($n = 32$). Twenty-nine of these resulted in death or permanent neurologic injury. Most of the involved practitioners were either oral surgeons or dentists, three were pedodontists, and one was a nurse anesthetist under the supervision of a dentist. None of the practitioners was an anesthesiologist (Coté et al., 2000b).

The dental practices were the only sites in these reports to have used nitrous oxide. In addition to the greater tendency toward the use of nitrous oxide, there was a greater tendency for these practitioners to use multiple drugs (more than three) compared with other practitioners: 39% and 13%, respectively. The authors conclude that many of these adverse events may have been prevented by consistency between monitoring guidelines (as now exists with sedation guidelines promulgated by the American Academy of Pediatrics and the American Academy of Pediatric Dentistry) and by practice and training requirements among health care professionals of differing specialties who administer sedation and anesthesia.

Although these conclusions may seem intuitive to those who regularly care for children, they are reinforced by recent reports suggesting that severe adverse outcomes in pediatric sedation or analgesia outside the operating room may be improved by consistency in guidelines, training, and adverse-event reporting across institutions and specialties that are implemented through well-designed sedation services (Cravero et al., 2006, 2009; Bhatt et al., 2009). In the latter study, Cravero and others (2009) show that whereas the incidence of pulmonary events (e.g., stridor, laryngospasm, excessive secretions, and central and obstructive sleep apnea) is high, they report a low incidence for cardiopulmonary resuscitation (0.4:10,000) and no mortalities in approximately 50,000 sedation procedures performed by various nonanesthesiologist pediatric specialists. Lightdale and others (2006) advocate the use of microstream capnography to enhance the safety of pediatric patients undergoing procedures under sedation or analgesia via early detection of hypoxemia caused by alveolar hypoventilation.

Although there are anecdotal reports and studies of adverse outcomes, complications, and side effects related to sedation and anesthesia in the dental literature, others have reported

on a safety record that is as good as, if not better than, that of the anesthesia community (Denman et al., 1968; Yee et al., 1985; Blayney et al., 1999; Girdler and Smith, 1999; Laskin, 1999; Saxen et al., 1999; Whitmire, 1999; Johnson et al., 2001; Manoharan et al., 2001; Yagiela, 2001; Perrott et al., 2003). The incidence of mortality rates in dental anesthesia is reported to be anywhere from 1:250,000 in the United Kingdom to 1:300,000 to less than 1:1 million in the United States (Cartwright, 1999; Brandom and Herlich, 1999; D'Eramo, 1999; Laskin, 1999).

As if there is not enough controversy within the anesthesia community, within the dental community there is also debate over who can best serve the patient requiring anesthesia for a dental procedure. Yagiela (2001) points out that members of the American Society of Dental Anesthesiologists, those who provide “approximately 25,000 pediatric general anesthetics per year,” subscribe closely to the American Academy of Pediatrics and American Society of Anesthesiologists guidelines for sedation and anesthesia. He also states that “since the organization’s inception 2 decades ago, there have been no known incidents of mortality or significant morbidity in children managed in the dental office by a dentist anesthesiologist” and intimates that safety may be improved in dental offices with a greater adherence to these guidelines by the dental community as a whole (Yagiela, 2001).

In contrast to the paucity of information about the safety and outcomes related to office-based anesthesia, the efficacy of anesthesia in pediatric ambulatory surgery in general is well known. As reported by Willetts and others (1997), outpatient surgery may date back to James H. Nicoll, a Glasgow surgeon who in the early 1900s successfully performed several thousand ambulatory procedures on young children at the West Graham Street Dispensary for Children. Contemporary literature continues to confirm over the past 50 years that for a growing variety of surgical procedures, the ambulatory setting for surgery and anesthesia is safe, cost effective, and therefore preferable to inpatient surgery (Postuma et al., 1987; Patel and Hannallah, 1988; Hannallah, 1991; Ghosh and Sallam, 1994; Blacoe et al., 2008; Shah et al., 2008; Mattila et al., 2009).

In one prospective study examining the efficacy of pediatric day surgery at the Children’s Hospital of Eastern Ontario, the overall complication rate was very low. The investigators, over 5 years, prospectively studied children undergoing various outpatient procedures, including myringotomy, tonsillectomy and adenoidectomy, dental procedures, and inguinal hernia repairs. Most of the children were between 2 and 7 years old, and the total number of cases approached 25,000. The reported complication rate was 1.6% per year. The most common complication was postoperative bleeding, primarily secondary to tonsillectomy and adenoidectomy. None of the complications resulted in permanent disability (Letts et al., 2001). In a retrospective study from Children’s National Medical Center focusing on pediatric otolaryngology procedures, Shah and others (2008) report that in close to 5000 cases (55% of total surgical cases) over 7 years, the rate of unanticipated outcomes was 0.2%. Similar to the previous study, the majority of adverse outcomes were related to posttonsillectomy and adenoidectomy bleeding.

Most of the information relative to the outcomes for office-based anesthesia and surgery is related to adult patients. In a retrospective report specifically looking at outcomes for plastic surgical procedures, Hoefflin and others (2001) reported no significant morbidity and no mortality over 18 years in more than 23,000 procedures in which general anesthesia was used. The anesthesia was provided by a board-certified anesthesi-

ologist, and the single facility was accredited by the American Association for Accreditation of Ambulatory Surgical Facilities (AAAASF) (Hoefflin et al., 2001). In this report, most of the patients underwent cosmetic surgery, with some patients having multiple procedures. The only incidents reported as significant by the authors were the rare occurrence of electrocardiograph and oxygen-monitor failure. None of these events resulted in any patient complications, although three patients were hospitalized for custodial care. Minor anesthetic complications included nausea and vomiting (fewer than 5%), postextubation sore throat (fewer than 5%), shivering, one case of dental damage, one case of delayed (10 days) deep vein thrombosis, and one case of carpal tunnel syndrome after intravenous catheter infiltration.

In a retrospective study comparing outcomes in physician offices and ambulatory surgery centers in Florida, Vila and others (2003) found that despite new regulations imposed by the Florida Board of Medicine in the year 2000, between 2000 and 2002 there was a significantly increased risk of adverse incidents and deaths in offices (65.8:100,000 and 5.3:100,000, respectively) compared with ambulatory surgery centers (9.2:100,000 and 0.8:100,000, respectively). Furthermore, the authors estimated that a significant number of injuries and at least six deaths per year could have been prevented had all surgical cases been performed in an ambulatory surgery center.

In another report and as a follow-up study to previous reports, Coldiron and others (2008) reviewed critical surgical incidents that occurred in physicians’ offices in the state of Florida from 2000 to 2007 subsequent to mandatory reporting that began in February 2000 (Coldiron 2001, 2002). This mandatory reporting initially resulted from several newspaper accounts of poor patient outcomes and questions of whether office anesthesia and surgery were safe. Those incidents requiring reporting are listed in [Box 35-1](#).

In the data obtained from Florida’s Agency for Health Care Administration, there were 31 deaths and 143 procedure-related complications and hospital transfers. Most of the bad outcomes occurred during “nonmedically-indicated” cosmetic surgery such as liposuction or liposuction with abdominoplasty. Plastic surgeons were responsible for 48% of all deaths and 52% of hospital transfers. Interestingly, most of the deaths (78%) occurred in ASA PS I patients. These authors note that the reported deaths and complications were unrelated to whether the physician was board certified or whether the physician had similar surgical

Box 35-1 Incidents in Surgical Offices Requiring Reporting by the State of Florida

- Death
- Brain damage
- Wrong patient surgery
- Wrong site surgery
- Wrong procedure
- Surgery to remove an unplanned foreign object from a surgical procedure
- Transfer of a patient to a hospital
- Spinal damage
- Surgical repair of injuries or damage resulting from a planned surgical procedure

From Coldiron B: Office surgical incidents: 19 months of Florida data, *Dermatol Surg* 28:710, 2002.

privileges in a hospital (the latter being a mandatory requirement in some states). However, only 40% of facilities reporting adverse events were accredited by an independent agency. Despite the latter data, there are those who suggest that rigid state regulations and licensing laws along with accreditation of office-based surgical and anesthesia practices will help ensure patient safety (Kaushal et al., 2006).

Bitar and others (2003) retrospectively reviewed close to 5000 office-based plastic surgery procedures that were performed under monitored anesthesia care with sedation. The procedures in this study were performed by board-certified plastic surgeons, and anesthesia was provided by a CRNA. Nearly all patients were reported to be ASA PS I or II (99.9%), and the majority of patients were adult females (92%). The most common complications reported in this study were dyspnea (0.05%, $n = 2$), protracted nausea and vomiting (0.2%, $n = 6$), and unplanned hospital admission (0.05%, $n = 2$). One patient required intubation without prolonged sequelae. The author reported no cardiac arrests, deaths, or any incidence of deep vein thrombosis or pulmonary embolus. The author concluded that office anesthesia and surgery were safe when using appropriate protocols and patient selection.

One Pittsburgh-based office dental anesthesiologist practice, delivering approximately 30,000 anesthetics from between 2004 and 2009, reports no mortality or major morbidity, including central nervous system injury. Furthermore, this practice reports no instances of aspiration, pulmonary embolism, local anesthetic toxicity, or malignant hyperthermia. There was one unplanned hospital admission, not related to anesthesia, involving massive bleeding from a mandibular arteriovenous malformation from which the patient made a full recovery after transfer to an acute care hospital (Finder, personal communication, January 2010).

In another office-based dental anesthesia practice in Seattle, 4321 pediatric (younger than 12 years old) dental procedures have been completed since the year 2000 (Isackson, personal communication, 2010). Dr. Isackson reports no serious adverse events. There were no unplanned hospital admissions, although one patient was referred to a primary care physician for cardiac evaluation. Minor respiratory events and immediate and delayed postoperative nausea and vomiting (PONV) each occurred in 0.07% of cases, with one patient in the group who experienced nausea and vomiting requiring office assessment by a primary care physician.

Koch and others (2003) reported on several office-based anesthesia practices from various regions of the United States that were performed between 1981 and 2002. In this report, the authors noted no intraoperative deaths in over 64,000 anesthesia cases. Furthermore, in a subset of pediatric patients that comprised this report, one Chicago-based office anesthesia practice reported no intraoperative deaths, significant perioperative morbidity, or emergent hospital transfers in over 600 pediatric anesthesia cases. This number is now approximately 1200 cases and includes only one pediatric emergent hospital transfer (a possible malignant hyperthermia case). All complications continue to be minor, with a reported incidence of immediate and delayed PONV of less than 0.07% and 1%, respectively. Children in this subset ranged in age from 18 months to 17 years. Most of the children were younger than 6 years old and were classified as ASA PS I or II patients (Barinholtz, personal communication, 2009). These safety results are consistent with those reported by others caring for special-needs dental patients in the office-based setting (Caputo, 2009).

TABLE 35-2. Patient Characteristics in Analysis of Claims Made in Office-Based Anesthesia Incidents

	Ambulatory (n = 753)	Office Based (n = 14)
Age (mean yr)	41	45
Female (%)	58	64
ASA PS class I/II (%)	82	89
Elective surgery (%)	97	100
Anesthesia type		
General (%)	66	71
MAC (%)	10	14
Surgical procedure		
Dental (%)	3	21
Plastic surgery (%)	32*	64*
Other (%)	64†	14†

From Domino KB: Office-based anesthesia: lessons learned from the Closed Claims Project, *ASA Newsletter*, 2001, American Society of Anesthesiologists.

* $p < 0.05$, Ambulatory vs. office based.

† $p < 0.01$, Ambulatory vs. office based.

MAC, Monitored anesthesia care.

In a review of the ASA's Closed Claims Project database, Domino (2001) compared claims (all age populations) made against anesthesiologists in the office setting ($n = 14$) with those made in other ambulatory surgery settings ($n = 753$). Claims for dental damage and for nonoperative pain management were excluded from this analysis. Although patient demographics were similar in both groups (Table 35-2), most of the claims in the office-based setting were related to plastic surgery or dental procedures, whereas in the ambulatory setting, most claims were related to procedures other than plastic or dental. The severity of injury appeared greater in the office-based setting compared with other ambulatory sites. In this initial report, most of the claims made in other ambulatory sites (62%) were for "temporary or nondisabling injury," whereas most of the claims from the office-based setting were for death (64%). The author pointed out, however, that without a denominator, a true risk assessment for each site cannot be ascertained. Subsequent data from the ASA Closed Claims Analysis, with more claims in both the ambulatory (total, $n = 877$) and office-based settings (total, $n = 29$), continue to show a preponderance of death and brain damage in the office-based setting, although at a reduced (40%) incidence (Posner, personal communication, 2009). Likewise, Jimenez and others (2007), in a closed claims analysis of 532 pediatric cases from 1973 to 2000 (not exclusively ambulatory or office-based, but from 1990 to 2000 the highest percentage of the claims involved dental, otolaryngologic, and maxillofacial surgeries), found that death and brain damage were also the dominant injuries in malpractice claims, although the proportion of these claims decreased in the 10 years before 2001.

In both office-based settings and ambulatory settings, Domino (2001) noted that respiratory events were most common. A summary of airway-related complications and drug-related complications in office-based claims is shown in Table 35-3. Although the timing for injury was similar for both

TABLE 35-3. Damaging Events in Office-Based Anesthesia Claims

Type of Event	Ambulatory Anesthesia (n = 666)		Office Based (n = 12)	
	Number	%	Number	%
Respiratory	150	22	6	50
Cardiovascular	67	10	1	8
Equipment	74	11	1	8
Drug related	58	9	3	25
Block-needle trauma	41	6	1	8

From Domino KB: Office-based anesthesia: lessons learned from the Closed Claims Project, *ASA Newsletter*, 2001, American Society of Anesthesiologists.

sites, there tended to be fewer claims for events occurring after discharge in the other ambulatory claims (7%) than for the office-based claims (21%).

The Closed Claims Project analysis also discloses that a greater number of office-based claims continue to be potentially preventable with better monitoring (Posner, personal communication, 2009). In the earlier report, a greater percentage of office-based claims involved substandard care compared with other ambulatory settings (not statistically significant), and payment was made in a higher percentage of claims (92% vs. 59%) and for a higher median payment (\$200,000 vs. \$85,000) for office-based claims than for other ambulatory settings (Domino, 2001).

LEGISLATION AND REGULATIONS

There are many entities presently imparting their influences on the practice of office-based anesthesia and surgery. These include, but are not limited to, state regulatory bodies; federal regulatory agencies such as the Centers for Medicare and Medicaid Services (CMS) and the Office of the Inspector General (OIG); national medical professional societies; national medical and safety organizations such as the Federation of State Medical Boards (FSMB, 2002), the National Committee for Quality Assurance (NCQA), and the National Patient Safety Foundation (NPSF); accrediting organizations such as the American Association for Accreditation of Ambulatory Surgery Facilities (AAAASF), the Accreditation Association for Ambulatory Health Care (AAAH), and The Joint Commission; and the insurance industry. Also, in 2003, the AMA published the *Core Principles for Office-Based Surgery* that are currently endorsed by government agencies, the accrediting bodies, and specialty societies.

The main problem with regulation and legislation concerning office-based surgery and anesthesia is the wide regulatory variability that exists among states. Some states are highly regulated, whereas other states have no regulations (Fig. 35-2). In the states that do have regulations, these regulations are often ambiguous. State regulations regarding facility structure, personnel, equipment, and credentialing of individual practitioners differ widely. A more complete compendium of state regulations is available through the ASA Office of Governmental and Legal Affairs (ASA, 2009). In addition to state agencies and legislation,

professional societies can regulate practice by establishing practice guidelines, practice standards, and advisories. The disadvantage of professional societies is that they run the risk of being self-interest groups. Consistent regulatory control could also be achieved by recognizing established accrediting bodies as oversight organizations. The organizations most commonly involved in the accreditation of ambulatory surgery centers are AAAASF, AAAHC, and The Joint Commission.

Historically, AAAASF, known until the early 1990s as the American Association for Accreditation of Ambulatory Plastic Surgery Facilities (AAAAPSF), was created to accredit only outpatient plastic surgery facilities. However, as other medical specialties moved procedures to free-standing outpatient settings, this organization became active in accrediting these facilities as well (AAAASF, 2003).

In contrast to AAAHC and The Joint Commission, AAAASF accredits facilities over a much narrower spectrum of medical specialties. The surgical specialties include colon and rectal surgery, obstetrics and gynecology, ophthalmology, orthopedic surgery, otolaryngology, plastic surgery, general surgery, and urology. AAAASF is particularly restrictive in its practitioner credentialing. This organization requires all surgeons to be certified by the American Board of Medical Specialties (ABMS) and requires all of its surgeons practicing at an ambulatory or office-based facility to have hospital privileges for the same procedures being performed in the office facility (AAAASF, 2003). AAAASF will only accredit a practice where the surgeons practice in their area of board certification. Furthermore, the AAAASF will not accredit an organization if propofol is not administered by an anesthesiologist or a properly supervised CRNA or anesthesia assistant.

The Joint Commission and AAAHC, in addition to the facilities mentioned for AAAASF, approve facilities where oral and maxillofacial, dental, dermatologic, podiatric, cosmetic, vascular, and pain procedures are performed. Although these two organizations are not as restrictive on the practitioner-privilege issue as the AAAASF, their credentialing policies are complete.

In addition to defining requirements for surgical personnel, all three organizations offer accreditation processes that outline expectations for the facilities as they relate to meeting standards for the facility physical plant (e.g., by ensuring that state, local, Occupational Safety and Health Administration [OSHA], and National Fire Protection Association regulations are followed), anesthesia administration, monitoring, equipment and personnel, ancillary staff, patient transfer policies, patient safety and emergency resuscitation issues, quality improvement, and patient satisfaction issues. A summary of some of the similarities and differences between the three most visible accrediting organizations is given in Table 35-4.

Whether accreditation affects outcomes in office-based surgery and anesthesia is uncertain. In a survey study, the AAAASF sent a questionnaire to its accredited facilities that addressed patient safety in plastic surgery office facilities. Two hundred forty-one of 418 facilities responded to the questionnaire. Over 5 years 400,000 surgical procedures were studied, and the authors reported the risk of significant complications to be 1:213 and the risk of death to be 1:57,000 cases. They concluded that overall risk in an accredited office is comparable with that of other ambulatory surgery sites (free-standing or hospital based) (Morello et al., 1997). In a retrospective review of an accredited office-based plastic surgery facility, Byrd and others

2009 OFFICE-BASED SURGERY AND ANESTHESIA REQUIREMENTS

This table was current as of the time of the publication, however state health statutes, regulations, health department, and medical licensure regulations are different for each state and should be reviewed and updated accordingly. A summary of state regulations is provided by the ASA Washington Office that can be found at www.asahq.org/Washington/rulesregs.htm. This site is maintained by the ASA and contains a state by state summary of Office-Based Anesthesia legislative activity.

*Physician supervision or direction requirements derived from other sources of state law, not from OBA requirements.

- ¹AL: Encouraged for Levels 4 (deep sedation) and 5 (general).
- ²AL: Direction of the general and regional anesthesia should be provided by a physician who is immediately and physically present.
- ³AL: Report within 3 business days surgical related deaths and events resulting in emergency transfer to hospital, anesthetic surgical events requiring CPR, unscheduled hospitalization related to surgery, and surgical site deep wound infection.
- ⁴AZ: A physician who uses general anesthesia when performing office-based surgery using sedation must obtain a health care institution license as required by the Department of Health Services.
- ⁵CA: Report within 15 days after occurrence death or transfer to hospital for period exceeding 24 hours.
- ⁶CO: Surgeon should have staff privileges or document satisfactory completion of training such as Board certification or certify comparable background, training and experience.
- ⁷FL: Level I: Surgeon's CME should include proper dosages; management of toxicity or hypersensitivity to regional anesthetic drugs.
- ⁸FL: Level II, IIA: Surgeon must have staff privileges or be able to document satisfactory completion of training such as Board certification or comparable background, training and experience. Level III: Physician must have staff privileges.
- ⁹FL: Send incident report by certified mail within 15 calendar days after occurrence of the adverse incident.
- ¹⁰IL: An operating physician must either maintain clinical privileges to administer anesthesia in a hospital or ASC or have CMEs in anesthesia to administer anesthesia or enter into a practice agreement with a CRNA to provide anesthesia. Training and experience may be met by completing CME hours: 8 hours for conscious sedation, 34 hours for deep sedation, regional anesthesia and/or general anesthesia. No training and experience requirements when an anesthesiologist administers or supervises the administration of anesthesia. (upheld by Illinois Appellate Court)
- ¹¹IN: Effective January 1, 2010
- ¹²IN: CRNAs must administer anesthesia under the direction of and in the immediate presence of a physician.
- ¹³IN: Privileges at either an accredited hospital or ASC. Alternatively, the governing body of the office is responsible for a peer review process for privileging practitioners based on nationally recognized credentialing standards.
- ¹⁴KS: Report within 15 calendar days of discovery of event: transfer to ER; unscheduled hospital admission within 72 hours of discharge; death within 72 hours of surgery; unplanned extension of surgery (more than 4 hours); foreign object remaining in patient; wrong surgical procedure, site, or patient.
- ¹⁵LA: Accreditation not required, but offices accredited by JCAHO, AAAASF, or AAAHC and those that are part of but physically separated from a licensed hospital are exempt from the regulations.
- ¹⁶LA: Physician performing surgery must have current staff privileges or board certification in specialty encompassing office procedure and possess current hospital admitting privileges.
- ¹⁷LA: Report within 15 days after occurrence resulting in transfer to ER, office readmission with 72 hours of discharge, unscheduled hospital admission within 72 hours of discharge, death within 30 days of surgery.
- ¹⁸MA: Level II, III: Pre-accrediting survey prior to surgical procedures; definitive accreditation survey 6 months after procedures begin.
- ¹⁹MA: Level II, III: Surgeon must have staff privileges at hospital or accredited outpatient facility or document satisfactory completion of training such as Board certification/Board eligibility or comparable background, formal training, or experience as determined by MA BRM.
- ²⁰MA: Reporting requirements are not specific; guidelines recommend following all BRM adverse incident rules.
- ²¹MS: Level I: Surgeon's CME should include proper dosages and management of toxicity or hypersensitivity to regional anesthetic drugs.
- ²²MS: Report within 15 days after occurrence any surgical event in the immediate peri-operative period that is life-threatening, or requires special treatment or hospitalization that is related to anesthesia or surgery.
- ²³MS: Level II, III: required of surgeon who does not have privileges at hospital within reasonable proximity.
