Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods, they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

The eighth edition of *Smith's Anesthesia for Infants and Children* is dedicated to Dr. Robert Moors Smith, who died on November 25, 2009, 2 weeks before he would have been 97. The eulogy published by the Harvard Medical School's Office of Communications began with this statement: "The Harvard Medical School flag is at half-mast today in memory of Robert M. Smith, MD, Clinical Professor of Anesthesia, former Chief of Anesthesiology at Children's Hospital Boston and pioneer in clinical anesthesiology in children." This was an extraordinary tribute from an institution that has produced literally hundreds of world leaders in medicine.

Dr. Smith was one of the most distinguished pioneers of modern anesthesia for children in the world. In the United States he was considered the "Father of Pediatric Anesthesiology." During his tenure at Children's Hospital Boston, Dr. Smith was a superb and compassionate clinician and educator who continually advanced practices in pediatric anesthesia and kept abreast with the fast progress of increasingly complex surgery on smaller and younger patients. He was an early advocate of compassionate patient safety—more than 30 years before the term even existed.

Along with Dr. Margo Deming of Philadelphia, Dr. Smith was an early supporter of endotracheal intubation with sterile and child-appropriate-sized tubes to prevent aspiration and postintubation croup. He also encouraged the wrapping of small children to prevent heat loss. In the early 1950s when the monitoring of infants and children consisted of visual observation of the patient and intermittent palpation of the patient's radial pulse, Dr. Smith pioneered a new approach of continuous

physiological monitoring. By using a stethoscope taped on the chest wall over the trachea and heart, Dr. Smith could assess ongoing changes in heart and breath sounds. Furthermore, Dr. Smith, together with Ms. Betty Lank, his chief nurse anesthetist, developed a homemade latex infant blood pressure cuff (referred to as the *Smith cuff*) and advocated its routine use for patient safety when inhaled anesthetics consisted of diethyl-ether and cyclopropane. These advancements were early steps in the development of elaborate physiological monitoring systems that are essential for safe anesthesia care today.

In 1959, Dr. Smith published the first comprehensive textbook for pediatric anesthesia, entitled *Anesthesia for Infants and Children*. It was well received among practitioners and trainees in pediatric anesthesia and soon became a classic, often referred to as the "Bible of Pediatric Anesthesia." For the ensuing 20 years until his retirement from Harvard in 1980, Dr. Smith revised and expanded the book through the fourth edition, as he kept abreast with the rapid progress in the practice and science of pediatric anesthesia and other pediatric surgical specialties. Shortly thereafter, Dr. Smith asked the current editors to assume the editorship. To continue his vision, the book was modified and expanded to a multi-authored volume and was renamed *Smith's Anesthesia for Infants and Children* in Dr. Smith's honor. The fifth through the seventh editions were published between 1990 and 2006. With this eighth edition, *Smith's Anesthesia for Infants and Children* has been in publication for more than half a century, making it the longest ongoing textbook of pediatric anesthesiology in the world. It has been a great honor and privilege for us to carry on Dr. Smith's legacy.

Dr. Robert Moors Smith

CONTRIBUTORS

Ann G. Bailey, MD
Professor, Anesthesiology and Pediatrics
University of North Carolina
Chapel Hill, North Carolina

David Barinholtz, MD
President and CEO, Mobile Anesthesiologists, LLC
Chicago, Illinois

Victor C. Baum, MD
Professor, Anesthesiology and Pediatrics
Executive Vice-Chair, Department of Anesthesiology
Director, Cardiac Anesthesia

FOREWORD TO THE EIGHTH EDITION

Dr. Robert Moors Smith, a distinguished pioneer of modern pediatric anesthesia who was known as the “Father of Pediatric Anesthesia” in the United States, passed away on November 25, 2009, 2 weeks before he would have turned 97. In 1959, Dr. Smith wrote the first comprehensive textbook, *Anesthesia for Infants and Children*, specifically dedicated to the anesthetic management and care of children when pediatric anesthesia was in its infancy and the essentials of pediatric anesthesia practice were barely taking form.

During the following 2 decades as pediatric anesthesia expanded along with the rapid development and expansion of pediatric surgery, Dr. Smith published three additional revised and updated editions with few contributors. The book remained popular as the primary reference source of pediatric anesthesia practice and was often referred to as the “Bible” for practicing pediatric anesthesiologists.

After the fourth edition was published in 1980 and before his retirement from Children’s Hospital Boston and Harvard Medical School, Dr. Smith transferred the honor and responsibility of continuing the legacy of his textbook to me, a former fellow and associate in the 1960s and one of the few contributors to the later editions.

From the 1980s and onward, we witnessed continual, if not exponential, expansions in pediatric anesthesia and related fields, with the expansion of pediatric surgical subspecialties and techniques, including the development of neonatal and pediatric intensive care units and intensive care medicine; improvements in anesthesia-related equipment, monitors, and newer anesthetic and adjuvant drugs; establishment of clinical practice standards; expansions in postgraduate anesthesiology training programs; and the development of clinical and basic research activities directly or indirectly related to anesthesiology,

physiology, pharmacology, and cell and molecular biology. It became obvious that a single-author textbook in our subspecialty was no longer feasible or desirable.

I was extremely fortunate to have Dr. Peter J. Davis join me to face the new challenge. Our cordial and productive collaboration has lasted for more than 2 decades and still continues today. Peter and I changed the format of the book and expanded it to a multi-author textbook. We published the fifth edition in 1990 with the modified title *Smith’s Anesthesia for Infants and Children* to honor Dr. Smith’s legacy (against Dr. Smith’s initial protest). In subsequent editions in 1996 (sixth edition) and 2006 (seventh edition), we added new chapters authored by experts in specific fields to keep up with the development and expansion of science and practice of pediatric anesthesia, including critical care medicine, psychology, regional anesthesia, pain medicine, and bariatric surgery.

Anesthesia for Infants and Children has surpassed half a century of continual publication since the first edition in 1959, and I have been extremely fortunate to have been closely associated with Bob Smith professionally as well as personally since my fellowship days in Boston in the 1960s. (Bob was particularly pleased to note the half-century mark of his publication when I visited him for the last time in the early summer of 2009 in his lifelong hometown of Winchester, Massachusetts.) With the passing of a giant in the field, it is also the time to pass the torch to Peter Davis as the principal editor, with Dr. Franklyn Cladis as a new member, for the eighth edition, which is dedicated to the memory of Dr. Robert Moors Smith and his glorious life as a family man, compassionate pediatric physician, and a kind mentor to former trainees.

Etsuro K. Motoyama, MD, FAAP

PREFACE

Dr. Robert Moors Smith's legacy is as a pioneer and a great educator in pediatric anesthesia. Long before the terminology became fashionable—before it even existed—Dr. Smith advocated patient monitoring and safety. In the 1950s, when pediatric anesthesia was still in its infancy, he made the use of the precordial stethoscope and the pediatric blood pressure cuff (Smith cuff) a standard of care. In 1959, he wrote a major comprehensive anesthesia textbook, *Anesthesia for Infants and Children*, which was specifically dedicated to the anesthetic management and care of children.

The first four editions of this book were written almost entirely by Dr. Smith himself. The scope of Dr. Smith's scholarship was reflected in the breadth of his firsthand clinical experience, his keen sense of observation, and his ability to apply scientific and technical developments in medicine and anesthesia to the field of pediatric anesthesia. In 1988, Dr. Smith became the first pediatric anesthesiologist to receive the Distinguished Service Award from the American Society of Anesthesiologists.

In 1980, with Dr. Smith's retirement from the Harvard Medical School faculty and the anesthesia directorship of Children's Hospital Boston, the task of updating this classic textbook was bestowed upon Drs. Motoyama and Davis. The fifth edition, published in 1990, was multi-authored and was reorganized to include new subjects of importance in the ever-expanding field of anesthesiology and pediatric anesthesiology in particular. In the fifth edition, the editors tried to maintain Dr. Smith's compassion, philosophy, and emphasis on the personal approach to patients. To honor his pioneering work and leadership (and against Dr. Smith's initial strong resistance), the title of the fifth edition of the textbook was modified to read *Smith's Anesthesia for Infants and Children*.

In 1996, the sixth edition of the textbook was published. New developments with inhaled anesthetic agents (sevoflurane and desflurane), intravenous agents (propofol), neuromuscular-blocking agents, and anesthetic adjuncts, coupled with changes in the approach to pediatric pain management and airway management, were highlights.

In 2006, the seventh edition further expanded those areas of development. The roles of airway management, regional anesthesia, new local anesthetic agents, and innovative regional anesthetic techniques had been further developed. Newer intravenous anesthetic agents and adjuncts were also included in this edition while maintaining Dr. Smith's principles regarding patient safety and compassion.

The eighth edition has been prepared with the same considerations as the previous seven editions: to give anesthesia care providers comprehensive coverage of the physiology, pharmacology, and clinical anesthetic management of infants and children of all ages. This edition remains organized into four sections. Part I, Basic Principles, has been updated with major revisions to the chapters Respiratory Physiology in Infants and Children, Cardiovascular Physiology, Regulation of Fluids and Electrolytes, Thermoregulation: Physiology and Perioperative Disturbances, and Pharmacology of Pediatric Anesthesia. A chapter on Behavioral Development has been added to this section to help the clinician to better understand the normal behavioral responses of children. Part II, General Approach to Pediatric Anesthesia, has had a number of changes in the authorship of the chapters. New chapters on Pain Management, Blood Conservation, Airway Management, and Regional Anesthesia have been added. In addition, real-time use of ultrasound has been incorporated into the website to further enhance the techniques of regional anesthesia. All other chapters in this section have been updated by the same group of contributors as in the seventh edition. Part III, Clinical Management of Specialized Surgical Problems, contains new material. In response to the increasing number of neonatal and fetal surgeries, a new chapter on Neonatology for Anesthesiologists has been added. This is a chapter designed to explore the physiology, development, and care of high-risk neonates. This chapter complements the chapters Anesthesia for Fetal Surgery and Anesthesia for General Surgery in the Neonate. In addition to Neonatology for Anesthesiologists, a chapter on Anesthesia for Conjoined Twins has been added. The chapters on congenital heart disease have been reorganized and written by new contributors. Other chapters with new contributors include Anesthesia for Plastic Surgery, Anesthesia for Neurosurgery, Anesthesia for Fetal Surgery, and Anesthesia for Burn Injuries. The remaining chapters in this section have been updated by the same group of contributors. Part IV, Associated Problems in Pediatric Anesthesia, contains updated and revised chapters on Cardiopulmonary Resuscitation, Medicolegal and Ethical Aspects, Malignant Hyperthermia, and Systemic Disorders. A new chapter on Critical Care Medicine has been added. Of note, the chapter History of Pediatric Anesthesia has been updated by Dr. Mark A. Rockoff, who had direct consultation with Dr. Robert M. Smith before Dr. Smith's death. The appendixes,

which can be found online at www.expertconsult.com, include an updated list of drugs and their dosages, normal growth curves, normal values for pulmonary function tests in children, and an expanded list of common and uncommon syndromes of clinical importance for pediatric anesthesiologists.

In keeping with the advancement in technology, this edition is now in color and the text material is further supplemented by a website. Videos of airway techniques, single-lung isolation, regional anesthesia, the use of ultrasound, and anatomic dissections of congenital heart lesions are accessible with just a click of the mouse. In addition, supplemental materials on

organ transplantation, airway lesions, and pediatric syndromes are available.

In summary, considerable developments and progress in the practice of pediatric anesthesia over the past decade are reflected in this new edition. The emphasis on the safety and well-being of our young patients during the perianesthetic period remains unchanged.

ACKNOWLEDGMENTS

The project of revising a classic medical textbook presents many opportunities and challenges. The chance to review the many new developments that have emerged in pediatric anesthesia since the publication of the last edition of *Smith's Anesthesia for Infants and Children* in 2006 and to evaluate their effects on clinical practice has indeed been exciting. As always, we are deeply indebted to the extraordinary work done and commitment made by Dr. Robert M. Smith. Beginning shortly after World War II, Dr. Smith pioneered pediatric anesthesia in the United States. Between 1959 and 1980, he published the first four editions of his book, *Anesthesia for Infants and Children*. His work made this textbook a classic, establishing a quality and record of longevity. The first through fourth editions were written almost exclusively by Dr. Smith, except for the chapter on respiratory physiology by E.K. Motoyama. Since the late 1980s when Dr. Smith passed the book to Drs. Motoyama and Davis, the subsequent fifth, sixth, and seventh editions have utilized the talents and expertise of many renowned pediatric anesthesiologists throughout North America. The seventh edition had been expanded by the addition of new chapters, new contributors, and an enclosed DVD. The eighth edition brings change to the book in both content and presentation. New chapters and new contributors have further advanced our knowledge base. The presentation of the material has been enhanced by the use of color and by providing access to a website to further supplement the book's written text material. In addition, the editorial components of the book have been changed and expanded. Franklyn Cladis has joined the book's lineage of editors.

Our ability to maintain this book's standard of excellence is not just a reflection of the many gifted contributors but is also a result of the level of support that we have received at work and at home. We wish to thank the staff members of the Department of Anesthesiology at Children's Hospital of Pittsburgh of UPMC and the University of Pittsburgh Medical Center for their support and tolerance.

Our special thanks go to Shannon Barnes, editorial assistant, as well as Susan Danfelt and Patty Klein, administrative assistants, of the Department of Anesthesiology, Children's Hospital of Pittsburgh of UPMC, for their many hours of diligent work on the book. We are also appreciative of Dr. Basil Zitelli, Professor of Pediatrics, University of Pittsburgh at Children's Hospital of Pittsburgh of UPMC, for his generosity in allowing us to use many of the photographs published in his own book, *Atlas of Pediatric Physical Diagnosis*.

Our special thanks also go to Elsevier's Natasha Andjelkovic, acquisitions editor; Julie Mirra, developmental editor; and Cheryl Abbott, senior project manager, for their editorial assistance.

Finally, as with the previous two editions, we are deeply indebted to our family members Katie, Evan, Julie, and Zara Davis; Yoko, Eugene, and Ray Motoyama; and Joseph Losee and Hudson Cladis Losee for remaining loyal, for being understanding, and for providing moral support throughout the lengthy and, at times, seemingly endless project.

Regional Analgesia in Infants and Children	5	Summary	9

In the past few decades, new scientific knowledge of physiology and pharmacology in developing humans, as well as technologic advancements in equipment and monitoring, has markedly changed the practice of pediatric anesthesia. In addition, further emphasis on patient safety (e.g., correct side-site surgery, correct patient identification, correct procedure, appropriate prophylactic antibiotics) coupled with advances in minimally invasive pediatric surgery, have created a need for better pharmacologic approaches to infants and children, as well as improved skills in pediatric anesthetic management.

As a result of the advancements and emphasis on pediatric subspecialty training and practice, the American Board of Anesthesiology has now come to recognize the subspecialty of pediatric anesthesiology in its certification process.

PERIOPERATIVE MONITORING

In the 1940s and 1950s, the techniques of pediatric anesthesia, as well as the skills of those using and teaching them, evolved more as an art than as a science, as [†]Dr. Robert Smith vividly and eloquently recounts through his firsthand experiences in his chapter on the history of pediatric anesthesia (see Chapter 41, History of Pediatric Anesthesia, as updated by Mark Rockoff). The anesthetic agents and methods available were limited, as was the scientific knowledge of developmental differences in organ-system function and anesthetic effect in infants and children. Monitoring pediatric patients was limited to inspection of chest movement and occasional palpation of the pulse until the late 1940s, when Smith introduced the first physiologic monitoring to pediatric anesthesia by using the precordial stethoscope

for continuous auscultation of heartbeat and breath sounds (Smith, 1953; 1968). Until the mid-1960s, many anesthesiologists monitored only the heart rate in infants and small children during anesthesia and surgery. Electrocardiographic and blood-pressure measurements were either too difficult or too extravagant and were thought to provide little or no useful information. Measurements of central venous pressure were thought to be inaccurate and too invasive even in major surgical procedures. The insertion of an indwelling urinary (Foley) catheter in infants was considered invasive and was resisted by surgeons.

Smith also added an additional physiologic monitoring: soft, latex blood-pressure cuffs suitable for newborn and older infants, which encouraged the use of blood pressure monitoring in children (Smith, 1968). The “Smith cuff” (see Chapter 41, History of Pediatric Anesthesia, Fig. 41-4) remained the standard monitoring device in infants and children until the late 1970s, when it began to be replaced by automated blood pressure devices.

The introduction of pulse oximetry for routine clinical use in the early 1990s has been the single most important development in monitoring and patient safety, especially related to pediatric anesthesia, since the advent of the precordial stethoscope in the 1950s (see Chapters 10, Equipment; 11, Monitoring; and 40, Safety and Outcome) (Smith, 1956). Pulse oximetry is superior to clinical observation and other means of monitoring, such as capnography, for the detection of intraoperative hypoxemia (Coté et al., 1988, 1991). In addition, Spears and colleagues (1991) have indicated that experienced pediatric anesthesiologists may not have an “educated hand” or a “feel” adequate to detect changes in pulmonary compliance in infants. Pulse oximetry has revealed that postoperative hypoxemia occurs commonly among otherwise healthy infants and children undergoing simple surgical

[†]Deceased.

procedures, presumably as a result of significant reductions in functional residual capacity (FRC) and resultant airway closure and atelectasis (Motoyama and Glazener, 1986). Consequently, the use of supplemental oxygen in the postanesthesia care unit (PACU) has become a part of routine postanesthetic care (see Chapter 3, Respiratory Physiology).

Although pulse oximetry greatly improved patient monitoring, there were some limitations, namely motion artifact and inaccuracy in low-flow states, and in children with levels of low oxygen saturation (e.g., cyanotic congenital heart disease). Advances have been made in the new generation of pulse oximetry, most notably through the use of Masimo Signal Extraction Technology (SET). This device minimizes the effect of motion artifact, improves accuracy, and has been shown to have advantages over the existing system in low-flow states, mild hypothermia, and moving patients (Malviya et al., 2000; Hay et al., 2002; Irita et al., 2003).

Monitoring of cerebral function and blood flow, as well as infrared brain oximetry have advanced the anesthetic care and perioperative management of infants and children with congenital heart disease and traumatic brain injuries. Depth of anesthesia can be difficult to assess in children, and anesthetic overdose was a major cause of anesthesia-associated cardiac arrest and mortality. Depth-of-anesthesia monitors (bispectral index monitor [BIS], Patient State Index, Narcotrend) have been used in children and have been associated with the administration of less anesthetic agent and faster recovery from anesthesia. However, because these monitors use electroencephalography and a sophisticated algorithm to predict consciousness, the reliability of these monitors in children younger than 1 year old is limited.

In addition to advances in monitors for individual patients, hospital, patient, and outside-agency initiatives have focused on more global issues. Issues of patient safety, side-site markings, time outs, and proper patient identification together with the appropriate administration of prophylactic antibiotics have now become major priorities for health care systems. The World Health Organization (WHO) checklists have been positive initiatives that have ensured that the correct procedure is performed on the correct patient, as well as fostered better communication among health care workers. In anesthesia, patient safety continues to be a mantra for the specialty. Improved monitoring, better use of anesthetic agents, and the development of improved airway devices coupled with advancements in minimally invasive surgery, continue to advance the frontiers of pediatric anesthesia as a specialty medicine, as well as improve patient outcome and patient safety.

ANESTHETIC AGENTS

More than a decade after the release of isoflurane for clinical use, two volatile anesthetics, desflurane and sevoflurane, became available in the 1990s in most industrialized countries. Although these two agents are dissimilar in many ways, they share common physiochemical and pharmacologic characteristics: very low blood-gas partition coefficients (0.4 and 0.6, respectively), which are close to those of nitrous oxide and are only fractions of those of halothane and isoflurane; rapid induction of and emergence from surgical anesthesia; and hemodynamic stability (see Chapters 7, Pharmacology; 13, Induction Maintenance and Recovery; and 34, Same-Day Surgical Procedures). In animal

models, the use of inhaled anesthetic agents has been shown to attenuate the adverse effects of ischemia in the brain, heart, and kidneys.

Although these newer, less-soluble, inhaled agents allow for faster emergence from anesthesia, emergence excitation or delirium associated with their use has become a major concern to pediatric anesthesiologists (Davis et al., 1994; Sarner et al., 1995; Lerman et al., 1996; Welborn et al., 1996; Cravero et al., 2000; Kuratani and Oi, 2008). Adjuncts, such as opioids, analgesics, serotonin antagonists, and α_1 -adrenergic agonists, have been found to decrease the incidence of emergence agitation (Aono et al., 1999; Davis et al., 1999; Galinkin et al., 2000; Cohen et al., 2001; Ko et al., 2001; Kulka et al., 2001; Voepel-Lewis et al., 2003; Lankinen et al., 2006; Aouad et al., 2007; Tazeroualti et al., 2007; Erdil et al., 2009; Bryan et al., 2009; Kim et al., 2009).

Propofol has increasingly been used in pediatric anesthesia as an induction agent, for intravenous sedation, or as the primary agent of a total intravenous technique (Martin et al., 1992). Propofol has the advantage of aiding rapid emergence and causes less nausea and vomiting during the postoperative period, particularly in children with a high risk of vomiting. When administered as a single dose (1 mg/kg) at the end of surgery, propofol has also been shown to decrease the incidence of sevoflurane-associated emergence agitation (Aouad et al., 2007).

Remifentanyl, a μ -receptor agonist, is metabolized by non-specific plasma and tissue esterases. The organ-independent elimination of remifentanyl, coupled with its clearance rate (highest in neonates and infants compared with older children), makes its kinetic profile different from that of any other opioids (Davis et al., 1999; Ross et al., 2001). In addition, its ability to provide hemodynamic stability, coupled with its kinetic profile of rapid elimination and nonaccumulation, makes it an attractive anesthetic option for infants and children. Numerous clinical studies have described its use for pediatric anesthesia (Wee et al., 1999; Chiaretti et al., 2000; Davis et al., 2000, 2001; German et al., 2000; Dönmez et al., 2001; Galinkin et al., 2001; Keidan et al., 2001; Chambers et al., 2002; Friesen et al., 2003). When combined, intravenous hypnotic agents (remifentanyl and propofol) have been shown to be as effective and of similar duration as propofol and succinylcholine for tracheal intubation.

The development of more predictable, shorter-acting anesthetic agents (see Chapter 7, Pharmacology) has increased the opportunities for pediatric anesthesiologists to provide safe and stable anesthesia with less dependence on the use of neuromuscular blocking agents.

AIRWAY DEVICES AND ADJUNCTS

Significant changes in pediatric airway management that have patient-safety implications have emerged over the past few years. The laryngeal mask airway (LMA), in addition to other supraglottic airway devices (e.g., the King LT-D, the Cobra pharyngeal airway), has become an integral part of pediatric airway management. Although the LMA is not a substitute for the endotracheal tube, LMAs can be safely used for routine anesthesia in both spontaneously ventilated patients and patients requiring pressure-controlled support. The LMA can also be used in the patient with a difficult airway to aid in ventilation and to act as a conduit to endotracheal intubation both with and without a fiber optic bronchoscope.

In addition to supraglottic devices, advances in technology for visualizing the airway have also improved patient safety. Since the larynx could be visualized, at least 50 devices intended for laryngoscopy have been invented. The newer airway-visualization devices have combined better visualizations, video capabilities, and high resolution.

The development and refinement of airway visualization equipment such as the Glidescope, Shikani Seeing Stylet, and the Bullard laryngoscope have added more options to the management of the pediatric airway and literally give the laryngoscopist the ability to see around corners (see Chapters 10, Equipment; and 12, Airway Management).

The variety of pediatric endotracheal tubes (ETTs) has focused on improved materials and designs. ETTs are sized according to the internal diameter; however, the outer diameter (the parameter most likely involved with airway complications) varies according to the manufacturer (Table 1-1). Tube tips are both flat and beveled, and a Murphy eye may or may not be present. The position of the cuff varies with the manufacturer. The use of cuffed endotracheal tubes in pediatrics continues to be controversial. In a multicenter, randomized prospective study of 2246 children from birth to 5 years of age undergoing general anesthesia, Weiss and colleagues (2009) noted that cuffed ETTs compared with uncuffed ETTs did not increase the risk of postextubation stridor (4.4% vs. 4.7%) but did reduce the need for ETT exchanges (2.1% vs. 30.8%). However, the role of cuffed ETTs in neonates and infants who require prolonged ventilation has yet to be determined.

INTRAOPERATIVE AND POSTOPERATIVE ANALGESIA IN NEONATES

It has long been thought that newborn infants do not feel pain the way older children and adults do and therefore do not require anesthetic or analgesic agents (Lippman et al., 1976). Thus, in the past, neonates undergoing surgery were often not afforded the benefits of anesthesia. Later studies, however, indicated that pain experienced by neonates can affect behavioral

development (Dixon et al., 1984; Taddio et al., 1995, 2005). Rats exposed to chronic pain without the benefit of anesthesia or analgesia showed varying degrees of neuroapoptosis (Anand et al., 2007). However, to add further controversy to the issue of adequate anesthesia for infants, concerns regarding the neurotoxic effects of both intravenous and inhalational anesthetic agents (GABAergic and NMDA antagonists) have been raised. Postoperative cognitive dysfunction (POCD) has been noted in adult surgical patients (Johnson et al., 2002; Monk et al., 2008). In adults, POCD may also be a marker for 1-year survival after surgery. Although POCD is an adult phenomenon, animal studies by multiple investigators have raised concerns about anesthetic agents being toxic to the developing brains of infants and small children (Jevtic-Todorovic et al., 2003, 2008; Mellon et al., 2007; Wang and Slikker, 2008). Early work by Uemura and others (1985) noted that synaptic density was decreased in rats exposed to halothane in utero. Further work with rodents, by multiple investigators, has shown evidence of apoptosis in multiple areas of the central nervous system during the rapid synaptogenesis period. This window of vulnerability appears to be a function of time, dose, and duration of anesthetic exposure. In addition to the histochemical changes of apoptosis, the exposed animals also demonstrated learning and behavioral deficits later in life.

In addition to apoptotic changes that occurred in rodents, Slikker and colleagues have demonstrated neuroapoptotic changes in nonhuman primates (rhesus monkeys) exposed to ketamine (an NMDA antagonist). As with the rodents, ketamine exposure in monkeys resulted in long-lasting deficits in brain function (Dr. Merle Poule, personal communication on the Safety of Key Inhaled and Intravenous Drugs in Pediatric Anesthesia [SAFEKIDS] Scientific Workshop, November 2009, White Oaks Campus Symposium). How these animal studies relate to human findings is unclear to date. However, three clinical studies have been reported, and all three studies are retrospective. Wilder et al. (2009) studied a cohort group of children from Rochester, Minnesota, and noted that children exposed to two or more anesthetics in the first 4 years of life were more likely to have learning

Modified from Weiss et al.: Shortcomings of cuffed paediatric tracheal tubes. *Brit J Anaesth* 92:78–88, 2004.

disabilities, compared with children exposed to one anesthetic or none at all. Kalkman and others (2009) studied a group of children undergoing urologic surgery before age 6 years and reported that there was a tendency for parents to report more behavioral disturbances than those operated on at a later age. However, in a twin cohort study from the Netherlands, Bartels and coworkers (2009) reported no causal relationship between anesthesia and learning deficits in 1,143 monozygotic twin pairs.

In an effort to determine the impact of anesthetic agents or neurocognitive development, a collaborative partnership between the U.S. Food and Drug Administration (FDA) and the International Anesthesia Research Society has formed Safety of Key Inhaled and Intravenous Drugs in Pediatric Anesthesia (SAFEKIDS), a program designed to fund and promote research in this area.

REGIONAL ANALGESIA IN INFANTS AND CHILDREN

Although conduction analgesia has been used in infants and children since the beginning of the twentieth century, the controversy about whether anesthetic agents can be neurotoxic has caused a resurgence of interest in regional anesthesia (Abajian et al., 1984; Williams et al., 2006).

As newer local anesthetic agents with less systemic toxicity become available, their role in the anesthetic/analgesic management of children is increasing. Studies of levobupivacaine and ropivacaine have demonstrated safety and efficacy in children that is greater than that of bupivacaine, the standard regional anesthetic used in the 1990s (Ivani et al., 1998, 2002, 2003; Hansen et al., 2000, 2001; Lönnqvist et al., 2000; McCann et al., 2001; Karmakar et al., 2002). A single dose of local anesthetics through the caudal and epidural spaces is most often used for a variety of surgical procedures as part of general anesthesia and for postoperative analgesia. Insertion of an epidural catheter for continuous or repeated bolus injections of local anesthetics (often with opioids and other adjunct drugs) for postoperative analgesia has become a common practice in pediatric anesthesia. The addition of adjunct drugs, such as midazolam, neostigmine, tramadol, ketamine, and clonidine, to prolong the neuroaxial blockade from local anesthetic agents has become more popular, even though the safety of these agents on the neuroaxis has not been determined (see Chapters 15, Pain Management; and 16, Regional Anesthesia) (Ansermino et al., 2003; de Beer and Thomas, 2003).

In addition to neuroaxial blockade, specific nerve blocks that are performed with or without ultrasound guidance have become an integral part of pediatric anesthesia (see Chapter 16, Regional Anesthesia). The use of ultrasound has allowed for the administration of smaller volumes of local anesthetic and for more accurate placement of the local anesthetic (Ganesh et al., 2009; Gurnaney et al., 2007; Willschke et al., 2006). The use of catheters in peripheral nerve blocks has also changed the perioperative management for a number of pediatric surgical patients. Continuous peripheral nerve catheters with infusions are being used by pediatric patients at home after they have been discharged from the hospital (Ganesh et al., 2007). The use of these at-home catheters has allowed for shorter hospital stays. In addition, the use of regional techniques with ultrasound guidance, coupled with the natural interest in pain management,

has allowed for pediatric anesthesiologists to spearhead pediatric acute and chronic pain management programs.

In addition to advances in anesthetic pharmacology and equipment, advances in the area of pediatric minimal invasive surgery have improved patient morbidity, shortened the length of hospital stays, and improved surgical outcomes (Fujimoto et al., 1999).

Although minimally invasive surgery (MIS) imposes physiologic challenges in the neonate and small infant, numerous neonatal surgical procedures can nevertheless be successfully approached with such methods, even in infants with single ventricle physiology (Georgeson, 2003; Ponsky and Rothenberg, 2008). The success of MIS has allowed for the evolution of robotic techniques, stealth surgery (scarless surgery), and Natural Orifice Transluminal Endoscopic Surgery (NOTES) (Dutta and Albanese, 2008; Dutta et al., 2008; Isaza et al., 2008).

FUNDAMENTAL DIFFERENCES IN INFANTS AND CHILDREN

Regardless of all the advances in equipment, monitoring, and patient safety initiatives, pediatric anesthesia still requires a special understanding of anatomic, psychological, and physiologic development. The reason for undertaking a special study of pediatric anesthesia is that children, especially infants younger than a few months, differ markedly from adolescents and adults. Many of the important differences, however are not the most obvious. Although the most apparent difference is size, it is the physiologic differences related to general metabolism and immature function of the various organ systems (including the heart, lungs, kidneys, liver, blood, muscles, and central nervous system) that are of major importance to the anesthesiologist.

Psychological Differences

For a child's normal psychological development, continuous support of a nurturing family is indispensable at all stages of development; serious social and emotional deprivation (including separation from the parents during hospitalization), especially during the first 2 years of development, may cause temporary or even lasting damage to psychosocial development (Forman et al., 1987). A young child who is hospitalized for surgery is forced to cope with separation from parents, to adapt to a new environment and strange people, and to experience the pain and discomfort associated with anesthesia and surgery (see Chapters 2, Behavioral Development; and 8, Psychological Aspects).

The most intense fear of an infant or a young child is created by separation from the parents, and it is often conceived as loss of love or abandonment. The sequence of reactions observed is often as follows: angry protest with panicky anxiety, depression and despair, and eventually apathy and detachment (Bowlby, 1973). Older children may be more concerned with painful procedures and the loss of self-control that is implicit with general anesthesia (Forman et al., 1987). Repeated hospitalizations for anesthesia and surgery may be associated with psychosocial disturbances in later childhood (Dombro, 1970). In children who are old enough to experience fear and apprehension during anesthesia and surgery, the emotional factor may be of greater

concern than the physical condition; in fact, it may represent the greatest problem of the perioperative course (see Chapter 8, Psychological Aspects) (Smith, 1980).

All of these responses can and should be reduced or abolished through preventive measures to ease the child's adaptation to the hospitalization, anesthesia, and surgery. The anesthesiologist's role in this process, as well as having a basic understanding of neurobehavioral development, are important (Table 1-2).

TABLE 1-2. Aspects of Developmental Assessment and Common Developmental Milestones

Follows dangling object from midline through a range of 90°	1 mo
Follows dangling object from midline through a range of 180°	3 mo
Consistent conjugate gaze (binocular vision)	4 mo
Alerts or quiets to sound	0-2 mo
Head up 45°	2 mo
Head up 90°	3-4 mo
Weight on forearms	3-5 mo
Weight on hands with arms extended	5-6 mo
Complete head lag, back uniformly rounded	Newborn
Slight head lag	3 mo
Rolls front to back	4-5 mo
Rolls back to front	5-6 mo
Sits with no support	7 mo
Hands predominantly closed	1 mo
Hands predominantly open	3 mo
Foot play	5 mo
Transfers objects from hand to hand	6 mo
Index finger approach to small objects and finger-thumb opposition	10 mo
Plays pat-a-cake	9-10 mo
Pulls to stand	9 mo
Walks with one hand held	12 mo
Runs well	2 y
Social smile	1-2 mo
Smiles at image in mirror	5 mo
Separation anxiety/stranger awareness	6-12 mo
Interactive games: peek-a-boo and pat-a-cake	9-12 mo
Waves "bye-bye"	10 mo
Cooing	2-4 mo
Babbles with labial consonants ("ba, ma, ga")	5-8 mo
Imitates sounds made by others	9-12 mo
First words (≈4-6, including "mama," "dada")	9-12 mo
Understands one-step command (with gesture)	15 mo

Differences in Response to Pharmacologic Agents

The extent of the differences among infants, children, and adults in response to the administration of drugs is not just a size conversion. During the first several months after birth, rapid development and growth of organ systems take place, altering the factors involved in uptake, distribution, metabolism, and elimination of anesthetics and related drugs. Interindividual variability of a response to a given drug may be determined by a variety of genetic factors. Genetic influences in biotransformation, metabolism, transport, and receptor site all affect an individual's response to a drug. These changes appear to be responsible for developmental differences in drug response and can be further modified by age-related and environmental-related factors. The pharmacology of anesthetics and adjuvant drugs and their different effects in neonates, infants, and children are discussed in detail in Chapter 7, Pharmacology.

Anatomic and Physiologic Differences

Body Size

As stated, the most striking difference between children and adults is size, but the degree of difference and the variation even within the pediatric age group are hard to appreciate. The contrast between an infant weighing 1 kg and an overgrown and obese adolescent weighing more than 100 kg who appear in succession in the same operating room is overwhelming. It makes considerable difference whether body weight, height, or body surface area is used as the basis for size comparison. As pointed out by Harris (1957), a normal newborn infant who weighs 3 kg is one third the size of an adult in length but $\frac{1}{9}$ th the adult size in body surface area and $\frac{1}{21}$ of adult size in weight (Fig. 1-1). Of these body measurements, body surface area (BSA) is probably the most important, because it closely parallels variations in basal metabolic rate measured in kilocalories per hour per square meter. For this reason, BSA is believed to be a better criterion than age or weight in judging basal fluid and nutritional requirements. For clinical use, however, BSA proves somewhat difficult to determine, although a nomogram such as that of Talbot and associates (1952) facilitates the procedure considerably (Fig. 1-2). For the anesthesiologist who carries a pocket calculator, the following formulas may be useful to calculate BSA:

Formula of DuBois and DuBois (1916)

$$BSA(m^2) = 0.007184 \times \text{Height}^{0.725} \times \text{Weight}^{0.425}$$

Formula of Gehan and George (1970)

$$BSA(m^2) = 0.0235 \times \text{Height}^{0.42246} \times \text{Weight}^{0.51456}$$

At full-term birth, BSA averages 0.2 m², whereas in the adult it averages 1.75 m². A table of average height, weight, and BSA is given for reference in Table 1-3. A simpler, crude estimate of BSA for children of average height and weight is given in Table 1-4. The formula:

$$BSA(m^2) = (002 \times \text{kg}) + 0.40$$

is also reasonably accurate in children of normal physique weighing 21 to 40 kg (Vaughan and Litt, 1987).

■ **FIGURE 1-1.** Proportions of newborn to adult with respect to weight, surface area, and length. (From Crawford JD, Terry ME, Rourke GM: Simplification of drug dosage calculation by application of the surface area principle, *Pediatrics* 5:785, 1950.)

The caloric need in relation to BSA of a full-term infant is about 30 kcal/m² per hour. It increases to about 50 kcal/m² per hour by 2 years of age and then decreases gradually to the adult level of 35 to 40 kcal/m² per hour.

Relative Size or Proportion

Less obvious than the difference in overall size is the difference in relative size of body structure in infants and children. This is particularly true with the head, which is large at birth (35 cm in circumference)—in fact, larger than chest circumference. Head circumference increases by 10 cm during the first year and an additional 2 to 3 cm during the second year, when it reaches three-fourths of the adult size (Box 1-1).

At full-term birth, the infant has a short neck and a chin that often meets the chest at the level of the second rib; these infants are prone to upper airway obstruction during sleep. In infants with tracheostomy, the orifice is often buried under the chin unless the head is extended with a roll under the neck. The chest is relatively small in relation to the abdomen, which is protuberant with weak abdominal muscles (Fig. 1-3). Furthermore, the rib cage is cartilaginous and the thorax is too compliant to resist inward recoil of the lungs. In the awake state, the chest wall is maintained relatively rigid with sustained inspiratory muscle tension, which maintains the end-expiratory lung volume functional residual capacity (FRC). Under general anesthesia, however, the muscle tension is abolished and FRC collapses, resulting in airway closure, atelectasis, and venous admixture unless continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP) is maintained.

■ **FIGURE 1-2.** Body surface area nomogram for infants and young children. (From Talbot NB, Sobel FH, McArthur JW, et al.: Functional endocrinology from birth through adolescence, Cambridge, 1952, Harvard University Press.)

TABLE 1-3. Relation of Age, Height, and Weight to Body Surface Area (BSA)*

Age (y)	Height (cm)	Weight (kg)	BSA (m ²)
Premature	40	1	0.1
Newborn	50	3	0.2
1	75	10	0.47
2	87	12	0.57
3	96	14	0.63
5	109	18	0.74
10	138	32	1.10
13	157	46	1.42
16 (Female)	163	50	1.59
16 (Male)	173	62	1.74

* Based on standard growth chart and the formula of DuBois and DuBois (1916): BSA (m²) = 0.007184 × Height^{0.725} × Weight^{0.425}.

TABLE 1-4. Approximation of Body Surface Area (BSA) Based on Weight

Weight (kg)	Approximate BSA (m ²)
1-5	$0.05 \times \text{kg} + 0.05$
6-10	$0.04 \times \text{kg} + 0.10$
11-20	$0.03 \times \text{kg} + 0.20$
21-40	$0.02 \times \text{kg} + 0.40$

Modified from Vaughan VC III, Litt IF: Assessment of growth and development. In Behrman RE, Vaughn VC III, editors: *Nelson's textbook of pediatrics*, ed 13, Philadelphia, 1987, WB Saunders.

Box 1-1 Typical Patterns of Physical Growth

WEIGHT

Birth weight (BW) is regained by the tenth to fourteenth day.

Average weight gain per day: 0-6 mo = 20 g; 6-12 mo = 15 g.

BW doubles at ≈4 mo, triples at ≈12 mo, quadruples at ≈24 mo.

During second year, average weight gain per month: ≈0.25 kg.

After age 2 years, average annual gain until adolescence: ≈2.3 kg.

LENGTH/HEIGHT

By end of first year, birth length increases by 50%.

Birth length doubles by age 4 years, triples by 13 years.

Average height gain during second year: ≈12 cm.

After age 2 years, average annual growth until adolescence: ≈5 cm.

HEAD CIRCUMFERENCE

Average head growth per week: 0-2 mo = ≈0.5 cm; 2-6 mo = ≈0.25 cm.

Average total head growth: 0-3 mo = ≈5 cm; 3-6 mo = ≈4 cm; 6-9 mo = ≈2 cm; 9-12 mo = ≈1 cm.

FIGURE 1-3. A normal infant has a large head, narrow shoulders and chest, and a large abdomen.

Central and Autonomic Nervous Systems

The brain of the neonate is relatively large, weighing about 1/10 of body weight compared with about 1/50 of body weight in the adult. The brain grows rapidly; its weight doubles by 6 months of age and triples by 1 year. By the third week of gestation, the neural plate appears, and by 5 weeks the three main subdivisions of the forebrain, midbrain, and hindbrain are evident. By the eighth week of gestation, neurons migrate to form the cortical layers, and migration is complete by the sixth month. Cell differentiation continues as neurons, astrocytes, oligodendrocytes, and glial cells form. Axons and synaptic connections continually form and remodel. At birth, about one fourth of the neuronal cells are present. The development of cells in the cortex and brain stem is nearly complete by 1 year of age. Myelination and elaboration of dendritic processes continue well into the third year. Incomplete myelination is associated with primitive reflexes, such as the Moro and grasp reflexes in the neonate; these are valuable in the assessment of neural development.

At birth the spinal cord extends to the third lumbar vertebra. By the time the infant is 1 year old, the cord has assumed its permanent position, ending at the first lumbar vertebra (Gray, 1973).

In contrast to the central nervous system, the autonomic nervous system is relatively well developed in the newborn. The parasympathetic components of the cardiovascular system are fully functional at birth. The sympathetic components, however, are not fully developed until 4 to 6 months of age (Friedman, 1973). Baroreflexes to maintain blood pressure and heart rate, which involve medullary vasomotor centers (pressor and depressor areas), are functional at birth in awake newborn infants (Moss et al., 1968; Gootman, 1983). In anesthetized newborn animals, however, both pressor and depressor reflexes are diminished (Wear et al., 1982; Gallagher et al., 1987).

The laryngeal reflex is activated by the stimulation of receptors on the face, nose, and upper airways of the newborn. Reflex apnea, bradycardia, or laryngospasm may occur. Various mechanical and chemical stimuli, including water, foreign bodies, and noxious gases, can trigger this response. This protective response is so potent that it can cause death in the newborn (see Chapters 3, Respiratory Physiology; and 4, Cardiovascular Physiology).

Respiratory System

At full-term birth, the lungs are still in the stage of active development. The formation of adult-type alveoli begins at 36 weeks post conception but represents only a fraction of the terminal air sacs with thick septa at full-term birth. It takes more than several years for functional and morphologic development to be completed, with a 10-fold increase in the number of terminal air sacs to 400 to 500 million by 18 months of age, along with the development of rich capillary networks surrounding the alveoli. Similarly, control of breathing during the first several weeks of extrauterine life differs notably from control in older children and adults. Of particular importance is the fact that hypoxemia depresses, rather than stimulates, respiration. Anatomic differences in the airway occur with growth and development. Recently, the concept of the child having a funnel-shaped airway with the cricoid as the narrowest portion of the airway has been challenged. Based on bronchoscopic images, Dalal and colleagues (2009) suggest for infants and children the glottis,

not the cricoid, may be the narrowest portion. The development of the respiratory system and its physiology are detailed in Chapter 3, Respiratory Physiology.

Cardiovascular System

During the first minutes after birth, the newborn infant must change his or her circulatory pattern dramatically from fetal to adult types of circulation to survive in the extrauterine environment. Even for several months after initial adaptation, the pulmonary vascular bed remains exceptionally reactive to hypoxia and acidosis. The heart remains extremely sensitive to volatile anesthetics during early infancy, whereas the central nervous system is relatively insensitive to these anesthetics. Cardiovascular physiology in infants and children is discussed in Chapter 4.

Fluid and Electrolyte Metabolism

Like the lungs, the kidneys are not fully mature at birth, although the formation of nephrons is complete by 36 weeks' gestation. Maturation continues for about 6 months after full-term birth. The glomerular filtration rate (GFR) is lower in the neonate because of the high renal vascular resistance associated with the relatively small surface area for filtration. Despite a low GFR and limited tubular function, the full-term newborn can conserve sodium. Premature infants, however, experience prolonged glomerulotubular imbalance, resulting in sodium wastage and hyponatremia (Spitzer, 1982). On the other hand, both full-term and premature infants are limited in their ability to handle excessive sodium loads. Even after water deprivation, concentrating ability is limited at birth, especially in premature infants. After several days, neonates can produce diluted urine; however, diluting capacity does not mature fully until after 3 to 5 weeks of life (Spitzer, 1978). The premature infant is prone to hyponatremia when sodium supplementation is inadequate or with overhydration. Furthermore, dehydration is detrimental to the neonate regardless of gestational age. The physiology of fluid and electrolyte balance is detailed in Chapter 5, Regulation of Fluids and Electrolytes.

Temperature Regulation

Temperature regulation is of particular interest and importance in pediatric anesthesia. There is a better understanding of the physiology of temperature regulation and the effect of anesthesia on the control mechanisms. General anesthesia is associated with mild to moderate hypothermia, resulting from environmental exposure, anesthesia-induced central thermoregulatory inhibition, redistribution of body heat, and up to 30% reduction in metabolic heat production (Bissonette, 1991). Small infants have disproportionately large BSAs, and heat loss is exaggerated during anesthesia, particularly during the

induction of anesthesia, unless the heat loss is actively prevented. General anesthesia decreases but does not completely abolish thermoregulatory threshold temperature to hypothermia. Mild hypothermia can sometimes be beneficial intraoperatively, and profound hypothermia is effectively used during open heart surgery in infants to reduce oxygen consumption. Postoperative hypothermia, however, is detrimental because of marked increases in oxygen consumption, oxygen debt (dysoxia), and resultant metabolic acidosis. Regulation of body temperature is discussed in detail in Chapter 6, Thermoregulation.

SUMMARY

Pediatric anesthesia as a subspecialty has evolved, because the needs of infants and young children are fundamentally different from those of adults. The pediatric anesthesiologist should be aware of the child's cardiovascular, respiratory, renal, neuromuscular, and central nervous system responses to various drugs, as well as to physical and chemical stimuli, such as changes in blood oxygen and carbon dioxide tensions, pH, and body temperature. Their responses are different both qualitatively and quantitatively from those of adults and among different pediatric age groups. More importantly, the pediatric anesthesiologist should always consider the child's emotional needs and create an environment that minimizes or abolishes fear and distress.

There have been many advances in the practice of anesthesia to improve the comfort of young patients since the seventh edition of this book was published in 2006. These advances include a relaxation of preoperative fluid restriction, more focused attention to the child's psychological needs with more extensive use of preoperative sedation via the transmucosal route, the wide use of topical analgesia with a eutectic mixture of local anesthetic cream before intravenous catheterization, expanded use of regional anesthesia with improved accuracy and safety by means of ultrasound devices, and more generalized acceptance of parental presence during anesthetic induction and in the recovery room. Furthermore, a more diverse anesthetic approach has evolved through the combined use of regional analgesia, together with the advent of newer and less soluble volatile anesthetics, intravenous anesthetics, and shorter-acting synthetic opioids and muscle relaxants. Finally, the scope of pediatric anesthesia has significantly expanded with the recent development of organized pain services in most pediatric institutions. As a result, pediatric anesthesiologists have assumed the leading role as pain management specialists, thus further extending anesthesia services and influence beyond the boundary of the operating room.

Assessment of growth and development of infants and children typically falls under the domain of the pediatrician or pediatric subspecialist. Delays or deviations from normal often dictate the need to conduct extensive diagnostic evaluations and management strategies. Familiarity with developmental stages may also benefit the pediatric anesthesiologist, allowing the practitioner to recognize the different coping mechanisms children use to respond to the anxiety and stresses throughout the perioperative period. Growth issues, especially failure to thrive, may indicate a serious underlying medical condition that could affect the management and anesthetic plan for children.

A variety of processes are encompassed in growth and development: the formation of tissue; an increase in physical size; the progressive increases in strength and ability to control large and small muscles (gross motor and fine motor development); and the advancement of complexities of thought, problem solving, learning, and verbal skills (cognitive and language development). There is a systematic approach for tracking neurologic development and physical growth in infants, because attainment of milestones is orderly and predictable. However, a wide range exists for normal achievement. The mastering of a particular skill often builds on the achievement of an earlier skill. Delays in one developmental domain may impair development in another (Gessel and Amatruda, 1951). For example, immobility caused by a neuromuscular disorder prevents an infant from exploration of the environment, thus impeding cognitive development. A deficit in one domain might interfere with the ability to assess progress in another area. For example, a child with cerebral palsy who is capable of conceptualizing matching geometric shapes but does not have the gross or fine motor skills necessary to perform the function could erroneously be labeled as developmentally delayed.

It is possible for the anesthesiologist to obtain a gestalt of a child's growth and development level while recording a preop-

erative history and during the physical examination. However, the anesthesiologist needs to realize that these assessments are usually done by pediatricians over time and are best performed when the child is physically well, familiar with the examiner, and under minimal stress. Therefore, a child who is developing normally could be assessed as delayed during a preoperative assessment.

The goal of this chapter is to review the developmental and behavioral issues faced in routine pediatric practice to help the anesthesiologist tailor an anesthetic plan that is geared to the appropriate age of the child with the goal of decreasing postoperative complications such as behavioral disturbances, emotional reactions, or escalation in medical care. The chapter is divided into sections addressing growth and developmental milestones, including gross motor skills, fine motor skills, cognition, and language, followed by a section of clinical scenarios illustrating the relevance of developmental issues in pediatric anesthesia. The last section contains several common developmental disorders and related anesthetic issues.

PRENATAL GROWTH

The most dramatic events in growth and development occur before birth. These changes are overwhelmingly somatic, with the transformation of a single cell into an infant. The first eight weeks of gestation are known as the embryonic period and encompasses the time when the rudiments of all of the major organs are developed. This period denotes a time that the fetus is highly sensitive to teratogens such as alcohol, tobacco, mercury, thalidomide, and antiepileptic drugs. The average embryo weighs 9 g and has a crown-to-rump length of 5 cm. The fetal stage (more than 9 weeks' gestation) consists of increases in cell number and size and structural remodeling of organ systems (Moore, 1972).

During the third trimester, weight triples and length doubles as body stores of protein, calcium, and fat increase. Low birth weight can result from prematurity, intrauterine growth retardation (small for gestational age, SGA) or both. Large-for-gestational-age (LGA) infants are those whose weight is above the 90th percentile at any gestational age. Deviations from the normal relationship of infant weight gain with increasing gestational age can be multifactorial. Potential causes include maternal diseases (e.g., diabetes, pregnancy-induced hypertension, and seizure disorders), prenatal exposure to toxins (e.g., alcohol, drugs, and tobacco), fetal toxoplasmosis-rubella-cytomegalovirus-herpes simplex-syphilis (TORCHES) infections, genetic abnormalities (e.g., trisomies 13, 18, and 21), fetal congenital malformations (e.g., cardiopulmonary or renal malformations), and maternal malnutrition or placental insufficiency (Kinney and Kumar, 1988).

POSTNATAL GROWTH

Postnatal growth is measured by changes in weight, length, and head circumference plotted chronologically on growth charts. This is an essential component of pediatric health surveillance, because almost any problem involving physiologic, interpersonal, or social domains can adversely affect growth.

Growth milestones are the most predictable, taking into context each child's specific genetic and ethnic influences (Johnson and Blasco, 1997). It is essential to plot the child's growth on gender- and age-appropriate percentile charts. Charts are now available for certain ethnic groups and genetic syndromes such as Trisomy 21 and Turner's syndrome. Deviation from growth over time across percentiles is of greater significance for a child than a single weight measurement. For example, an infant at the fifth percentile of weight for age may be growing normally, may be failing to grow, or may be recovering from growth failure, depending on the trajectory of the growth curve.

Of the three parameters, weight is the most sensitive measurement of well-being and is the first to show deviance as an indication of an underlying problem. Causes of weight loss and failure to thrive include congestive heart failure, metabolic or endocrine disorders, malignancy, infections, and malabsorption problems. Inadequate increases in height over time occur secondary to significant weight loss, and decreased head circumference is the last parameter to change, signifying severe malnutrition. Pathologies such as hydrocephalus or increased intracranial pressure may appear on growth charts as head-circumference measurements that are rapidly increasing and crossing percentiles. Small head size can be associated with craniosynostosis or a syndromic feature. Significant changes in head-circumference measurements in children should alert the anesthesiologist to the potential of underlying neurologic problems.

Because significant weight fluctuation is a potential red flag for serious underlying medical conditions, anesthesiologists should be familiar with the normal weight gain expected for children. It is not unusual for a newborn's weight to decrease by 10% in the first week of life because of the excretion of excess extravascular fluid or possibly poor oral intake. Infants should regain or exceed birth weight by 2 weeks of age and continue to gain approximately 30 g/day, with a gradual decrease to 12 g/day

by the first year. Healthy, full-term infants typically double their birth weight at 6 months and triple it by 1 year of age. Many complex formulas are available to estimate the average weight for normal infants and children. A relatively simple calculation to recall is the "rule of tens"; e.g., the weight of a child increases by about 10 pounds per year until approximately 12 to 13 years of age for females and age 16 to 17 years for males. Therefore, one could expect weight gain of 20 pounds by age 2 years, 30 pounds by 3 years, 40 pounds by 4 years, and so on. The weight in pounds can be converted to kilograms by dividing it by 2.2. Length in centimeters is estimated by the following formula: (age in years \times 6) + 77.

DEVELOPMENTAL ASSESSMENT

Developmental assessment serves different purposes, depending on the age of the child. In the neonatal period, behavioral assessment can detect a wide range of neurologic impairments. During infancy, assessment serves to reassure parents and to identify sensory, motor, cognitive, and emotional problems early, when they are most amenable to treatment. Middle-childhood and adolescence assessments often help with addressing academic and social problems.

Milestones are useful indicators of mental and physical development and possible deviations from normal. It should be emphasized that milestones represent the average for children to attain and that there can be variable rates of mastery that fall into the normal range. An acceptable developmental screening test must be highly sensitive (detect nearly all children with problems); specific (not identify too many children without problems); have content validity, test-retest, and interrater reliability; and be relatively quick and inexpensive to administer. The most widely used developmental screening test is the Denver Developmental Screening Test (DDST), which provides a pass/fail rating in four domains of developmental milestones: gross motor, fine motor, language, and personal-social. The original DDST was criticized for underidentification of children with developmental disabilities, particularly in the area of language. The reissued DDST-II is a better assessment for language delays, which is important because of the strong link between language and overall cognitive development. [Table 2-1](#) lists the prevalence of some common developmental disabilities (Levy and Hyman, 1993).

TABLE 2-1. Prevalence of Developmental Disabilities

Condition	Prevalence per 1000
Cerebral palsy	2-3
Visual impairment	0.3-0.6
Hearing impairment	0.8-2
Mental retardation	25
Learning disability	75
Attention deficit hyperactivity disorder	150
Behavioral disorders	60-130
Autism	9-10

MOTOR DEVELOPMENT

Primitive Reflexes

The earliest motor neuromaturational markers are primitive reflexes that develop during uterine life and generally disappear between the third and sixth months after birth. Newborn movements are largely uncontrolled, with the exception of eye gaze, head turning, and sucking. Development of the infant's central nervous system involves strengthening of the higher cortical center that gradually takes over function of the primitive reflexes. Postural reflexes replace primitive reflexes between three and six months of age as a result of this development (Schott and Rossor, 2003). These reactions allow children to maintain a stable posture even if they are rapidly moved or jolted (Box 2-1).

The asymmetric tonic neck reflex (ATNR) or “fencing posture” is an example of a primitive reflex that is not immediately present at birth because of the high flexor tone of the newborn infant. When the neonate's head is turned to one side, there is increased extensor tone of the upper extremity on the same side and increased flexor tone on the occipital side. The ATNR is a precursor to hand-eye coordination, preparing the infant for gazing along the upper arm and voluntary reaching. The

Box 2-1 Definitions of Primitive Reflexes

Automatic stepping reflex: Although the infant cannot support his or her weight when a flat surface is presented to the sole of the foot, he or she makes a stepping motion by bringing one foot in front of the other.

Crossed extension reflex: When an extremity is acutely stimulated to withdraw, the flexor muscles in the withdrawing limb contract completely, whereas the extensor muscles relax. The opposite occurs (full extension, with relaxation of contracting muscles) in the opposite limb.

Galant reflex: An infant has the one side of the back stroked moves or swings in that direction.

Moro reflex: When the infant is startled with a loud noise or when the head is lowered suddenly, the head and legs extend and the arms raise up and out. Then the arms are brought in and the fingers close to make fists.

Palmar reflex: When an object is placed into the infant's hand or when the palm of the infant's hand is stroked with an object, the hand closes around the object.

Asymmetric tonic neck reflex (“fencing”): When the infant's head is rotated to one side, the arm on that side straightens and the opposite arm flexes.

Landau reflex: When the infant is held in a horizontal position, he or she raises the head and brings the legs up into a horizontal position. If the head is forced down (flexed) the legs also lower into a vertical position.

Derotational righting reflex: When the infant turns the head one direction, the body leans in the same direction to maintain balance.

Protective equilibrium reflex: When a lateral force is applied to the infant, he or she responds by leaning into the force and extending the contralateral arm.

Parachute reflex: When the infant is facing down and lowered suddenly, the arms extend out in a protective maneuver.

disappearances of this reflex at 4 to 6 months allows the infant mobility to roll over and begin to examine and manipulate objects in the midline with both hands.

The palmar grasp reflex is present at birth and persists until 4 to 6 months of age. When an object is placed in the infant's hand, the fingers close and tightly grasp the object. The grip is strong but unpredictable. The waning of the early grasp reflex allows infants to hold objects in both hands and ultimately to voluntarily let them go.

The Moro reflex is probably the most well-known primitive reflex and is present at birth. It is likely to occur as a startle to a loud noise or sudden changes in head position. The legs and head extend while the arms jerk up and out, followed by adduction of the arms and tightly clenched fists. Bilateral absence of the reflex may mean damage to the infant's central nervous system. Unilateral absence could indicate birth trauma such as a fractured clavicle or brachial plexus injury.

Postural reflexes support control of balance, posture, and movement in a gravity-based environment. The protective equilibrium response can be elicited in a sitting infant by abruptly pushing the infant laterally. The infant will extend the arm on the contralateral side and flex the trunk toward the side of the force to regain the center of gravity (Fig. 2-1). The parachute response develops around 9 months and is a response to a free-fall motion, where the infant extends the extremities in an outward motion to distribute weight over a broader area. Postural reactions are markedly slow in appearance in the infant who has central nervous system damage. Children who fail to gain postural control continue to display traces of primitive reflexes. They also have difficulty with control of movement affecting coordination, fine and gross motor development, and other associated aspects of learning, including reading and writing. Table 2-2 is a list of the average times of appearance and disappearance of the more common primitive reflexes.

■ **FIGURE 2-1.** The protective equilibrium response is demonstrated in an infant being pushed laterally. Note the extended contralateral arm.

TABLE 2-2. Primitive Reflexes

Reflex	Present by (Months)	Gone by (Months)
Automatic stepping	Birth	2
Crossed extension	Birth	2
Galant	Birth	2
Moro	Birth	3-6
Palmar	Birth	4-6
Asymmetric tonic neck ("fencing")	1	4-6
Landau	3	12-24
Derotational head righting	4	Persists
Protective equilibrium	4-6	Persists
Parachute	8-9	Persists

Gross Motor Skills

One principle in neuromaturational development during infancy is that it proceeds from cephalad to caudad and proximal to distal. Thus, arm movement comes before leg movement (Feldman, 2007). The upper extremity attains increasing accuracy in reaching, grasping, transferring, and manipulating objects. Gross motor development in the prone position begins with the infant tightly flexing the upper and lower extremities and evolves to hip extension while lifting the head and shoulders from a table surface around 4 to 6 months of age. When pulled to a sitting position, the newborn has significant head lag, whereas the 6-month-old baby, because of development of muscle tone in the neck, raises the head in anticipation of being pulled up.

Rolling movements start from front to back at approximately 4 months of age as the muscles of the lower extremities strengthen. An infant begins to roll from back to front at about 5 months. The abilities to sit unsupported (about 6 months old) and to pivot while sitting (around 9 to 10 month of age) provide increasing opportunities to manipulate several objects at a time (Needleman, 1996). Once thoracolumbar control is achieved and the sitting position mastered, the child focuses motor development on ambulation and more complex skills. Locomotion begins with commando-style crawling, advances to creeping on hands and knees, and eventually reaches pulling to stand around 9 months of age, with further advancement to cruising around furniture or toys. Standing alone and walking independently occur around the first birthday. Advanced motor achievements correlate with increasing myelination and cerebellum growth. Walking several steps alone has one of the widest ranges for mastery of all of the gross motor milestones and occurs between 9 and 17 months of age. Milestones of gross motor development are presented in [Table 2-3](#) and [Figure 2-2](#). The accomplishment of locomotion not only expands the infant's exploratory range and offers new opportunities for cognitive and motor growth, but it also increases the potential for physical dangers (Vaughan, 1992).

Most children walk with a mature gait, run steadily, and balance on one foot for 1 second by 3½ years of age. The sequence for additional gross motor development is as follows: running, jumping on two feet, balancing on one foot, hopping, and skipping. Finally, more complex activities such as throwing, catching, and kicking balls, riding bicycles, and climbing on playground equipment are mastered. Development beyond walking incorporates improved balance and coordination and progressive narrowing of additional physical support. Complex motor skills also incorporate advanced cognitive and emotional development that is necessary for interactive play with other children. [Figure 2-3](#) shows the red flags to watch for in the abnormal physical development of the infant.

TABLE 2-3. Cognitive and Language Communication Skills Development

Average Age of Attainment (Months)	Cognitive	Language Communication
2	Stares briefly at area when object is removed	Smiles in response to face or voice
4	Stares at own hand	Monosyllabic babble
8	Object permanence—uncovers toy after seeing it covered	Inhibits to "no" Follows one-step command <i>with</i> gesture (wave to "come here")
10	Separation anxiety from familiar people	Follows one-step command without gesture ("give it to me")
12	Egocentric play (pretends to drink from cup)	Speaks first real word
18	Cause and effect relationships no longer need to be demonstrated to understand (pushes car to move, winds toy on own) Distraction techniques may no longer succeed	Speaks 20 to 50 words
24	Mental activity is independent of sensory processing or motor manipulation (sees a child in a book with a mask on face and can later reenact event)	Speaks in two-word sentences
36	Capable of symbolic thinking	Speaks in three-word sentences
48	Immature logic is replaced Conventional logic and wisdom	Speaks in four-word sentences Follows three-step commands

1 Month
 Prone, lies tightly flexed with pelvis high. Head lags after shoulders when pulled to sit

12 Months
 Walks alone

3 Months
 Prone, rests on forearms. Partial head lag when pulled to sit

18 Months
 Runs

5 Months
 Rolls back to front

24 Months
 Jumps in place, throws overhand, walks down stairs holding rail

6 Months
 Sit without support. Lifts head before shoulders when pulled to sit

36 Months
 Balance on one foot for one second

7 Months
 Commando crawl

48 Months
 Hops on one foot

8 Months
 Four point kneeling, reaches with one hand. Acquires sitting position without support

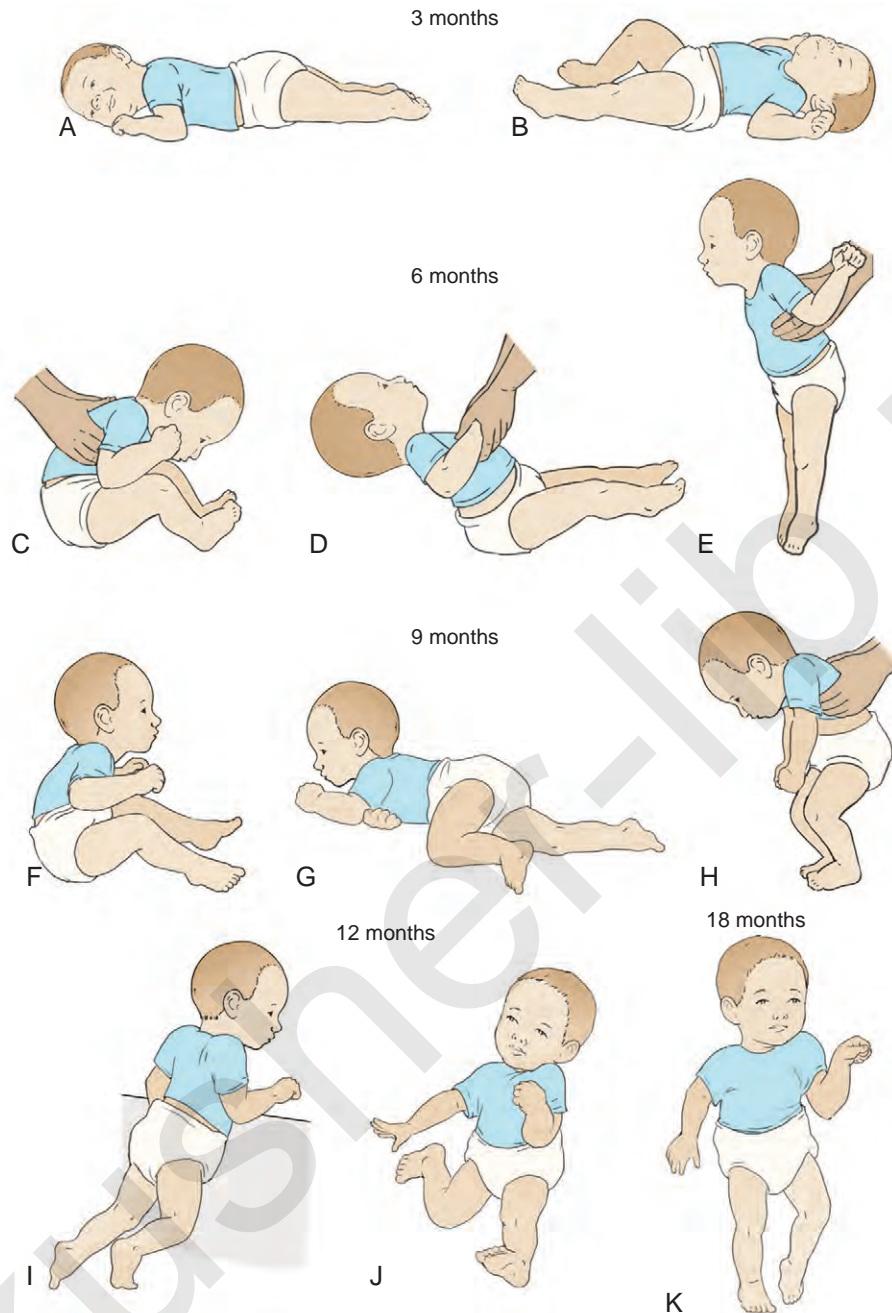

60 Months
 Catches a ball

10 Months
 Cruises around furniture

■ **FIGURE 2-2.** Gross motor skills development chart.

■ **FIGURE 2-3.** Abnormal developmental findings. **A**, Difficulty lifting head and stiff legs with little or no movement. **B**, Pushing back with head, keeping hands fisted, and lacking arm movement. **C**, Rounded back, inability to lift head up, and poor head control. **D**, Difficulty bringing arms forward to reach out, arching back, and stiffening legs. **E**, Arms held back and stiff legs. **F**, Using one hand predominantly; rounded back and poor use of arms when sitting. **G**, Difficulty crawling and using only one side of the body to move. **H**, Inability to straighten back and cannot bear weight on legs. **I**, Difficulty getting to standing position because of stiff legs and pointed toes; only using arms to pull up to standing. **J**, Sitting with weight to one side and strongly flexed or stiffly extended arms; using hand to maintain seated position. **K**, Inability to take steps independently, poor standing balance, many falls, and walking on toes. (Redrawn from *What Every Parent Should Know* [pamphlet], 2006, Pathways Awareness Foundation.)

Fine Motor Development

At birth, the neonate's fingers and thumbs are typically tightly fisted. Normal development moves from the primitive grasp reflex, where the infant reflexively grabs an object but is unable

to release it to a voluntary grasp and release of the object. By 2 to 3 months of age the hands are no longer tightly fisted, and the infant begins to bring them toward the mouth, sucking on the digits for self comfort. Objects can be held in either hand by age 3 months and transferred back and forth by 6 months.

1 Month
Hands tightly fist

2 Months
Grasps rattle

3 Months
Hands unfisted most of the time

4 Months
Reaches for and retains rattle, uses both hands

6 Months
Transfers objects hand to hand, immature hand rake of pellet

10 Months
Pincer grasp between thumb and index finger

12 Months
Pincer grasp between finger tips

18 Months
Tower of four cubes, scribbles spontaneously

24 Months
Tower of six cubes, turns pages of books one at a time, imitate vertical stroke

36 Months
Copies circle, cuts with small scissors

48 Months
Copies cross, draws a person with three parts

60 Months
Copies triangle

■ FIGURE 2-4. Fine motor skills development chart.

In early development, the upper extremities assist with balance and mobility. As the sitting position is mastered with improved balance, the hands become more available for manipulation and exploration. The evolution of the pincer grasp is the highlight of fine motor development during the first year. The infant advances from “raking” small objects into the palm to the finer pincer grasp, allowing opposition of the thumb and the index finger, whereby small items are picked up with precision. Children younger than 18 months of age generally use both hands equally well, and true “handedness” is not established until 36 months (Levine et al., 1999). Advancements in fine motor skills continue throughout the preschool years, when the child develops better eye-hand coordination with which to stack objects or reproduce drawings (e.g., crosses, circles, and triangles). [Figure 2-4](#) lists and demonstrates the chronologic order of fine motor development.

LANGUAGE DEVELOPMENT

Delays in language development are more common than delays in any other developmental domain (Glascoe, 2000). Language includes receptive and expressive skills. Receptive skills are the ability to understand the language, and expressive skills include the ability to make thoughts, ideas, and desires known to others. Because receptive language precedes expressive language, infants respond to several simple statements such as “no,” “bye-bye,” and “give me” before they are capable of speaking intelligible words. In addition to speech, expression of language can take the forms of gestures, signing, typing, and “body language.” Thus, speech and language are not synonymous. The hearing-impaired child or child with cerebral palsy may have normal receptive language skills and intellect to understand dialogue but needs other forms of expressive language to vocalize responses. Conversely, children may talk but fail to communicate; for example, a child with autism may vocalize by using “parrot talk” or echolalia that has no meaningful content and does not represent language.

Language development can be divided into the three stages of pre-speech, naming, and word combination. Pre-speech is characterized by cooing or babbling until around 8 to 10 months of age, when babbling becomes more complex with multiple syllables. Eventually random vocalization (“da-da”) is interpreted and reinforced by the parents as a real word, and the child begins to repeat it. The naming period (ages 10 to 18 months) is when the infant realizes that people have names and objects have labels. Once the infant’s vocalizations are reinforced as people or things, the infant begins to use them appropriately. At around 12 months of age some infants understand as many as 100 words and can respond to simple commands that are accompanied by gestures. Early into the second year a command without a gesture is understood. Expressive language is slower, and an 18-month-old child has a limited vocabulary of around 25 words. After the realization that words can stand for things, the child’s vocabulary expands at a rapid pace. Preschool language development begins with word combination at 18 to 24 months and is the foundation for later success in school. Vocabulary increases from 50 to 100 words to more than 2000 words during this time. Sentence structure advances from two- and three-word phrases to sentences incorporating all of the major grammatic rules. A simple correlate is that a child should increase the number of words in a sentence with advancing age; e.g., two-word sentences by 2 years of age, three-word sentences by age 3 years ([Table 2-3](#)).

Language is a critical barometer of both cognitive and emotional development (Coplan, 1995). Mental retardation may first surface as a concern with delayed speech and language development around 2 years of age; however, the average age of diagnosis is 3 to 4 years. All children whose language development is delayed should undergo audiologic testing. If a child’s expressive skills are advanced compared with his or her receptive skills (e.g., child speaks five-word sentences but does not understand simple commands), a pervasive development disorder could be the cause.

COGNITIVE DEVELOPMENT

The concept of a developmental line implies that a child passes through successive stages. The psychoanalytic theories of Sigmund Freud and Erik Erikson and the cognitive theory of Jean Piaget describe stages in the development of cognition and emotion that are as qualitatively different as the milestones attained in gross motor development.

At the core of Freudian theory is the idea of biologically determined drives. The core drive is sexual, broadly defined to include sensations that include excitation or tension and satisfaction or release (Freud, 1952). There are discrete stages: oral, anal, oedipal, latent, and genital. During these stages the focus of the sexual drive shifts with maturation and is at first influenced primarily by the parents and subsequently by an enlarging circle of social contacts. Defense mechanisms in early childhood can develop pathologically to disguise the presence of conflict. The emotional health of the child and adult depends on the resolution of the conflicts that arise throughout these stages.

Erikson’s chief contribution was to recast Freud’s stages in terms of the emerging personality (Erikson, 1963). For example, basic trust, the first of Erickson’s psychosocial stages, develops as infants learn that their urgent needs are met regularly. The consistent availability of a trusted adult creates the conditions for secure attachment. The next stage establishes the child’s internal sense of either autonomy vs. shame and doubt and corresponds to Freud’s anal stage. A sense of either identity or role confusion corresponds to the crisis experienced in Freud’s genital stage (puberty) ([Table 2-4](#)).

Piaget’s name is synonymous with the study of cognitive development. A central tenet of his theory is that cognition is qualitatively different at different stages of development (Hobson, 1985). During the sensorimotor stage, children learn basic things about their relationship with their environment. Thoughts about the nature of objects and their relationships are acted out and tied immediately to sensations and manipulation. With the arrival of language the nature of thinking changes dramatically, and symbols increasingly take the place of things and actions. Stages of preoperational thinking, concrete operations, and formal operations correspond to the different ages of preschool, school age, and adolescence, respectively. At all stages, children are not passive recipients of knowledge but actively seek out experience (assimilation) and use them to build on how things work.

Cognitive development and neuromaturational development are closely related, and it is sometimes difficult to distinguish between the two in the infant and child. Early in the neonatal period, cognitive development begins when the infant responds to visual and auditory stimuli by interacting with surroundings

TABLE 2-4. Classic Stage Theories of the Development of Emotion and Cognition

Theory	0-1 Years (Infancy)	2-3 Years (Toddler)	3-6 Years (Preschool)	6-12 Years (School Age)	12-20 Years (Adolescents)
Freud: psychosexual	Oral	Anal	Oedipal phallic	Latency	Puberty and genital
Erikson: psychosocial	Basic trust	Autonomy vs. shame and doubt	Initiative vs. guilt	Industry vs. inferiority	Identity vs. role confusion
Piaget: cognitive	Sensorimotor (stages I-IV)	Sensorimotor (stages V and VI) Egocentric thought	Preoperational	Concrete operational	Formal operational

to gain information. Activities such as mouthing, shaking, and banging objects provide information to the infant beyond the visual features. Infant exploration begins with the body, with activities such as staring intently at a hand and touching other body parts. These explorations represent an early discovery of “cause and effect,” as the infant learns that voluntary movements generate predictable tactile and visual sensations (e.g., kicking the side of the bed moves a mobile). Signs of abnormal cognitive development are outlined in Box 2-2.

A communication system develops between the infant and mother or primary caregiver. Accordingly, the infant begins to display anxiety at the end of this developmental period if the person most familiar to the child is not available. The ability to maintain an image of a person develops before that of an object, and therefore the infant may display separation anxiety when a loved one leaves the room. Object permanence, a major milestone, develops around 9 months when the infant understands that objects continue to exist even if they are covered up and not seen. With locomotion the child explores greater areas and develops a substantial sense of social self, as well as an early appreciation of the behavior standards expected by adults. Interactive and pretend play begins at 30 months, and playing in pairs occurs around 24 to 36 months.

Childhood cognitive development and the effect it has on the child’s perception of the hospitalization and surgery are important for the pediatric anesthesiologist to understand in order to help the child deal with the stresses during this time. One out of four children will be hospitalized by age 5 years. Although extreme emotional reactions are rare, at least 60% of children demonstrate signs of stress-related anxiety during the perioperative period. Children between the ages of 1 and 3 years, previously hospitalized children, and children who have undergone turbulent anesthetic inductions are at increased risk for exhibiting adverse postoperative behavioral reactions.

Box 2-2 Abnormal Cognitive Signs

- 1 month:** Failure to be alert to environmental stimuli. May indicate sensory impairment
- 5 months:** Failure to reach for objects. May indicate motor, visual, and/or cognitive deficit
- 6 months:** Absent babbling. May indicate hearing deficit
- 7 months:** Absent stranger anxiety. May be due to multiple care providers (eg, neonatal intensive care unit)
- 11 months:** Inability to localize sound. May indicate unilateral hearing loss

(Modified from Seid M et al.: Perioperative psychosocial interventions for autistic children undergoing ENT surgery, *Int J Ped Otorhinolaryngology*, 40:107, 1997.)

Stress and anxiety can be manifested by behavioral problems such as nightmares, phobias, agitation, avoidance of caregivers, emotional distress, and regressive behaviors (e.g., temper tantrums, bedwetting, and loss of previously acquired developmental milestones). Allowing adequate preoperative evaluation and psychological preparation for both the parent and child based on specific needs relative to the child’s developmental stage is a method the anesthesiologist can invoke to reduce the emotional trauma of anesthesia.

Erikson (1963) describes the infants’ motivations as dependent on the satisfaction of basic human needs (e.g., food, shelter, and love). According to Freud, the child directs all of his or her energies to the mother and fears her loss because her absence may jeopardize the child’s satisfaction creating tension and anxiety. This dependence is the essence of separation anxiety. Before this stage infants are able to accept surrogates and respond favorably to anyone holding them. Once stranger anxiety develops, active participation of the parents during the hospitalization should be encouraged to maintain a sense of security for the child and promote bonding (Thompson and Standford, 1981).

Toddlers have developed ambulation skills that allow exploration, but they are well bonded to their parents and much less willing to be separated, especially when they are stressed. They are too young to understand detailed explanations so procedures should be told in simple, nonthreatening language. Comprehension of conversation is more advanced than verbal expression. The receptive and expressive language discordance often results in frustration on the child’s behalf, putting toddlers at increased risk for stormy inductions and postoperative emotional and behavioral reactions. Toddlers also fear pain and bodily harm. Whenever possible, a parent or trusted caregiver should be present for potentially painful or threatening procedures. Children at this age are comforted by a familiar toy or treasured object and respond to magical thinking or stories.

The preschooler’s view of the world is egocentric or self-centered. The child is unable to understand or conceptualize another individual’s point of view, does not comprehend why people do not understand him or her, and has no appreciation for others’ feelings. These children have concerns with bodily integrity and demonstrate the need for reassurances. Anxiety can be allayed by giving the child a sense of mastery and participation, such as allowing him or her to “hold” the mask for induction. Their preoperational thinking is very literal, and it is important to use caution when using similes or metaphors, e.g., if a provider states that the child will be given a “stick” (intravenous line or shot), the child may wait to be handed a tree branch. At this stage, any explanation appears to be more important than the actual content of the explanation. Children given explanations, whether accurate or not, were found to have

fewer postoperative behavioral changes than those who were not given explanations (Bothe and Gladston, 1972). Although the preschooler's vocabulary is improving, cognitively the child may have difficulty remembering a sequence of events or establishing causality, leading to misconceptions about procedures.

School-age children, during the "concrete operations" stage, are more independent. Their activities become goal-oriented, and their language skills develop rapidly. They have a sense of conscience and can appreciate feelings of others. Children are able to draw on previous experience and knowledge to formulate predictions about related issues. They have an increased need for explanation and participation. Rather than giving children choices in the operating room (e.g., intravenous injection vs. mask for going to sleep), details about the procedure and options available for the child should be discussed preoperatively in a nonthreatening environment (McGraw, 1994).

Adolescents are caught in a difficult period between childhood and adulthood. Physically, they are maturing and may feel self-conscious about their bodies. Psychologically, they are striving to know who they are. Adolescents have developed the ability to recognize and exhibit mature defense mechanisms (e.g., the adolescent whose appendicitis "at least gets me out of my math test"). They are more likely to cooperate with a physician perceived to be attentive and nonjudgmental. Concerns regarding coping, pain, losing control, waking up prematurely, not waking up, and dying are very real for teenagers. Clear explanations and assurances should be provided regarding these issues. The need for independence and privacy is important and should be respected.

CLINICAL RELEVANCE OF GROWTH AND DEVELOPMENT IN PEDIATRIC ANESTHESIA

An overview of basic growth and development can be obtained in a preoperative consultation by reviewing the history and observing for gross and fine motor milestones during the physical examination. A 1-month-old infant displaying well-developed extensor tone when suspended in a ventral position might be interpreted by the parent as having advanced motor development when, in reality, issues of an upper motor neuron lesion should be considered. Other signs of spasticity are early rolling, pulling to a direct stand at 4 months of age, and walking on the toes. Persistent closing of fists beyond 3 months of age could be the earliest indication of neuromotor dysfunction. An afebrile 2-month-old baby with tachypnea, rales, audible murmur, and failure to gain weight should raise concerns about a significant cardiac lesion and the need for a cardiac consultation. A 7-month-old infant with poor head control who is unable to sit without support or to lift his or her chest off the table in the prone position may indicate hypotonia and a possible neuromuscular disorder. Spontaneous postures, such as "frog legging" when prone or scissoring may provide visual physical clues of hypotonia or spasticity, respectively. At 9 months of age, the child should stand erect on a parent's lap or cruise around office furniture, and the 12-month-old child will want to get down and walk. Weakness in the 3- or 4-year-old child may be best discovered by observing the quality of stationary posture and transition movements. Gower's sign (arising from sitting on the floor to standing using the hands to "walk up" the legs) is a classic example of pelvic girdle and quadriceps muscular weakness. Fine motor evaluation can be easily evaluated

by handing the infant a tongue depressor or toy. The newborn infant should grasp it reflexively; by 4 months of age, the infant should reach and retain the object, and by the age of 6 months, the child can transfer an object from hand to hand. The development of fine pincer grasp by 12 months of age allows the child to pick up small objects with precision, and increases the risk for foreign body aspiration. The observation of a child who constantly uses one hand while neglecting the other should prompt the clinician to examine the contralateral upper extremity for weakness associated with hemiparesis.

Abnormal head size, significant weight gain or loss, and short-stature issues may be indicative of genetic issues. The presence of three or more dysmorphic features should raise concerns of a syndromic feature with possible difficult airway issues. Almost 75% of superficial dysmorphic features can be found by examining the head, hands, and skin.

Down's Syndrome

Down's syndrome is the most common genetic abnormality worldwide, with an estimated prevalence of 1 out of 800 children (Sherman et al., 2007). Although this syndrome was described centuries earlier, Dr. John Langdon Down first reported its clinical description in 1866 (Megarbane et al., 2009). Down's syndrome is the most recognizable and best known chromosomal disorder. The extra copy in chromosome 21 affects several organs and results in a wide spectrum of phenotypical changes (Hartway, 2009). Down's syndrome is usually identified soon after birth by a characteristic pattern of dysmorphic features (Fig. 2-5) (Ranweiler, 2009). The diagnosis is confirmed by karyotype analysis with trisomy 21 present in 95% of persons with this syndrome (Gardiner and Davisson, 2000).

Perioperative responsibility is shared between the anesthesiologist and the surgeon. The anesthesiologist is responsible for preoperative risk evaluation, perioperative management, and subsequent patient optimization (Hartley et al., 1998). The preoperative evaluation provides the best opportunity to stratify the potential risks, because children with Down's syndrome often have multiple congenital anomalies, each of which has anesthetic implications (Fig. 2-5) (Santamaria et al., 2007). Important considerations in the operative management of these patients include assessment of their behavioral development, atlantoaxial instability, airway narrowing, and respiratory and cardiac malformations; these are critical issues that require special attention when considering anesthesia (Bhattarai et al., 2008). Wherever possible, preoperative therapeutic interventions must be initiated to reduce the risks associated with these concurrent diseases (Borland et al., 2004). For the anesthesiologist, a system-based approach to the patient with Down's syndrome may be most useful. For a complete discussion of the anesthetic concerns related to Down's Syndrome, see Chapter 36, Systemic Disorders.

Behavioral Considerations

Down's syndrome is the most common cause of mental retardation, which is characterized by developmental delays, language and memory deficits, and other cognitive abnormalities (Roizen and Patterson, 2003). The child's cognitive state and psychological status often allow the anesthesia provider to ascertain the appropriate technique based on the child's needs.

■ **FIGURE 2-5.** The congenital anomalies of Down's syndrome. (Modified from Ranweiler R: *Assessment and care of the newborn with Down syndrome*, *Adv Neonatal Care* 9:17, 2009; and Santamaria LB, Di Paola C, Mafrica F, et al: *Preanesthetic evaluation and assessment of children with Down's syndrome*, *The Scientific World Journal* 7:242, 2007.)

Older children and young adults with Down's syndrome have a higher prevalence of early Alzheimer's disease, further impairing cognitive function (Nieuwenhuis-Mark, 2009). Interestingly, children up to 6 years of age show age-related gains in adaptive function, but older children show no correlation between age and adaptive function (Dykens et al., 2006). In addition, the incidence of seizure disorders in those with Down's syndrome is 5% to 10% (Stafstrom et al., 1991).

Attention Deficit Hyperactivity Disorder

Attention deficit hyperactivity disorder (ADHD) is a disorder of inattention, hyperactivity, and impulsivity that affects 8% to 12% of children worldwide, with boys overrepresented by a ratio of about 3:1 (Biederman and Faraone, 2005). During child and adolescent development, ADHD is associated with greater risks for low academic achievement, poor school performance, retention in grade level, school suspensions and expulsions, poor peer and family relations, anxiety and depression, aggression, conduct problems, and delinquency (Barkley, 1997). The means of inheritance acquisition is probably multifactorial, but family, twin, and adoption studies have documented a strong genetic basis for ADHD (Thapar et al., 1999). The cellular theory suggests the frontosubcortical cerebellar regions of the brain have inadequate dopamine and noradrenaline to effectively provide inhibitory regulation (Biederman and Faraone, 2005).

Both the American Academy of Pediatrics (AAP) and the American Academy of Child and Adolescent Psychiatry (AACAP) recommend psychoactive medications for children, adolescents, and adults with ADHD. These medications are classified as stimulants or nonstimulants. Perioperative consequences of these medications include resistance to premedication, cardiovascular instability, altered anesthesia requirements (monitored anesthesia care), lower seizure thresholds, and increased postoperative nausea and vomiting (Forsyth et al., 2006).

As an example of medication interaction, one patient required large doses of midazolam while receiving methylphenidate (Ririe et al., 1997). ADHD drugs are associated with increased

blood pressure as a result of increased catecholamine levels, but the chronic use of stimulants can deplete these stores or down-regulate catecholamine receptors. Prolonged hypotension has been reported in older patients with ADHD, and cardiac arrest (requiring cardiopulmonary resuscitation) during anesthetic induction was reported in a teenager (Bohringer et al., 2000; Perruchoud and Chollett-Rivier, 2008).

Medications such as bupropion are associated with seizures in a dose-related manner. The seizure threshold can be lowered by concomitant administration of drugs such as antipsychotics, antidepressants, systemic steroids, tramadol, and sedating antihistamines. In addition, bupropion inhibits the enzyme responsible for converting tramadol to morphine, thereby reducing the analgesic effect of tramadol (Corner et al., 2002).

These cases highlight the potential difficulties of the drug-drug interactions while a patient is undergoing general anesthesia. Based on these observations, the anesthesiologist should request more details about the medications a patient is taking for ADHD, particularly if they are stimulants or nonstimulants, and the length of time the patient has been taking the medications. As in cardiac arrest, the implications and ramifications of anesthesia can be quite significant (Tables 2-5 and 2-6) (Perruchoud and Chollett-Rivier, 2008).

Autism

Autism affects 5 to 7 in 10,000 births, is found in all racial, ethnic, and social backgrounds, and is four times more common in males than females (Rudolph and Rudolph, 2003). Current data suggest that the actual rate is 40 out of 10,000 births and that one out of every 150 children in the United States is affected (Rutter, 2005). Autism is now recognized a psychiatric childhood disorder, and is listed in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) under the section of Pervasive Developmental Disorders (PDD). The diagnostic criteria for autistic disorders include qualitative impairments in social interactions, impairment in verbal and nonverbal communications, restricted range of interests, and resistance to

TABLE 2-5. The Mechanisms of Action of Commonly Used ADHD Medications

Commonly Used Drug	Mechanism of Action
Methylphenidate (Ritalin)	Blocks the reuptake of norepinephrine and dopamine Stimulates the cerebral cortex similarly to amphetamines
Dexamphetamine (Dexedrin)	Promotes the release of catecholamines through sympathomimetic amines, primarily dopamine and norepinephrine Competitively inhibits catecholamine reuptake by the presynaptic nerve terminal
Bupropion (Wellbutrin)	Inhibits the neuronal uptake of norepinephrine and dopamine
Atomoxetine, 25 mg (Strattera)	Selectively inhibits norepinephrine reuptake by the presynaptic nerve terminal

From Forsyth I et al.: Attention deficit hyperactivity disorder and anesthesia, *Paediatric anaesthesia*, 16:371, 2006.

change (APA, 2000). These children exhibit hyperactivity and patterns of behavior, activity, and interests that are restrictive, repetitive, and stereotyped.

The etiology is unknown in the vast majority of the cases. However, there is a small minority of patients with notable coexisting medical diseases, including macrocephaly (15% to 35%), seizure disorders (30%), fragile X syndrome (2% to 8%), and tuberous sclerosis (1% to 3%) (Box 2-2) (Bailey and Rutter, 1991; Williams et al., 2008).

TABLE 2-6. Possible Drug–Drug Interactions with ADHD

Potential Side Effects	Medications
Sympathomimetic drugs that may produce exaggerated cardiovascular effects	Ephedrine, tramadol, SSRIs, MAOIs, tricyclics, herbal remedies, and dietary supplements (e.g., ephedra, St. John's wort)
Stimulants with potential to increase anesthetic requirements	Methylphenidate, dexamphetamine
Stimulants with potential to exacerbate seizure activity	Tramadol, dextropropoxyphene, SSRIs, tricyclics

From Forsyth I et al.: Attention deficit hyperactivity disorder and anesthesia, *Paediatric anaesthesia*, 16:371, 2006.
SSRI, Selective serotonin reuptake inhibitor; MAOI, monoamine oxidase inhibitor.

Children with autism can present perioperative challenges to a pediatric anesthesia team (van der Walt and Moran, 2001). They are less able to understand the need for the procedures involved in surgery and have difficulty adjusting to the new routine of the hospital visit. Their perioperative anxiety level can be very high, and it may be difficult for them to interact with strangers, even caring and attentive perioperative staff. They are more sensitive to the visual and auditory stimuli of the hospital, particularly in the operating room, and even simple tactile stimuli such as the face mask may overwhelm their senses. Overall, these children are at high risk for severe distress and anxiety; consequently, morbidity and cost may be increased, and patient and parental satisfaction may be decreased.

Premedication varies depending on the requirements of each child, as well as the preferences of the individual anesthesiologist, who might generally use oral, intramuscular, or intravenous medications. Most institutions employ oral midazolam 0.5 mg/kg; however, the side effects are unpredictable and may not allow optimal anesthetic induction (Rainey and van der Walt, 1998). Ketamine is also an effective preoperative sedative, available in intravenous, intramuscular, and oral dosing. Oral ketamine has a 17% bioavailability, compared with 93% when given intramuscularly or intravenously (Clements et al., 1982). An effective transmucosal dosing combines ketamine 3 mg/kg mixed with midazolam 0.5 mg/kg (Funk et al., 2000).

If possible, the patient should undergo conditioning to become familiar with the hospital and the upcoming procedure (Nelson and Amplo, 2009). Diminished waiting time in the preoperative area can lessen fear and stress. Short, clear commands, with empathic positive and negative reinforcements, can help guide the patient through this difficult ordeal. Anesthesia management can be optimized by judicious use of premedication and parental presence during induction. The actual administration of an adequate dose of premedication can be the biggest challenge for the anesthesiologist working with an uncooperative or frightened child with delayed cognitive abilities. A balanced approach can help minimize the use of force, which is sometimes necessary, but nonetheless upsetting to the patient, the family, and the perioperative team. A discussion regarding the potential use of restraints during the perioperative period is imperative to clearly define the caregiver's expectations regarding this treatment modality. In summary, children with autism can present perioperative challenges, but thoughtful psychosocial and medical interventions can improve patient and parent satisfaction.

Among many physiologic adaptations for the survival of humans at birth, cardiorespiratory adaptation is by far the most crucial. The respiratory and circulatory systems must be developed sufficiently in utero for the newborn infant to withstand drastic changes at birth—from the fetal circulatory pattern with liquid-filled lungs to air breathing with transitional circulatory adaptation in a matter of a few minutes. The newborn infant must exercise an effective neuronal drive and respiratory muscles to displace the liquid filling the airway

system and to introduce sufficient air against the surface force in order to establish sufficient alveolar surface for gas exchange. At the same time, pulmonary blood vessels must dilate rapidly to increase pulmonary blood flow and to establish adequate regional alveolar ventilation/pulmonary perfusion (\dot{V}_A/\dot{Q}_P) for sufficient pulmonary gas exchange. The neonatal adaptation of lung mechanics and respiratory control takes several weeks to complete. Beyond this immediate neonatal period, the infant's lungs continue to mature at a rapid pace, and postnatal

development of the lungs and the thorax surrounding the lungs continues well beyond the first year of life. Respiratory function in infants and toddlers, especially during the first several months of life, as with cardiovascular system and hepatic function, is both qualitatively and quantitatively different from that in older children and adults, and so is their responses to pharmacologic agents, especially anesthetics.

This chapter reviews clinically relevant aspects of the development of the respiratory system and function in infants and children and their application to pediatric anesthesia. Such knowledge is indispensable for the proper care of infants and children before, during, and after general anesthesia and surgery, as well as for the care of those with respiratory insufficiency.

The respiratory system consists of the respiratory centers in the brainstem; the central and peripheral chemoreceptors; the phrenic, intercostal, hypoglossal (efferent), and vagal (afferent) nerves; the thorax (including the thoracic cage; the muscles of the chest, abdomen, and diaphragm); the upper (extrathoracic) and lower (intrathoracic) airways; the lungs; and the pulmonary vascular system. The principal function of the respiratory system is to maintain the oxygen and carbon dioxide (CO_2) equilibrium in the body. The lungs also make an important contribution to the regulation of acid-base (pH) balance. The maintenance of body temperature (via loss of water through the lungs) is an additional but secondary function of the lungs. The lungs are also an important organ of metabolism.

DEVELOPMENT OF THE RESPIRATORY SYSTEM

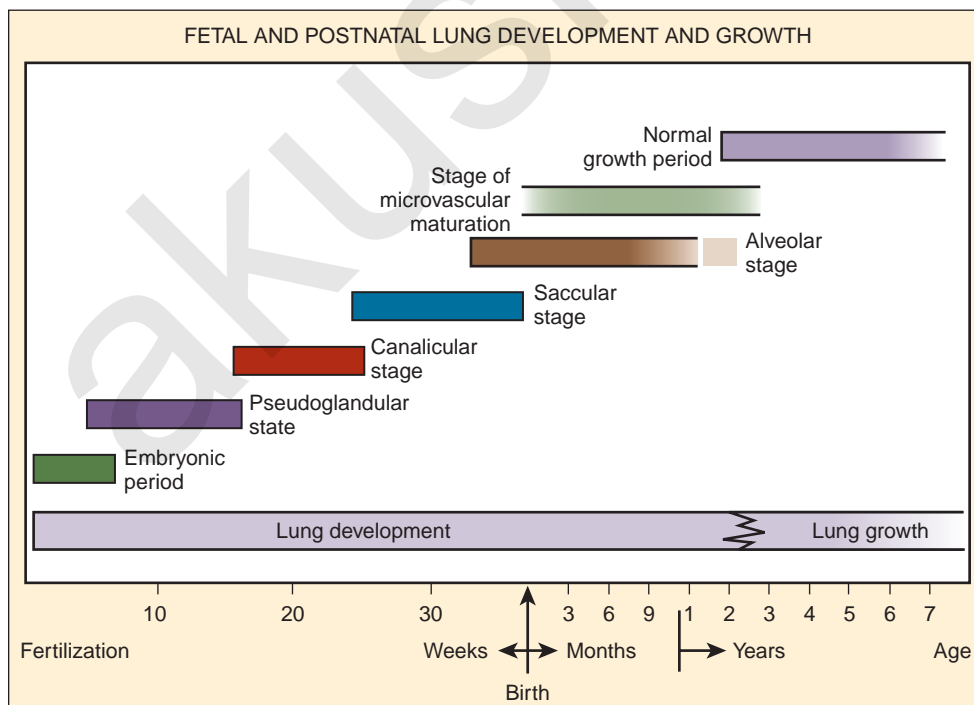

Prenatal Development of the Lungs

The morphologic development of the human lung is seen as early as several weeks into the embryonic period and continues well into the first decade of postnatal life and beyond

(Fig. 3-1). The fetal lungs begin to form within the first several weeks of the embryonic period, when the fetus is merely 3 mm in length. A groove appears in the ventral aspect of the foregut, creating a small pouch. The outgrowth of the endodermal cavity, with a mass of surrounding mesenchymal tissue, projects into the pleuroperitoneal cavity and forms lung buds. The future alveolar membranes and mucous glands are derived from the endoderm, whereas the cartilage, muscle, elastic tissue, and lymph vessels originate from the mesenchymal elements surrounding the lung buds (Emery, 1969).

During the pseudoglandular period, which extends until 17 weeks' gestation, the budding of the bronchi and lung growth rapidly take place, forming a loose mass of connective tissue. The morphologic development of the human lung is illustrated in Figure 3-2. By 16 weeks' gestation, preacinar branching of the airways (down to the terminal bronchioli) is complete (Reid, 1967). A disturbance of the free expansion of the developing lung during this stage, as occurs with diaphragmatic hernia, results in hypoplasia of the airways and lung tissue (Areechon and Reid, 1963). During the canalicular period, in midgestation, the future respiratory bronchioli develop as the relative amount of connective tissue diminishes. Capillaries grow adjacent to the respiratory bronchioli, and the whole lung becomes more vascular (Emery, 1969).

At about 24 weeks' gestation, the lung enters the terminal sac period, which is characterized by the appearance of clusters of terminal air sacs, termed *sacculi*, with flattened epithelium (Hislop and Reid, 1974). These sacculi are large and irregular with thick septa and have few capillaries in comparison with the adult alveoli (Boyden, 1969). At about 26 to 28 weeks' gestation, proliferation of the capillary network surrounding the terminal air spaces becomes sufficient for pulmonary gas exchange (Potter, 1961). These morphologic developments may occur earlier in some premature infants (born at 24 to 25 weeks' gestation) who have survived through neonatal intensive care. Starting at 28 weeks' gestation, air space wall

■ **FIGURE 3-1.** Stages of human lung development and their timing. Note the overlap between stages, particularly between the alveolar stage and the stage of microvascular maturation. Open-ended bars indicate uncertainty as to exact timing. (From Zeltner TB, Burri PH: *The postnatal development and growth of the human lung. II. morphology*, *Respir Physiol* 67:269, 1987.)

thickness decreases rapidly. From this period onward toward term, there is further lengthening of sacculi with possible growth of additional generations of air spaces. Some mammalian species, such as the rat, have no mature alveoli at birth (Burri, 1974). In contrast, alveolar development from sacculi begins in some human fetuses as early as 32 weeks' gestation, but alveoli are not uniformly present until 36 weeks' gestation (Langston et al., 1984). Most alveolar formation in humans takes place postnatally during the first 12 to 18 months of postnatal life, and development of respiratory bronchioles by transformation of preexisting terminal airways does not take place until after birth (Langston et al., 1984).

The fetal lung produces a large quantity of liquid, which expands the airways while the larynx is closed. This expansion produces the growth factor, such as human bombesin, and helps to stimulate lung growth and development (Sunday et al., 1988). The lung fluid is periodically expelled into the uterine cavity and contributes about one third of the total amniotic fluid. Prenatal ligation or occlusion of the trachea was tried in the 1990s with some success for the treatment of the fetus with congenital diaphragmatic hernia (Harrison et al., 1993). This treatment causes the expansion of the fetal airways and results in an accelerated growth of the otherwise hypoplastic lung.

The type II pneumocytes, which produce pulmonary surfactant that forms the alveolar lining layer, reduces surface tension

and stabilizes air spaces after air breathing, appear at about 24 to 26 weeks' gestation but occasionally as early as 20 weeks (Spear et al., 1969; Lauweryns, 1970). Idiopathic (or infantile) respiratory distress syndrome (IRDS), also known as hyaline membrane disease (HMD), which occurs in premature infants, is caused by the immaturity of the lungs with their insufficient pulmonary surfactant production and their inactivation by plasma proteins exuding onto the alveolar surface (see Surface Activity and Pulmonary Surfactant).

Experimental evidence from animals indicates that certain pharmacologic agents such as cortisol and thyroxin administered to the mother or directly to the fetus accelerate the maturation of the lungs, resulting in the early appearance of type II pneumocytes and surfactant (deLemos et al., 1970; Motoyama et al., 1971; Wu et al., 1973; Smith and Bagues, 1982; Rooney, 1985). Liggins and Howie (1972) reported accelerated maturation of human fetal lungs after the administration of corticosteroids to mothers 24 to 48 hours before the delivery of premature babies. Despite initial concern that steroids might potentially be toxic to other organs of the fetus, particularly to the development of the central nervous system, prenatal glucocorticoid therapy has been used widely since the 1980s to induce lung maturation and surfactant synthesis in mothers at risk of premature delivery (Avery, 1984; Avery et al., 1986).

NEONATAL RESPIRATORY ADAPTATION

Respiratory rhythmogenesis occurs in the fetus long before partition. The clamping of the umbilical cord and increasing arterial oxygen tensions and relative hyperoxia with air breathing (but not transient hypoxia) initiate and maintain rhythmic breathing at birth.

To introduce air into the fluid-filled lungs at birth, the newborn infant must overcome large surface force with the first few breaths. Usually a negative pressure of 30 cm H₂O is necessary to introduce air into the fluid-filled lungs. In some normal full-term infants, even with sufficient surfactant, a force of as much as -70 cm H₂O or more must be exerted to overcome the surface force (Fig. 3-3) (Karlberg et al., 1962). Usually fluid is rapidly expelled via the upper airways. The residual fluid leaves the lungs through the pulmonary capillaries and lymphatic channels over the first few days of life, and changes in compliance parallel this time course. All changes are delayed in the premature infant.

As the lungs expand with air, pulmonary vascular resistance decreases dramatically and pulmonary blood flow increases markedly, thus allowing gas exchange between alveolar air and pulmonary capillaries to occur. Changes in P_O₂, P_{CO}₂ (*P* stands for *partial pressure*), and pH are largely responsible for the dramatic decrease in pulmonary vascular resistance (Cook et al., 1963). The resultant large increases in pulmonary blood flow and the increase in left atrial pressure with a decrease in right atrial pressure reverse the pressure gradient across the atria and close (initially functionally and eventually anatomically) the foramen ovale, a right-to-left one-way valve. With these adjustments, the cardiopulmonary system approaches adult levels of ventilation/perfusion (\dot{V}_A/\dot{Q} balance within a few days (Nelson et al., 1962, 1963). The process of expansion of the lungs during the first few hours of life and the resultant circulatory adaptation for establishing pulmonary gas exchange are greatly influenced by the adequacy of pulmonary surfactant. It should be remembered that these changes are delayed in immature newborns.

Postnatal Development of the Lungs and Thorax

The development and growth of the lungs and surrounding thorax continue with amazing speed during the first year of life. Although the formation of the airway system all the way to the terminal bronchioles is complete by 16 weeks' gestation, alveolar formation begins only at about 36 weeks' gestation. At birth, the number of terminal air sacs (most of which are saccules) is between 20 and 50 million, only one tenth that of fully grown lungs of the child. Most postnatal development of alveoli from primitive saccules occurs during the first year and is essentially completed by 18 months of age (Langston et al., 1984). The morphologic and physiologic development of the lungs, however, continues throughout the first decade of life (Mansell et al., 1972).

During the early postnatal period, the lung volume of infants is disproportionately small in relation to body size. In addition, because of higher metabolic rates in infants (oxygen consumption per unit body weight is twice as high as that of adults), the ventilatory requirement per unit of lung volume in infants is markedly increased. Infants, therefore, have much less reserve of lung volume and surface area for gas exchange. This is the primary reason why infants and young children become rapidly desaturated with hypoventilation or apnea of relatively short duration.

In the neonate, static (elastic) recoil pressure of the lungs is very low (i.e., compliance, normalized for volume, is unusually high), which is not dissimilar to that of geriatric or emphysematous lungs, because the elastic fibers do not develop until the postnatal period (whereas elastic fibers in geriatric lungs are brittle and not functional) (Mansel et al., 1972; Fagan, 1976; Bryan and Wohl, 1986). In addition, the elastic recoil pressure of the infant's thorax (chest wall) is extremely low because of its compliant cartilaginous rib cage with poorly developed thoracic muscle mass, which does not add rigidity. These unique characteristics make infants more prone to lung collapse, especially under general anesthesia when inspiratory muscles are markedly relaxed (see maintenance of FRC below). Throughout

■ **FIGURE 3-3.** A, Typical pressure-volume curve of expansion of a gas-free lung. A-B, initial expansion. In the example, approximately 30 cm H₂O pressure will be necessary to overcome surface forces. C, Deflation to zero pressure with gas trapping. D-E, Subsequent breaths with a further increase in FRC (from C to D). B, Pressure-volume relationships during the first breath of a newborn weighing 4.3 kg. Here, 60 to 70 cm H₂O negative pressure was necessary to overcome the surface forces. (From Karlberg P et al.: *Respiratory studies in newborn infants. II. Pulmonary ventilation and mechanics of breathing in the first minutes of life, including the onset of respiration*, Acta Paediatr Scand 51:121, 1962.)

infancy and childhood, static recoil pressure of the lungs and thorax steadily increases (compliance, normalized for volume, decreases) toward normal values for young adults (Zapletal et al., 1971; Motoyama, 1977).

The actual size of the airway from the larynx to the bronchioles in infants and children, of course, is much smaller than in adolescents and adults, and flow resistance in absolute terms is extremely high. When normalized for lung volume or body size, however, infants' airway size is relatively much larger; airway resistance is much lower than in adults (Polgar, 1967; Motoyama, 1977; Stocks and Godfrey, 1977). Infants and toddlers, however, are more prone to severe obstruction of the upper and lower airways because their absolute (not relative) airway diameters are much smaller than those in adults. As a consequence, relatively mild airway inflammation, edema, or secretions can lead to far greater degrees of airway obstruction than in adults (e.g., as with subglottic croup [laryngotracheobronchitis] or acute supraglottitis [epiglottitis]).

Further description on the development of the lungs and thorax and their effects on lung function, especially under general anesthesia, are described later in the chapter. Perinatal and postnatal adaptations of respiratory control are included in the following section on the control of breathing.

Prenatal Development of Breathing

Respiratory rhythmogenesis occurs long before parturition. Dawes and others (1970) were the first to demonstrate "breathing" activities with rhythmic diaphragmatic contractions in the fetal lamb. They found it to be episodic and highly variable in frequency. Boddy and Robinson (1971) recorded movement of the human fetal thorax with an ultrasound device and interpreted this as evidence of fetal breathing. Later studies have shown that during the last 10 weeks of pregnancy, fetal breathing is present approximately 30% of the time (Patrick et al., 1980). The breathing rate in the fetus at 30 to 31 weeks' gestation is higher (58 breaths/min) than that in the near-term fetus (47 breaths/min). A significant increase in fetal breathing movements occurs 2 to 3 hours after a maternal meal and is correlated with the increase in the maternal blood sugar level (Patrick et al., 1980).

Spontaneous breathing movements in the fetus occur only during active, or rapid eye movement (REM), sleep and with low-voltage electrocortical activity, and they appear to be independent of the usual chemical and nonchemical stimuli of postnatal breathing (Dawes et al., 1972; Jansen and Chernick, 1983). Later studies, however, have clearly shown that the fetus can respond to chemical stimuli known to modify breathing patterns postnatally (Dawes et al., 1982; Jansen et al., 1982; Rigatto et al., 1988, 1992). In contrast, hypoxemia in the fetus abolishes, rather than stimulates, breathing movements. This may be related to the fact that hypoxemia diminishes the incidence of REM sleep (Boddy et al., 1974). It appears that normally low arterial oxygen tension, or P_{aO_2} (19 to 23 mm Hg), in the fetus is a normal mechanism inhibiting breathing activities in utero (Rigatto, 1992). Severe hypoxia induces gasping, which is independent of the peripheral chemoreceptors and apparently independent of rhythmic fetal breathing (Jansen and Chernick, 1974).

The near-term fetus is relatively insensitive to P_{aCO_2} changes. Extreme hypercapnia (P_{aCO_2} greater than 60 mm Hg) in the fetal lamb, however, can induce rhythmic breathing movement that is

preceded by a sudden activation of inspiratory muscle tone with expansion of the thorax and inward movement (inspiration) of amniotic fluid, as much as 30 to 40 mL/kg (an apparent increase in functional residual capacity [FRC]) (Motoyama, unpublished observation). When P_{aO_2} was reduced, breathing activities ceased, and there was a reversal of the sequence of events noted above (i.e., relaxation of the thorax, decreased FRC as evidenced by outward flow of amniotic fluid) (Motoyama, 2001).

The Hering-Breuer (inflation) reflex is present in the fetus. Distention of the lungs by saline infusion slows the frequency of breathing (Dawes et al., 1982). Transection of the vagi, however, does not change the breathing pattern (Dawes, 1974).

Maternal ingestion of alcoholic beverages abolishes human fetal breathing for up to 1 hour. Fetal breathing movement is also abolished by maternal cigarette smoking. These effects may be related to fetal hypoxemia resulting from changes in placental circulation Jansen and Chernick, 1983). It is not clear why the fetus must "breathe" in utero, when gas exchange is handled by the placental circulation. Dawes (1974) suggested that fetal breathing might represent "prenatal practice" to ensure that the respiratory system is well developed and ready at the moment of birth. Another reason may be that the stretching of the airways and lung parenchyma is an important stimulus for lung development; bilateral phrenic nerve sectioning in the fetal lamb results in hypoplasia of the lungs (Alcorn et al., 1980).

Perinatal Adaptation of Breathing

During normal labor and vaginal delivery, the human fetus goes through a period of transient hypoxia, hypercapnia, and acidemia. The traditional view of the mechanism of the onset of breathing at birth until the 1980s was that the transient fetal asphyxia stimulates the chemoreceptors and produces gasping, which is followed by rhythmic breathing at birth that is aided by thermal, tactile, and other sensory stimuli. Subsequent studies have challenged this concept (Chernick et al., 1975; Baier et al., 1990; Rigatto, 1992). The current concept regarding the mechanism of continuous neonatal breathing is summarized in [Box 3-1](#).

Once the newborn has begun rhythmic breathing, ventilation is adjusted to achieve a lower P_{aCO_2} than is found in older children and adults ([Table 3-1](#)). The reason for this difference is not clear but most likely is related to a poor buffering capacity in the neonate and a ventilatory compensation for metabolic acidosis. The P_{aO_2} of the infant approximates the adult level within a few weeks of birth (Nelson, 1976).

Box 3-1 Mechanism of Continuous Neonatal Breathing

- The onset of breathing activities occurs not at birth but in utero, as a part of normal fetal development.
- The clamping of the umbilical cord initiates rhythmic breathing.
- Relative hyperoxia with air breathing, compared with low fetal P_{aO_2} , augments and maintains continuous and rhythmic breathing.
- Continuous breathing is independent of the level of P_{aCO_2} .
- Breathing is unaffected by carotid denervation.
- Hypoxia depresses or abolishes continuous breathing.

TABLE 3-1. Normal Blood-Gas Values

	Pao ₂ (mm Hg)	Sao ₂ (%)	Paco ₂ (mm Hg)	pH
Pregnant woman at term	88*	96	32	7.40
Umbilical vein	31	72*	42	7.35
Umbilical artery	19	38*	51	7.29

Child and adult (artery)	99	97	41	7.40

*Estimated values.

Control of breathing in the neonate evolves gradually during the first month of extrauterine life and beyond and is different from that in older children and adults, especially in the response to hypoxemia and hyperoxia. The neonates' breathing patterns and responses to chemical stimuli are detailed after a general overview of the control of breathing.

CONTROL OF BREATHING

The mechanism that regulates and maintains pulmonary gas exchange is remarkably efficient. In a normal person, the level of Paco₂ is maintained within a very narrow range, whereas oxygen demand and carbon dioxide production vary greatly during rest and exercise. This control is achieved by a precise matching of the level of ventilation to the output of carbon dioxide. Breathing is produced by the coordinated action of a number of inspiratory and expiratory muscles. Inspiration is produced principally by the contraction of the diaphragm, which creates negative intrathoracic pressure that draws air into the lungs. Expiration, on the other hand, is normally produced passively by the elastic recoil of

the lungs and thorax. It may be increased actively by the contraction of abdominal and thoracic expiratory muscles during exercise. During the early phase of expiration, sustained contraction of the diaphragm with decreasing intensity (braking action) and the upper airway muscles' activities and narrowing of the glottic aperture impede and smoothen the rate of expiratory flow.

Rhythmic contraction of the respiratory muscles is governed by the respiratory centers in the brainstem and tightly regulated by feedback systems so as to match the level of ventilation to metabolic needs (Fig. 3-4) (Cherniack and Pack, 1988). These feedback mechanisms include central and peripheral chemoreceptors, stretch receptors in the airways and lung parenchyma via the vagal afferent nerves, and segmental reflexes in the spinal cord provided by muscle spindles (Cherniack and Pack, 1988). The control of breathing comprises neural and chemical controls that are closely interrelated.

Neural Control of Breathing

Respiratory neurons in the medulla have inherent rhythmicity even when they are separated from the higher levels of the

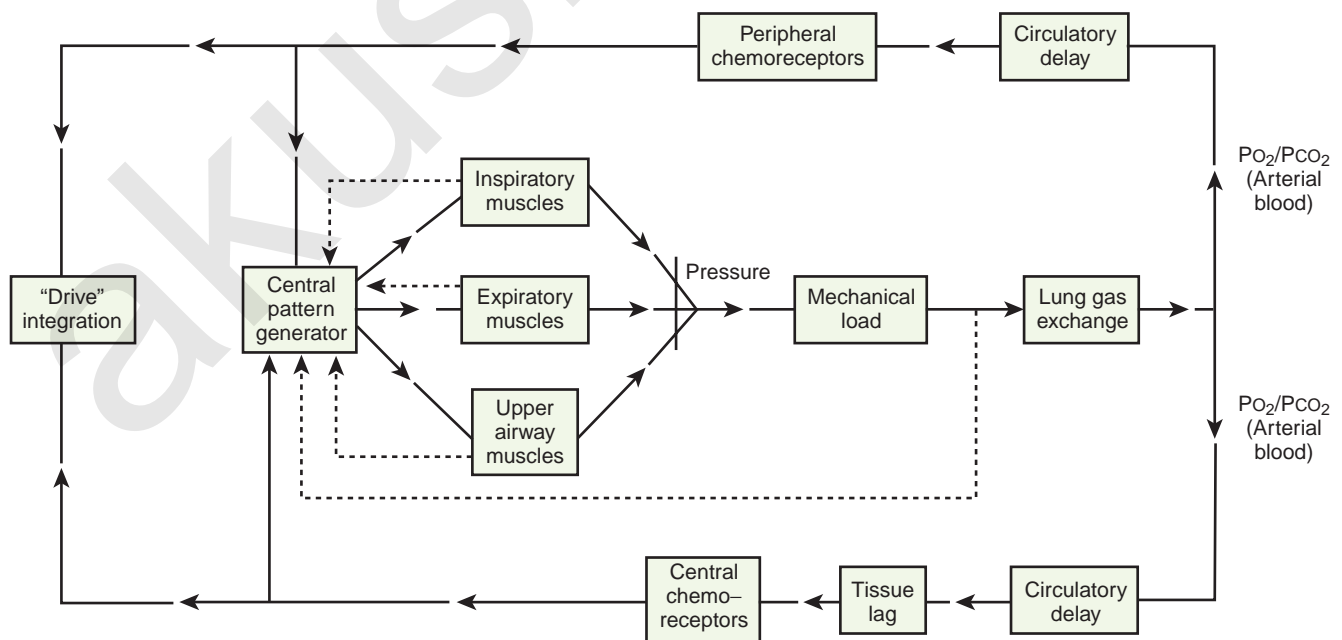

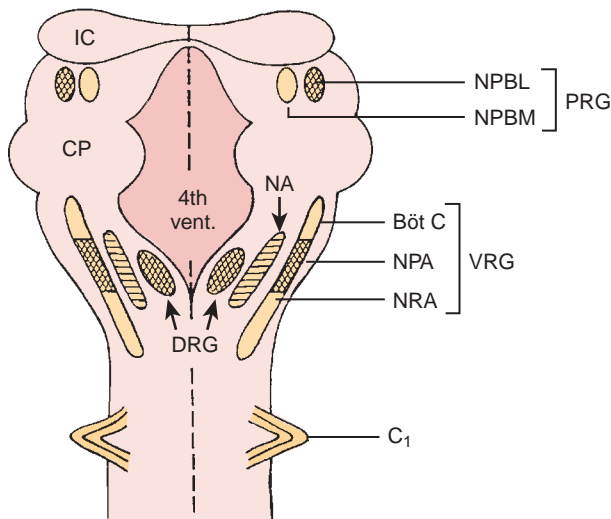

FIGURE 3-4. Block diagram of multi-input, multi-output system that controls ventilation.

■ **FIGURE 3-5.** Schematic representation of the respiratory neurons on the dorsal surface of the brainstem. (From Tabatabai M, Behnia R: *Neurochemical regulation of respiration*. In Collins VJ, editor: *Physiological and pharmacological basis of anesthesia*, Philadelphia, 1995, Williams & Wilkins.)

brainstem. In the cat, respiratory neurons are concentrated in two bilaterally symmetric areas in the medulla near the level of the obex. The dorsal respiratory group of neurons (DRG) is located in the dorsomedial medulla just ventrolateral to the nucleus tractus solitarius and contains predominantly inspiratory neurons. The ventral respiratory group of neurons (VRG), located in the ventrolateral medulla, consists of both inspiratory and expiratory neurons (Fig. 3-5) (von Euler, 1986; Tabatabai and Behnia, 1995; Berger, 2000).

Dorsal Respiratory Group of Neurons

The DRG is spatially associated with the tractus solitarius, which is the principal tract for the ninth and tenth cranial (glossopharyngeal and vagus) nerves. These nerves carry afferent fibers from the airways and lungs, heart, and peripheral arterial chemoreceptors. The DRG may constitute the initial intracranial site for processing some of these visceral sensory afferent inputs into a respiratory motor response (Berger, 2000).

On the basis of lung inflation, three types of neurons have been recognized in the DRG: type $I\alpha$ (*I* stands for *inspiratory*), type $I\beta$, and pump (P) cells. Type $I\alpha$ is inhibited by lung inflation (Cohen, 1981a). The axons of these neurons project to both the phrenic and the external (inspiratory) intercostal motoneurons of the spinal cord. Some type $I\alpha$ neurons have medullary collaterals that terminate among the inspiratory and expiratory neurons of the ipsilateral VRG (Merrill, 1970).

The second type, $I\beta$, is excited by lung inflation and receives synaptic inputs from pulmonary stretch receptors. There is

controversy as to whether $I\beta$ axons project into the spinal cord respiratory neurons; the possible functional significance of such spinal projections is unknown. Both $I\alpha$ and $I\beta$ neurons receive excitatory inputs from the central pattern generator (or central inspiratory activity) for breathing, so that when lung inflation is terminated or the vagi in the neck are cut, the rhythmic firing activity of these neurons continues (Cohen, 1981a, 1981b; Feldman and Speck, 1983).

The third type of neurons in the DRG receives no input from the central pattern generator. The impulse of these neurons, the P cells, closely follows lung inflation during either spontaneous or controlled ventilation (Berger, 1977). The P cells are assumed to be relay neurons for visceral afferent inputs (Berger, 2000).

The excitation of $I\beta$ neurons by lung inflation is associated with the shortening of inspiratory duration. The $I\beta$ neurons appear to promote inspiration-to-expiration phase-switching by inhibiting $I\alpha$ neurons. This network seems to be responsible for the Hering-Breuer reflex inhibition of inspiration by lung inflation (Cohen, 1981a, 1981b; von Euler, 1986, 1991).

The DRG thus functions as an important primary and possibly secondary relay site for visceral sensory inputs via glossopharyngeal and vagal afferent fibers. Because many of the inspiratory neurons in the DRG project to the contralateral spinal cord and make excitatory connections with phrenic motoneurons, the DRG serves as a source of inspiratory drive to phrenic and possibly to external intercostal motoneurons (Berger, 2000).

Ventral Respiratory Group of Neurons

The VRG extends from the rostral to the caudal end of the medulla and has three subdivisions (Fig. 3-5). The Bötzing complex, located in the most rostral part of the medulla in the vicinity of the retrofacial nucleus, contains mostly expiratory neurons (Lipski and Merrill, 1980; Merrill et al., 1983). These neurons send inhibitory signals to DRG and VRG neurons and project into the phrenic motoneurons of the spinal cord, causing its inhibition (Bianchi and Barillot, 1982; Merrill et al., 1983). The physiologic significance of these connections may be to ensure inspiratory neuronal silence during expiration (reciprocal inhibition) and to contribute to the “inspiratory off-switch” mechanism.

The nucleus ambiguus (NA) and nucleus paraambigualis (NPA), lying side by side, occupy the middle portion of the VRG. Axons of the respiratory motoneurons originating from the NA project along with other vagal efferent fibers and innervate the laryngeal abductor (inspiratory) and adductor (expiratory) muscles via the recurrent laryngeal nerve (Barillot and Bianchi, 1971; Bastel and Lines, 1975). The NPA contains mainly inspiratory ($I\gamma$) neurons, which respond to lung inflation in a manner similar to that of $I\alpha$ neurons. The axons of these neurons project both to phrenic and external (inspiratory) intercostal motoneuron pools in the spinal cord. The nucleus retroambigualis (NRA) occupies the caudal part of the VRG and contains expiratory neurons whose axons project into the spinal motoneuron pools for the internal (expiratory) intercostal and abdominal muscles (Merrill, 1970; Miller et al., 1985).

The inspiratory neurons of the DRG send collateral fibers to the inspiratory neurons of the NPA in the VRG. These connections may provide the means for ipsilateral synchronization of the inspiratory activity between the neurons in the DRG

and those in the VRG (Merrill, 1979, 1983). Furthermore, axon collaterals of the inspiratory neurons of the NPA on one side project to the inspiratory neurons of the contralateral NPA, and vice versa. These connections may be responsible for the bilateral synchronization of the medullary inspiratory motoneuron output, as evidenced by synchronous bilateral phrenic nerve activity (Merrill, 1979, 1983).

Pontine Respiratory Group of Neurons

In the dorsolateral portion of the rostral pons, both inspiratory and expiratory neurons have been found. Inspiratory neuronal activity is concentrated ventrolaterally in the region of the nucleus parabrachialis lateralis (NPBL). The expiratory activity is centered more medially in the vicinity of the nucleus parabrachialis medialis (NPBM) (Fig. 3-5) (Cohen, 1979; Mitchell and Berger, 1981). The respiratory neurons of these nuclei are referred to as the pontine respiratory group (PRG), which was, and sometimes still is, called the pneumotaxic center, although the term is generally considered obsolete (Feldman, 1986). There are reciprocal projections between the PRG neurons and the DRG and VRG neurons in the medulla. Electrical stimulation of the PRG produces rapid breathing with premature switching of respiratory phases, whereas transection of the brainstem at a level caudal to the PRG prolongs inspiratory time (Cohen, 1971; Feldman and Gautier, 1976). Bilateral cervical vagotomies produce a similar pattern of slow breathing with prolonged inspiratory time; a combination of PRG lesions and bilateral vagotomy in the cat results in apneusis (apnea with sustained inspiration) or apneustic breathing (slow rhythmic respiration with marked increase end inspiratory hold) (Feldman and Gaultier, 1976; Feldman, 1986). The PRG probably plays a secondary role in modifying the inspiratory off-switch mechanism (Gautier and Bertrand, 1975; von Euler and Trippenbach, 1975).

Respiratory Rhythm Generation

Rhythmic breathing in mammals can occur in the absence of feedback from peripheral receptors. Because transection of the brain rostral to the pons or high spinal transection has little effect on the respiratory pattern, respiratory rhythmogenesis apparently takes place in the brainstem. The PRG, DRG, and VRG have all been considered as possible sites of the central pattern generator, although its exact location is still unknown (Cohen, 1981b; von Euler, 1983, 1986). A study with an *in vitro* brainstem preparation of neonatal rats has indicated that respiratory rhythm is generated in the small area in the ventrolateral medulla just rostral to the Böttinger complex (pre-Böttinger complex), which contains pacemaker neurons (Smith et al., 1991).

The pre-Böttinger complex contains a group of neurons that is responsible for respiratory rhythmogenesis (Smith et al., 1991; Pierrefiche et al., 1998; Rekling and Feldman, 1998). Although the specific cellular mechanism responsible for rhythmogenesis is not known, two possible mechanisms have been proposed (Funk and Feldman, 1995; Ramirez and Richter, 1996). One hypothesis is that the pacemaker neurons possess intrinsic properties associated with various voltage- and time-dependent ion channels that are responsible for rhythm generation. Rhythmic activity in these neurons may depend on the presence of an input system that may be necessary to maintain the neuron's membrane potential in a range in which the voltage-dependent properties of the cell's ion channels result in rhythmic behavior. The

network hypothesis is the alternative model in which the interaction between the neurons produces respiratory rhythmicity, such as reciprocal inhibition between inhibitory and excitatory neurons and recurrent excitation within any population of neurons (Berger, 2000). The output of this central pattern generator is influenced by various inputs from chemoreceptors (central and peripheral), mechanoreceptors (e.g., pulmonary receptors and muscle and joint receptors), thermoreceptors (central and peripheral), nociceptors, and higher central structures (such as the PRG). The function of these inputs is to modify the breathing pattern to meet and adjust to ever-changing metabolic and behavioral needs (Smith et al., 1991).

Airway and Pulmonary Receptors

The upper airways, trachea and bronchi, lungs, and chest wall have a number of sensory receptors sensitive to mechanical and chemical stimulation. These receptors affect ventilation as well as circulatory and other nonrespiratory functions.

Upper Airway Receptors

Stimulation of receptors in the nose can produce sneezing, apnea, changes in bronchomotor tone, and the diving reflex, which involves both the respiratory and the cardiovascular systems. Stimulation of the epipharynx causes the sniffing reflex, a short, strong inspiration to bring material (mucus, foreign body) in the epipharynx into the pharynx to be swallowed or expelled. The major role of receptors in the pharynx is associated with swallowing. It involves the inhibition of breathing, closure of the larynx, and coordinated contractions of pharyngeal muscles (Widdicombe, 1985; Nishino, 1993; Sant'Ambrogio et al., 1995).

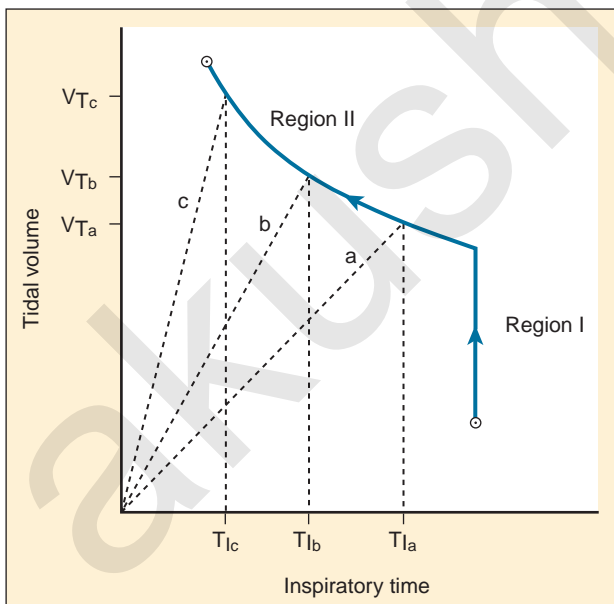

The larynx has a rich innervation of receptors. The activation of these receptors can cause apnea, coughing, and changes in the ventilatory pattern (Widdicombe, 1981, 1985). These reflexes, which influence both the patency of the upper airway and the breathing pattern, are related to transmural pressure and air flow. Based on single-fiber action-potential recordings from the superior laryngeal nerve in the spontaneously breathing dog preparation in which the upper airway is isolated from the lower airways, three types of receptors have been identified: pressure receptors (most common, about 65%), "drive" (or irritant) receptors (stimulated by upper airway muscle activities), and flow or cold receptors (Sant'Ambrogio et al., 1983; Fisher et al., 1985). The laryngeal flow receptors show inspiratory modulation with room air breathing but become silent when inspired air temperature is raised to body temperature and 100% humidity or saturation (Sant'Ambrogio et al., 1985). The activity of pressure receptors increases markedly with upper airway obstruction (Sant'Ambrogio et al., 1983).

Tracheobronchial and Pulmonary Receptors

Three major types of tracheobronchial and pulmonary receptors have been recognized: slowly adapting (pulmonary stretch) receptors and rapidly adapting (irritant or deflation) receptors, both of which lead to myelinated vagal afferent fibers and unmyelinated C-fiber endings (J-receptors). Excellent reviews on pulmonary receptors have been published (Pack, 1981; Widdicombe, 1981; Sant'Ambrogio, 1982; Coleridge and Coleridge, 1984).

Slowly adapting (pulmonary stretch) receptors. Slowly adapting (pulmonary stretch) receptors (SARs) are mechanoreceptors that lie within the submucosal smooth muscles in the membranous posterior wall of the trachea and central airways (Bartlett et al., 1976). A small proportion of the receptors are located in the extrathoracic upper trachea (Berger, 2000). SARs are activated by the distention of the airways during lung inflation and inhibit inspiratory activity (Hering-Breuer inflation reflex), whereas they show little response to steady levels of lung inflation. The Hering-Breuer reflex also produces dilation of the upper airways from the larynx to the bronchi. Although SARs are predominantly mechanoreceptors, hypocapnia stimulates their discharge, and hypercapnia inhibits it (Pack, 1981). In addition, SARs are thought to be responsible for the accelerated heart rate and systemic vasoconstriction observed with moderate lung inflation (Widdicombe, 1974). These effects are abolished by bilateral vagotomy.

Studies by Clark and von Euler (1972) have demonstrated the importance of the inflation reflex in adjusting the pattern of ventilation in the cat and the human. In cats anesthetized with pentobarbital, inspiratory time decreases as tidal volume increases with hypercapnia, indicating the presence of the inflation reflex in the normal tidal volume range. Clark and von Euler demonstrated an inverse hyperbolic relationship between the tidal volume and inspiratory time. In the adult human, inspiratory time is independent of tidal volume until the latter increases to about twice the normal tidal volume, when the inflation reflex appears (Fig. 3-6). In the newborn, particularly the premature newborn, the inflation reflex is present in the eupneic range for a few months (Olinsky et al., 1974).

■ **FIGURE 3-6.** Relationship between tidal volume (V_t) and inspiratory time (T_i) as ventilation is increased in response to respiratory stimuli. Note that in region I, V_t increases without changes in T_i . Also shown as dashed lines are the V_t trajectories for three different tidal volumes in region II. (From Berger AJ: *Control of breathing*. In Murray JF, Nadel JA: *Textbook of respiratory medicine*, Philadelphia, 1994, WB Saunders.)

Apnea, commonly observed in adult patients at the end of surgery and anesthesia with the endotracheal tube cuff still inflated, may be related to the inflation reflex, because the trachea has a high concentration of stretch receptors (Bartlett et al., 1976; Sant'Ambrogio, 1982). Deflation of the cuff promptly restores rhythmic spontaneous ventilation.

Rapidly adapting (irritant) receptors. Rapidly adapting (irritant) receptors (RARs) are located superficially within the airway epithelial cells, mostly in the region of the carina and the large bronchi (Pack, 1981; Sant'Ambrogio, 1982). RARs respond to both mechanical and chemical stimuli. In contrast to SARs, RARs adapt rapidly to large lung inflation, distortion, or deflation, thus possessing marked dynamic sensitivity (Pack, 1981). RARs are stimulated by cigarette smoke, ammonia, and other irritant gases including inhaled anesthetics, with significant interindividual variability (Sampson and Vidruk, 1975). RARs are stimulated more consistently by histamine and prostaglandins, suggesting their role in response to pathologic states (Coleridge et al., 1976; Sampson and Vidruk, 1977; Vidruk et al., 1977; Berger, 2000). The activation of RARs in the large airways may be responsible for various reflexes, including coughing, bronchoconstriction, and mucus secretion. Stimulation of RARs in the periphery of the lungs may produce hyperpnea. Because RARs are stimulated by deflation of the lungs to produce hyperpnea in animals, they are considered to play an important role in the Hering-Breuer deflation reflex (Sellick and Widdicombe, 1970). This reflex, if it exists in humans, may partly account for increased respiratory drive when the lung volume is abnormally decreased, as in premature infants with IRDS and in pneumothorax.

When vagal conduction is partially blocked by cold, inflation of the lung produces prolonged contraction of the diaphragm and deep inspiration instead of inspiratory inhibition. This reflex, the paradoxical reflex of Head, is most likely mediated by RARs. It may be related to the complementary cycle of respiration, or the sigh mechanism, that functions to reinflate and re-aerate parts of the lungs that have collapsed because of increased surface force during quiet, shallow breathing (Mead and Collier, 1959). In the newborn, inflation of the lungs initiates gasping. This mechanism, which was considered to be analogous to the paradoxical reflex of Head, may help to inflate unaerated portions of the newborn lung (Cross et al., 1960).

C-Fiber endings. Most afferent axons arising from the lungs, heart, and other abdominal viscera are slow conducting (slower than 2.5 m/sec), unmyelinated vagal fibers (C-fibers). Extensive studies by Paintal (1973) have suggested the presence of receptors supposedly located near the pulmonary or capillary wall (juxtapulmonary capillary or J-receptors) innervated by such C-fibers. C-fiber endings are stimulated by pulmonary congestion, pulmonary edema, pulmonary microemboli, and irritant gases such as anesthetics. Such stimulation causes apnea followed by rapid, shallow breathing, hypotension, and bradycardia. Stimulation of J-receptors also produces bronchoconstriction and increases mucus secretion. All these responses are abolished by bilateral vagotomy. In addition, stimulation of C-fiber endings can provoke severe reflex contraction of the laryngeal muscles, which may be partly responsible for the laryngospasm observed during induction of anesthesia with isoflurane or halothane.

In addition to receptors within the lung parenchyma (pulmonary C-fiber endings), there appear to be similar

nonmyelinated nerve endings in the bronchial wall (bronchial C-fiber endings) (Coleridge and Coleridge, 1984). Both chemical and, to a lesser degree, mechanical stimuli excite these bronchial C-fiber endings. They are also stimulated by endogenous mediators of inflammation, including histamine, prostaglandins, serotonin, and bradykinin. Such stimulation may be a mechanism of C-fiber involvement in disease states such as pulmonary edema, pulmonary embolism, and asthma (Coleridge and Coleridge, 1984).

The inhalation of irritant gases or particles causes a sensation of tightness or distress in the chest, probably caused by its activation of pulmonary receptors. The pulmonary receptors may contribute to the sensation of dyspnea in lung congestion, atelectasis, and pulmonary edema. Bilateral vagal blockade in patients with lung disease abolished dyspneic sensation and increased breath-holding time (Noble et al., 1970).

Chest-Wall Receptors

The chest-wall muscles, including the diaphragm and the intercostal muscles, contain various types of receptors that can produce respiratory reflexes. This subject has been reviewed extensively (Newsom-Davis, 1974; Duron, 1981). The two types of receptors that have been most extensively studied are muscle spindles, which lie parallel to the extrafusal muscle fibers, and the Golgi tendon organs, which lie in series with the muscle fibers (Berger, 2000).

Muscle spindles are a type of slowly adapting mechanoreceptors that detect muscle stretch. As in other skeletal muscles, the muscle spindles of respiratory muscles are innervated by γ -motoneurons that excite intrafusal fibers of the spindle.

Intercostal muscles have a density of muscle spindles comparable with those of other skeletal muscles. The arrangement of muscle spindles is appropriate for the respiratory muscle load-compensation mechanism (Berger, 2000). By comparison with the intercostal muscles, the diaphragm has a very low density of muscle spindles and is poorly innervated by the γ -motoneurons. Reflex excitation of the diaphragm, however, can be achieved via proprioceptive excitation within the intercostal system (Decima and von Euler, 1969).

Golgi tendon organs are located at the point of insertion of the muscle fiber into its tendon and, like muscle spindles, are a slowly adapting mechanoreceptor. Activation of the Golgi tendon organs inhibits the homonymous motoneurons, possibly preventing the muscle from being overloaded (Berger, 2000). In the intercostal muscles, fewer Golgi tendon organs are present than muscle spindles, whereas the ratio is reversed in the diaphragm.

Chemical Control of Breathing

Regulation of alveolar ventilation and maintenance of normal arterial P_{CO_2} , pH, and P_{O_2} are the principal functions of the medullary and peripheral chemoreceptors (Leusen, 1972).

Central Chemoreceptors

The medullary, or central, chemoreceptors, located near the surface of the ventrolateral medulla, are anatomically separated from the medullary respiratory center (Fig. 3-7). They respond to changes in hydrogen ion concentration in the adjacent

FIGURE 3-7. View of the ventral surface of the medulla shows the chemosensitive zones. The rostral (R) and caudal (C) zones are chemosensitive. The intermediate (I) zone is not chemosensitive but may have a function in the overall central chemosensory response. The roman numerals indicate the cranial nerves. (From Berger AJ, Hornbein TF: *Control of respiration*. In Patton HD et al., editors: *Textbook of physiology*, ed 21, Philadelphia, 1989, WB Saunders.)

cerebrospinal fluid rather than to changes in arterial P_{CO_2} or pH (Pappenheimer et al., 1965). Since CO_2 rapidly passes through the blood-brain barrier into the cerebrospinal fluid, which has poor buffering capacity, the medullary chemoreceptors are readily stimulated by respiratory acidemia. In contrast, ventilatory responses of the medullary chemoreceptors to acute metabolic acidemia and alkalemia are limited because changes in the hydrogen ion concentration in arterial blood are not rapidly transmitted to the cerebrospinal fluid. In chronic acid-base disturbances, the pH of cerebrospinal fluid (and presumably that of interstitial fluid) surrounding the medullary chemoreceptors is generally maintained close to the normal value of about 7.3 regardless of arterial pH (Mitchell et al., 1965). Under these circumstances, ventilation becomes more dependent on the hypoxic response of peripheral chemoreceptors.

Peripheral Chemoreceptors

The carotid bodies, located near the bifurcation of the common carotid artery, react rapidly to changes in P_{aO_2} and pH. Their contribution to the respiratory drive amounts to about 15% of resting ventilation (Severinghaus, 1972). The carotid body has three types of neural components: type I (glomus) cells, presumably the primary site of chemotransduction; type II (sheath) cells; and sensory nerve fibers (McDonald, 1981). Sensory nerve fibers originate from terminals in apposition to the glomus cells, travel via the carotid sinus nerve to join the glossopharyngeal nerve, and then enter the brainstem. The sheath cells envelop both the glomus cells and the sensory nerve terminals.

A variety of neurochemicals have been found in the carotid body, including acetylcholine, dopamine, substance P, enkephalins, and vasoactive intestinal peptide. The exact functions of these cell types and the mechanisms of chemotransduction and the specific roles of these neurochemicals have not been well established (Berger, 2000).

The carotid bodies are perfused with extremely high levels of blood flow and respond rapidly to an oscillating P_{aO_2} rather than a constant P_{aO_2} at the same mean values (Dutton et al., 1964; Fenner et al., 1968). This mechanism may be partly responsible for hyperventilation during exercise.

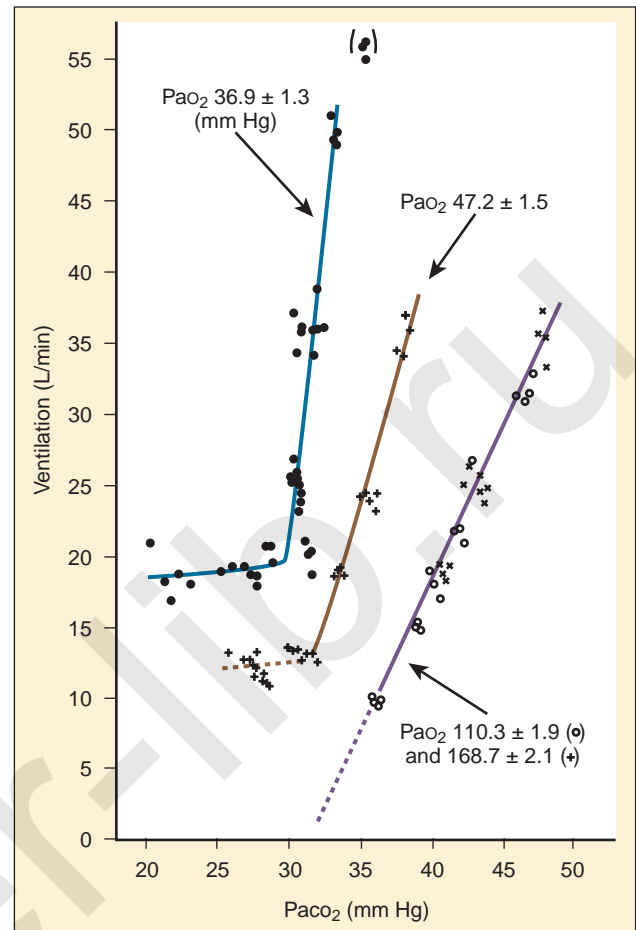

The primary role of peripheral chemoreceptors is their response to changes in arterial P_{O_2} . Moderate to severe hypoxemia (P_{aO_2} less than 60 mm Hg) results in a significant increase in ventilation in all age groups except for newborn, particularly premature, infants, whose ventilation is decreased by hypoxemia (Dripps and Comroe, 1947; Rigatto et al., 1975b). Peripheral chemoreceptors are also partly responsible for hyperventilation in hypotensive patients. Respiratory stimulation is absent in certain states of tissue hypoxia, such as moderate to severe anemia and carbon monoxide poisoning; despite a decrease in oxygen content, P_{aO_2} in the carotid bodies is maintained near normal levels, so that the chemoreceptors are not stimulated.

In acute hypoxemia, the ventilatory response via the peripheral chemoreceptors is partially opposed by hypocapnia, which depresses the medullary chemoreceptors. When a hypoxic environment persists for a few days, for example, during an ascent to high altitude, ventilation increases further as cerebrospinal fluid bicarbonate decreases and pH returns toward normal (Severinghaus et al., 1963). However, later studies demonstrated that the return of cerebrospinal fluid pH toward normal is incomplete, and a secondary increase in ventilation precedes the decrease in pH, indicating that some other mechanisms are involved (Bureau and Bouverot, 1975; Foster et al., 1975). In chronic hypoxemia that lasts for a number of years, the carotid bodies initially exhibit some adaptation to hypoxemia and then gradually lose their hypoxic response. In people native to high altitudes, the blunted response of carotid chemoreceptors to hypoxemia takes 10 to 15 years to develop and is sustained thereafter (Sorensen and Severinghaus, 1968; Lahiri et al., 1978). In cyanotic heart diseases, the hypoxic response is lost much sooner but returns after surgical correction of the right-to-left shunts (Edelman et al., 1970).

In patients who have chronic respiratory insufficiency with hypercapnia, hypoxic stimulation of the peripheral chemoreceptors provides the primary impulse to the respiratory center. If these patients are given excessive levels of oxygen, the stimulus of hypoxemia is removed, and ventilation decreases or ceases. P_{CO_2} further increases, patients become comatose (CO_2 narcosis), and death may follow unless ventilation is supported. Rather than oxygen therapy, such patients need their effective ventilation increased artificially with or without added inspired oxygen.

Response to Carbon Dioxide

The graphic demonstration of relations between the alveolar or arterial P_{CO_2} and the minute ventilation (\dot{V}_E/P_{CO_2}) is commonly known as the CO_2 response curve (Fig. 3-8). This curve normally reflects the response of the chemoreceptors and respiratory center to CO_2 . The CO_2 response curve is a useful means for evaluation of the chemical control of breathing, provided that

■ **FIGURE 3-8.** Effect of acute hypoxemia on the ventilatory response to steady-state P_{aO_2} in one subject. Inspired oxygen was adjusted in each experiment to keep P_{aO_2} constant at the level as indicated. (From Nielsen M, Smith H: *Studies on the regulation of respiration in acute hypoxia*, Acta Physiol Scand 24:293, 1951.)

the mechanical properties of the respiratory system, including the neuromuscular transmission, respiratory muscles, thorax, and lungs, are intact. In normal persons, ventilation increases more or less linearly as the inspired concentration of carbon dioxide increases up to 9% to 10%, above which ventilation starts to decrease (Dripps and Comroe, 1947). Under hypoxic conditions the CO_2 response is potentiated, primarily via carotid body stimulation, resulting in a shift to the left of the CO_2 response curve (Fig. 3-8) (Nielsen and Smith, 1951). On the other hand, anesthetics, opioids, and barbiturates in general depress the medullary chemoreceptors and, by decreasing the slope, shift the CO_2 response curve progressively to the right as the anesthetic concentration increases (Fig. 3-9) (Munson et al., 1966).

A shift to the right of the CO_2 response curve in an awake human may be caused by decreased chemoreceptor sensitivity to CO_2 , as seen in patients whose carotid bodies had been destroyed (Wade et al., 1970). It may also be caused by lung disease and resultant mechanical failure to increase ventilation despite intact neuronal response to carbon dioxide. In patients with various central nervous system dysfunctions, the CO_2 response may be partially or completely lost (Ondine's curve) (Severinghaus and Mitchell, 1962). In the awake state,

FIGURE 3-9. CO₂ response curve with halothane. Family of steady-state CO₂ response curves in one subject awake and at three levels of halothane anesthesia. Note progressive decrease in ventilatory response to Pao₂ with increasing anesthetic depth (MAC; ventilatory response in awake state was measured in response to end-tidal Pco₂). (Courtesy Dr. Edwin S. Munson; data from Munson ES, et al.: *The effects of halothane, fluroxene, and cyclopropane on ventilation: a comparative study in man*, *Anesthesiology* 27:716, 1966.)

these patients have chronic hypoventilation but can breathe on command. During sleep, they further hypoventilate or become apneic to the point of CO₂ narcosis and death unless mechanically ventilated or implanted with a phrenic pacemaker (Glenn et al., 1973).

It has been difficult to separate the neuronal component from the mechanical failure of the lungs and thorax, because the two factors often coexist in patients with chronic lung diseases (Guz et al., 1970). Whitelaw and others (1975) demonstrated that occlusion pressure at 0.1 second (P_{0.1}), or the negative mouth pressure generated by inspiratory effort against airway occlusion at FRC) correlates well with neuronal (phrenic) discharges but is uninfluenced by mechanical properties of the lungs and thorax. The occlusion pressure is a useful means for the clinical evaluation of the ventilatory drive.

As mentioned previously, hypoxemia potentiates the chemical drive and increases the slope of the CO₂ response curve (\dot{V}_E/P_{CO_2}). Such a change has been interpreted as “a synergistic (or multiplicative) effect” of the stimulus, whereas a parallel shift of the curve has been considered as “an additive effect.” This analysis may be useful for descriptive purposes, but it is misleading. Because ventilation is the product of tidal volume and frequency ($\dot{V}_E = V_T \times f$), an additive effect on its components could result in a change in the slope of the CO₂ response curve. Obviously, the responses of tidal volume and frequency to CO₂ should be examined separately to understand the effect of various respiratory stimulants and depressants.

Milic-Emili and Grunstein (1975) proposed that ventilatory response to CO₂ be analyzed in terms of the mean inspiratory

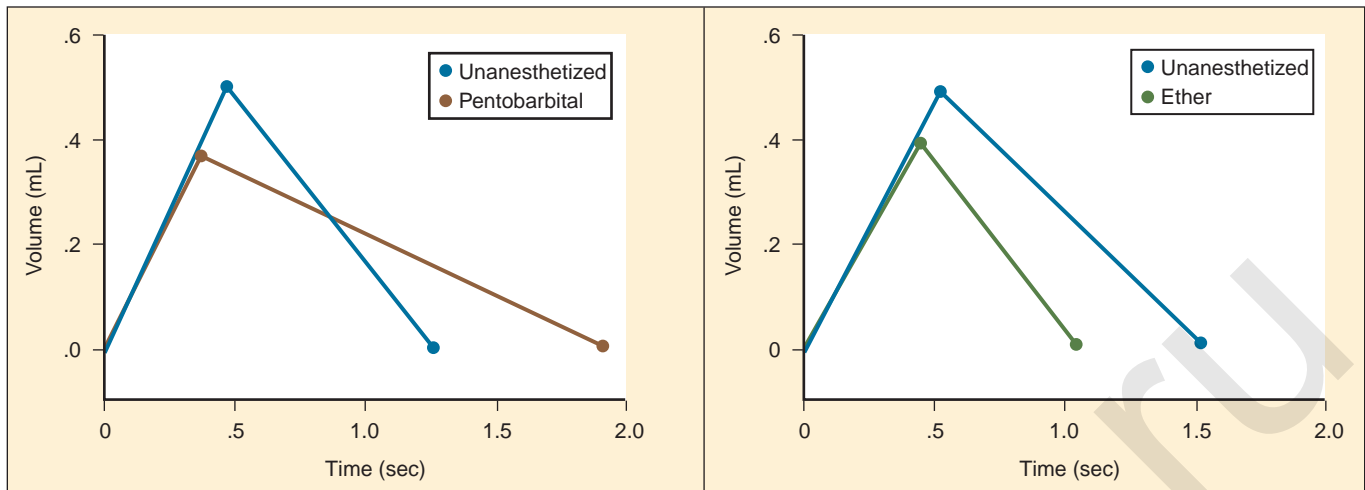

FIGURE 3-10. Schematic drawing of tidal volume and timing components on time-volume axes. V_T , Tidal volume; T_I , inspiratory time; T_E , expiratory time; T_{TOT} , total time for respiratory cycle; f , respiratory frequency; V_T/T_I , mean inspiratory flow rate; T_I/T_{TOT} , respiratory duty cycle.

flow (V_T/T_I , where V_T is tidal volume and T_I is the inspiratory time) and in terms of the ratio of inspiratory time to total ventilatory cycle duration or respiratory duty cycle (T_I/T_{TOT}) (Fig. 3-10). Because the tidal volume is equal to $V_T/T_I \times T_I$ and respiratory frequency (f) is $1/T_{TOT}$, ventilation can be expressed as follows:

$$\dot{V}_E = V_T \times f = V_T / T_I \times T_I / T_{TOT}$$

The advantage of analyzing the ventilatory response in this fashion is that V_T/T_I is an index of inspiratory drive, which is independent of the timing element. The tidal volume, on the other hand, is time dependent, because it is $(V_T/T_I) \times T_I$. The second parameter, T_I/T_{TOT} , is a dimensionless index of effective respiratory timing (respiratory duty cycle) that is determined by the vagal afferent or central inspiratory off-switch mechanism or by both (Bradley et al., 1975). From this equation, it is apparent that in respiratory disease or under anesthesia, changes in pulmonary ventilation may result from a change in V_T/T_I , T_I/T_{TOT} , or both. A reduction in T_I/T_{TOT} indicates that the relative duration of inspiration decreased or that expiration increased. Such a reduction in the T_I/T_{TOT} ratio may result from changes in central or peripheral mechanisms. In contrast, a reduction in V_T/T_I may indicate a decrease in the medullary inspiratory drive or neuromuscular transmission or an increase in inspiratory impedance (i.e., increased flow resistance, decreased compliance, or both). By relating the mouth occlusion pressure to V_T/T_I , it becomes clinically possible to determine whether changes in the mechanics of the respiratory system contribute to the reduction in V_T/T_I (Milic-Emili, 1977).

Analysis of inspiratory and expiratory durations provides useful information on the mechanism of anesthetic effects

■ **FIGURE 3-11.** Schematic summary of changes in the average respiratory cycle in a group of newborn rabbits before and after sodium pentobarbital anesthesia (*left*) and before and during ether anesthesia (*right*). Measurements obtained during spontaneous room air breathing. Zero on the time axis indicates onset of inspiration. Mean inspiratory flow is represented by the slope of the ascending limb of the spirograms. (Modified from Milic-Emili: *Recent advances in the evaluation of respiratory drive*, *Int Anesthesiol Clin* 15:75, 1977.)

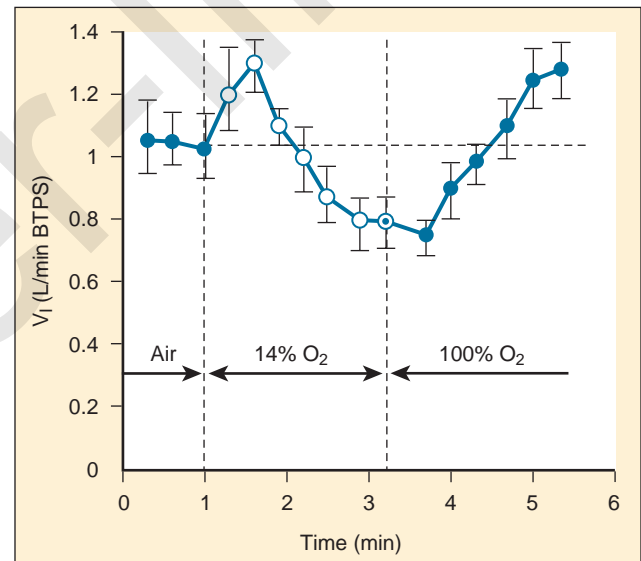

on ventilation. Figure 3-11 illustrates the effect of pentobarbital, which depresses minute ventilation, and diethyl ether, which “stimulates” ventilation in newborn rabbits. With both anesthetics the mean inspiratory flow (V_T/T_I) did not change, but V_T decreased because T_I was shortened. With pentobarbital, however, T_E was prolonged disproportionately, and T_I/T_{TOT} and frequency decreased; consequently, minute ventilation was decreased. With ether, on the other hand, ventilation increased as the result of disproportionate decrease in T_E and consequent increases in T_I/T_{TOT} and frequency (Milic-Emili, 1977).

Control of Breathing in Neonates and Infants

Response to Hypoxemia in Infants

During the first 2 to 3 weeks of age, both full-term and premature infants in a warm environment respond to hypoxemia (15% oxygen) with a transient increase in ventilation followed by sustained ventilatory depression (Brady and Ceruti, 1966; Rigatto and Brady, 1972a, 1972b; Rigatto et al., 1975a) (Fig. 3-12). In infants born at 32 to 37 weeks’ gestation, the initial period of transient hyperpnea is abolished in a cool environment, indicating the importance of maintaining a neutral thermal environment (Cross and Oppe, 1952; Ceruti, 1966; Perlstein et al., 1970). When 100% oxygen is given, a transient decrease in ventilation is followed by sustained hyperventilation. This ventilatory response to oxygen is similar to that of the fetus and is different from that of the adult, in whom a sustained decrease in ventilation is followed by little or no increase in ventilation (Dripps and Comroe, 1947). By 3 weeks after birth, hypoxemia induces sustained hyperventilation, as it does in older children and adults.

The biphasic depression in ventilation has been attributed to central depression rather than to depression of peripheral chemoreceptors (Albersheim et al., 1976). In newborn monkeys, however, tracheal occlusion pressure, an index of central neural drive, and diaphragmatic electromyographic output were increased above the control level during both the

■ **FIGURE 3-12.** Effect on ventilation of 14% oxygen (hypoxia) from room air and then to 100% oxygen (hyperoxia) in three newborn infants. Ventilation (mean \pm SEM) is plotted against time. During acute hypoxia there was a transient increase in ventilation followed by depression. Hyperoxia increased ventilation. (Modified from Lahiri S, et al.: *Regulation of breathing in newborns*, *J Appl Physiol* 44:673, 1978.)

hyperpneic and the hypopneic phases in response to hypoxic gas mixture (LaFramboise et al., 1981; LaFramboise and Woodrum, 1985). These findings imply that the biphasic ventilatory response to hypoxemia results from changes in the mechanics of the respiratory system (thoracic stiffness or airway obstruction), rather than from neuronal depression, as has been assumed (Jansen and Chernick, 1983). Premature infants continue to show a biphasic response to hypoxemia even at 25 days after birth (Rigatto, 1986). Thus, in terms of a proper response to hypoxic challenge, maturation of the respiratory system may be related to postconceptional rather than postnatal age.

Response to Carbon Dioxide in Infants

Newborn infants respond to hypercapnia by increasing ventilation but less so than do older infants. The slope of the CO₂ response curve increases appreciably with gestational age as well as with postnatal age, independent of postconceptional age (Rigatto et al., 1975a, 1975b, 1982; Frantz et al., 1976). This increase in slope may represent an increase in chemosensitivity, but it may also result from more effective mechanics of the respiratory system. In adults the CO₂ response curve both increases in slope and shifts to the left with the severity of hypoxemia (Fig. 3-8). In contrast, in newborn infants breathing 15% oxygen, the CO₂ response curve decreases in slope and shifts to the right (Fig. 3-13). Inversely, hyperoxemia increases the slope and shifts the curve to the left (Rigatto et al., 1975a).

Upper Airway Receptor Responses in the Neonatal Period

Newborn animals are particularly sensitive to the stimulation of the superior laryngeal nerve either directly or through the receptors (such as water in the larynx), which results in ventilatory depression or apnea. In anesthetized newborn puppies and kittens, negative pressure or air flow through the larynx isolated from the lower airways produced apnea or significant prolongation of inspiratory and expiratory time and a decrease in tidal volume, whereas similar stimulation caused little or no effect in 4- to 5-week-old puppies or in adult dogs and cats (Al-Shway and Mortola, 1982; Fisher et al., 1985).

In a similar preparation using puppies anesthetized with pentobarbital, water in the laryngeal lumen produced apnea, whereas phosphate buffer with sodium chloride and neutral pH did not. The principal stimulus for the apneic reflex was the absence or reduced concentrations of chloride ion (Boggs and

Bartlett, 1982). In awake newborn piglets, direct electric stimulation of the superior laryngeal nerve caused periodic breathing and apnea associated with marked decreases in respiratory frequency, hypoxemia, and hypercapnia with minimal cardiovascular effects. Breathing during superior laryngeal nerve stimulation was sustained by an arousal system (Donnelly and Haddad, 1986). The strong inhibitory responses elicited in newborn animals by various upper airway receptor stimulations have been attributed to the immaturity of the central nervous system (Lucier et al., 1979; Boggs and Bartlett, 1982).

Active Vs. Quiet Sleep

During the early postnatal period, full-term infants spend 50% of their sleep time in active or REM sleep compared with 20% REM sleep in adults (Stern et al., 1969; Rigatto et al., 1982). Wakefulness rarely occurs in neonates. Premature neonates stay in REM sleep most of the time, and quiet (non-REM) sleep is difficult to define before 32 weeks' postconception (Rigatto, 1992). Neonates, particularly prematurely born neonates, therefore breathe irregularly.

Neurologic and chemical control of breathing in infants is related to the state of sleep (Scher et al., 1992). During quiet sleep, breathing is regulated primarily by the medullary respiratory centers and breathing is regular with respect to timing as well as amplitude and is tightly linked to chemoreceptor input (Bryan and Wohl, 1986). During REM sleep, however, breathing is controlled primarily by the behavioral system and is irregular with respect to timing and amplitude (Phillipson, 1994).

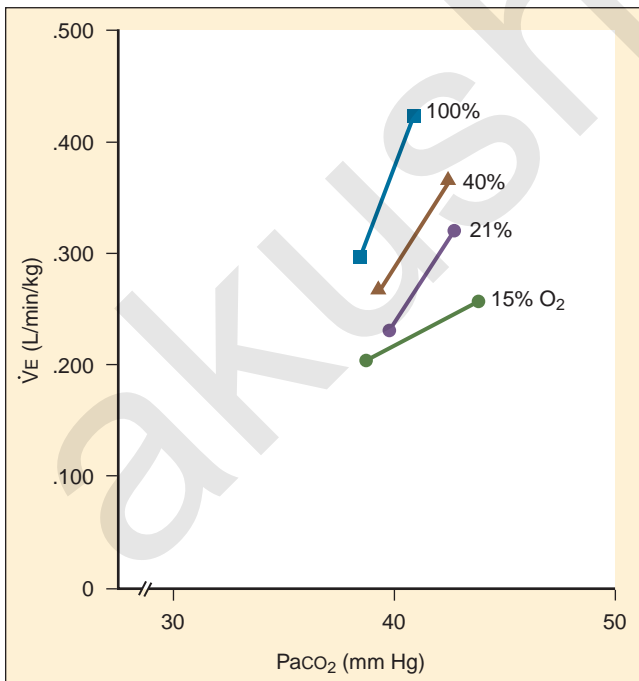

Periodic Breathing and Apnea

Periodic Breathing

Periodic breathing, in which breathing is interposed with repetitive short apneic spells lasting 5 to 10 seconds with minimal hemoglobin desaturation or cyanosis, occurs normally even in healthy neonates and young infants during wakefulness, REM sleep, and non-REM sleep (Rigatto et al., 1982). Periodic breathing tends to be more regular in quiet sleep than in active sleep and has been observed more often during active sleep (Rigatto et al., 1982) or during quiet sleep (Kelly et al., 1985). Minute ventilation increases during REM sleep due to increases in respiratory frequency with little change in tidal volume (Kalapezi et al., 1981; Rigatto et al., 1982).

An addition of 2% to 4% CO₂ to the inspired gas mixture abolishes periodic breathing, probably by causing respiratory stimulation (Chernick et al., 1964). Nevertheless, the ventilatory response to hypercapnia seems to be diminished during periodic breathing (Rigatto and Brady, 1972a). The decreased hypercapnic response appears to result from changes in respiratory mechanics rather than from a reduction in chemosensitivity, because respiratory center output as determined by airway occlusion pressure is greater during REM sleep than during non-REM sleep.

The incidence of periodic breathing was reported to be 78% in full-term neonates, whereas the incidence was much higher (93%) in preterm infants (mean postconceptional age of 37.5 weeks) (Kelly et al., 1985; Glotzbach et al., 1989). The incidence of periodic breathing diminishes with increasing post-conceptual age and decreases to 29% by 10 to 12 months of age (Fenner et al., 1973; Kelly et al., 1985).

■ **FIGURE 3-13.** Mean steady-state CO₂ response curves at different inspired oxygen concentrations in eight preterm infants. The slope of the CO₂ response decreases with decreasing oxygen. (From Rigatto H et al.: *Effects of O₂ on the ventilatory response*, J Appl Physiol 39:896, 1975.)

Apnea of Prematurity and Hypoxia

Central apnea of infancy is defined as cessation of breathing for 15 seconds or longer or a shorter respiratory pause associated with bradycardia (heart rate less than 100 beats/min, cyanosis, or pallor (Brooks, 1982). Apnea is common in preterm infants and may be related to an immature respiratory control mechanism (Jansen and Chernick, 1983). Most preterm infants with a birth weight of less than 2 kg have apneic spells at some time (Spitzer and Fox, 1984). Glotzbach and others (1989) reported a 55% incidence of central apnea in preterm infants, whereas it was rarely found in full-term infants (Kelly et al., 1985). These studies, however, were based on a relatively small number of infants admitted to a single institution.

The report by the Collaborative Home Infant Monitoring Evaluation (CHIME) Study Group has shed a new light on the understanding of the incidence and extent of apnea in infancy (Hunt et al., 1999; Ramanathan et al., 2001). The CHIME study was based on the recordings of respiratory inductive plethysmography, electrocardiography (ECG), and pulse oximetry in normal infants and those with increased risk of sudden infant death syndrome (SIDS), and it involved a total of 1079 infants during the first 6 months after birth (Hunt et al., 1999; Ramanathan et al., 2001). This report has revealed evidence that the control of breathing and oxygenation during sleep in healthy term infants are not as precise as have been assumed. Normal infants, up to 2% to 3%, commonly have prolonged central, obstructive, or mixed apnea lasting up to 30 seconds, which is associated with oxygen desaturation (Ramanathan et al., 2001). With a simple upper respiratory infection, prolonged obstructive sleep apneas were recorded in a few normal full-term infants but were present in 15% to 30% of preterm infants. The risk of having such episodes was 20 to 30 times higher among preterm infants than in full-term infants before 43 weeks' postconception (Hunt et al., 1999). Healthy term infants had an average baseline SpO₂ of 98% throughout the recorded period. However, hypoxemia (SpO₂ less than 90%, occasionally in the 70% to 80% range) occurred in 59% of these normal term infants in 0.6% of recorded cases (Hunt et al., 1999). Thus, levels of hypoxemia or hypoxia previously considered pathologic are relatively common occurrences among normal infants.

Apparent life-threatening events (ALTE) are characterized by an episode of sudden onset characterized by color change (cyanosis or pallor), tone change (limpness or rarely stiffness), and apnea, which requires immediate resuscitation to revive the infant and restore normal breathing (National Heart, Lung, and Blood Consensus Development Conference, National Institutes of Health, 1987). The incidence of ALTE is as high as 3% and may occur in previously healthy infants. Overnight polysomnography (PSG) is particularly useful in the evaluation of infants with a history of unexplained apnea. Treatable pathologic conditions, however, were found only in about 30% of infants, and thus normal PSG results are not necessarily diagnostic for the purpose of ruling out ALTE (Ramanathan et al., 2001).

Postoperative Apnea

Life-threatening apnea has been reported postoperatively in prematurely born infants earlier than 41 weeks' postconception, particularly in those with a history of apneic spells after simple surgical procedures, such as inguinal herniorrhaphy, and can occur up to 12 hours postoperatively (Steward, 1982;

Liu et al., 1983). These reports resulted in a general consensus among the pediatric anesthesiologists that infants younger than 44 weeks' postconception be admitted for overnight observation after inguinal hernia repair for safety. In a subsequent report, including various surgical procedures, apnea was reported in 4 of 18 prematurely born infants who were 49 to 55 weeks' postconceptional age (Kurth et al., 1987). The authors of this report proposed that premature infants younger than 60 weeks' postconception should be admitted for overnight observation, which raised a controversy as to what postconceptional age is safe and appropriate for the same-day discharge from the hospital for the prematurely born infant (Kurth et al., 1987). Malviya and others (1993) analyzed the relationship between the incidence of postoperative apnea and maturation. They reported a high incidence of postoperative apnea (26%) in infants younger than 44 weeks' postconception, whereas the incidence of apnea in those older than 44 weeks was only 3%.

Subsequently, Coté and others (1995) performed a meta-analysis of the data from previously published studies of postoperative apnea in premature infants after inguinal hernia repairs. They concluded that postoperative apnea was strongly and inversely correlated to both gestational age as well as postconceptual age and was associated with a previous history of apnea. The probability of postoperative apnea in those older than 44 weeks postconceptual age decreases significantly (to 5%) but still exists. Another important finding of this classic paper was that postoperative hypoxemia, hypothermia, and (most importantly) anemia (hematocrit value of less than 30) are significant risk factors regardless of gestational or postconceptual age (see Chapter 13, Induction, Maintenance, and Recovery). Most of these studies occurred in the period when infants were predominantly anesthetized with halothane and without regional (caudal) block to maintain a lighter level of anesthesia with spontaneous breathing during surgery. Postoperative apnea still exists with newer anesthetic agents (e.g., sevoflurane or desflurane), but appears to occur much less often.

Both theophylline and caffeine have been effective in reducing apneic spells in preterm infants (Aranda and Trumen, 1979). Caffeine is especially useful for premature infants during the postanesthetic period (Welborn et al., 1988). Xanthine derivatives are known to prevent muscle fatigue, and their respiratory stimulation in the premature infant may occur via both central and peripheral mechanisms (Aubier et al., 1981).

Maintenance of the Upper Airway and Airway Protective Reflexes

Pharyngeal Airway

The pharyngeal airway, unlike the laryngeal airway, is not supported by a rigid bony or cartilaginous structure. Its wall consists of soft tissues and is surrounded by muscles for breathing and for swallowing and is contained in a fixed bony structure (i.e., the maxilla, mandible, and spine) (Isono, 2006). Anatomic imbalance between the bony structure (the container—micrognathia, facial anomalies) and the amount of the soft tissues (the content—macroglossia, adenotonsillar hypertrophy, obesity) would result in the pharyngeal airway narrowing and obstruction (Fig. 3-14) (Isono, 2006).

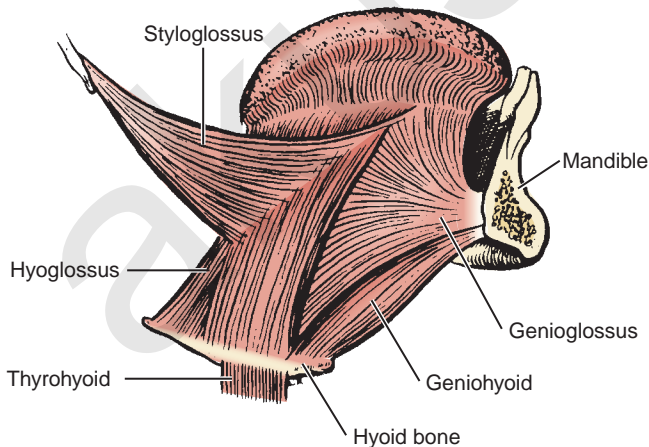

Even the normal pharyngeal airway is easily obstructed by the relaxation of the velopharynx (soft palate), posterior displacement of the mandible (and the base of the tongue) in the

■ **FIGURE 3-14.** A mechanical model of the pharyngeal airway (right) is produced based on structures surrounding the pharyngeal airway on a CT scan (left). (From Isono S: *Developmental changes of pharyngeal airway patency: implications for pediatric anesthesia*, *Pediatr Anesth* 16:109, 2006.)

supine position during sleep, flexion of the neck, or external compression over the hyoid bone. The pharyngeal airway also is easily collapsed by negative pressure within the pharyngeal lumen created by inspiratory effort, especially when airway-maintaining muscles are depressed or paralyzed (Issa and Sullivan, 1984; Reed et al., 1985; Roberts et al., 1985). In neonates, with a relatively hypoplastic mandible, the oropharynx and the entrance to the larynx at the level of the aryepiglottic folds are the areas most easily collapsed (Reed et al., 1985).

Mechanical support to sustain the patency of the pharynx against the collapsing force of luminal negative pressure during inspiration is given by both the sustained muscle tension and cyclic contraction of the pharyngeal dilator muscles, acting synchronously with the contraction of the diaphragm. These include the genioglossus, geniohyoid, sternohyoid, sternothyroid, and thyrohyoid muscles (Fig. 3-15) (Bartlett et al., 1973; Pack et al., 1988; Thach, 1992). Similar phasic activities have

■ **FIGURE 3-15.** Lateral view of the musculature of the tongue and its relationship with a mandible and hyoid bone. (From Kuna ST, Remmers JE: *Pathophysiology and mechanisms of sleep apnea*. In Fletcher EC, editor: *Abnormalities of respiration during sleep*, Orlando, FL, 1986, Grune & Stratton.)

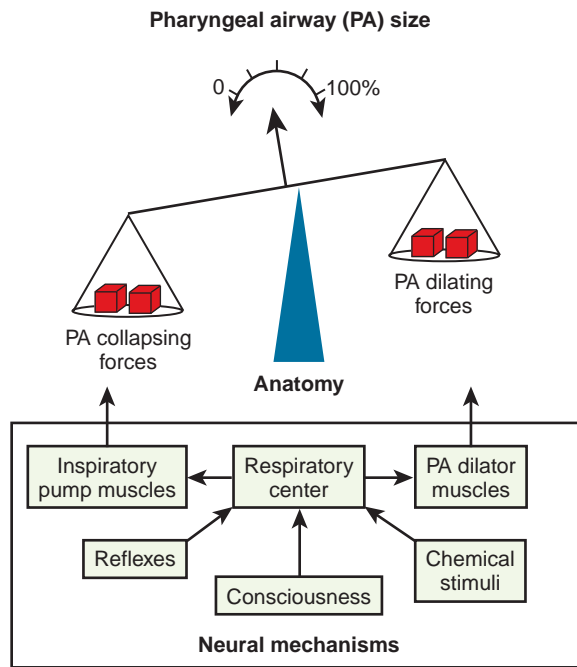

been recorded in the scalene and sternomastoid muscles in humans (Onal et al., 1981; Drummond, 1987).

A neural balance model of pharyngeal airway maintenance proposed by Remmers et al. (1978) and Brouillette and Thach (1979) and further modified by Isono (2006) is shown in Figure 3-16. In this model, the suction (collapsing) force created in the pharyngeal lumen by the inspiratory pump muscles (primarily the diaphragm) must be well balanced by the activities of pharyngeal airway dilator muscles to maintain upper airway patency. Increased nasal and pharyngeal airway resistance (partial obstruction) exaggerates the suction force. In addition, once pharyngeal closure occurs, the mucosal adhesion force of the collapsed pharyngeal wall becomes an added force acting against the opening of pharyngeal air passages (Reed et al., 1985).

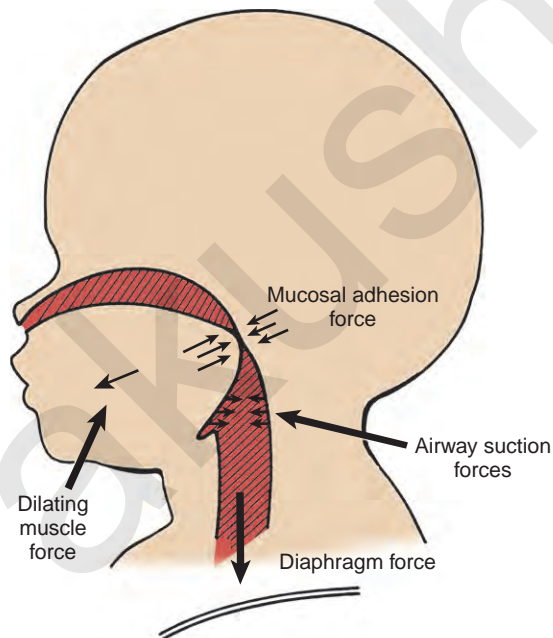

Several reflex mechanisms are present to maintain the balance between the dilating and collapsing forces in the pharynx. Chemoreceptor stimuli such as hypercapnia and hypoxemia stimulate the airway dilators preferentially over the stimulation of the diaphragm so as to maintain airway patency (Brouillette and Thach, 1980; Onal et al., 1981, 1982). Negative pressure in the nose, pharynx, or larynx activates the pharyngeal dilator muscles and simultaneously decreases the diaphragmatic activity (Fig. 3-17) (Mathew et al., 1982a, 1982b; Hwang et al., 1984; Thach, 1992). Such an airway pressure reflex is especially prominent in infants younger than 1 year of age (Thach et al., 1989). Upper airway mechanoreceptors are located superficially in the airway mucosa and are easily blocked by topical anesthesia (Mathew et al., 1982a, 1982b). Sleep, sedatives, and anesthesia depress upper airway muscles more than they do the diaphragm (Sauerland and Harper, 1976; Ochiai et al., 1989, 1992). The arousal from sleep shifts the balance toward pharyngeal dilation (Thach, 1992).

Laryngeal Airway

The larynx is composed of a group of cartilage, connecting ligaments, and muscles. It maintains the airway, and the glottis functions as a valve to occlude and protect the lower airways from the alimentary tract. It is also an organ for phonation (Proctor, 1977a, 1977b, 1986; Fink and Demarest, 1978). With

■ **FIGURE 3-16.** A neural and anatomic balance model of the pharyngeal airway (PA) maintenance by Remmers et al. (1978) in adults and Brouillette and Thach (1979) in infants illustrating the balance of opposing forces that affect PA size. Airway collapsing forces (suction force created by inspiratory pump muscles) and dilating forces (pharyngeal dilator muscles) are shown on either side of the fulcrum, and neural mechanisms controlling this balance are in the box below the balance. (Redrawn from Isono S: *Developmental changes of pharyngeal airway patency: implications for pediatric anesthesia*, *Pediatr Anesth* 16:109, 2006.)

■ **FIGURE 3-17.** Schematic illustration of sequence of events showing one of the ways in which the upper airway pressure reflex operates to preserve pharyngeal airway patency. (From Thach BT: *Neuromuscular control of the upper airway*. In Beckerman RC et al., editors: *Respiratory control disorders in infants and children*, Baltimore, 1992, Williams & Wilkins.)

the exception of the anterior nasal passages, the larynx at the subglottis is the narrowest portion of the entire airway system in all ages (Eckenhoff, 1951). The cricoid cartilage forms a complete ring, protecting the upper airway from compression.

For over half a century, the shape of pediatric larynx was thought to be “funnel shaped,” with the narrowest point at the laryngeal exit (cricoid ring), in contrast to the adult larynx, which is “cylindrical” in shape. This belief was based on the well-referenced classic paper by Eckenhoff in 1951; Eckenhoff quoted the work of Bayeux in 1897, more than half a century before his time, whose description was based on moulages (plaster casting) made from cadaveric larynx from 15 children between the ages of 4 months and 14 years. Indeed, Eckenhoff’s original paper cautioned that “the measurements so derived may not be completely applicable to the living” (Eckenhoff, 1951; Motoyama, 2009). More recently, however, both Litman and colleagues (2003) and Dalal and colleagues (2009) using two entirely different methodologies in living infants and children under general anesthesia, found that the dimensions of the larynx in infants and children are more cylindrical than funnel-shaped, as in adults, and the cylindrical shape does not change significantly with growth. In addition, both Litman and Dalal’s papers confirmed that the cricoid opening is the narrowest point of the larynx; however, in paralyzed children the opening at the vocal cords (larynx glottidis) may be narrower than the opening of the cricoid cartilage, but it is expandable beyond the opening of the cricoid ring (Eckenhoff, 1951; Dalal et al., 2009). Perhaps more important clinically, both groups found with statistical significance that the cricoid opening is not circular but mildly elliptical with a smaller transverse diameter. This means that a tight-fitting, uncuffed endotracheal tube or even a “best-fitted” tube in young children with acceptable pressure leak (i.e., 20 cm H₂O) would exert more compression, if not ischemia, on the transverse mucosa of the cricoid ring (Motoyama, 2009). This finding provides theoretic evidence and further supports the recent trend of favoring cuffed endotracheal tubes over uncuffed endotracheal tubes in infants and children for their safety.

The glottis widens slightly during tidal inspiration and narrows during expiration, thus increasing laryngeal air flow resistance (Bartlett et al., 1973). Laryngeal resistance is finely regulated in neonates and young infants to dynamically maintain end expiratory lung volume (FRC) well above the small lung volume determined by the opposing elastic recoil forces of the thorax and the lungs, as is discussed in a later part of this chapter (Harding, 1984; England and Stogren, 1986). In infants with IRDS, expiration is often associated with “grunting” caused by narrowing of the glottic aperture. This grunting apparently maintains intrinsic positive end-expiratory pressure (PEEP), also known as $PEEP_i$ or *autoPEEP*, during the expiratory phase and presumably prevent or reduce premature closure of airways and air spaces. In infants with IRDS, when grunting is eliminated by endotracheal intubation, respiratory gas exchange deteriorates rapidly and critically to the point of cardiorespiratory arrest unless continuous positive airway pressure (CPAP) is applied (Gregory et al., 1971).

Airway Protective Reflexes

Upper airway protective mechanisms involve both the pharynx and larynx and include sneezing, swallowing, coughing, and pharyngeal or laryngeal closure. Laryngospasm is a sustained tight closure of the vocal cords caused by the stimulation of the

superior laryngeal nerve, a branch of the vagus, and contraction of the adductor muscles that persists beyond the removal of the stimulus. In puppies, it is elicited by repetitive stimulation of the superior laryngeal nerve with typical adductor after-discharge activity. This response is not evoked by the stimulation of the recurrent laryngeal nerve (Suzuki and Sasaki, 1977). Hyperventilation and hypocapnia, as well as light anesthesia, increase the activity of adductor neurons, reduce the mean threshold of the adductor reflex, or increase upper airway resistance (Suzuki and Sasaki, 1977; Nishino et al., 1981). Hyperthermia and decreased lung volume also facilitate laryngospasm produced by stimulation of the superior laryngeal nerve (Sasaki, 1979; Haraguchi et al., 1983). Contrarily, hypoventilation and hypercapnia, positive intrathoracic pressure, and deep anesthesia depress excitatory adductor after-discharge activity and increase the threshold of the reflex that precipitates laryngospasm (Suzuki and Sasaki, 1977; Ikari and Sasaki, 1980; Nishino et al., 1981). Hypoxia below an arterial P_{O_2} of 50 mm Hg also increases the threshold for laryngospasm (Ikari and Sasaki, 1980).

These findings are clinically relevant, suggesting a fail-safe mechanism by which asphyxia (hypoxia and hypercapnia) tends to prevent sustained laryngospasm. In healthy, awake adults, laryngospasm by itself is self-limited and not a threat to life. On the other hand, in the presence of cardiopulmonary compromise, such as may occur during anesthesia (particularly in infants), laryngospasm may indeed become life threatening (Ikari and Sasaki, 1980). Increased depth of anesthesia increases the reflex threshold and diminishes excitatory adductor after discharge in puppies (Suzuki and Sasaki, 1977). This finding is in accord with the clinical experience that laryngospasm occurs most readily under light anesthesia and that it can be broken by deepening anesthesia or awakening the patient. In puppies, positive intrathoracic pressure inhibits the glottic closure reflex and laryngospasm. This supports the clinical observation that during the emergence from anesthesia in infants and young children, maintenance of PEEP and inflation of the lungs at the time of extubation seem to reduce both the incidence and severity of laryngospasm (Motoyama, unpublished observation).

Infants are particularly vulnerable to laryngospasm. Animal studies suggest that during a discrete interval after birth and before complete neurologic maturation, there is a period of transient laryngeal hyperexcitability. This may relate to the transient reduction in central latency and a reduction in central inhibition of the vagal afferent nerve. If these observations in puppies are applicable to human infants, they may explain the susceptibility of infants and young children to laryngospasm and have some causal relation in unexpected infant death such as SIDS (Sasaki, 1979).

Infants, particularly premature neonates, exhibit clinically important airway protective responses to fluid at the entrance to the larynx (Davies et al., 1988; Pickens et al., 1989). This response seems to trigger prolonged apnea in neonates and breath-holding during inhalation induction of anesthesia in children. When a small quantity (less than 1 mL) of warm saline solution is dripped into the nasopharynx in a sleeping infant, it pools in the piriform fossa and then overflows into the interarytenoid space at the entrance to the larynx. This area is densely populated with various nerve endings, including a structure resembling a taste bud. The most common response to fluid accumulation is swallowing. The infant also develops central apnea with either the glottis open or closed; coughing

is rare (Pickens et al., 1989). Apneic responses are more prominent with water than with saline solution (Davies et al., 1988).

These findings appear clinically important in pediatric anesthesia. During inhalation induction, pharyngeal reflexes (swallowing) are abolished, whereas laryngeal reflexes remain intact, as Guedel (1937) originally described for ether anesthesia. Secretions would accumulate in the hypopharynx without swallowing and cause breath-holding, resulting from central apnea, a closure of the glottis, or both. Positive pressure ventilation using a mask and bag instead of suctioning the pharynx would push secretions farther down into the larynx, stimulate the superior laryngeal nerve, and trigger real laryngospasm.

Anesthetic Effects on Control of Breathing

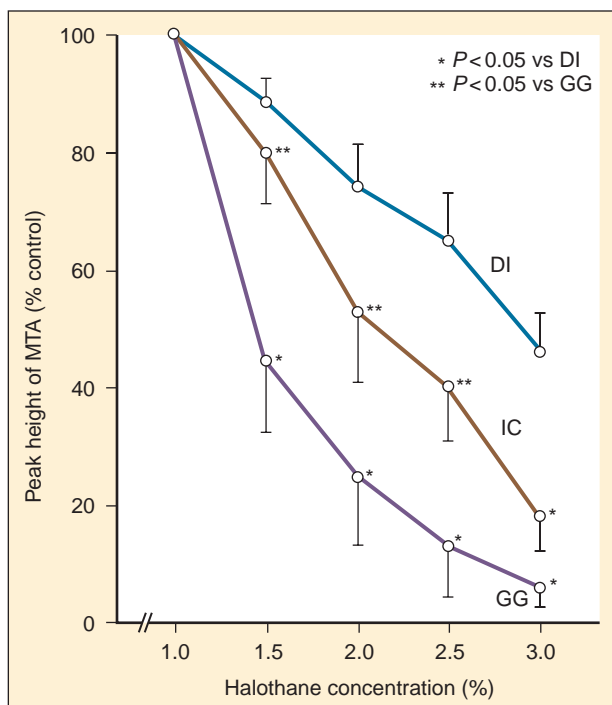

Effects of Anesthetic on Upper Airway Receptors

Inhalation induction of anesthesia is often associated with reflex responses such as coughing, breath-holding, and laryngospasm. Volatile anesthetics stimulate upper airway receptors directly and affect ventilation. In dogs spontaneously breathing through tracheostomy under urethane-chloralose anesthesia, an exposure of isolated upper airways to halothane caused depression of respiratory-modulated mechanoreceptors or pressure receptors, whereas irritant receptors and flow (cold) receptors were consistently stimulated in a dose-dependent manner (Nishino et al., 1993). Responses to isoflurane and enflurane were less consistent. Laryngeal respiratory-modulated mechanoreceptors may be a part of a feedback mechanism that maintains the patency of upper airways; the depression of this feedback mechanism may play an important role in the collapse of upper airways during the induction of anesthesia. Furthermore, activation of irritant receptors by halothane and other volatile anesthetics may be responsible for laryngeal reflexes such as coughing, apnea, laryngospasm, and bronchoconstriction seen during inhalation induction of anesthesia (Nishino et al., 1993).

The same group of investigators showed that in young puppies (younger than 2 weeks old), exposure of isolated upper airways to halothane (and to a lesser extent to isoflurane) resulted in a marked depression of ventilation (less than 40% of control) associated with decreases in both tidal volume and respiratory frequency (Sant'Ambrogio et al., 1993). Ventilatory effects caused by the exposure of isolated upper airways to volatile anesthetics were present but only mildly in 4-week-old puppies, whereas adult dogs were not affected. The superior laryngeal nerve section and topical anesthesia of the nasal cavity completely abolished the effects of halothane and isoflurane in the isolated upper airways of puppies (Sant'Ambrogio et al., 1993). Laryngeal receptor output in response to volatile anesthetics was not measured in this study. These findings in puppies appear to be clinically relevant because infants and young children often develop manifestations of upper airway reflexes during inhalation induction.

Effects of Anesthetics on Upper Airway Muscles

The genioglossus, geniohyoid, and other pharyngeal and laryngeal abductor muscles have phasic inspiratory activity synchronous with diaphragmatic contraction, in addition to their tonic activities that maintain upper airway patency in both animals and human neonates (Bartlett et al., 1973; Brouillette

■ **FIGURE 3-18.** Decrease in phasic inspiratory muscle activity, expressed as peak height of moving time average (MTA), in percent change from control (1% halothane), during halothane anesthesia in adult cats. Values are mean \pm SEM. * $P < 0.05$ compared with the diaphragm (DI); ** $P < 0.05$ compared with the genioglossus muscle (GG). (From Ochiai R et al.: *Effects of varying concentrations of halothane on the activity of the genioglossus, intercostals, and diaphragm in cats: an electromyographic study*, *Anesthesiology* 70:812, 1989.)

and Thach, 1979). The genioglossus and geniohyoid muscles increase the caliber of the pharynx by displacing the hyoid bone and the tongue anteriorly and are the most important muscles for the maintenance of oropharynx patency (Fig. 3-15). They have both phasic inspiratory activity and tonic activity throughout the respiratory cycle in awake humans (Onal et al., 1981). These activities of the genioglossus muscle and presumably other pharyngeal and laryngeal abductor muscles are easily depressed by alcohol ingestion, sleep, and general anesthesia; their depression would result in upper airway obstruction (Remmers et al., 1978; Brouillette and Thach, 1979; Nishino et al., 1984, 1985; Bartlett et al., 1990).

Sensitivity to anesthetics differs among various inspiratory muscles and their neurons. In studies in cats with the use of electromyography, Ochiai et al. (1989) demonstrated that the phasic inspiratory activity of the genioglossus muscle was most sensitive to the depressant effect of halothane at a given concentration, whereas the diaphragm was most resistant; the sensitivity of inspiratory intercostal muscles was intermediate (Fig. 3-18). In addition, phasic genioglossus activity was more readily depressed in kittens than in adult cats. Phasic genioglossus activity was completely abolished with 1.5% halothane or more in all kittens studied, whereas the activity was diminished but present in most adult cats even at 2.5% (Ochiai et al., 1992).

Early depression of the genioglossus muscle and other pharyngeal dilator muscles appears to be responsible for upper airway obstruction in infants and young children, especially during

the induction of inhalation anesthesia. Because of the higher sensitivity to anesthetic depression, the upper airway muscles failed to increase the intensity of contraction to keep the pharynx patent while the diaphragm continues to contract vigorously and the negative feedback mechanism to attenuate its contraction may be diminished or lost (Brouillette and Thach, 1979; Ochiai et al., 1989; Isono et al., 2002). Partial upper airway obstruction may occur more often in infants and young children than is clinically apparent during anesthesia by mask without an oral airway. Keidan et al. (2000) found in infants and children breathing spontaneously under halothane anesthesia that the work of breathing (as an index of the degree of upper airway obstruction) significantly increased when breathing by mask without an oral airway than with an oral airway in place, even when partial upper airway obstruction was not clinically apparent. An addition of CPAP (5 to 6 cm H₂O) further improved airway patency as evidenced by significant decreases in the work of breathing (Keidan et al., 2000).

Effects of Anesthetic on Neural Control of Breathing

Most general anesthetics, opioids, and sedatives depress ventilation. They variably affect minute ventilation (\dot{V}_E), its components (V_T , f , V_T/T_I), and respiratory duty cycle (T_I/T_{TOT}). All inhaled anesthetics significantly depress ventilation in a dose-dependent fashion (Fig. 3-9). This subject has been extensively reviewed; information in human infants and children, however, remains limited (Hickey and Severinghaus, 1981; Pavlin and Hornbein, 1986).

Studies in adult human volunteers using the occlusion technique and the timing component analysis have indicated that the reduction in tidal volume with anesthetics results primarily from a reduction in the neural drive of ventilation (Milic-Emili and Grunstein, 1975; Whitelaw et al., 1975; Derenne et al., 1976; Wahba, 1980). Inspiratory time tends to decrease, but the respiratory duty cycle is relatively unaffected. In several studies in children 2 to 5 years of age, breathing was relatively well maintained at a light level of halothane (0.5 minimum alveolar concentration [MAC]) (Murat et al., 1985; Lindahl et al., 1987; Benameur et al., 1993). In deeper, surgical levels of anesthesia (1.0 to 1.5 MAC), breathing was depressed in a dose-dependent manner and hypercapnia resulted. Decreased \dot{V}_E was associated with reduced V_T and increased respiratory frequency. The neural respiratory drive was depressed as evidenced by reduced V_T/T_I , whereas the duty cycle (T_I/T_{TOT}) either tended to increase without changes in T_I or decreased slightly (Murat et al., 1985; Lindahl et al., 1987; Benameur et al., 1993). In infants younger than 12 months of age, ventilatory depression was more pronounced and the duty cycle did not increase, partly because of high chest-wall compliance and pronounced thoracic deformity (thoracoabdominal asynchrony) compared with older children (Benameur et al., 1993).

When an external load was imposed on the airway system of an awake individual, ventilation was maintained by increased inspiratory effort (Whitelaw et al., 1975). This response was greatly diminished or abolished by the effect of general anesthetics, opioids, and barbiturates (Nunn and Ezi-Ashi, 1966; Isaza et al., 1976; Kryger et al., 1976b; Savoy et al., 1982). In children under light halothane anesthesia (0.5 MAC), an addition of a resistive load initially decreased tidal volume. However, tidal volume returned to baseline within 5 minutes (Lindahl et al., 1987).

Effects of Anesthetic on Chemical Control of Breathing

In the dog, inhaled anesthetics diminish or abolish the ventilatory response to hypoxemia in a dose-dependent manner (Weiskopf et al., 1974; Hirshman et al., 1977). In human adult volunteers, the hypoxic ventilatory response was disproportionately depressed in light halothane anesthesia compared with the response to hypercapnia (Knill and Gelb, 1978). At 1.1 MAC of halothane, the hypoxic ventilatory response was completely abolished, whereas the hypercapnic response was about 40% of control in the awake state. Even at a subanesthetic or trace level (0.05 to 0.1 MAC), halothane, isoflurane, and enflurane attenuated the hypoxic ventilatory response to about 30% of the control group, whereas hypercapnic response was essentially intact (Knill and Gelb, 1978; Knill and Clement, 1984). The site of the anesthetics' action appears to be at the peripheral (carotid) chemoreceptors, because of the rapid response in humans as well as the direct measurement of neuronal chemoreceptor output in the cat (Davies et al., 1982; Knill and Clement, 1984).

Subsequently, Temp and others (1992, 1994) challenged these findings by demonstrating that 0.1 MAC of isoflurane had no demonstrable ventilatory effect on hypoxia. On the other hand, Dahan and others (1994) confirmed the original findings by Knill and Gelb (1978). The reason for the conflicting results appeared to be related to the contribution of visual and auditory inputs (Robotham, 1994). The study by Temp and others (1994) was conducted while the volunteers were watching television (open-eyed), whereas the volunteers in the study by Dahan and others (1994) were listening to soothing music with their eyes closed (but not asleep).

Pandit (2004) conducted a meta-analysis of 37 studies in 21 publications and analyzed the conflicting response to hypoxia under trace levels of anesthetics. Pandit's analysis supported the prediction by Robotham (1994) that the study condition has a major impact on the outcome of the study. Pandit concluded that the main factor for the difference in hypoxic response was the anesthetic agent used ($p < 0.002$). Additional factors included subject stimulation ($p < 0.014$) and agent-stimulation interaction ($p < 0.04$), whereas the rate of induction of hypoxia or the level of P_{CO_2} had no effect (Pandit, 2000).

The effect of subanesthetic concentrations of inhaled anesthetics on ventilation in infants and children has not been studied. However, high incidences of postoperative hypoxemia in otherwise healthy infants and children without an apparent hypoxic ventilatory response in the postanesthetic period suggest that the hypoxic ventilatory drive in infants and children may be blunted with the presence of residual, subanesthetic levels of inhaled anesthetics (Motoyama and Glazener, 1986).

Summary

The understanding of the control of breathing during the perinatal and early postnatal periods has increased significantly. In general, neural and chemical controls of breathing in older infants and children are similar to those in adolescents and adults. A major exception to this general statement is found in neonates and young infants, especially prematurely born infants younger than 40 to 44 weeks' postconception. In these infants, hypoxemia is a potent respiratory depressant, rather than a stimulant, either centrally or because of changes in respiratory mechanics. These infants often develop periodic breathing without apparent hypoxemia, and occasionally they experience

central apnea with possible serious consequences, most likely because of immature respiratory control mechanisms.

LUNG VOLUMES

Postnatal Development of the Lungs

In the human fetus, alveolar formation does not begin until about 4 weeks before birth, although development of the airways, including the terminal bronchioles, are completed by 16 weeks' gestation (Reid, 1967; Langston et al., 1984). The full-term newborn infant has 20 to 50 million terminal airspaces, mostly primitive saccules from which alveoli later develop (Thurlbeck, 1975; Langston et al., 1984). During the early postnatal years, development and growth of the lungs continue at a rapid pace, particularly with respect to the development of new alveoli. By 12 to 18 months of age, the number of alveoli reaches the adult level of 400 million or more; subsequent lung development and growth are associated with increases in alveolar size as well as further structural development (see Development of the Respiratory System) (Dunnill, 1962; Langston et al., 1984).

During the early period of postnatal lung development, the lung volume of infants is disproportionately small in relation to body size. Furthermore, because the infant's metabolic rate in relation to body weight is nearly twice that of the adult, the ventilatory requirement per unit of lung volume in infants is greatly increased. Infants seem to have far less reserve in lung surface area for gas exchange. Furthermore, general anesthesia markedly reduces the end expiratory lung volume (FRC, or relaxation volume, V_r), especially in young infants, reducing their oxygen reserve severely. Normal values for lung volumes and function in persons of various ages are compiled in Table 3-2.

Total lung capacity (TLC) is the maximum lung volume allowed by the strength of the inspiratory muscles stretching the thorax and lungs. Subdivisions of TLC are shown schematically in Figure 3-19. Residual volume (RV) is the amount of air remaining in the lungs after maximum expiration and is approximately 25% of TLC in healthy children. FRC is determined by the balance between the outward stretch of the thorax and the inward recoil of the lungs and is normally roughly 50% of TLC in the upright posture in healthy children and young adults; it is about 40% when they are in the supine position (Fig. 3-20). The two opposing forces create an average negative average pleural pressure of approximately -5 cm H_2O in older children and adults. In the neonate the pleural pressure is only slightly negative or nearly atmospheric.

Functional Residual Capacity and Its Determinants

In infants, outward recoil of the thorax is exceedingly low, and inward recoil of the lungs is only slightly lower than that of adults (Agostoni, 1959; Bryan and Wohl, 1986). Consequently, the FRC (or, more appropriately, V_r) of young infants at static conditions (e.g., apnea, under general anesthesia, or paralysis) decreases to 10% to 15% of TLC, a level incompatible with normal gas exchange because of airway closure, atelectasis, and V/Q imbalance (Fig. 3-21) (Agostoni, 1959). In awake infants and young children, however, FRC is dynamically maintained by a number of mechanisms for preventing the collapse of the

lungs, including a sustained inspiratory muscle tension to make the thorax stiffer (Box 3-2) (see Elastic Properties). FRC in young infants is therefore dynamically determined; there is no fixed level of FRC.

In normal children and adolescents, lung volumes are related to body size, especially height. In most instances, the relative size of the lung compartment appears to be approximately constant from school-aged children to young adults (see Table 3-2). A study in anesthetized and paralyzed infants and children indicates that TLC, as measured with a tracer gas washout technique, is relatively small in infants (60 mL/kg) when the lungs are inflated with relatively low inflation pressure (20 to 25 cm H₂O; the recruitment of previously collapsed air space with this

pressure might not have been complete) (Thorsteinsson et al., 1994). TLC in children older than 1.5 years of age (determined with inflation pressures of 35 to 40 cm H₂O) increases with growth until about 5 years of age (body weight, 20 kg), when it reaches that of older children and adolescents (90 mL/kg).

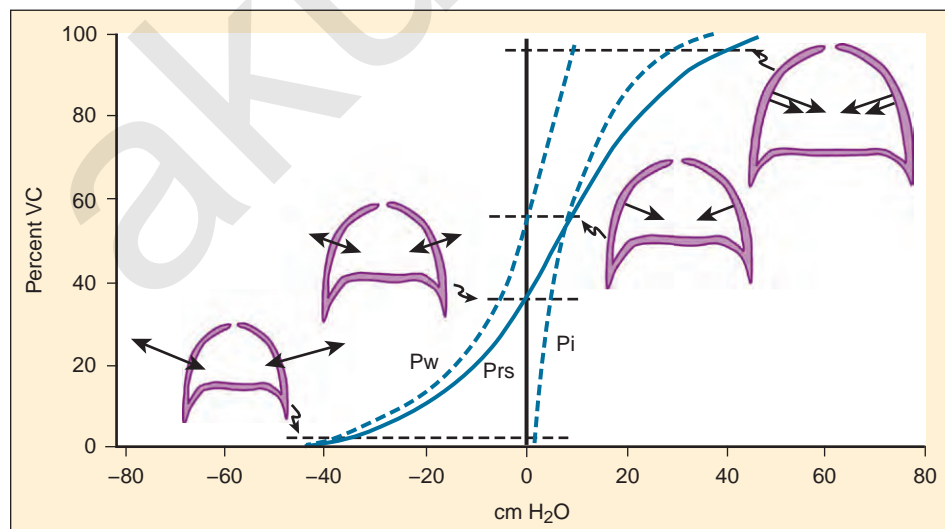

Negative pressure surrounding the lungs is the same, with respect to lung expansion, as positive pressure within the airways; thus, the net transpulmonary pressure represents the force expanding or contracting the lungs. In contrast, negative intrathoracic pressure has quite a different effect from positive airway pressure with respect to pulmonary circulation and the ventilation/pulmonary perfusion relationship.

Anesthesia, surgery, abdominal distention, and disease may all alter lung volumes. The patient in the prone or supine position has a smaller FRC than the patient standing or sitting, because the abdominal contents shift. FRC is further decreased under general anesthesia with or without muscle relaxants (Westbrook et al., 1973). (see Effect of General Anesthesia on FRC)

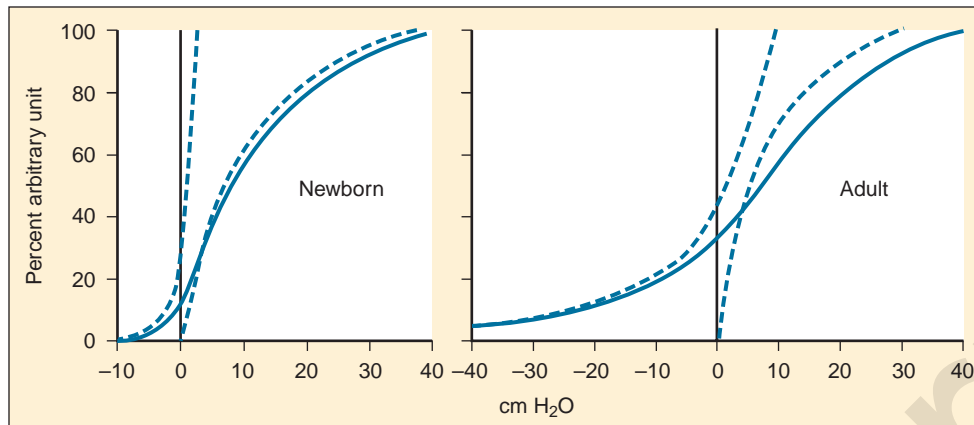

The importance of the air remaining in the lungs at the end of normal expiration is often overlooked. This gas volume (FRC) serves as a buffer to minimize cyclic changes in P_{CO₂} and P_{O₂} of the blood during each breath. In addition, the fact that air normally remains in the lungs throughout the respiratory cycle means that relatively few alveoli collapse. Although alveolar collapse does not occur during normal breathing in healthy, awake infants and children, unusually high pressures are needed to expand the lungs when they are liquid filled at birth, collapsed after open-chest surgery, or during general anesthesia without the maintenance of PEEP, especially in young infants (von Ungern-Sternbery, 2006). Transpulmonary pressure of 30 to 40 cm H₂O (and occasionally even more) is needed to reexpand the collapsed lungs. Thereafter, 5 to 7 cm H₂O of PEEP appears adequate to prevent airway closure and to maintain FRC.

Mechanics of Breathing

To ventilate the lungs, the respiratory muscles must overcome certain opposing forces within the lungs themselves. These forces have both elastic and resistive properties. Although respiratory mechanics in adults have been studied extensively

■ **FIGURE 3-20.** Static volume-pressure curves of the lung (*P_i*), chest wall (*P_w*), and respiratory system (*P_{rs}*) during relaxation in the sitting position. The static forces of the lung and chest wall are pictured by the arrows in the side drawings. The dimensions of the arrows are not to scale; the volume corresponding to each drawing is indicated by the horizontal broken lines. (From Agostoni E, Mead J: *Statics of the respiratory system*. over the past five decades, most available information on infants and young children has emerged relatively recently (Bryan and Wohl, 1986; ATS/ERS Joint Committee, 1993).

Elastic Properties

Compliance of the Lungs and Thorax

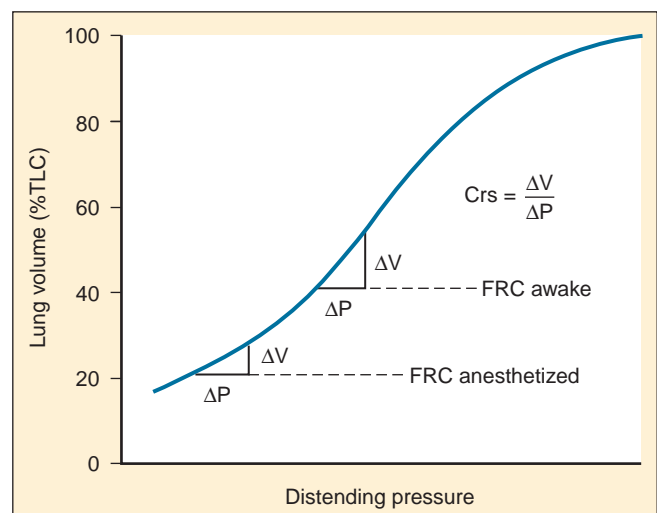

When the lungs are expanded by the contraction of inspiratory muscles or by positive pressure applied to the airways, elastic recoil of the lungs and thoracic structures surrounding the lungs counteracts to reduce lung volume. This elastic force is fairly constant over the range of normal tidal volumes, but it increases at the extremes of deflation or inflation (Fig. 3-22). The elastic properties of the lungs and respiratory system (lungs and thorax) are measured and expressed as lung compliance (C_L) or respiratory system compliance (C_{rs}) in units of volume change per unit of pressure change. The following equation is derived:

$$C_L = \Delta V / \Delta P$$

where ΔV is usually the tidal volume and ΔP is the change in transpulmonary pressure (the difference between the airway and pleural pressures [$\Delta P = P_{ao} - P_{pl}$]) for C_L , and for C_{rs} , ΔP is transrespiratory pressure (the difference between the airway pressure at end-inspiratory occlusion and atmospheric pressure

[$\Delta P = P_{ao} - P_b$]) necessary to produce the tidal volume. These measurements are made at points of no flow, that is, at the extremes of tidal volume when there is no flow-resistive component (static compliance). Lung compliance may vary with changes in the midposition of tidal ventilation with no inherent alteration in the elastic characteristics of the lungs (Fig. 3-22). The elastic properties of the lungs are described more accurately by measuring pressure-volume relationships over the entire range of TLC.

In normal persons, lung compliance measured during the respiratory cycle (i.e., the dynamic compliance during quiet breathing) is approximately the same as the static compliance. When there is airway obstruction, however, the ventilation of some lung units may be functionally decreased, resulting in decreased dynamic compliance, whereas the static compliance is relatively unaffected. This difference between static and

■ **FIGURE 3-22.** Schematic representation of the pressure-volume (P-V) curve and compliance of the respiratory system (C_{rs}). At the midpoint of the P-V curve (indicated as FRC awake), the slope and compliance ($C_{rs} = \Delta P / \Delta V$) are the highest. When FRC is decreased to the lower, flatter portion of the P-V curve under general anesthesia or paralysis (indicated as FRC anesthetized), C_{rs} decreases even without changes in the mechanics of the lungs or the respiratory system.

dynamic compliance increases with increasing respiratory frequency (frequency dependence of compliance) and is a sign of airway obstruction (Woolcock et al., 1969).

Quiet, normal expiration occurs passively, resulting from the elastic recoil of the lungs and chest wall and involves little or no additional work. The situation in the infant or in the anesthetized and spontaneously breathing patient may be somewhat different, because expiration may have an active phase (Munson et al., 1966). To consider volume-pressure relationships from another point of view, a normal tidal volume may be obtained using transpulmonary pressures of approximately 4 to 6 cm H₂O in persons of all sizes, provided that the lungs are normal, they are normally expanded initially, and the airways are patent. The total transthoracopulmonary pressure needed to ventilate the lungs with positive pressure in a closed chest is, in the adult, approximately twice the required transpulmonary pressure during spontaneous breathing, because the thoracic structures must also be expanded. The chest wall in the newborn is extremely compliant and therefore requires almost no force for expansion (Fig. 3-21). The combined compliance of the chest wall and lungs, or the compliance of the total respiratory system (Crs), is expressed as follows:

$$1 / C_{rs} = 1 / C_L + 1 / C_w$$

where *C_L* is lung compliance and *C_w* is chest-wall compliance. The equation can be expressed in terms of elastance (E), an inverse of compliance (E = 1/C):

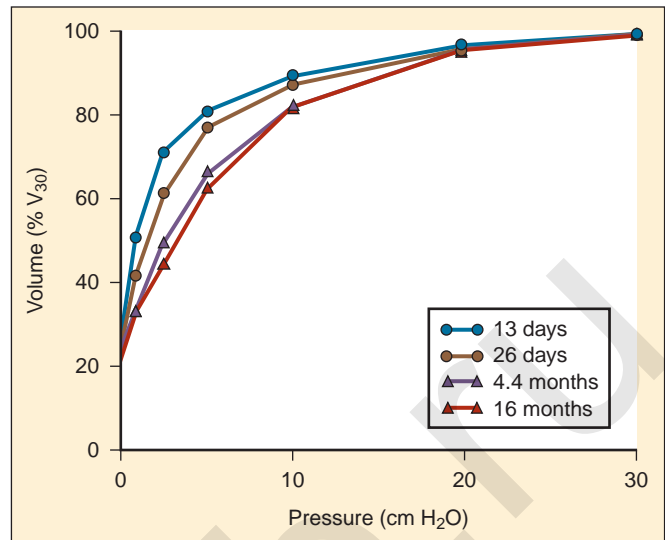

$$E_{rs} = E_L + E_w$$

where *E_{rs}* is the elastance of the total respiratory system, *E_L* is lung elastance, and *E_w* is chest wall elastance. Lung compliance in normal humans of different sizes is generally directly proportional to lung size (see Table 3-2). The compliance is expressed per unit of lung volume (e.g., per FRC, vital capacity [VC], or TLC) for comparison (termed *specific compliance*).

Developmental Changes in the Compliance of the Lungs and Thorax

After the initial period of neonatal adaptation, the compliance of the infant's lungs is extremely high (elastic recoil is low), probably because of absent or poorly developed elastic fibers (Fig. 3-23) (Fagan, 1976, 1977; Motoyama, 1977). Oddly enough, their functional characteristics resemble those of geriatric, emphysematous lungs with pathologically high compliance caused by the loss of functioning elastic fibers (Fig. 3-24). Thus, at both extremes of human life, the lungs are prone to premature airway closure (Mansell et al., 1972). Elastic recoil pressure of the lungs at 60% TLC increases from about 1 cm H₂O in the newborn to 5 cm H₂O at 7 years of age and 9 cm H₂O at 16 years of age (Fagan, 1976, 1977; Zapletal et al., 1987).

In infants the outward recoil of the chest wall is exceedingly small, because the rib cage is cartilaginous and horizontal, and the respiratory muscles are not well developed, whereas the inward recoil of the lungs is only moderately decreased compared with that in adults (Agostoni, 1959; Gerhardt and Bancalari, 1980). Consequently, the static balance of these opposing forces would decrease FRC to a very low level (Fig. 3-22). Such a reduction in FRC would make parenchymal airways unstable and subject them to collapse. In reality, however,

■ **FIGURE 3-23.** Pressure-volume curves obtained from excised lungs at autopsy. Data are grouped by postnatal ages, as shown by symbols. It is evident that elastic recoil pressure (horizontal distance between nil distending pressure and the curve at a given distending volume) increases with postnatal development of the lungs. (Data from Fagan DG: *Post-mortem studies of the semistatic volume-pressure characteristics of infants' lungs*, Thorax 31:534, 1976; Fagan DG: *Shape changes in static V-P loops for children's lungs related to growth*, Thorax 32:193, 1977.)

■ **FIGURE 3-24.** Static pressure-volume curves (deflation limbs) of the lungs in various conditions as indicated. (From Bates DV, editor: *Respiratory function in disease*, ed 3, Philadelphia, 1989, WB Saunders.)

dynamic FRC in spontaneously breathing infants is maintained at around 40% TLC, a value similar to that in adults in the supine position, because of a number of possible mechanisms or their combinations (Bryan and Wohl, 1986).

Maintenance of Functional Residual Capacity in Infants

Infants terminate the expiratory phase of the breathing cycle before lung volume reaches the relaxation volume, or true FRC, determined by the balance of opposing chest wall and lung elastic recoil (Kosch and Stark, 1979). This “premature” cessation

of the expiratory phase, which $PEEP_i$ with higher FRC, probably results partly from the relatively long time constant of the respiratory system in infants in relation to their high respiratory rate (Olinsky et al., 1974). Additional mechanisms may also help maintain dynamic FRC above the relaxation volume. Glottic closure, or laryngeal braking, during the expiratory phase of the breathing cycle is an important mechanism for the establishment of sufficient air space in the lungs during the early postnatal period (Fisher et al., 1982). Diaphragmatic braking, the diminishing diaphragmatic activity extending to the expiratory phase of breathing, is another important mechanism that extends expiratory time and maintains FRC (Box 3-2).

Among all mechanisms that maintain FRC, tonic contractions of both the diaphragm and the intercostal muscles throughout the respiratory cycle in awake infants appear to be most important. This mechanism effectively stiffens the chest wall and maintains a higher end expiratory lung volume (Muller et al., 1979). Henderson-Smart and Read (1979) have shown a 30% decrease in thoracic gas volume in sleeping infants changing from non-REM to REM sleep. This large reduction in dynamic FRC may result from loss of tonic activity of the respiratory muscles, loss of laryngeal braking, diaphragmatic braking, or all of these factors. All of these important mechanisms for maintaining FRC in infants (and to a lesser extent in older children) are lost with general anesthesia or muscle relaxants, causing marked reductions in FRC, airway closure and atelectasis (Serafini et al., 1999).

When is the FRC no longer determined dynamically but determined by the balance between the recoils of the thorax and the lungs to the opposing direction, as in adults? Colin and others (1989) have shown that, in infants and children during quiet, natural sleep, the transition from dynamically determined to relaxed end expiratory volume or FRC takes place between 6 and 12 months of age. By 1 year of age the breathing pattern is predominantly that of relaxed end-expiratory volume, just as in older children and adults. These findings coincide with the upright posture and development of thoracic tissue and muscle strength in infants.

The breathing pattern of infants younger than 6 months of age is predominantly abdominal (diaphragmatic) and the contribution of the rib cage (external intercostal muscles) to tidal volume is relatively small (20 to 40%), reflecting instability of the thorax or weakness of the intercostal muscles. After 9 months of age, the rib cage component of tidal volume increases to a level (50%) similar to that of older children and adolescents, reflecting the maturation of the thoracic structures (Hershenson et al., 1990). Furthermore, a study by Papastamelos and others (1995) has shown that the stiffening of the chest wall continues throughout infancy and early childhood. By 12 months of age, however, chest wall compliance (which is extremely high in neonates) decreases and nearly equals lung compliance. The chest wall becomes more stable and can resist the inward recoil of the lungs and maintain FRC passively. These relatively recent findings support the notion that the stability of the respiratory system is achieved by 1 year of age.

Effects of General Anesthesia on Functional Residual Capacity

General anesthesia with or without muscle relaxation results in a significant reduction of FRC in adult patients in the supine position soon after the induction of anesthesia, whereas FRC

is unchanged during anesthesia in the sitting position (Rehder et al., 1971, 1972b, 1974; Westbrook et al., 1973). A decrease in FRC is associated with reductions in both lung and thoracic compliance, but the mechanism responsible for the reduction in FRC and the sequence of events that changes respiratory mechanics were not understood for many years.

In an excellent study, deTroyer and Bastenier-Geens (1979) showed that when a healthy volunteer was partially paralyzed with pancuronium, the outward recoil of the thorax decreased, whereas lung recoil (compliance) did not. This change altered the balance between the elastic recoil of the lung and thorax in opposite directions, and consequently FRC diminished. The compliance of the lungs decreased shortly thereafter, resulting from the reduced FRC and resultant airway closure. Based on their findings, deTroyer and Bastenier-Geens postulated that, in the awake state, inspiratory muscles have intrinsic tone that maintains the outward recoil and rigidity of the thorax. Anesthesia or paralysis would abolish this muscle tone, reducing thoracic compliance followed by a reduction in FRC, and eventually lung compliance in rapid succession (in a matter of a few minutes).

In healthy young adults, a reduction of FRC during general anesthesia is limited to between 9% and 25% from the awake control levels (Laws, 1968; Rehder et al., 1972; Westbrook et al., 1973; Hewlett et al., 1974; Juno et al., 1978). In older individuals, the average reduction in FRC is more (30%), probably because of lower elastic recoil pressure, increased closing capacity and further airway closure, and eventual atelectasis (Bergman, 1963).

With the more compliant thoraces of infants and young children, general anesthesia and muscle relaxation would be expected to produce more profound reductions in FRC than in adolescents and adults. Henderson-Smart and Read (1979) have shown a 30% reduction in thoracic gas volume (FRC) in infants, changing the sleep pattern from non-REM to REM sleep with increased muscle flaccidity. In children 6 to 18 years of age under general anesthesia and paralysis, Dobbins and others (1973) found marked reductions in FRC (average reduction, 35%) from their own awake control values, as measured with a helium dilution technique. The average decrease in FRC among those younger than 12 years of age was 46%. Fletcher and others (1990) demonstrated that compliance of the respiratory system (Crs) in infants and children under general anesthesia decreased about 35%, a value comparable with the reduction reported in adults under similar conditions (Westbrook et al., 1973; Rehder and Marsh, 1986). This reduction in Crs occurred both during spontaneous breathing and during manual ventilation with low tidal volume after muscle relaxants were given. When tidal volume was doubled, however, Crs returned to pre-anesthetic control levels.

These findings are in accord with previous findings in adults and support the notion that anesthesia reduces FRC (deTroyer and Bastenier-Geens, 1979; Hedenstierna and McCarthy, 1980). The finding that a larger tidal volume increases Crs toward control values also indicates that FRC decreases to the lower, flatter portion of the pressure-volume curve, which would lead to airway closure (Fig. 3-22). Motoyama and others (1982a) reported moderate decreases in FRC (−46%) in children as measured with helium dilution and a marked decrease (−71%) in infants under halothane anesthesia and muscle paralysis, approaching the relaxation volume in the newborn infant reported by Agostoni (1959).

Until recently, the possible differential effect on FRC of general anesthesia without muscle paralysis vs. general anesthesia with muscle paralysis was not critically compared. Westbrook et al. (1973) reported a 25% reduction in FRC in healthy young adults in the supine position after anesthesia with intravenous sodium thiopental. They did not find a statistically significant difference in the extent of reductions in FRC with thiopental alone vs. those with an addition of muscle relaxant (d-tubocurarine), although the mean reduction in FRC was somewhat more with the relaxant. A more recent study in anesthetized infants and toddlers clearly demonstrated that addition of muscle paralysis in anesthetized children results in additional marked reductions in FRC (on top of the reduction by the effect of general anesthesia) (von Ungern-Sternberg et al., 2006). Furthermore, the reduction in FRC in infants less than 6 months of age was extreme (FRC, 21.3 to 12.2 mL/kg or -43%) as compared with reductions in toddlers (25.6 to 23.0 mL/kg or -10%) (von Ungern-Sternberg et al., 2006). This marked loss of FRC in infants represents the collapse of their extremely compliant thorax with inspiratory muscle paralysis and massive airway closure that would eventually result in atelectasis, uneven distribution of ventilation, V/Q imbalance, and hypoxemia unless the lungs are reexpanded and supported with PEEP.

Effect of Positive End-Expiratory Pressure Under General Anesthesia

Thorsteinsson and others (1994) reported that the lung volume at FRC (or relaxation volume, V_r) was at a lower, flatter portion of the pressure-volume (P-V) curve in all anesthetized infants and children studied. To restore FRC to the normal or steepest portion of the P-V curve of the respiratory system seen in the awake state (with the highest compliance), a PEEP of 5 to 6 cm H_2O had to be added to infants younger than 6 months of age and more than 12 cm H_2O in older children (Thorsteinsson et al., 1994). A more recent study in children (aged 2 to 6 years) also showed that PEEP as high as 17 cm H_2O is needed to raise the lung volume to the steepest portion (highest compliance) of the P-V curve (Kaditis et al., 2008).

Shortly after the induction of anesthesia and muscle relaxation in adult patients, increased density appearing on computed tomography (CT) scans in the dependent portion of the lung has been described in the literature. This increased density could be reduced or eliminated by adding PEEP (Brismar et al., 1985). Serafini and others (1999) were the first to report evidence of airway closure and atelectasis in young children (aged 1 to 3 years; mean age of 1.8 years) on a CT scan in the dependent portion of the lungs shortly after the inhalation induction of anesthesia and intubation. These patients were given three deep inflations of the lungs (sighs) with 40% oxygen in nitrous oxide and ventilated with 10 mL/kg of tidal volume. Atelectasis-increased density (airway closure or atelectasis) appeared on the CT scan almost immediately when patients were ventilated without PEEP (Fig. 3-25, A). When the patients were ventilated for 5 minutes with an addition of PEEP (5 cm H_2O) with the same ventilator settings and end tidal P_{CO_2} , the density disappeared from the repeated CT scans in all 10 children studied, indicating the recruitment of atelectic lung segments (Fig. 3-25, B) (Serafini et al., 1999).

Because the stability of the thorax increases during the first year of life, it is likely that the thorax would resist the airway collapse and atelectasis with increasing age (Papastamelos

FIGURE 3-25. Computed tomography (CT) scan of the thorax during general endotracheal anesthesia. **A**, Transverse CT scan of the thorax 5 minutes after the induction of anesthesia without PEEP. Note the appearance of atelectasis (density) in the dependent regions of both lungs. **B**, Transverse CT scan of the thorax during anesthesia with a PEEP of 5 cm H_2O , showing the complete disappearance of atelectasis in the dependent regions of both lungs. (From Serafini G et al.: *Pulmonary atelectasis during paediatric anaesthesia: CT scan evaluation and effects of positive end-expiratory pressure (PEEP)*, *Paediatr Anaesth* 9:225, 1999.)

et al., 1995). Motoyama (1996) examined this possibility by measuring respiratory system compliance in infants and young children under 6 years of age who were undergoing halothane-nitrous oxide endotracheal anesthesia. These patients were ventilated either with or without PEEP (6 cm H_2O) for 15 minutes preceded by deep sighs. After a period of ventilation with PEEP, respiratory system compliance was consistently higher after PEEP than without PEEP. There were significant age-related differences in the degree of increase in compliance after PEEP (6 cm H_2O) vs. no PEEP (Fig. 3-26). The average increase of respiratory system compliance with PEEP was greatest in infants younger than 8 months of age (75% higher with PEEP vs. without PEEP). In contrast, in older infants and toddlers (aged 9 months to 2.5 years), an average increase in compliance with PEEP was 22%; in children (aged 2.5 and 5.5 years), the increase was 9%, the level one would expect in adults. These results reflect greater reductions in FRC (or increases in airway closure and atelectasis) in the younger age groups (Motoyama, 1996).

FIGURE 3-26. Compliance of the respiratory system (Crs) under general anesthesia in infants and children and the effect of PEEP. An addition of PEEP (5 to 6 cm H₂O) improves (restores) Crs significantly in all age groups studied. The beneficial effect of PEEP was most dramatic in infants younger than 8 months (see text). (From Motoyama EK: *Effects of positive end-expiratory pressure (PEEP) on respiratory mechanics and oxygen saturation (SpO₂) in infants and children under general anesthesia*, *Anesthesiology* 85:A1099, 1996.)

Persistent airway closure during general anesthesia would result in resorption atelectasis because alveolar gas (mostly oxygen and nitrous oxide) trapped below the occluded airways would be rapidly absorbed. Resultant pulmonary V/Q imbalance and right-to-left shunting of blood in the lung may reduce arterial Po₂ in the postanesthetic recovery room. Such an effect would be expected to be more profound in infants. Motoyama and Glazener (1986) studied arterial oxygen saturation (SpO₂) with a pulse oximeter in otherwise healthy infants and children before and after general anesthesia for simple, relatively short, surgical procedures (e.g., inguinal hernia repair or myringotomy tube insertions). On arrival at the postanesthetic care unit (PACU), the mean SpO₂ was 93% (estimated Pao₂, 66 mm Hg), significantly reduced from the preoperative value of 97%. In some children, SpO₂ decreased to the low 70s (estimated Pao₂ of less than 40 mm Hg). These patients showed no sign of hypoxic ventilatory stimulation with normal cutaneous Pco₂ (Motoyama and Glazener, 1986).

A large percentage (20% to 40%) of otherwise healthy infants and children develop oxygen desaturation (SpO₂ of less than or equal to 94%) during transport and on arrival at the PACU (Motoyama and Glazener, 1986; Pullertis et al., 1987; Patel et al., 1988). A later study of postoperative hypoxemia involving 1152 patients ranging from infants to adults has demonstrated that hemoglobin desaturation occurs sooner, is more pronounced, and lasts longer in infants than in children and longer in children than in adults (Xue et al., 1996). All children, therefore, should be given oxygen by mask during the transport from the operating room and on arrival at the PACU until they can maintain satisfactory oxygen saturation by pulse oximeter without supplemental oxygen (see Chapter 11, Monitoring).

Closing Volume and Closing Capacity

Beside the lungs and chest wall, the air passages themselves have a compliance that may be important. With deep inspiration,

the airway caliber increases in size (interdependent of airways and lung volume), whereas the airway caliber decreases during passive expiration, with an even bigger increase during forced expiration with dynamic compression. Closing volume (CV) is the lung volume above RV at which air flow during expiration ceases from dependent lung zones (i.e., lower lung segments in the upright position), presumably because of the closure or collapse of small airways. Closing capacity (CC) is the sum of CV above RV plus RV.

$$CC = CV + RV$$

Whether this closure is anatomic or merely the result of dynamic compression and reduction in flow (see Dynamic Properties) is controversial (Hughes et al., 1970; Hyatt et al., 1973). Because the patency of small airways depends in part on the elastic recoil of the lungs, CC as a percentage of TLC is relatively high in young children and would be even higher, at least theoretically, in infants (Mansell et al., 1972). CC increases with aging as well as with small airway disease, such as chronic bronchitis caused by smoking and emphysema in adults.

Lung compliance is reduced in most situations in which lung volume is decreased (e.g., the removal of lung tissue, atelectasis, and intrapulmonary tumors), although it is normal when corrected for lung volumes. Compliance is also decreased when surface forces are increased, as it is in IRDS with increased surface force (or decreased surfactant), or when elastic recoil is abnormally increased (e.g., in interstitial pulmonary fibrosis).

Emphysema is associated with a loss of elastic recoil and therefore an abnormal increase in compliance. Chest-wall compliance decreases with conditions such as scleroderma, kyphoscoliosis, and ankylosing spondylitis involving the thoracic structures.

Dynamic Properties

Breathing involves cyclic contractions of respiratory muscles and the generation of force, which must overcome resistive and elastic properties of the lung and chest wall. The resistive properties of the respiratory system include the resistance to air flow within the airways, the tissue viscoelastic resistance or the resistance of the lung and thoracic tissues themselves to deformation, and inertial resistance (inertance) resulting from the movement of gas molecules within the airways, especially at high velocities. In contrast to compliance (or elastance), which is measured at points of no flow, flow resistance is present only when the lung is in motion.

Airway Resistance

The pressure required to overcome frictional resistance and produce flow between the alveoli (Palv) and the airway opening (Pao) is proportional to flow rate. Airway resistance (Raw) is expressed as pressure gradient across the airways (P = Pao – Palv) per unit flow (V̇):

$$Raw = \frac{P}{\dot{V}(\text{cmH}_2\text{O/L/sec})}$$

If the respiratory system is assumed to have a single compartment with a constant elastance or compliance (E = 1/C) and

a constant resistance (R), the equation of forces acting on the respiratory system can be expressed as follows:

$$P = E\dot{V} + R\dot{V} + I\dot{V}$$

In tidal breathing, inertance (I) is very small and can be ignored. During normal tidal breathing, approximately 90% of the pressure gradient required is needed to overcome the elastic forces, and the remaining 10% of the pressure is expended to counter the flow resistance (Sly and Hayden, 1998).

Flow resistance is related to the length (l), radius of the tube (r), and the viscosity of the gas (η) as follows:

$$R = \frac{8l\eta}{\pi r^4}$$

Assuming a laminar flow (as seen in small or peripheral airways), it is apparent from this equation (Poiseuille's law) that the most important factor affecting flow resistance is the change in the radius of the tube (airways), because resistance is inversely proportional to the fourth power of the radius. (When the flow is turbulent, as occurs in large airways, the flow resistance increases approximately with r^5 .) Therefore, airway resistance in infants with smaller airway diameters is much higher, in absolute terms, than airway resistance in older children and adults. It might also be expected that inflammation or secretions in the airway system would result in exaggerated degrees of obstruction in infants compared with older children and adults (Fig. 3-27). One such example may be the severe and often life-threatening obstruction of upper airways seen only in infants and young children with acute supraglottitis (epiglottitis) and subglottic croup (laryngotracheobronchitis). However, in relation to body size, the caliber of airways in general is wider, and airway resistance is lower in infants and children compared with adults (Motoyama, 1977; Stocks and Godfrey, 1977).

In absolute terms, airway resistance in the newborn is very high (19 to 28 cm H₂O/L per second). It decreases to less than 2 cm H₂O/L per second in the adolescent and the adult. In relative terms (as expressed per unit of lung volume, usually FRC or specific resistance), specific airway resistance is relatively low, or conductance (Gaw, the reciprocal of resistance; $G = 1/R$) is very high in the newborn. The specific conductance ($sGaw = Gaw/FRC$) decreases rapidly during the first year of life, indicating a rapid increase in lung volume (alveolar formation) in relation to airway size (Stocks and Godfrey, 1977, 1978). Between 6 and 18

years of age, Gaw increases linearly with increases in height; However, sGaw stays fairly constant throughout this period at about 0.2 L/sec per cm H₂O (Zapletal et al., 1969, 1976, 1987).

Distribution of Airway Resistance

Rohrer's earlier work (1915) led to the belief that peripheral airways of small caliber were the major contributors to total airway resistance. However, the elegant morphometric studies of Weibel (1963) with airway castings in inflated lungs proved that the total cross-sectional area of each generation of airways increases dramatically toward the periphery, like a cross section of a trumpet, on the cross-sectional area vs. airway-generation plot (Fig. 3-28). Indeed, about two thirds of the total airway resistance exists between the airway opening and the trachea, and most of the remaining resistance is in the large central airways. The airways smaller than a few millimeters in diameter (peripheral airways) contribute only about 10% of total resistance (Macklem and Mead, 1967).

These findings have important clinical implications. If the peripheral airways contribute little to the total airway resistance, disease processes involving small airways—such as emphysema in adults, cystic fibrosis (CF) in children, and bronchopulmonary dysplasia (BPD) in infants—will not be detectable by measurement of the total airway resistance. For instance, complete obstruction of half of the peripheral airways would increase the total airway resistance by only 5% to 6%, an increase within the usual variation in measurements. For this reason, the peripheral airways used to be called the “quiet zone” of the lung (Mead, 1970). Apparently, the measurement of total airway resistance is not a sensitive clinical test for detecting small airway obstruction.

The airway system extends from the airway opening at the nares or the mouth to the alveolar duct at the periphery of the lung. Functionally, the airway system can be subdivided into the upper (extrathoracic) and lower (intrathoracic) airways. The upper airway begins at the airway opening (the mouth or the nose—normally the mouth in quiet breathing) and include the nasal or oral cavity, the pharynx, the larynx, and the upper most segment of the trachea before it enters into the thorax. The lower airway begins with the thoracic inlet of the trachea, the trachea, bronchi, bronchioli, and alveolar ducts entering the alveoli (Box 3-3).

Upper Airway Resistance

During quiet breathing, air-flow resistance through the nasal passages accounts for approximately 65% of total airway resistance in adults (Ferris et al., 1964). This is more than twice the resistance during mouth breathing. For air warming, humidification, and particle filtration, it is important that one preferentially or instinctively breathe through the nose despite its higher resistance (Proctor, 1977a, 1977b). Stocks and Godfrey (1978) found nasal resistance comprised approximately 49% of the total airway resistance in European infants, whereas it was significantly less in infants of African origin (31%). Overall, upper airway resistance is approximately two thirds of the total airway resistance.

Except when crying, newborn infants are obligatory nose breathers. The cephalad position of the epiglottis and close approximation of the soft palate to the tongue and epiglottis in neonates may be a reason why mouth breathing is more

Box 3-3 Airway System and Resistance

UPPER AIRWAYS: EXTRATHORACIC

Mouth/nose, pharynx, larynx (the narrowest segment)
Upper airway resistance: 65% of total R_{aw}

LOWER AIRWAYS: INTRATHORACIC

Lower airway resistance: 35% of total R_{aw}
Central (large) airways: trachea, large bronchi
Peripheral (small) airways: small bronchi, bronchioli
Central airways: 90% of lower R_{aw} (30%)
Peripheral airways: 10% of lower R_{aw} (<5%)

difficult than nose breathing (Moss, 1965; Sasaki et al., 1977a). When the nasal airway is occluded, some infants, especially during REM sleep, do not respond sufficiently to initiate adequate mouth breathing and obstructive apnea ensues. In infants, the insertion of a nasogastric tube significantly increases total resistance by as much as 50% and may compromise breathing (Stocks, 1980).

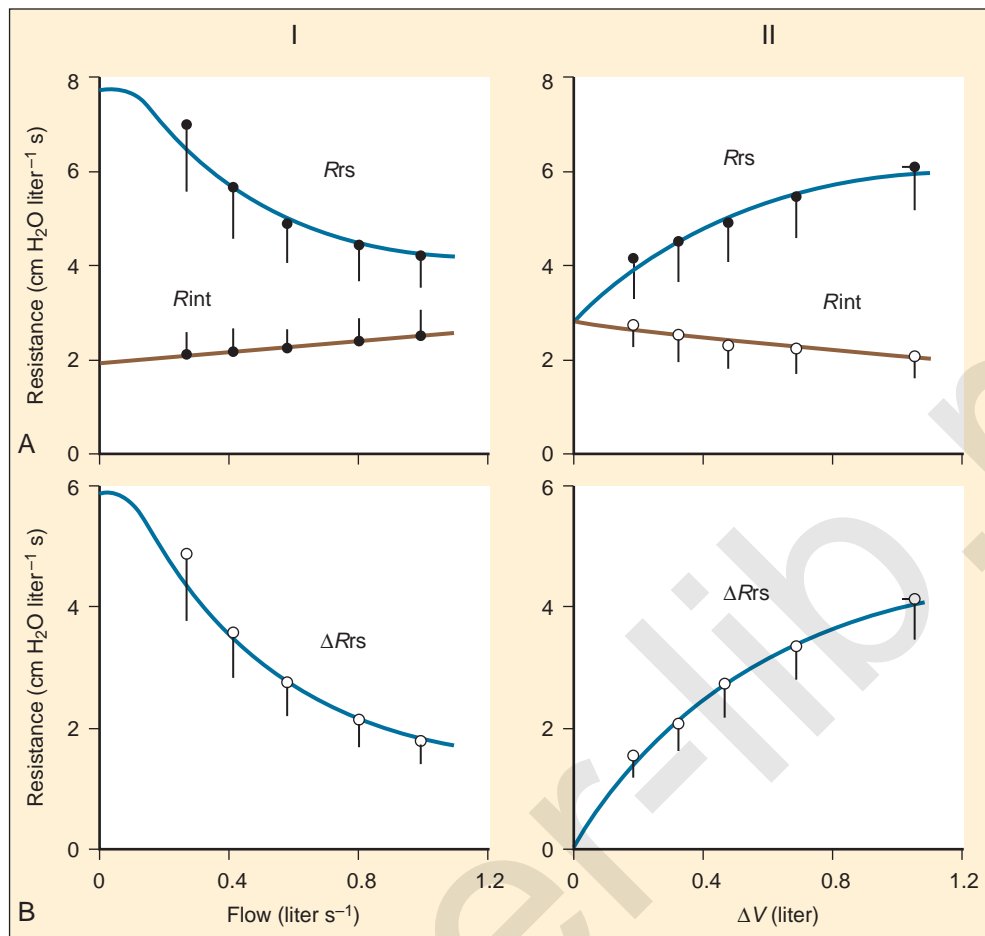

Lower Airway Resistance

Between the trachea and the alveolar duct are an average of 23 (mean of 17 to 27) airway generations or branchings (Fig. 3-28) (Weibel, 1963). As gas molecules move from the trachea toward the terminal airways during inspiration, the radius of the successive generations of airways becomes smaller and the flow resistance is expected to increase. In reality, however, the total

cross-sectional area of the airway segments increases dramatically toward the periphery, although the diameter of successive single airways decreases. This is because the number of airways increases markedly and, consequently, the flow resistance of airways decreases toward the periphery (Weibel, 1963) (Fig. 3-28). Using a retrograde catheter technique, Macklem and Mead (1967) demonstrated that the peripheral airways, less than about 1 mm in diameter (around 14th generation), contribute less than 10% of the lower airway resistance (or 3% of the total airway resistance).

Tissue Viscoelastic Resistance

It has been assumed that airway (frictional) resistance represents the majority of total respiratory system resistance during breathing, and the pressure needed to overcome tissue viscous resistance during inspiration was estimated to be about 35% in adults and 28% in children (Bryan and Wohl, 1986). However, studies since the 1980s in both anesthetized animals and humans on mechanical ventilation have indicated that viscoelastic resistance, or the energy required to counter the hysteresis or viscoelasticity of the lungs and thoracic tissues, contributes a significantly greater proportion of the total resistance than previously assumed (Milic-Emili et al., 1990). Furthermore, both airway resistance (R_{aw}) and viscoelastic resistance (R_{vis} or ΔR) have been found to be flow and volume dependent (i.e., both R_{aw} and R_{vis} change with volume and/or flow changes) and to the opposite directions. Airway resistance (R_{aw}) increases with increasing flow as a result of higher turbulence, whereas R_{aw} decreases with increasing lung volume, because airway caliber also increases with

■ **FIGURE 3-29.** Flow and volume dependence of respiratory system resistance (R_{rs}) and its subdivisions, resistive component (R_{int} , mostly airway resistance, R_{aw}) and viscoelastic component (ΔR_{rs} or R_{visc}) ($R_{rs} = R_{int} + \Delta R_{rs}$). **A,I**, Average relationship of R_{rs} and R_{int} with increasing inspiratory flow on X-axis at a constant inspiratory volume (0.47 L) in 16 anesthetized and paralyzed adult subjects. **B,I**, Similar relationship between ΔR_{rs} with variable inspiratory flow. **A,II**, Average relationship of R_{rs} and R_{int} with variable inspiratory volume on X-axis at a constant inspiratory flow (0.56 L/sec) in the same subjects as **A,I**. **B,II**, Similar relationship in terms of ΔR_{rs} . Bars, 1SD. (Modified from D'Angelo E et al.: *Respiratory mechanics in anesthetized paralyzed humans*, J Appl Physiol 67:2556, 1989.)

volume. The traditional view had been that the total resistance followed the same direction of flow resistance because it was thought to be the majority of total respiratory system resistance. Paradoxically, R_{vis} decreases with increasing flow, when the volume is kept constant, and when the flow rate is kept constant R_{vis} increases with increasing lung volume (Fig. 3-29) (D'Angelo et al., 1989). Furthermore, the direction of changes in total resistance followed that of R_{vis} rather than that of R_{aw} . Studies in children who have been anesthetized and ventilated have shown a similar flow and volume dependence of R_{vis} exist in adults; that is, opposite of the direction of changes in R_{aw} , although the total resistance did not necessarily follow the changes in R_{vis} that occurred in adults (Fig. 3-30) (Kaditis et al., 2008).

This evidence and new understanding on the behavior of viscoelastic resistance have important clinical implications. Traditionally, the patient with airway obstruction has been treated with large tidal volumes and a slow respiratory rate to allow complete exhalation to avoid intrinsic PEEP_i and air trapping. With the new understanding, it makes more sense to have patients breathe with a smaller tidal volume and higher

respiratory rate in order to minimize total respiratory system resistance and decrease work of breathing (Kaditis et al., 1999b, 2008).

Time Constant of the Respiratory System

When the lung is allowed to empty passively from end inspiration to FRC, the speed of lung deflation is determined by the product of respiratory system resistance and compliance ($R \times C$ or R/E), which is a unit of time (time constant, τ). If the respiratory system is considered as a single compartment with a constant resistance and compliance within the tidal volume range of breathing (which is a reasonable assumption in healthy individuals), then $\tau = R \times C$.

Under these conditions, the volume-time profile can be represented by an exponential decay and at 1 time constant (1τ), tidal volume is reduced by 63%. It requires $3 \times \tau$ to nearly complete exhalation to FRC. In healthy children and adults, τ is 0.4 to 0.5 seconds; it is slightly shorter in neonates (0.2 to 0.3 seconds) (Bryan and Wohl, 1986). In patients with obstructive lung disease, such as bronchial asthma, τ is increased because of an

■ **FIGURE 3-30.** Flow and volume dependence of respiratory system resistance (R_{rs}) and its subdivisions, flow-resistive component (R_{int} or R_{aw}) and viscoelastic component (ΔR or R_{vis}) ($R_{rs} = R_{int} + \Delta R$), in eight healthy children aged 2.3 to 6.5 years under general endotracheal anesthesia. **A**, Average relationship of R_{rs} , R_{int} , and ΔR with increasing inspiratory flow on X-axis at a constant end-inspiratory volume (V_r , 12 mL/kg). ΔR and R_{rs} decreased significantly with increasing flow as in adults (see Fig. 3-29). **B**, Average relationship of R_{rs} , R_{int} , and ΔR with increasing volume on x-axis while flow was kept constant (15 mL/sec per kg) in the same subjects as in **A**. R_{int} decreases with increasing volume as expected, whereas ΔR increased with increasing volume. Unlike in adults, there was no volume dependence of R_{rs} ; Bars, 1 SEM; \dot{V}_I , inspiratory flow; V_r , relaxation volume or end expiratory volume. (From Kaditis AG et al.: *Effect of lung expansion and PEEP on respiratory mechanics in anesthetized children*, *Pediatr Anesth* 106:775, 2008.)

increase in airway resistance; it is also increased markedly in patients breathing through an endotracheal tube under general anesthesia.

The Concept of Flow Limitation and Maximum Expiratory Flow-Volume Curves

During quiet breathing, pleural pressure remains subatmospheric, whereas during forced expiration, pleural pressure increases considerably above atmospheric pressure and in turn increases alveolar pressure. The resultant pressure gradient between the alveoli and the airway opening (atmospheric)

■ **FIGURE 3-31.** Flow-volume curves obtained when a subject performs a series of vital capacity expirations of graded effort, varying from a very slow breath out to one of maximal speed and effort. (From Bates DV et al., editors: *Respiratory function in disease: an introduction to the integrated study of the lung*, Philadelphia, 1971, WB Saunders.)

produces the expiratory flow. In the periphery of the lungs this pressure within the airways is even higher than the increased pleural pressure by effort because of the additional elastic recoil pressure of the lung. In comparison, in major intrathoracic airways the pressure within the lumen is near atmospheric and lower than the surrounding pleural pressure. At some point along the airways the pressure within the airway lumen should equal the pleural pressure surrounding the airway (equal pressure point [EPP]) (Mead et al., 1967). During forced expiration, the airway between EPP and the trachea is dynamically compressed, and the flow rates consequently become independent of effort (i.e., additional expiratory effort or pressure does not increase flow) (Fig. 3-31). Under these circumstances (dynamic flow limitation), the maximum expiratory flow rate (\dot{V}_{max} or MEF) is determined by the flow resistance of the upstream segment (R_{us}) between the alveoli and the EPP and the elastic recoil pressure of the lung (P_{stl}), as follows (Mead et al., 1967):

$$\dot{V}_{max} = \frac{P_{stl}}{R_{us}}$$

According to the wave-speed theory of expiratory flow limitation, compliance or collapsibility of lower airways around the EPP (choke point) is an additional determinant of MEF rate (Dawson and Elliott, 1977; Hyatt, 1986).

The maximum expiratory flow volume (MEFV) curve obtained during forced expiration from TLC to residual volume relates instantaneous MEFs to corresponding lung volumes (Fig. 3-32). Clinically, the measurement of MEF rate is an extremely sensitive test for the detection of obstruction of the lower airways toward the periphery (quiet zone) of the lungs because it eliminates the component of upper airway resistance

■ **FIGURE 3-32.** MEFV curve on volume-flow axis on the right is contrasted with spirometric tracing (spirogram) on volume-time axis on the left during a single forced vital capacity (VC) maneuver. $FEV_{1.0}$, Forced expiratory volume in 1 second; $PEFR$, peak expiratory flow rate; MEF_{50} , MEF_{25} , MEF at 50% and 25%, respectively, of forced VC. between the mouth and EPP and is independent of the degree of effort or cooperation by the patient (Zapletal et al., 1971) (see Measurements of Pulmonary Function).

Distribution of Flow Resistance

On the basis of physiologic measurements in lungs obtained at autopsy, Hogg and others (1970) reported that airway conductance of the peripheral airways in children younger than 6 years of age was disproportionately low (i.e., resistance was high). They postulated that the diameter of small airways of the same generation was disproportionately smaller in infants than in older children and adults. Although this theory is consistent with the high incidence of severe lower airway disease in infants, it conflicts with later physiologic data obtained from healthy infants. Studies of MEFV curves in anesthetized infants and children, and more recently in sedated infants, showed that at low lung volumes, the MEF normalizes for lung volume and that the conductance of the upstream segment is disproportionately high in infants and decreases with age, indicating that lower airway resistance toward the periphery of the lung parenchyma is relatively lower, rather than higher, in the early postnatal years (Fig. 3-33) (Motoyama, 1977; Lambert et al., 2004).

Summary

Compliance of the respiratory system has both lung and chest-wall components. During artificial ventilation of a healthy adult, about one half of the inspiratory pressure is required to expand

■ **FIGURE 3-33.** MEF at 25% FVC from forced deflation flow-volume curves vs. height in anesthetized boys and girls. MEF_{25} is expressed in FVC units per second to normalize for lung size. FVC-adjusted MEF_{25} is disproportionately higher in infants than in older children. (From Motoyama EK: *Pulmonary mechanics during early postnatal years*, *Pediatr Res* 11:220, 1977.)

the lungs and one half is needed to expand the chest wall. In infants, the chest wall is extremely compliant and requires little pressure to expand. Accordingly, airway pressure during artificial ventilation should be reduced. In absolute terms, lung compliance increases with body or lung size. In relative terms, however, lung compliance is relatively high in infants and decreases with age, as elastic recoil pressure of the lungs increases. Most of the flow resistive force against breathing is exerted within the upper and large central airways; the small airways contribute only a fraction of total flow resistance. Flow resistance in absolute terms is largest when air passages are smallest; thus, infants are more prone to airway obstruction of the upper and lower airways. When lung volumes are taken into account, however, total airway resistance is relatively low during the newborn period and increases rapidly during the first year, as lung volume increases with alveolar formation. Resistance of smaller (parenchymal) airways appears to be relatively low at birth and increases with age. The contribution of viscoelastic resistance from the lungs and thoracic tissue hysteresis has been found to be much larger than had been recognized in the past. Both flow-resistive and tissue viscoelastic resistance change with increasing flow and volume, but the directions of changes are opposite to each other. Forming a complex mechanism, the tonic activities of the pharyngeal and laryngeal dilator muscles protect the pharyngeal airway from collapse. During spontaneous breathing, the genioglossus and other upper airway muscles contract synchronously with the diaphragm and increase upper airway caliber. These muscles are easily depressed by sleep and anesthesia, causing upper airway obstruction both at the velopharynx and, to a lesser extent, at the base of the tongue, resulting in upper airway obstruction during anesthesia.

VENTILATION

Ventilation involves the movement of air in and out of the lungs. The diaphragm is the most important muscle for normal inspiration, although the intercostal and accessory respiratory muscles aid in a maximal inspiratory effort. Quiet expiration results from the elastic recoil of the lungs and chest wall and the relaxation of the diaphragm. The expiration of a newborn, even when resting or asleep, appears active rather than passive, as it appears in the older child and adult. A similar active expiration has been observed in anesthetized patients, but the mechanism is unknown (Freund et al., 1964). Forced expiration is accomplished with the aid of the spinal flexors, the intercostal muscles, and especially the abdominal muscles.

Tidal volume (V_T) is the amount of air moved into or out of the lungs with each breath. Minute volume (\dot{V}_E) is the amount of air breathed in or out in a minute, or as follows:

$$\dot{V}_E = V_T \times f$$

The frequency (f) of quiet breathing decreases with increasing age. The exact basis for this change is unknown but may be related to the work of breathing. Humans seem to adjust their respiratory rate and tidal volume so that ventilatory needs are accomplished with a minimum of work (McIlroy et al., 1954). The relatively high rate in newborns (average, 34 breaths/min) as compared with adults (10 to 12 breaths/min) is consistent with this minimum work concept (Fig. 3-34) (Cook et al., 1957). Mead (1960), however, has presented data indicating that in the

■ **FIGURE 3-34.** Calculated pulmonary work in newborns vs. respiratory rate. The theoretical minimum work of respiration occurs at a rate of 37 breaths/min. Observed resting respiratory rates were 38 breaths/min. (From Cook CD et al.: *Studies of respiratory physiology in the newborn infant. VI. measurements of mechanics of respiration*, J Clin Invest 36:440, 1957.)

normal resting state, respiration is adjusted to require a minimum average force of the respiratory muscles. Mead postulated that the principal site of the sensory end of the control mechanism is in the lungs. In certain situations, the minimum work of breathing and minimum average force required would occur at the same frequency of respiration, but this would not invariably be true.

Dead Space and Alveolar Ventilation

Only part of the minute volume is effective in gas exchange—the alveolar ventilation (\dot{V}_A). The remainder merely ventilates the respiratory dead space. If the minute noneffective ventilation ($\dot{V}_E - \dot{V}_A$) is divided by the frequency, the physiologic respiratory dead space is calculated. In the normal person, the physiologic and anatomic dead spaces are approximately equal because alveolar dead space is negligible. Because the air passages are compliant structures, the size of the dead space correlates closely with the degree of lung expansion. When airway obstruction and emphysema are present, dead space increases. However, physiologic dead space is influenced more by the evenness of gas distribution within the lungs and by the perfusion of the alveoli. Thus, when ventilation of the lungs is uneven (as in asthma or CF) or the blood supply to various areas of the lungs decreases (as with pulmonary emboli), the physiologic dead space increases.

Although the anatomic dead space represents an inefficient part of the respiratory tract with respect to gas exchange, it does have two important functions: warming and humidifying gas on inspiration. These functions are compromised by endotracheal intubation or tracheostomy.

In a healthy person, dead space can be estimated as 1 mL/pound of body weight (Radford et al., 1954). In children and

young adults, a more exact estimate may be obtained from the relation of dead space to body height (Hart et al., 1963).

The dead space to tidal volume (V_D/V_T) ratio in normal lungs is approximately constant (0.3) from infancy to adulthood (Table 3-2). An absolute increase in dead space, however, whether caused by respiratory abnormalities or external apparatus, is much more critical to the infant than to the adult because of the infant's small tidal volume and the relatively larger volume of dead space added.

Alveolar ventilation, or the minute effective ventilation, may be expressed in terms of the carbon dioxide in the peripheral arterial blood. Thus, the following equation is applicable:

$$\dot{V}_A = \frac{(P_B - 47) \times \dot{V}CO_2}{P_{aCO_2}}$$

where $\dot{V}CO_2$ is the carbon dioxide production per minute, P_{aCO_2} is the arterial carbon dioxide tension, and $P_B - 47$ is the barometric pressure minus water vapor tension at 37° C.

The difference between minute volume and alveolar ventilation ($\dot{V}_E - \dot{V}_A$) is the wasted ventilation caused by physiologic dead space. The concept of alveolar ventilation may be easier to understand if it is considered similar in some way to the renal clearance of a substance; in the lungs, CO_2 is the substance being cleared. If CO_2 remains constant when alveolar ventilation is halved, P_{aCO_2} doubles. Measurement of alveolar ventilation provides a far better index of the efficacy of ventilation than measurement of minute volume. Minute volume may be very large, but if it is composed mostly of dead space or ineffective ventilation, it may be inadequate and P_{aCO_2} may start to increase.

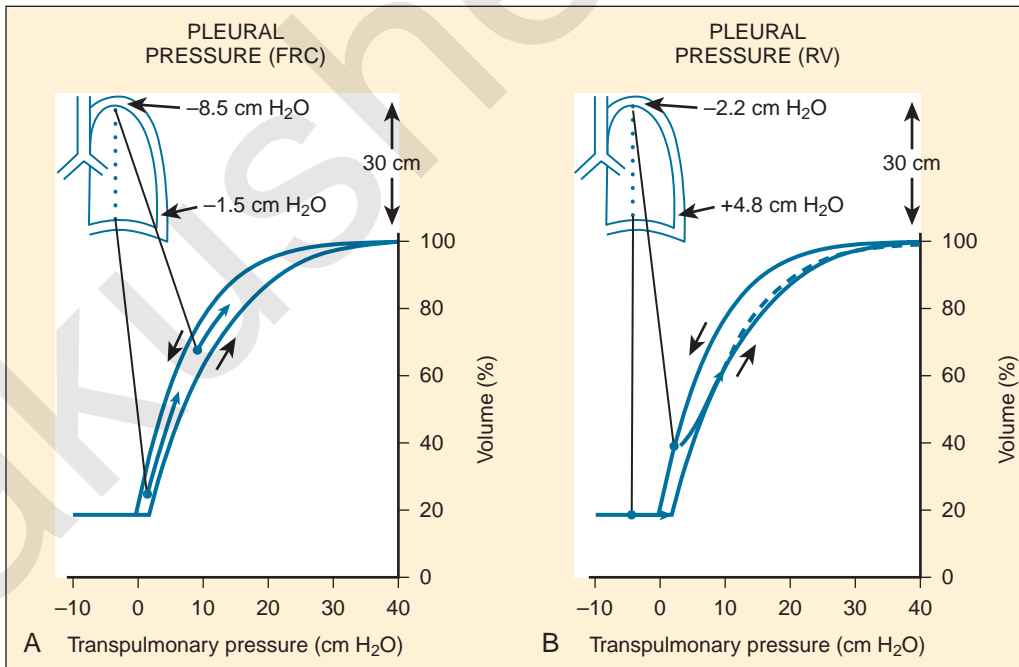

Physiologic dead space is calculated from the CO_2 tensions between arterial blood and mixed expired gas (P_{etCO_2}) and is often expressed as a fraction of the tidal volume:

$$V_D / V_T = \frac{P_{aCO_2} - P_{etCO_2}}{P_{aCO_2}}$$

Alveolar ventilation is considerably higher per unit of lung volume in the healthy infant than in the adult. This is expected because the oxygen consumption is also higher per unit of lung volume or body weight in the infant (Cook et al., 1955).

Distribution of Ventilation

The distribution of ventilation is affected by a number of factors. At end expiration with the mouth open and the larynx relaxed, alveolar pressure is zero, or atmospheric. The interpleural pressure is negative, and there is a vertical pressure gradient. The pressure surrounding the apex of the lung is more negative than that at the base. Accordingly, the transmural or distending pressure at the apex is greater and the regional FRC is larger than that at the base (Fig. 3-35, A). At the end of tidal inspiration, a greater proportion of the inspired air is distributed to the base because the regional FRC is at the steepest portion of the pressure-volume curve at the base. In a lateral decubitus position, the lower part of the lung receives a larger tidal volume than the upper part (Kaneko et al., 1966). In adults with unilateral lung disease, pulmonary gas exchange can be improved by positioning with the healthy lung down, or dependent (Remolina et al., 1981).

■ **FIGURE 3-35.** Effect of vertical gradient of pleural surface pressure on distribution of tidal ventilation. **A**, At the beginning of lung inflation from functional residual capacity (FRC), lower regions are operating on a steeper part of the compliance curve of lungs than upper regions. Accordingly, during slow inspiration from FRC, ventilation is greater in lower lung regions (arrows). **B**, At RV, pleural surface pressure at lung base is positive (+4.8 cm H₂O) and lower airways are closed. Consequently, at the beginning of slow inspiration from RV, lower lung regions are not ventilated and the uppermost part of the lung is preferentially ventilated (arrows). (From Milic-Emili J: *Pulmonary statics*. In Widdicombe JG, editor: *Respiratory physiology*, MTP international review of science, Series 1, vol 2, Borough Green, Kent, 1974, Butterworth.)

In infants with unilateral lung disease, however, the opposite seems to be the case. In the lateral decubitus position, oxygenation improves when the healthy lung is uppermost (Heaf et al., 1983; Davies et al., 1985). Furthermore, Heaf and others (1983) have shown by means of a krypton-81m ventilation scan that in infants and children up to 27 months of age, with or without radiologic evidence of lung disease, ventilation is preferentially increased in the uppermost part of the lung and diminished in the dependent lung (Fig. 3-36). This paradoxical distribution of ventilation in young children may be explained by premature airway closure (Davies et al., 1985). Because the infant's chest wall is extremely compliant, the pleural pressure is near atmospheric. The condition resembles that of adults breathing at extremely low lung volumes (or near RV) (Fig. 3-35, B). Under these circumstances, airway closure occurs and, in the lateral decubitus position, ventilation preferentially shifts to the uppermost part of the lung (Milic-Emili et al., 1966). In paralyzed, mechanically ventilated adults, tidal ventilation is preferentially shifted to the uppermost part of the lung, presumably by a similar mechanism (i.e., reduction of FRC and airway closure) (Rehder et al., 1972).

Distortion of regional mechanical properties in the lungs results in far greater variations in the distribution of ventilation than is produced by gravitational forces. The product of regional flow resistance (R , expressed as pressure/flow in $\text{cm H}_2\text{O/mL per second}$) and compliance (C , expressed as volume/pressure in $\text{mL/cm H}_2\text{O}$) determines the regional ventilation in the lungs. The product of resistance and compliance ($R \times C$) is a unit of time, termed the time constant (τ), as previously discussed. In diseased lungs, such as with asthma, BPD, and CF, the regional time constant becomes abnormal in affected areas, resulting in an uneven distribution of ventilation. The distribution of ventilation may be studied by measuring a

nitrogen wash-out curve. The subject breathes 100% oxygen, and the decay of the alveolar nitrogen concentration is measured in successive expirations. Both in normal children and adults, nitrogen concentration is less than 2.5% after 7 minutes of oxygen breathing. This value is increased in patients with an uneven distribution of ventilation because the elimination of nitrogen from poorly ventilated areas is prolonged. In addition, radioactive xenon ventilation scans have been used to demonstrate macroscopic ventilatory abnormalities to aid in the interpretation of perfusion lung scans.

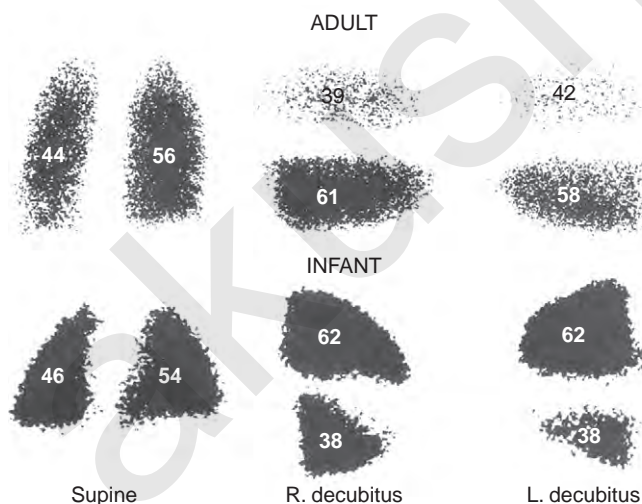

Clinical Implications

The anesthesiologist often controls a patient's ventilation manually or mechanically during general anesthesia, because most anesthetic techniques cause spontaneous ventilation to decrease or cease. This is because most anesthetics are potent respiratory depressants, and because the endotracheal tube and the anesthesia circuit add elastic and resistive loads to breathing. Because anesthesia generally causes a decrease in FRC, the uneven distribution of ventilation, and an increase in physiologic dead space, the tidal volume must be increased. The mechanical dead space and internal compliance of anesthetic equipment also must be taken into account for the proper estimation of a patient's ventilatory requirement. Physiologic dead space is further increased in patients with preexistent lung dysfunction. For these reasons, it is practical to start with a tidal volume of 10 to 15 mL/kg, or roughly 1.5 to 2.0 times that required in awake individuals.

The inspiratory-to-expiratory (I/E) ratio is set to 1:2, a duty cycle (T_i/T_{TOT}) of 0.33. Respiratory frequency should be 10 to 14 breaths/min in adolescents, 14 to 20 breaths/min in children, and 20 to 30 breaths/min in infants. Once the mechanical ventilation is established, it can be decreased and refined with the aid of capnographic monitoring. In patients with obstructive lung disease who have a prolonged respiratory system time constant, expiratory time is increased to allow sufficient time for passive lung deflation. Passive expiration is an exponential function and takes three times the time constant to return to FRC (Lamb, 2000). The addition of a low level of PEEP (5 to 7 $\text{cm H}_2\text{O}$) restores the volume (FRC) lost from the relaxation of inspiratory muscles and helps prevent airway closure.

Summary

Ventilation comprises effective (alveolar) and dead space ventilation. In healthy subjects, ventilation in relation to body size is increased in early infancy and then remains fairly constant throughout childhood and adolescence. Changes in Pao_2 reflect changes in alveolar ventilation; thus, capnographic monitoring of end tidal Pco_2 is useful for adjusting and maintaining appropriate alveolar ventilation. There is a vertical, hydrostatic gradient in negative pressure in the pleural space. Uneven distribution of ventilation exists both in health and in disease. The regional resting volume (FRC) is highest in the uppermost part of the lung, whereas the regional tidal volume is largest in the lowermost region of the lung in a spontaneously breathing subject. The opposite relationship exists in spontaneously breathing infants as well as in patients under anesthesia who are mechanically ventilated. In diseased lungs, uneven distribution

■ **FIGURE 3-36.** Posterior krypton 81m ventilation lung scan in a healthy 31-year-old man and in a 2-month-old girl. In the adult, ventilation is preferentially distributed to the dependent lung; in the infant, the reverse is seen, with ventilation greater in the uppermost lung. For all scans, the distribution of ventilation to each lung is expressed as a percentage of the total to both lungs. (From Heaf DP et al.: Postural effects on gas exchange in infants, *N Engl J Med* 308:1505, 1983.)

of regional compliance (C), resistance (R), and a time constant ($R \times C$) cause maldistribution of ventilation and increased physiologic dead space.

GAS DIFFUSION

The ultimate purpose of pulmonary ventilation is to allow the diffusion of oxygen through the alveolar epithelial lining, basement membrane, and capillary endothelial wall into the plasma and red cells and diffusion of CO_2 in the opposite direction. The distance for gases to diffuse between the alveolar space and the capillary lumen is extremely small, about 0.3 μm in humans (Weibel, 1973). Because these processes apparently follow the physical laws of diffusion, without any active participation by the lung tissue, pressure gradients must exist or gas exchange will not occur. On the other hand, if the gradient is increased by changes in gas tension either within the alveoli or in the blood, gas exchange is more rapid. Furthermore, because the blood Po_2 affects the blood Pco_2 , changes in one moiety alter diffusion of the other. CO_2 diffuses approximately 20 times faster than oxygen in a gas-liquid environment. Therefore impairment of CO_2 diffusion does not become apparent in clinical situations until extremely severe disease is present.

The diffusing capacity of the lungs may be measured with a foreign gas, carbon monoxide (CO), used in small concentrations (less than or equal to 0.3%), or with various concentrations of inspired oxygen (Forster, 1957). The subjects of diffusion and diffusing capacity have been reviewed.

The diffusing capacity of carbon monoxide (DLCO) can be measured with a single breath technique by adding an inert gas to the inhaled gas mixture with a single alveolar gas sample (Ogilve et al., 1957). The DLCO test is not exactly a measure of diffusing capacity, because *diffusing* implies that the uptake of CO is attributable to diffusion alone and *capacity* implies it is a maximal limit (Crapo et al., 2001). Indeed, the term *transfer factor* (TLCO) has become a standard term in most countries outside of North America (Forster, 1983; Cotes et al., 1993). The role of DLCO measurement in lung function testing is to provide information on the transport of gas from alveolar air to hemoglobin in pulmonary capillaries. More specifically, DLCO measures the uptake of CO from the lungs per minute per unit of CO driving pressure, as follows:

$$D_{LCO} = \frac{\dot{V}_{CO}}{P_{ACO} - P_{CCO}}$$

where CO is uptake of \dot{V}_{CO} (mL/min), P_{ACO} is alveolar partial pressure of CO, and P_{CCO} is average pulmonary capillary partial pressure of CO. Because the basic equation is flow/pressure change ($\dot{V}/\Delta P$), DLCO is a measure of conductance ($G = 1/R$).

Although the diffusion of gases within the lungs is necessary for survival, comparatively few conditions occurring in children affect diffusion per se. Diffusing capacity is decreased in the "alveolar capillary block syndrome" (Bates, 1962). This decrease was considered to result primarily from increased thickness of the alveolocapillary membranes; but it is now believed that uneven distribution of ventilation with a resulting V/Q imbalance is the more important cause of arterial oxygen desaturation (Finley et al., 1962). Diffusing capacity changes with hemoglobin concentrations; it increases as hemoglobin concentration increases. A correction factor has to be used according to the recommendation of American Thoracic Society guidelines (1995). Anemia,

on the other hand, is associated with a decrease in diffusing capacity. This is partially explained by the decreased ability of blood to carry the inspired gases. Patients with congenital heart disease and left-to-right shunts often have an increased DLCO caused by increased blood volume and flow in the lungs (Bucci and Cook, 1961). Conversely, diffusing capacity may be reduced when the pulmonary blood flow is markedly decreased, as in pulmonic stenosis.

PULMONARY CIRCULATION

Perinatal and Postnatal Adaptation

In prenatal life, pulmonary vascular resistance is high and most of the right ventricular output runs parallel to the left ventricular output, bypassing the lungs and flowing into the descending aorta through the ductus arteriosus. With the onset of ventilation at birth, the pulmonary vascular resistance suddenly decreases and blood flow through the lungs increases, enabling the organism to exchange oxygen and CO_2 and sustain independent existence. The principal factors that control this vital adjustment in vascular resistance are chemical changes (i.e., changes in Po_2 and Pco_2 or pH) in the environment of the pulmonary vessels (Cook et al., 1963). An increase in Po_2 also produces constriction and subsequent closure of the ductus arteriosus. The pulmonary arterial pressure, which is slightly higher than the pressure in the ascending aorta in the fetus, suddenly decreases at birth and then continues to decrease, with a gradual decline in pulmonary vascular smooth muscle mass approaching the adult level within the first year of life (Assali and Morris, 1964; Rudolph, 1970). If the lungs do not expand adequately (as in IRDS of the neonate) and Po_2 remains low, the pulmonary vascular resistance and pressure may remain high, and there may be prolonged patency of the ductus arteriosus and persistent right-to-left shunting of blood (Strang and MacLeish, 1961) (see Chapter 4, Cardiovascular Physiology).

Under normal postnatal conditions, the systemic and pulmonary vascular beds are connected in series to form a continuous circuit. Although the systemic circulation has a high vascular resistance with a large pressure gradient between the arteries and veins, the pulmonary circulation presents a low resistance to flow.

Both hypoxemia and hypercapnia constrict the pulmonary vascular bed and increase resistance to flow. Chronic hypoxemia is associated with a pulmonary hypertension that returns to or toward normal when the hypoxemia is corrected (Goldring et al., 1964). Pulmonary hypertension that persists for months or years results in right-sided heart failure (cor pulmonale), which then further complicates the existing pulmonary insufficiency.

Under normal circumstances, the arterial blood from the left ventricle contains up to 5% unsaturated blood (venous admixture). This comes mainly from the bronchial circulation but also in part from blood in the pulmonary circulation bypassing the alveoli and from blood flowing through the thebesian veins. This physiologic venous admixture depresses the arterial Po_2 from approximately 102 to 97 mm Hg. In certain conditions, such as V/Q imbalance (including decreased diffusing capacity), the amount of the venous admixture through the lungs increases sufficiently to cause significant arterial hypoxemia. Venous admixture also occurs because of intrapulmonary shunting as

the result of atelectasis, pulmonary arteriovenous fistula, pulmonary hemangiomas, and increased collateral (bronchial) circulation, as in bronchiectasis. In addition, shunting may occur at the cardiac level when there is congenital heart disease with right-to-left shunting.

Nitric Oxide and Postnatal Adaptation

The vascular endothelial cells release various vasoactive factors that affect vascular tone. Nitric oxide (NO) is a unique endogenous regulatory molecule involved in a wide variety of biological activities, including systemic and pulmonary vasodilation, neurotransmission, and immunomodulation (Welch and Loscalzo, 1994). Under physiologic conditions, NO is produced from the amino acid L-arginine catalyzed by constitutive NO synthase (cNOS) with a number of cofactors (nicotinamide adenine dinucleotide phosphate [NADPH], flavoproteins, tetrahydrobiopterin, reduced glutathione, and heme complex) and with the presence of ionized calcium and calmodulin. NO in the vascular endothelial cells diffuses into the adjacent vascular smooth muscle cells, stimulates guanylate cyclase activity, and increases cyclic guanylate monophosphate (cGMP), resulting in controlled smooth muscle relaxation and vasodilation (Furchgott and Vanhoutte, 1989; Moncada et al., 1989). In normal lungs, basal release of endothelium-derived NO contributes to the maintenance of low pulmonary vascular resistance (Celemajer et al., 1994; Stamler et al., 1994).

Certain cytokines and bacterial endotoxins induce a NO synthase isoform (inducible NOS [iNOS]) in macrophages, neutrophils, vascular and airway smooth muscles, and other cell types that normally do not produce cNOS. A massive release of NO by iNOS via activated macrophages and other cell types appears to be the primary cause of profound vasodilation and systemic hypotension in septic shock (Cohen, 1995).

Distribution of Pulmonary Perfusion

As with regional ventilation, gravity results in a nonuniform distribution of pulmonary blood flow in normal lungs. West (1965) divided the characteristics of upright lung perfusion into three zones, which were later modified to four zones, of flow distribution (Fig. 3-37) (Hughes et al., 1968). Perfusion of lung tissue depends on the interrelation among three pressures: alveolar pressure (P_A), pulmonary arterial pressure (P_a), and pulmonary venous pressure (P_v). Because pulmonary circulation normally is a low-pressure circuit, the pulmonary perfusion pressure varies from the top to the bottom of the lung, barely overcoming the hydrostatic pressure to reach the apex of the tall upright adult lung. Both pulmonary perfusion pressure and flow are relatively increased at the lung base (West, 1994).

In zone I, the apical-most part, alveolar pressure is higher than both pulmonary arterial and venous pressures. Alveolar capillary blood flow is absent in this zone or is only intermittently occurring with peak pulsatile pressure and flow. Ventilation in zone I is mostly wasted. Excessive PEEP increases zone I, thus increasing alveolar dead space, whereas increased pulmonary perfusion pressure, as occurs in exercise or hypoxemia, decreases or abolishes zone I.

In zone II (the waterfall zone), as the vertical distance above the heart decreases (with alveolar pressure uniform throughout the lung), arterial pressure becomes higher than surrounding

■ **FIGURE 3-37.** Four zones of lung perfusion. Zone I has no flow because alveolar pressure exceeds pulmonary arterial pressure, thereby collapsing alveolar vessels. Zone II is present when pulmonary arterial pressure exceeds alveolar pressure and both are greater than pulmonary venous pressure. This is termed the *vascular waterfall*, because flow is unaffected by downstream (pulmonary venous) pressure. Zone III is characterized by a constant driving force, the difference between pulmonary arterial and venous pressure. Both are greater than alveolar pressure. Flow increases throughout zone III, even though driving pressure is constant because the absolute pressures lower in the lung distend the vessels to a greater extent, thereby lowering resistance. Zone IV has less flow per unit lung volume, probably because of the increased parenchymal pressure surrounding pulmonary vessels. (From Hughes JMB et al.: *Effect of lung volume on the distribution of pulmonary blood flow in man*, *Respir Physiol* 4:58, 1968.)

alveolar pressure while venous pressure remains lower than alveolar pressure. The driving pressure in this zone is the difference between arterial and alveolar pressures ($P_a - P_A$), which determines blood flow regardless of venous or downstream pressure (waterfall phenomenon). The blood flow increases linearly as the driving pressure increases toward the base of the lung until pulmonary venous pressure equals alveolar pressure.

In zone III, both arterial and venous pressures are higher than alveolar pressure. The driving pressure for blood flow becomes the difference between arterial and venous pressures ($P_a - P_v$) throughout this zone. Although the pressure gradient is the same throughout zone III, blood flow is greater toward the base, presumably because both arterial and venous pressures are greater and the pulmonary vascular bed is more distended. The relationships among arterial, venous, and alveolar pressures in zones I to III are summarized as follows:

- Zone I: $P_A > P_a > P_v$
- Zone II: $P_a > P_A > P_v$
- Zone III: $P_a > P_v > P_A$

In zone IV, blood flow is progressively decreased toward the base of the lung, presumably because of increased interstitial pressure surrounding the extraalveolar vessels. This zone increases in size with reduction in the lung volume toward RV (Hughes et al., 1968; West, 1994).

The vertical distance between the top and the bottom of the lung is decreased in the supine position, resulting in the disappearance of zone I. Zone II also decreases as pulmonary

venous pressure becomes higher throughout the lung in the supine position. The effect of gravity in infants and small children, particularly in the supine position, would be small, although it has not been documented.

Ventilation/Perfusion Relationships

To achieve normal gas exchange in the lung the regional distribution of ventilation and pulmonary perfusion must be balanced. Without this balance, pulmonary gas exchange is impaired, even when the overall levels of ventilation and perfusion are adequate. The normal value for the ventilation/perfusion (\dot{V}_A/\dot{V}_P , \dot{V}_A/\dot{Q} , or simply V/Q) ratio is about 0.8. Studies with radioactive gases have shown that the elastic and resistive properties of various parts of the lung, as well as the pulmonary blood flow, are influenced by gravity. Both components of the V/Q ratio are affected by changes in a patient's position (West, 1965).

When the patient is in the upright position, blood flow and ventilation are both less in the apex than in the base of the lungs. Because the difference in blood flow between the apex and the base is relatively greater than that in ventilation, the V/Q ratio increases from the bottom to the top of the lungs, as shown in Figures 3-38 and 3-39. The apical regions (high V/Q) have higher alveolar P_{O_2} and lower P_{CO_2} and partial pressure of nitrogen (P_{N_2}), whereas the basal areas (low V/Q) have lower P_{O_2} and higher P_{CO_2} and P_{N_2} . Gravity has a greater effect on the V/Q ratio in hypotensive and hypovolemic patients and may be exaggerated with positive-pressure ventilation. In the supine position, similar differences exist between the anterior and posterior parts of the lung, but they are smaller. During exercise, pulmonary arterial pressure and blood flow, as well as ventilation, are increased and more evenly distributed. In infants and children the distribution of pulmonary blood flow is more uniform than in adults because the pulmonary arterial pressure is relatively high, and the gravity effect in the lungs is less.

In diseased lungs, changes in the V/Q ratio occur as the result of uneven ventilation, uneven perfusion, or both; for example,

FIGURE 3-39. Effect of vertical height (expressed as the level of the anterior ends of the ribs) on ventilation and pulmonary blood flow (left ordinate) and the V/Q ratio (right ordinate). (From West JB: Ventilation/blood flow and gas exchange, ed 2, Oxford, 1970, Blackwell Scientific Publications.)

compression or occlusion of pulmonary vessels, reduced pulmonary vascular bed, or intrapulmonary-anatomic right-to-left shunting may contribute to nonuniform perfusion. In congenital heart diseases with increased pulmonary blood flow caused by left-to-right shunting, the V/Q ratio is decreased. When perfusion is diminished, as in tricuspid atresia or pulmonic stenosis with tetralogy of Fallot, V/Q is increased.

The lungs appear to have an intrinsic regulatory mechanism that, to a limited extent, preserves a normal V/Q ratio. In areas with a high V/Q ratio, a low P_{CO_2} tends to constrict airways and dilate pulmonary vessels, and the opposite occurs in areas with a low V/Q ratio. In the latter case, in addition to the effect of P_{CO_2} , hypoxic pulmonary vasoconstriction (HPV) decreases regional blood flow and helps to increase V/Q ratios toward normal. The administration of drugs such as isoproterenol, nitroglycerin,

FIGURE 3-38. Effect of distribution of ventilation and perfusion on regional gas tensions in erect man. The lung is divided into nine horizontal slices, and the position of each slice is shown by its anterior rib markings. Vol, Relative lung volume; \dot{V}_A , regional alveolar ventilation; Q, regional perfusion; \dot{V}_A/\dot{Q} , V/Q ratio; R, respiratory exchange ratio. (From West JB: Regional differences in gas exchange in the lung of erect man, J Appl Physiol 17:893, 1962.)

theophylline, and sodium nitroprusside diminishes or abolishes HPV and increases intrapulmonary shunting (Goldzimer et al., 1974; Colley et al., 1979; Hill et al., 1979; Benumof, 1994). All inhaled anesthetics depress HPV in vitro, contributing to an increase in venous admixture during general anesthesia (Sykes et al., 1972; Bjertnaes, 1978). The effect of inhaled anesthetics on HPV, however, has not been conclusive in vivo (Marshall and Marshall, 1980, 1985; Pavlin and Su, 1994).

Wagner and others (1974) have developed a quantitative method of studying the continuous spectrum of V/Q mismatch. The technique is based on the pattern of elimination of multiple inert gases infused intravenously. At steady state after intravenous infusion of test gases dissolved in saline solution, arterial, mixed-venous, and expired gas samples are obtained, and minute ventilation and cardiac output are measured. The ratio of arterial to mixed venous concentration (retention) and the ratio of expired to mixed venous concentration (excretion) are computed for each gas, and retention-solubility and excretion-solubility curves are drawn by the computer. The ratio of the two curves represents the distribution of perfusion and ventilation on the spectrum of V/Q ratios (Fig. 3-40) (West, 1974, 1994; Benumof, 1994).

■ **FIGURE 3-40.** Upper graph shows the average distribution of V/Q ratios in young semirecumbent normal subjects. The 95% range covers V/Q from 0.3 to 2.1. The corresponding variations of P_{O_2} , P_{CO_2} , and oxygen saturation in the end-capillary blood can be seen in the lower panel. (From West JB: *Blood flow to the lung and gas exchange*, Anesthesiology 41:124, 1974.)

Low Ventilation/Perfusion Ratio and Lung Collapse While Breathing Oxygen

In a lung unit with a low regional V/Q ratio while breathing oxygen, collapse of the lung unit occurs, leading to atelectasis. As alveolar ventilation to the lung unit (\dot{V}_A) decreases, regional expiratory volume (V_E) decreases progressively in comparison with regional inspiratory volume (V_I) as it approaches the amount of oxygen taken up by regional pulmonary blood flow. A point is reached at which the expired alveolar volume falls to zero (West, 1974). This situation occurs at the "critical" inspired V/Q. With inspired ratios less than the critical V/Q value, the lung unit becomes unstable; oxygen may enter rather than leave the lung unit during the expiratory phase or the unit may gradually collapse (Figure 3-41) (West, 1975). Figure 3-42 shows the calculated relationship between the critical inspired V/Q and the concentration of inspired oxygen (assuming mixed venous P_{O_2} of 40 mm Hg and P_{CO_2} of 45 mm Hg and no nitrogen exchange occurring across the whole lung). From Figure 3-42, it can be seen that lung units with V/Q of less than 0.01 become vulnerable when F_{iO_2} is increased above 0.5, whereas lung units with inspiratory \dot{V}_A/\dot{Q} of 0.1 are not at risk even with 100% oxygen (West, 1975). Although a V/Q of less than 0.1 is uncommon in normal awake children, lung units with a V/Q of less than 0.1 may occur in the diseased lung as well as in the normal lung under general anesthesia.

OXYGEN TRANSPORT

For normal metabolism, oxygen must be transported continuously to all body tissues. Changes in oxygen demand are met by the integrated response of three major functional components of the oxygen transport system: pulmonary ventilation, cardiac output, and blood hemoglobin concentration and characteristics. With acute oxygen demand, such as with extreme exercise, high fever, or acute hypoxemia (less than 60 mm Hg), oxygen transport is increased mainly by increased cardiac output, whereas alveolar ventilation is increased to maintain proper levels of alveolar P_{O_2} and P_{CO_2} . Chronic hypoxemia increases erythropoietin production, thereby increasing erythrocyte

■ **FIGURE 3-41.** Schematic drawings to explain the development of shunts in lung units with low inspiratory \dot{V}_A/\dot{Q}_P (\dot{V}_{AI}/\dot{Q}) caused by breathing high concentrations of oxygen. **A**, Stable; there is a small expired alveolar ventilation (\dot{V}_A) and the unit is stable. **B**, Critical; inspired \dot{V}_A is decreased slightly from A and expired \dot{V}_A falls to zero. **C**, Unstable; inspired \dot{V}_A is further reduced and gas enters into the lung unit during the expiratory phase. **D**, Unstable; reverse inspiration during expiratory phase is prevented and the unit gradually collapses. (From West JB: *New advances in pulmonary gas exchange*, Anesth Analg 54:409, 1975.)

FIGURE 3-42. Relationship between inspired oxygen concentration and critical inspiratory \dot{V}_{A}/\dot{Q}_c , the value at which the expired ventilation of a given lung unit falls to zero. Lung units whose \dot{V}_{A}/\dot{Q}_c is less than the critical value may be unstable and easily collapse. (From West JB: *New advances in pulmonary gas exchange*, Anesth Analg 54:409, 1975.)

production from the normal daily rate of approximately 1% of circulating red cell mass to about 2%. Thus, increasing red cell mass in response to chronic hypoxemia is a slow process (Finch and Lenfant, 1972). Hemoglobin concentrations greater than the normal level (15 g/dL) raise viscosity and increase blood flow resistance until the plasma volume is also increased (Thorling and Erslev, 1968).

The amount of oxygen carried by the plasma depends on its solubility and is small (0.31 mL/dL per 100 mm Hg). Most oxygen molecules in blood combine reversibly with hemoglobin to form oxyhemoglobin. Each molecule of hemoglobin combines with four molecules of oxygen; 1 g of oxyhemoglobin combines with 1.34 mL of oxygen.

Oxygen Affinity of Hemoglobin and P_{50}

The oxygen-hemoglobin dissociation curve reflects the affinity of hemoglobin for oxygen (Fig. 3-43). As blood circulates through the normal lungs, oxygen tension increases from the mixed-venous P_{O_2} of around 40 mm Hg to pulmonary capillary P_{O_2} of above 105 mm Hg, and hemoglobin is saturated to about 97% in arterial blood. (Unfortunately, most pulse oximeters commercially available today are artificially modified to read 100% saturation in healthy subjects breathing room air rather than 97%; see later discussion.) The shape of the dissociation curve is such that further increases in P_{O_2} result in a very small increase in oxygen saturation (S_{O_2}) of hemoglobin.

The blood of normal adults has S_{O_2} of 50% when P_{O_2} is 27 mm Hg at 37° C and a pH of 7.4. The P_{50} , which is the P_{O_2} of whole blood at 50% S_{O_2} , indicates the affinity of hemoglobin for oxygen. An increase in blood pH increases the oxygen affinity

FIGURE 3-43. Schematic representation of oxygen dissociation curve and factors that affect blood oxygen affinity. Oxygen partial pressure at 50% oxygen saturation (P_{50}) is a convenient index of oxygen affinity. P_{50} of adult blood (at 37° C; pH, 7.40; P_{CO_2} , 40 mm Hg) is roughly 27 mm Hg and is influenced by a number of factors. H^+ , hydrogen ion concentration; P_{aO_2} , arterial oxygen tension; S_{aO_2} , Arterial oxygen saturation; T° , blood temperature; 2,3 DPG, 2,3-diphosphoglycerate.

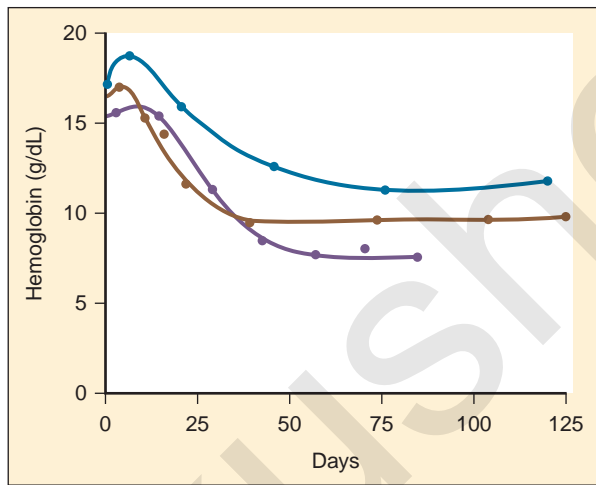

of hemoglobin (Bohr effect) and shifts the oxygen-hemoglobin (O_2 -Hb) dissociation curve to the left. Similarly, a decrease in temperature also increases oxygen affinity and shifts the O_2 -Hb dissociation curve to the left; a decrease in pH or an increase in temperature has the opposite effect and the O_2 -Hb curve shifts to the right (Comroe, 1974) (Fig. 3-43).

Benesch and Benesch (1967) and Chanutin and Curnish (1967) demonstrated that the oxygen affinity of a hemoglobin solution decreases by the addition of organic phosphates, in particular 2,3-diphosphoglycerate (2,3-DPG) and adenosine triphosphate (ATP), which bind to deoxyhemoglobin but not to oxyhemoglobin. Human erythrocytes contain an extremely high concentration of 2,3-DPG, averaging about 4.5 mol/mL, compared with ATP (1 mol/mL) and other organic phosphates (Oski and Delivoria-Papadopoulos, 1970). Thus, an increase in red cell 2,3-DPG decreases the oxygen affinity of hemoglobin, increases P_{50} (shifts the dissociation curve to the right), and increases the unloading of oxygen at the tissue level. Increases in 2,3-DPG and P_{50} have been found in chronic hypoxemia.

In the newborn, blood oxygen affinity is extremely high and P_{50} is low (18 to 19 mm Hg), because 2,3-DPG is low and fetal hemoglobin (HbF) reacts poorly with 2,3-DPG (Fig. 3-44). Oxygen delivery at the tissue level is low despite high red blood cell mass and hemoglobin level. After birth, the total hemoglobin level decreases rapidly as the proportion of HbF diminishes, reaching its lowest level by 2 to 3 months of age (physiologic anemia of infancy) (Fig. 3-45). During the same early postnatal period, P_{50} increases rapidly; it exceeds the normal adult value by 4 to 6 months of age and reaches the highest value ($P_{50} = 30$) by 10 months and remains high during the first decade of life

■ **FIGURE 3-44.** Schematic representation of oxygen-hemoglobin dissociation curves with different oxygen affinities. In infants older than 3 months with high P_{50} (30 mm Hg vs. 27 mm Hg in adults), tissue oxygen delivery per gram of hemoglobin is increased. In neonates with a lower P_{50} (20 mm Hg) and a higher blood oxygen affinity, tissue oxygen unloading at the same tissue PO_2 is reduced.

■ **FIGURE 3-45.** Hemoglobin concentration in infants of varying degrees of maturation at birth. *Blue*, Full-term infants; *brown*, premature infants with birth weights of 1200 to 2350 g; *purple*, premature infants with birth weights less than 1200 g. (From Nathan DG, Oski FA: Hematology of infancy and childhood, ed 3, Philadelphia, 1987, WB Saunders.)

(Fig. 3-46) (Oski and Delivoria-Papadopoulos, 1970; Oski, 1973a, 1973b). This high P_{50} is associated with a relatively low hemoglobin level (10 to 11 g/dL) and an increased level of 2,3-DPG, probably related to the process of general growth and development and high plasma levels of inorganic phosphate (Card and Brain, 1973). These observations engendered a hypothesis to explain why hemoglobin levels are relatively lower in children than in adults (physiologic “anemia” of childhood) (Card and Brain, 1973). Because children have a lower oxygen affinity for hemoglobin, oxygen unloading at the tissue level is increased.

■ **FIGURE 3-46.** Oxyhemoglobin equilibrium curve of blood from normal term infants at different postnatal ages. The P_{50} on day 1 is 19.4 ± 1.8 mm Hg and has shifted to 30.3 ± 0.7 at age 11 months (normal adults = 27.0 ± 1.1 mm Hg). (From Oski FA: *The unique fetal red cell and its function*, Pediatrics 51:494, 1973b.)

TABLE 3-3. Oxygen Unloading Changes with Age

Age	P_{50} (mm Hg)	Percent Saturation at Venous Oxygen Tension of 40 mm Hg	Hemoglobin (g/100 mL)	Oxygen Unloaded* (mL/100 mL)
1 day	19.4	87	17.2	1.84
3 wk	22.7	80	13.0	2.61
6-9 wk	24.4	77	11.0	2.65
3-4 mo	26.5	73	10.5	3.10
6 mo	27.8	69	11.3	3.94
8-11 mo	30.0	65	11.8	4.74
5-8 yr	29.0	67	12.6	4.73
9-12 yr	27.9	69	13.4	4.67
Adult	27.0	71	15.0	4.92

Data from Oski FA: Designation of anemia on a functional basis, *J Pediatr* 83:353, 1973a.

*Assumes arterial oxygen saturation of 95%.

Thus, a lower level of hemoglobin in infants and children is just as efficient, in terms of tissue oxygen delivery, as a higher hemoglobin level in adults (Oski, 1973a) (Table 3-3). Table 3-4 compares the hemoglobin concentrations at different ages in terms of equal tissue oxygen unloading (Motoyama et al., 1974).

TABLE 3-4. Hemoglobin Requirements for Equivalent Tissue Oxygen Delivery

	P ₅₀ (mm Hg)	Hemoglobin for Equivalent O ₂ Delivery (g/dL)						
		7	8	9	10	11	12	13
Adult	27	7	8	9	10	11	12	13
Infant >6 mo	30	5.7	6.5	7.3	8.2	9.0	9.8	10.6
Neonate <2 mo	24	10.3	11.7	13.2	14.7	16.1	17.6	19.1

Data calculated from Motoyama EK et al.: Functional basis of childhood anemia [abstract], *Am Soc Anesthesiology* 283, 1974.

Acceptable Hemoglobin Levels

These findings have important clinical implications for anesthesiologists. Until the 1980s it was assumed that children with a hemoglobin level of less than 10 g/dL were not acceptable for general anesthesia and surgery. This level of hemoglobin has been used arbitrarily without the knowledge of different oxygen affinity and tissue oxygen unloading at different ages. It appears from Table 3-4 that if a hemoglobin level of 10 g/dL is acceptable for an adult with a P₅₀ of 27 mm Hg, 8.2 g/dL should theoretically be adequate for an infant older than 8 months of age with an average P₅₀ of 30 mm Hg (without considering the high level of metabolism and oxygen consumption). In contrast, for a 2-month-old premature infant with a P₅₀ of 24 mm Hg, a hemoglobin level of 10 g/dL is equivalent to only 6.8 g/dL in adults, and this may be inadequate to provide sufficient tissue oxygenation in patients with limited cardiac output or oxygen desaturation.

With the advent of human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) and the resultant anxiety among the medical community and the lay public about homologous blood transfusion, the criteria for transfusion have changed significantly since the 1980s. At the consensus-developing conference by the National Institutes of Health and the Food and Drug Administration on Perioperative Red Blood Cell Transfusion, it was agreed that the available evidence does not support the “10/30” rule (that is, hemoglobin, 10 g/dL, or hematocrit, 30%), although the literature is remarkable for its lack of carefully controlled, randomized studies that would provide definitive conclusions (Consensus Conference, 1988). Other data suggest that cardiac output does not increase dramatically in healthy adult humans until the hemoglobin value decreases to approximately 7 g/dL.

At the Consensus Conference (1988) it was also agreed that the decision to transfuse red blood cells in a specific patient should take into consideration the many factors that comprise clinical judgment. These factors include the duration of anemia, the intravascular volume, the extent of surgery, the probability of massive blood loss, and the presence of coexisting conditions such as impaired cardiopulmonary function and inadequate cardiac output. A general consensus on the acceptable perioperative levels of hemoglobin and hematocrit in infants and young children has not emerged, and the lowest safe limit of hemoglobin for infants less than 2 months of age has not been determined, although in sick infants it is desirable to maintain a hemoglobin level of 12 to 13 g/dL or a hematocrit of 40% (equivalent to 8 g/dL in adults) (see Chapter 14, Blood Conservation).

There has been controversy about what constitutes abnormally low oxygen saturation in infants and children postoperatively and what is considered clinically unsafe. Mok and others (1986) reported that during the first week of life, oxygen saturation as monitored with pulse oximetry (SpO₂) was noticeably decreased, especially during REM sleep (mean SpO₂, 92%) and during feeding (SpO₂, 91%). After 4 weeks of age, however, SpO₂ was more stable and was maintained at or above 94% during sleep. Thus, an SpO₂ of less than 94% can be considered as physiologically abnormal in infants beyond the first week of age. A study in preterm infants (mean gestational age, 33 weeks; postconceptional age, 37 weeks) has shown that median SpO₂ at the time of discharge was 99.5% and increased to 100% at follow-up 6 weeks later. The preterm infants had higher baseline saturation and no more incidence of desaturation than full-term infants of equivalent postconceptional ages (Poets et al., 1992). It is generally agreed that SpO₂ less than 95% in otherwise healthy infants and children is abnormal and that these patients require oxygen supplementation.

The routine use of pulse oximetry has dramatically improved the anesthesiologist's ability to monitor and properly maintain proper oxygenation (Coté et al., 1988, 1991). This is especially true for premature infants, who are susceptible to oxygen toxicity and retinopathy of prematurity, even when breathing room air (Wilson-Mikity syndrome). In premature infants weighing less than 1300 g, the incidence of retinopathy of prematurity increases markedly with exposure to 12 or more hours of Pao₂ exceeding 80 mm Hg (Flynn et al., 1992). Arterial oxygen saturation (Sao₂) must be adjusted properly so as to maintain Pao₂ in the normal neonatal range of 60 to 80 mm Hg (Orzalesi et al., 1967). As mentioned, oxygen affinity to hemoglobin is very high in the neonate and decreases rapidly during the first 3 to 6 months of life (Oski, 1973a, 1973b, 1981). Estimated Pao₂ should be adjusted according to age, as shown in Table 3-5. In the newborn, whose P₅₀ is 18 to 20 mm Hg, the range of Sao₂ to maintain adequate Pao₂ (60 to 80 mm Hg) is 97% to 98% (assuming no transfusion with adult blood has been given), whereas in the adult (P₅₀, 27), it is 91% to 96%. In the neonate, Sao₂ of 91% corresponds to Pao₂ of 41 mm Hg. Although the values in Table 3-5, based on Severinghaus's nomogram for the Bohr effect, are only estimates, published data comparing arterial Po₂ and oxygen saturation seem to agree well with values in the nomogram (Severinghaus, 1966; Ramanathan et al., 1987; Bucher et al., 1989).

Unfortunately, another factor compounding the confusion (and clinically too important to ignore) is that the most commonly used pulse oximeters in the United States are artificially set to read 2% to 3% higher at the 90% to 95% range than actual arterial oxygen hemoglobin saturation (as measured by means of cooximetry), and that the pulse oximeters most commonly used in Europe tend to read somewhat lower than actual arterial oxygen saturation (Jennis and Peabody, 1987; Bucher et al., 1989). Unfortunately, a newer and technologically advanced pulse oximeter with less motion artifact, which has increasingly been used in the United States and elsewhere, also has artificially increased readings; it also reads 2% to 3% higher, matching the reading of the more traditionally used pulse oximeter (M. Patterson, 1995, personal communications). In view of these findings, the range of SpO₂ of 93% to 95%, corresponding to an estimated Pao₂ of 66 to 74 mm Hg in adults (but only 40 to 50 mm Hg in neonates), often recommended as desirable maintenance levels for neonates and premature infants in intraoperatively or in the intensive care settings, appears much too low

TABLE 3-5. Estimated PO₂ at Different P₅₀ Values of Hemoglobin*

Data calculated from Severinghaus JW: Blood gas calculator, *J Appl Physiol* 21:1108, 1966.

*Data are calculated with the assumption that the shift in oxygen dissociation curve of hemoglobin because of changes in its oxygen affinity at neutral pH (7.40) is the same as the shift caused by the Bohr effect.

[†]Po₂ at which oxygen saturation of hemoglobin (So₂) is 50%.

for adequate tissue oxygenation. Furthermore, respiratory alkalosis, which may result from assisted or controlled ventilation, would shift the oxygen hemoglobin dissociation curve further to the left (P₅₀ even lower than it already is) and decrease PaO₂ and tissue oxygen delivery even further at this range of oxygen saturation (Fig. 3-43). Therefore, in clinical practice, SpO₂ levels of 95% to 97% (corresponding PaO₂ of 50 to 70 mm Hg in neonates and 60 to 80 mm Hg in infants 1 to 2 months old) but not higher, should be considered.

Some anesthetics affect the oxygen affinity of hemoglobin. The presence of cyclopropane (although it has not been used since the 1970s) significantly decreases oxygen affinity and increases P₅₀ by 3 mm Hg without changes in the 2,3-DPG levels, whereas halothane has minimal effects (Orzalesi et al., 1971). Exposure to 50% nitrous oxide, on the other hand, has been reported to produce a marked reversible increase in oxygen affinity; P₅₀ decreased from 26 to 18 mm Hg, a level similar to that of HbF (Fournier and Major, 1984). This finding contrasts with a report based on one patient by Prime (1951), who found no effect with 70% nitrous oxide, and with a study by

Smith and others (1970) who reported a 3 mm Hg rightward shift of P₅₀ with an unspecified concentration of nitrous oxide. The finding of Fournier and Major above may be of considerable clinical importance. Although less often used of late, nitrous oxide anesthesia combined with hyperventilation would markedly increase the oxygen affinity of hemoglobin and decrease oxygen unloading at the tissue level. This effect could be hazardous in neonates whose P₅₀ is unusually low even without respiratory alkalosis or nitrous oxide.

Surface Activity and Pulmonary Surfactant

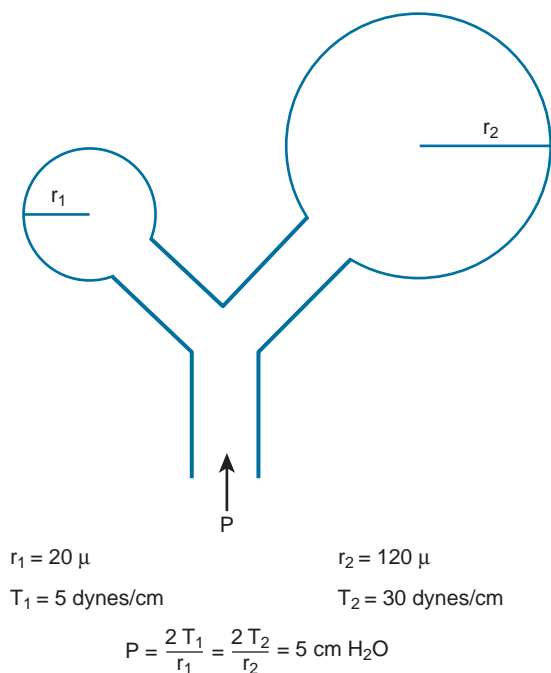

The alveolar surfaces of human lungs are lined with surface-active materials with unique properties that are responsible for the stability of air spaces. These materials, which contain specific phospholipids and proteins (discussed later), are collectively called pulmonary surfactant.

The relationship among pressure (P), surface tension (T), and radius (r) of a sphere, such as a soap bubble, is expressed by the Laplace equation as follows:

$$P = 2T / r$$

It can be seen from this equation that if surface tension is constant, in a number of connected spheres the smallest sphere has the highest pressure. Thus, the smaller spheres would empty their gas contents into the larger ones. If this concept applied to lung units, the lungs would be unstable, with most units collapsing into several large ones, as seen in the lung of an infant with IRDS. Fortunately, such instability does not exist in normal lungs. As Clements and others (1958) first demonstrated, saline extract of normal lungs exhibits extremely low surface tensions (0 to 5 dynes/cm) with dynamic compression of the surface area increasing surface tension (up to 30 to 50 dynes/cm) during expansion of the surface area. In comparison, pure water has a fixed surface tension of about 72 dynes/cm in room temperature and soap bubbles exhibit relatively low (20+ dynes/cm) but fixed surface tension. These findings by Clements et al. indicate that, in normal lungs, the surface tension decreases as the alveolar radius decreases during exhalation and vice versa; the stability of the air spaces is maintained regardless of the size of each alveolus or lung unit (Fig. 3-47).

The alveolar lining layer obtained from lung lavage contains approximately 10% lipoprotein and 90% phospholipid. Of the phospholipid fraction of surfactant, phosphatidylcholine constitutes about 70%, of which about 60% (about 40% of total phospholipid fraction) is surface active "disaturated" dipalmitoylphosphatidylcholine with saturated palmitate (C-16) in both R₁ and R₂ positions of the three carbon skeleton of phospholipid, whereas other phosphatidylcholines contain unsaturated fatty acids in the R₂ position and are not surface active (Figs. 3-48 and 3-49). Phosphatidylglycerol, another surface active phospholipid, was subsequently identified in the lung extract and comprises about 10% of surfactant fraction (Rooney et al., 1974). Phosphatidylglycerol appears late during the development; its appearance or reappearance coincide with the recovery from IRDS and acute respiratory distress syndrome (ARDS) in adults and with the loss of surfactant (Lewis and Jobe, 1993). Other phospholipids include sphingomyelin (also surface active), phosphatidylethanolamine and phosphatidylinositol, which are not surface active (Rooney, 1985). The production of phosphatidylcholine increases towards term, whereas that of

Phospholipid classes

- Phosphatidylcholine: X = CH₂ - CH₂ - ⁺N(CH₃)₃
- Phosphatidylethanolamine: X = CH₂ - CH₂ - ⁺NH₃
- Phosphatidylglycerol: X = CH₂ - CHOH - CH₂OH
- Phosphatidylinositol: X = C₆H₆(OH)₅
- Phosphatidylserine: X = CH₂ - CH(COO⁻) - ⁺NH₃

■ **FIGURE 3-48.** Molecular structure of glycerophospholipids. Glycerophospholipids have two fatty acyl chains (R₁ and R₂) attached by ester linkages to a three-carbon glycerol backbone. A polar head group, which determines the phospholipid class, is also attached to the glycerol backbone. The classes shown are PC, Phosphatidylcholine or lecithin; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; and PS, phosphatidylserine. Only the disaturated PC (DPPC) with saturated 16 carbon fatty acid chains (palmitates) on both R₁ and R₂ positions and PG are surface active and constitutes major fractions of surfactant phospholipids. (From Notter RH: *Lung surfactants: basic science and clinical applications*, New York, 2000, Marcel Dekker.)

■ **FIGURE 3-49.** Composition of surfactant. DPPC, Dipalmitoylphosphatidylcholine; PC, phosphatidylcholine; PG, phosphatidylglycerol; PL, phospholipids.

sphingomyelin decreases. The ratio of these phospholipids (L/S ratio) in the amniotic fluid has been used as an index of fetal lung maturity (Kulovich et al., 1979).

Inadequacy or deficiency of the surfactant system is important in several clinical conditions. Historically, Avery and Mead (1959) showed that the minimum surface tension of lung extracts from premature infants dying of IRDS was unusually high when measured on the Wilhelmy balance. Surface-active phosphatidylcholine is markedly decreased or even absent in the alveolar linings in these lungs (Boughton et al., 1970). These findings partially explain the atelectasis and low compliance in the lungs of infants with this syndrome.

There are four surfactant proteins (SP) that have been identified (SP-A, SP-B, SP-C, and SP-D), which comprise about 10% of surfactant on the mature alveolar surface (see Fig. 3-49). Of these, SP-B and SP-C are intimately linked to the stability of surface active monolayer at the alveolar surface. They are both predominantly expressed in type II alveolar epithelial cells (pneumocytes) and Clara cells in the bronchioles. SP-B is essential for myelin formation of the lamellar inclusions in type II cells and promotes surface adsorption of dipalmitoylphosphatidylcholine in the lipid mixtures and an addition of the mixture of surface active phospholipids, and SP-B restores the normal pressure-volume curves of the lungs in the animal model of IRDS (Suzuki et al., 1989; Rider et al., 1993).

Surfactant proteins SP-A and SP-D are similar in structure, containing proline-rich collagen domain in addition to carbohydrate domain (called collectins). In mature lungs, SP-A is predominantly expressed in type II pneumocytes and Clara cells, whereas SP-D is widely expressed in various epithelial surfaces in the body (Hull et al., 2000). SP-A and SP-D seems to function primarily as innate host defense molecules in the airways and alveoli (Jobe and Weaver, 2002). SP-A increases production of NO by macrophages and promotes killing of pathogens. SP-A also down-regulates general inflammatory responses of the lung by decreasing the generation of TNF-alpha and other inflammatory cytokines and granulocyte recruitment and activation (Jobe and Weaver, 2002). A decrease in SP-A is probably common in patients with severe lung injury. Infants born

with decreased SP-A/dipalmitoylphosphatidylcholine ratio are at increased risk of developing BPD and dying (Hallman et al., 1991).

Surfactant phospholipids and proteins are produced within the type II pneumocytes, stored in the osmiophilic lamellar inclusions within these cells, and excreted into the alveolar surface, forming tubular myelins and subsequently spreading to form surface-active alveolar lining layers (Figs. 3-50, 3-51, and 3-52) (Kikkawa et al., 1965).

Fujiwara and others first reported, with impressive results, the instillation in the trachea of bovine surfactant in premature infants born with surfactant deficiency (Fujiwara et al., 1980). Surfactant replacement therapy using human, bovine, or synthetic surfactant in premature infants with IRDS has been established as an important and essential form of therapy, reducing morbidity and mortality (Merritt et al., 1986; Lang et al., 1990; Hoekstra et al., 1991; Long et al., 1991; Holms, 1993). Surfactant replacement therapy has been extended to cover other clinical conditions with surfactant deficiency or inactivation not only in premature infants but also in full-term infants, children, and adults. These conditions include neonates with persistent pulmonary hypertension (PPHN) in whom surfactant production by type II pneumocytes is depressed because of severe pulmonary hypoperfusion and hypoxia; neonates with severe congenital diaphragmatic hernia (CDH) whose immature lungs are damaged by ventilator-induced lung injury and surfactant inactivation by plasma protein leak on the alveolar surface; meconium aspiration syndrome caused by pulmonary

hypoperfusion, inflammation, and inactivation of surfactant by protein leak; and ARDS in children and adults (Jobe, 1993; Pramanik et al., 1993).

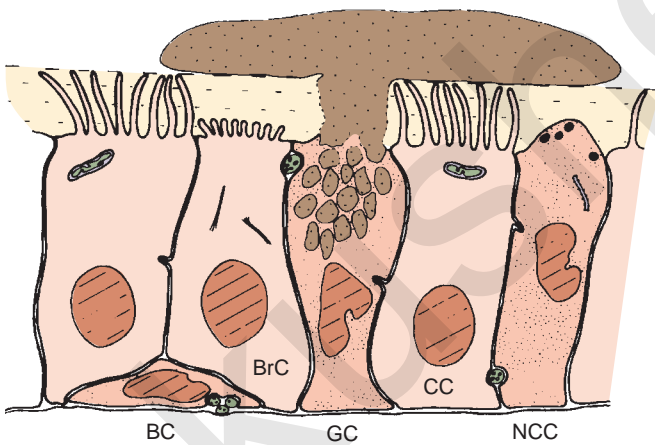

CILIARY ACTIVITY

The tracheal and bronchial walls are lined with pseudostratified epithelium that consists of ciliated cells, nonciliated serous and brush cells, and abundant mucus-secreting goblet cells. The submucosal area contains numerous serous and mucous cell glands, which are major contributors of the mucus in the respiratory tract. Under normal circumstances both goblet cells and mucus-secreting glands diminish in number toward the periphery of the airway system. The mucosal surface is covered by a serous fluid layer, in which the cilia beat. Above this periciliary layer of serous fluid lie discontinuous flakes of mucus (rather than the continuous mucous blanket assumed previously), which are moved cephalad by the cilia (Fig. 3-53) (Jeffery and Reid, 1977).

The cilia in the respiratory tract play an important role in the removal of mucoïd secretions, foreign particles, and cell

■ **FIGURE 3-52.** Life cycle of pulmonary surfactant. SP-A, SP-B, SP-C, and phospholipids are packaged in lamellar inclusion bodies and secreted by type II alveolar epithelial cells (pneumocytes) into the air space. Lamellar bodies unfold into tubular myelin, which gives rise to the phospholipid-surfactant protein film at the air-liquid interface. Used surfactant phospholipids are released from the film as small vesicles, which are taken up and recycled or degraded by type II cells. Alveolar macrophages also take up surfactant and degrade it. SP-A, SP-B, SP-C, Surfactant proteins A, B, and C.

■ **FIGURE 3-53.** The ultrastructure of airway epithelium represented diagrammatically. Cilia beat in a fluid layer of low viscosity above which move flakes of mucus. Ciliated cells (CC), goblet cells (GC), nonciliated "serous" cells (NCC), brush cells (BrC), and basal cells (BC) are shown, as are nerves penetrating the epithelium. (From Jeffery PK, Reid LM: *The respiratory mucous membrane*. In Brain JD et al., editors: *Respiratory defense mechanisms*, New York, 1977, Marcel Dekker.)

debris and are an essential defense mechanism of the airway system. These cilia move in a synchronous, whip-like fashion at a rate of 600 to 1300 times per minute. They can move particles toward the mouth at the rate of about 1.5 to 2 cm/min (Lichtiger et al., 1975).

Ciliary function is influenced by the thickness of the mucous layer and other factors that can occur with dehydration or infection. In tissue culture, some viral infections reduce ciliary motion as much as 50%, and repeated infections in vivo can destroy the cilia completely (Kilburn and Salzano, 1966). Inhalation of warm air with 50% humidity maintains normal ciliary activity, whereas breathing dry air for 3 hours results in a complete cessation of mucus movement. Ciliary activity can be restored by breathing warm, saturated air (Forbes, 1974; Hirsch et al., 1975). Breathing 100% oxygen and controlled positive-pressure ventilation also affect ciliary function (Wolfe et al., 1972; Forbes, 1976; Forbes and Gamsu, 1979).

Inhaled anesthetics seem to decrease ciliary function in both animals and humans. Forbes and Horrigan (1977) observed a dose-related depression of ciliary activity during halothane and enflurane anesthesia. The same group of investigators found delayed mucus clearance during and 6 hours after discontinuation of halothane or diethyl ether anesthesia (Forbes and Gamsu, 1979). These findings suggest that inhaled anesthesia has adverse effects on mucociliary clearance, especially in patients with pulmonary disease. The effect of anesthetics on mucociliary clearance in infants and children has not been reported.

MEASUREMENTS OF PULMONARY FUNCTION IN INFANTS AND CHILDREN

Airway obstruction is often difficult to assess clinically, particularly in young infants. For instance, what appears to be stridor may not indicate obstruction of the upper or extrathoracic airways. Similarly, although wheezing commonly represents disorders of relatively large intrathoracic airways (such as bronchial asthma), other airway dysfunction, from the upper airways (such as stridor) to the lower airways (such as rhonchi from secretions) can be mistaken for wheezing.

Another cause of abnormal breath sounds is an airway abnormality as narrowing of the airway lumen by mucosal edema, compression, secretions, foreign objects, or hyperreactive airway smooth muscles. Stridor and wheezing may also be caused by increased collapsibility of the airways, as seen in laryngotracheomalacia that involves both the upper and lower (large central) airways. A careful evaluation of the medical history and physical examination are obviously essential and helpful but may be inadequate to determine the exact nature of the disorder.

Pulmonary function tests (PFTs) are most effective in evaluating the respiratory status of infants and children and in documenting the site(s), nature, and extent of airway dysfunction. In addition, pulmonary function tests allow objective and quantitative assessment of airway reactivity such as occurs with bronchial asthma and BPD and the response of airway reactivity to bronchodilator therapy. For a detailed account of various measurements of pulmonary function in children and adolescents, the publications by Polgar and Promadhat (1971) and Bates (1989) should be consulted.

Until recently, PFTs relied almost entirely on the understanding and cooperation of children who could respond to the commands of pulmonary technicians to perform various test maneuvers. PFTs, therefore, have been effective only for intelligent and cooperative children older than 5 or 6 (sometimes as young as 3) years of age. More recently, new techniques have been developed to perform modified PFTs in anesthetized, paralyzed,

and intubated infants and children using a forced deflation or in infants and toddlers under heavy sedation with chest compression (also known as a “squeeze technique”) (Motoyama et al., 1987; Frey et al., 2000; Weiner et al., 2003). Both of these techniques produce MEFV curves for analysis.

The most common types of pulmonary disability may be classified under the general headings of restrictive diseases and obstructive diseases, although there is considerable overlap between the two groups. Restrictive disorders, whether intrapulmonary or extrapulmonary in origin, result in reduced lung volumes. Relatively common restrictive disorders in infants and children, from the anesthesiologist’s point of view, include persistent PPHN and CDH in the newborn period, congestive (also obstructive) heart failure, pulmonary fibrosis, kyphoscoliosis, obesity, and abdominal distention in older children.

In patients after surgery, especially those given muscle relaxants, the VC is a practical guide to muscle strength. A VC of at least twice the tidal volume (15 mL/kg; normal range, 60 to 70 mL/kg) appears necessary to maintain adequate spontaneous ventilation. The measurement of peak inspiratory and expiratory pressures against airway occlusion at FRC provides additional information. A minimum of 30 cm H₂O is needed for effective coughing and adequate spontaneous breathing.

Obstructive pulmonary disorders may be classified into upper and lower airway diseases. Most of the severe upper airway diseases, such as acute epiglottitis and subglottic croup, occur in infancy and early childhood. Occasionally, however, upper airway obstruction can be seen in children with obstructive sleep apnea syndrome (OSAS) with chronic adenotonsillar hypertrophy, as well as in children with subglottic stenosis associated with prolonged intubation or tracheostomy. Vascular ring and vascular sling are rare but are associated with severe tracheobronchial (large central airway) obstruction.

The lower airway disorders commonly seen among children include BPD, CF, bronchial asthma, reactive airways disease associated with gastroesophageal reflux, and heart disease with left-to-right shunting and pulmonary hypertension.

Standard Tests of Pulmonary Function

As mentioned above, Standard PFTs are largely limited to children older than 5 years who can understand and cooperate with the test procedures. In newborns, some physiologic indicators of pulmonary function can be measured using modifications of standard tests. The relatively recent introduction of tests that are applicable in infants and young children has considerably broadened the ability to assess their pulmonary dysfunction (Weiner et al., 2003). Zapletal and others (1987) compiled pulmonary function indices in children from the data he and his coworkers accumulated over the last two decades. Some of these normal values are reproduced in Appendix C (see www.expertconsult.com).

Measurement of Lung Volumes

TLC and its subdivisions (see Fig. 3-19 and the discussion of lung volumes) are measured either with spirometry and the gas dilution technique or with body plethysmography. FRC is commonly measured by the gas dilution technique with rebreathing of a known concentration of helium (10% He in O₂). TLC is obtained by adding inspiratory capacity (IC) and FRC. RV is

the difference between TLC and VC, the maximum amount of air one can breathe out from TLC. Forced vital capacity (FVC) is the VC obtained during maximum expiratory effort. Normally, FVC and VC in the same healthy person are nearly identical, but in patients with obstructive airway disease, airway closure worsens with effort and FVC may become considerably smaller than VC. VC per se is not a useful indicator for differential diagnosis, because it decreases in both obstructive and restrictive lung disorders such as atelectasis and pulmonary fibrosis. TLC, on the other hand, is decreased in restrictive disease but is increased by air trapping in obstructive disorders.

Gas dilution techniques underestimate TLC in obstructive lung disease, because the test gas molecules (helium) do not sufficiently penetrate into trapped gas compartments. Under these circumstances, body plethysmography should be used to measure FRC more accurately. Measurement of FRC (or thoracic gas volume [TGV]) with body plethysmography is accomplished with a panting (or short, rapid breathing) maneuver against mouth occlusion. TGV is derived from simultaneous changes in lung volume (V) and airway pressure (P) using Boyle’s law ($P \times V = k$). When body plethysmography is not available, addition of a low level of end-expiratory positive airway pressure (EPAP) during helium rebreathing increases gas mixing, probably by preventing airway closure or by keeping the collateral channels open. The difference in calculated FRC with and without EPAP correlates well with the degree of air trapping in the lung (Motoyama et al., 1982b). In obstructive lung disease, FRC and in particular RV, in relation to TLC (FRC/TLC, RV/TLC), are markedly increased.

Flow Function with Spirometry

In clinical pulmonary function laboratories, airway obstruction is usually assessed by the analysis of maximal forced expiration using a spirometer. The resultant volume change in relation to time is displayed on a kymograph (Fig. 3-54). Peak expiratory flow rate (PEFR) is by far the simplest of all expiratory flow

FIGURE 3-54. A spirometric tracing of forced vital capacity (FVC). FEV_{1.0}, forced expiratory volume in 1 second; MMEFR, maximum mid-expiratory flow rate, or FEF₂₅₋₇₅; RV, residual volume; TLC, total lung capacity. (From Motoyama EK: *Physiologic alterations in tracheostomy*. In Myers EN et al., editors: *Tracheostomy*, New York, 1985, Churchill Livingstone.)

measurements. PEFR is decreased most drastically by obstruction of the upper or large lower (central) airways, even when other indices of airway function are within normal limits. It is also decreased in patients with typical asthma, which primarily involves central airways, with severe peripheral airway disease such as CF, and with neuromuscular disorders. The measurement of PEFR is not a sensitive test for discriminating among various types of lung disease. Another major disadvantage of PEFR is that it varies with the degree of effort and cooperation, particularly in young children.

For many decades, the forced expiratory volume in 1 second ($FEV_{1.0}$) and maximum mid-expiratory flow rate (MMEFR or FEF_{25-75}) have been used extensively to evaluate airway function. These parameters are obtained from spirographic tracings made during an FVC maneuver from maximal inspiration (TLC) down to RV (see Fig. 3-54).

A reduction in $FEV_{1.0}$ correlates well with the clinical severity of lung disease, both in adults and in children. $FEV_{1.0}$ is expressed both in absolute terms and as a percentage of the value predicted on the basis of gender, age, and height. It is also expressed in relation to FVC ($FEV_{1.0}/FVC$). In obstructive lung disease, $FEV_{1.0}$ is decreased both in absolute terms and in relation to FVC because of prolonged expiration. On the other hand, in restrictive lung disease such as pulmonary fibrosis, in which airways are wide open, $FEV_{1.0}$ is decreased but $FEV_{1.0}/FVC$ may be normal or even increased. The FEF_{25-75} is the average flow rate between 25% and 75% of FVC. Compared with $FEV_{1.0}$, FEF_{25-75} is a more sensitive index of airway disease involving smaller airways.

The major limitations of these indices of airway function are that they are variable depending on the patient's effort; they are also inadequate for identifying the site of obstruction (e.g., the upper vs. lower airways or the central vs. peripheral airways).

Measurement of Airway Resistance

The standard technique for evaluating airway obstruction has been the measurement of airway resistance (R_{aw}) and forced expiratory flow. Airway resistance is the most direct index of airway obstruction. It is, however, rarely used in clinical settings for several reasons: it requires a body plethysmograph, which is too costly, needs a trained pulmonology technician to perform it, and is too complicated for routine use. Furthermore, airway resistance is not a sensitive indicator of disease involving the lower airways, particularly small, peripheral airways, because the latter contribute only a fraction of total airway resistance, and abnormally high airway resistance does not indicate the site or location of airway disease.

Airway resistance is influenced by the degree of lung inflation. As the lung volume increases, the airways expand and airway resistance falls. The airway conductance (G_{aw}), the reciprocal of resistance, changes linearly with lung volume in children (Zapletal et al., 1969).

Maximum Expiratory Flow-Volume Curves

Unlike other conventional indices of airway function that express volume change per unit of time (i.e., flow rates), MEFV curves relate MEF rates to corresponding lung volumes during a FVC maneuver (see Fig. 3-32). As mentioned previously, the intrathoracic airways downstream (toward the mouth) from the

EPP are subjected to dynamic compression during forced exhalation. As a result, the MEF rate at low lung volumes (i.e., less than 50% FVC) becomes independent of effort and is determined by the flow resistance of the upstream segment of airways between the alveoli and EPP (R_{us}) and by the static recoil pressure of the lung (P_{stl}):

$$\dot{V}_{max} = P_{stl} / R_{us}$$

The measurement of MEF rate is a very sensitive test of lower airway obstruction, because it eliminates the component of the upper and lower central airway resistance between the mouth and EPP, which may amount to as much as 80% to 90% of the total airway resistance. Another advantage of MEFV curve analysis over conventional spirometry is that it is independent of effort put forth in determining the MEF rate, particularly in young children, whose effort may be submaximal or inconsistent. The normal values of MEF rate in children are shown in Appendix C (see www.expertconsult.com).

Figure 3-55 is a schematic representation of MEFV curves from a patient with CF whose flow function is only mildly affected with a classic spirometry. PEFR is within normal limits, whereas values of MEF rate at 50% and 25% of FVC (FEF_{50} and FEF_{75} , respectively) are markedly reduced. With MEFV curves, lower airway disease can be further divided into central vs. peripheral airway disorders by repeating MEFV curves with air (21% oxygen in nitrogen) vs. a 20% oxygen–80% helium mixture.

■ **FIGURE 3-55.** MEFV curve of a 13-year-old boy with CF (brown line) compared with predicted MEFV curve (blue line) breathing air. Note that PEFR is within normal limits, whereas MEFs at 50% (MEF_{50}) and at 25% (MEF_{25} or MEF_{75}) are markedly reduced, indicating lower airway obstruction. The second MEFV curve (purple line) was obtained while he was breathing an 80% helium/20% oxygen mixture (He curve). The He curve crosses the air curve at 30% FVC (\dot{V}_{iso}/\dot{V}), indicating peripheral airway disease. TLC, Total lung capacity; RV, residual volume; FVC, forced vital capacity. (From Motoyama EK: *Physiologic alterations in tracheostomy*. In Myers EN et al., editors: *Tracheostomy*, New York, 1985, Churchill Livingstone.)

In healthy persons, the flow-limiting segment (EPP) is located in the central airways, usually within the first five generations of the tracheobronchial tree (Zapletal et al., 1969). Because the flow pattern is turbulent and dependent on density, air, with an average molecular weight of 29, has a lower flow rate than does the helium-oxygen mixture, with a much lighter average molecular weight of 9.6. In the case of peripheral airway obstruction, EPP moves upstream (peripherally) toward the area of obstruction, where the flow pattern is laminar and therefore dependent on viscosity. The viscosity of helium is higher than that of nitrogen, so flow rates in helium MEFV curves (He curve) at lower lung volumes become less than those in MEFV curves with air (air curve). In Figure 3-55, the He curve crosses the air curve at 30% of FVC (volume of isoflow). Volume of isoflow of more than 20% of FVC is considered evidence of peripheral airway obstruction (Hutcheon et al., 1974). In children with mild to moderate asthma, both PEFR, an indicator of large airway function, and MEF_{25} (or FEF_{75}), an indicator of lower airway function, are decreased because asthma involves constriction of both large and medium or even smaller airways (Fig. 3-56).

In contrast, in a typical case of mild CF with primary peripheral airway disease, MEF_{25} is markedly reduced but PEFR is within normal limits (Fig. 3-55). Figures 3-56 and 3-57 illustrate changes in flow and volume function in a 9-year-old boy with bronchial asthma. The control or baseline MEFV curve (curve 1 in Fig. 3-56) is markedly reduced from the predicted curve (curve 3). His FVC is decreased because of air trapping and increases in RV. After an inhalation of nebulized bronchodilator, there is a marked increase in overall expiratory flow rates with decreased air trapping and a resultant increase in FVC (curve 2). TLC is increased toward the predicted value.

■ **FIGURE 3-56.** MEFV curves of a 9-year-old boy with bronchial asthma before (1) and after (2) inhalation of nebulized bronchodilator compared with a predicted MEFV curve (3). The volume between TLC and the vertical line for each MEFV curve is the forced expiratory volume in 1 sec ($FEV_{1.0}$). Note that PEFR, $FEV_{1.0}$, and MEFs at same volumes are all markedly diminished in the control curve. The bronchodilator produced a marked improvement in all flow parameters. (From Motoyama EK: *Airway function tests in infants and children*, Int Anesthesiol Clin 26:6, 1988.)

■ **FIGURE 3-57.** Bar graphs representing changes in TLC and its subdivisions in a 9-year-old boy with bronchial asthma before (control) and after bronchodilator use in relation to predicted values. Note the increase in TLC and RV and the reduction in VC in the control period caused by air trapping. The RV/TLC and FRC/TLC ratios are abnormally increased. Bronchodilator use nearly abolished air trapping and restored VC. Compare these values with his flow function in Figure 3-56. IRV, Inspiratory reserve volume; ERV, expiratory reserve volume; V_T , tidal volume; IC, inspiratory capacity. (From Motoyama EK: *Airway function tests in infants and children*, Int Anesthesiol Clin 26:6, 1988.)

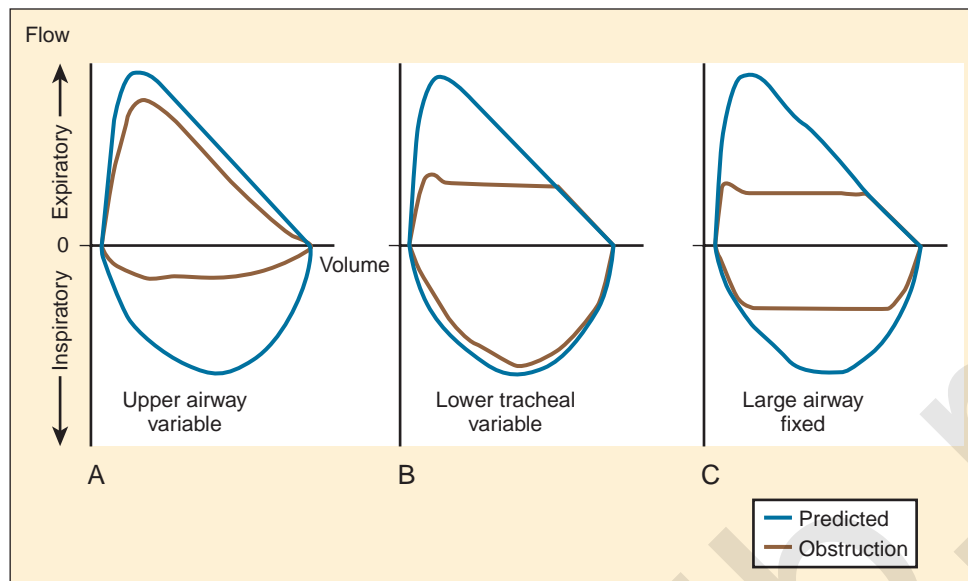

Evaluation of Upper Airway Function

Upper airway obstruction is not uncommon in infants and young children because of anatomic factors such as a relatively large heads, short necks, and small mandibles in relation to tongue size. Also, the caliber of the upper airways is smaller in absolute terms than in older children and adults. Common causes of upper airway obstruction include, in descending order, obstructive sleep apnea (pharyngeal obstruction), laryngomalacia, vocal cord paralysis and dysfunction, laryngeal papillomas, and subglottic stenosis of various causes. In addition, in older children, severe inspiratory obstruction may occur as the result of conversion reaction (Appelblatt and Baker, 1981). This condition may be mistakenly diagnosed as severe bronchial asthma. In some patients with bronchial asthma, the primary site of airway obstruction is in the upper airways, with the clinical manifestation of coughing (Christopher et al., 1983).

The conventional pulmonary function tests already described are used primarily to detect impairment of lower, intrathoracic airway function and are inadequate for the evaluation of upper airway obstruction.

The intrathoracic airways narrow during forced expiration because of dynamic compression, whereas during forced inspiration they expand because of increases in surrounding negative pleural pressure. By contrast, the caliber of the extrathoracic trachea and larynx expands during forced expiration and narrows during forced inspiration, particularly when there is obstruction.

Functionally, obstructive airway lesions in the upper airways and large intrathoracic (central) airways can be classi-

■ **FIGURE 3-58.** Schematic tracing of maximum expiratory-inspiratory flow-volume curves. **A**, Variable upper airway obstruction caused by papillomatosis of the larynx. **B**, Variable central (intrathoracic) airway obstruction caused by tracheomalacia. **C**, Fixed-type obstruction due to tracheal stenosis. (From Motoyama EK: *Physiologic alterations in tracheostomy*. In Myers et al., editors: *Tracheotomy*, New York, 1985, Churchill Livingstone.)

fied into “variable” and “fixed” types of obstruction, based on the ability of the obstructed segment of the airways to alter its caliber in response to changes in transmural pressure. In variable extrathoracic airway obstruction, inspiratory flow is markedly reduced because of pharyngeal collapse during inspiration, whereas expiratory flow is relatively unchanged (Fig. 3-58, A). The opposite is true with variable intrathoracic large airway obstruction (Fig. 3-58, B). Large-airway obstruction of a fixed type limits both inspiratory and expiratory flows nearly equally, because the changes in transmural pressure do not affect airway caliber (Fig. 3-58, C). The measurement of maximum expiratory-inspiratory-flow-volume curves is useful in diagnosing the location (extrathoracic vs. intrathoracic) and the nature (variable vs. fixed) of large airway obstruction (Kryger et al., 1976a; Frenkiel et al., 1980). Figure 3-58, A shows the maximum expiratory-inspiratory-flow-volume curve of a 7-year-old girl with laryngeal papillomatosis, who, because of her “wheezing” (in reality, it was stridor) had previously been thought to have bronchial asthma. She had nearly normal MEFV curves with severe reductions in inspiratory flow. She did not respond to bronchodilators.

Airway Reactivity

Because wheezing is often a manifestation of airway reactivity or airway hyperresponsiveness, it is important to examine positive response to bronchodilators (hyperresponsiveness) or to stimuli that provoke bronchoconstriction (airway reactivity). The most commonly used pulmonary function test for this purpose is the measurement of flow rates during forced expiration. Traditionally, $FEV_{1.0}$ and FEF_{25-75} have been used. More recently, however, measurements of MEF on MEFV curves at 50% and 25% of FVC (MEF_{50} , MEF_{75}) have shown to be most sensitive (Zapletal et al., 1971). Some healthy children (up to 15% of the general population) may respond to a bronchomotor

challenge, but the degree of response is relatively small, usually less than 5% of the control value in $FEV_{1.0}$ and not more than 20% of the control value in FEF_{25-75} and MEFs. When the response is beyond these ranges, airway hyperreactivity or bronchial asthma is suspected. In children, inhalation of aerosolized β_2 -adrenergic agonists, such as albuterol (salbutamol) and metaproterenol, is used for bronchodilation. To provoke bronchoconstriction, exercise challenge has been used widely in children. The inhalation of bronchoconstrictors such as methacholine and histamine, although a more definitive test, is used less often because of its discomfort in patients whose cooperation is less than optimal (Chatham et al., 1982).

It has been recognized that exercise-induced bronchoconstriction results not from exercise per se but from reduction in tracheobronchial mucosal temperature caused by vigorous mouth breathing of dry air and resultant evaporative heat loss (McFadden et al., 1982). The exercise challenge test, therefore, has been replaced by cold air challenge with normocapnic hyperpnea with added CO_2 , which gives more consistent results (Deal et al., 1980). When MEFV curves are used to evaluate bronchial reactivity, MEF must be compared at the same lung volume before and after the challenge, which could change RV and, therefore, FVC. Because the absolute lung volume often is not available in clinical settings, MEF (at 50% or 25% FVC) should be compared at the same volume below TLC, rather than at the volume above RV. The rationale for this practice is that TLC is altered relatively little (although affected by severe air trapping or its release) by comparison with large changes in RV.

Pulmonary Function Tests in Infants

Advances in neonatal intensive care and improved survival of premature infants with varying degrees of chronic lung disease of prematurity since the 1980s prompted the focused interest and development of innovative techniques for pulmonary

function testing in neonates, infants, and young children. A position paper was published by the International Committee on Infant Lung Mechanics based on critical evaluation of these techniques (American Thoracic Society/European Respiratory Society [ATS/ERS] Joint Committee, 1993). Guidelines for laboratory conditions, preparation of infants, sedation, and patient safety have also been published by the same group and by others (Gaultier et al., 1995; Quanjer et al., 1995; Frey et al., 2000; Weiner et al., 2003).

Measurements of Dynamic Respiratory Mechanics

Maximum or Partial Expiratory Flow-Volume Curves

Two techniques have been developed to produce flow-volume curves to evaluate lower airway function (ATS/ERS Joint Committee, 1993). Motoyama (1977) and Motoyama and others (1987) produced MEFV curves by “forced deflation” in infants and young children who were intubated and ventilated under sedation or general anesthesia and paralysis. With this technique, a moderate negative pressure is applied to the endotracheal tube at maximal inflation of the lung (TLC). While the lungs are rapidly deflated (within a few seconds), instantaneous expiratory flow and integrated volume signals produce an MEFV curve. MEF is obtained at 25% and 10% of FEV. This forced deflation technique was found to be safe and reproducible and extremely sensitive for the evaluation of smaller airway function. The average normal value for FEF_{75} in full-term infants was 49 mL/kg per second and MEF_{75}/FVC , an index of upstream conductance (or the caliber of airways toward the periphery), was 1.12, whereas in preterm infants without apparent lung disease MEF_{75} was 95 mL/kg per second and the MEF_{75}/FVC was 1.67. This indicates that in preterm infants, airway caliber in relation to lung volume is much larger than in full-term infants (Nakayama et al., 1991; ATS/ERS Joint Committee, 1993). A major drawback of this technique, however, is that its application is limited to the infants already intubated under general anesthesia or being cared for in the intensive care unit setting.

Another technique is the infant “squeeze” or “hugging” (thoracoabdominal compression) technique, originally reported by Adler and Wohl (1978) and later improved by Taussig and others (1982). In this technique a double-layer inflatable “jacket” is wrapped around the thorax and abdomen of a sedated infant. The inner compression bag is attached to a reservoir of compressed air, and the jacket is inflated rapidly at the end of spontaneous tidal inspiration. A partial flow-volume curve is produced, and MEF at the end tidal volume (MEF_{FRC}) is measured. Although the reproducibility of this test is somewhat limited, it has an advantage over the deflation technique in that it can be applied to infants who are not intubated. One major problem with this technique is that although it seems to work in infants with lower airway obstruction by producing flow limitation, the pressure and flow developed by external thoracoabdominal compression are insufficient to produce dynamic compression of the intrathoracic airways in healthy infants; no predicted normal values could be obtained (ATS/ERS Joint Committee, 1993).

After the discussion at the mentioned ATS/ERS Joint Committee meetings, a modification of the “infant hugging” technique was developed. This technique, a raised volume thoracoabdominal compression technique, is accomplished by increasing the end-inspiratory volume initially to 20 cm H₂O

and eventually to 30 cm H₂O by occluding the expiratory valve and “stacking” several tidal breaths while inspiratory flow is maintained (Feher et al., 1996; Goldstein et al., 2001; Weiner et al., 2003). With this modified squeeze technique, expiratory flow limitation was achieved even in healthy infants (Lambert et al., 2004). The advantage of this technique over the forced deflation technique is that infants can be studied with sedation alone, rather than under general endotracheal anesthesia or under sedation with muscle relaxation in ICU settings.

Measurements of Passive Respiratory Mechanics

The total respiratory system compliance (dynamic compliance) can be measured during the respiratory cycle by measuring the tidal volume and peak inspiratory pressure. In patients with airway dysfunction, however, dynamic compliance does not reflect the true (static) compliance. This problem is circumvented by a brief occlusion of the airway at end inspiration. This approach is based on the principle that the active Hering-Breuer reflex in young infants causes a brief period of apnea during occlusion of the airway at lung volumes above FRC. The passive mechanical properties of the respiratory system can then be determined during this brief moment of respiratory muscle relaxation by removing the upper airway occlusion and allowing the lungs to deflate passively to FRC or relaxation volume (Mortola et al., 1982; Zin et al., 1982). The static compliance of the total respiratory system (C_{rs}) is obtained by dividing the tidal volume by the relaxation pressure at the mouth during the occlusion and relaxation of the respiratory muscles, which reflects the elastic recoil of the respiratory system (LeSouef et al., 1984). In addition, by extrapolation from the plot of a flow-volume loop during passive deflation from airway occlusion, the resistance of the total respiratory system and the time constant can be obtained (LeSouef et al., 1984). This technique can also be applied in intubated patients under general anesthesia or in intensive-care-unit settings, although the resistance of the endotracheal tube per se would be a major component of measured resistance.

According to published data compiled by the ATS/ERS Joint Committee (1993) dynamic lung compliance values for infants and both term and preterm infants range from 1.1 to 2.0 mL/kg per cm H₂O, whereas static compliance values range from 1.0 to 1.6 mL/kg per cm H₂O. Quasistatic compliance of the thorax (C_w) in preterm infants (6.4) exceeds that of term infants (4.2) (ATS/ERS Joint Committee, 1993). Compliance of the total respiratory system (C_{rs}) between 1 and 12 months of age can be expressed as follows:

$$C_{rs} = 0.87 + 26.3 \times \text{Height}^3 \text{ (Masters et al., 1987) or } \\ C_{rs} = 0.88 \times \text{Weight in kg}^{1.09} \text{ (Marchal and Crance, 1987)}$$

Values for airway resistance (R_{aw}) have been reported as:

$$R_{aw} = 0.047 - 0.036 \times \text{Height}^3 \text{ (Masters et al., 1987) or } \\ R_{aw} = 5.36 \times \text{Weight in kg}^{-0.75} \text{ (Marchal et al., 1988)}$$

FRC is low in infants. As measured with the gas (helium)-dilution method in infants sedated with chloral hydrate, the mean FRC was reported as 20.2 ± 4.7 mL/kg (SD; range, 20 to 24 mL/kg) up to 18 months of age, whereas FRC or TGV obtained by means of body plethysmography was higher: 23.8 ± 5.3 mL/kg (range, 29 to 34 mL/kg) (ATS/ERS Joint Committee, 1993; McCoy et al., 1995). The reason for the discrepancy between the two methods is unknown, but the

TABLE 3-6. Predicted Values of Respiratory Rate and Tidal Volume in Infants*

Age (mo)	Birth	3	6	9	12
Respiratory rate (breaths/min)	47	38	33	29	26
Tidal volume (mL/kg)	7.4	9	9	9	9

Modified from ATS Assembly on Pediatrics and the ERS Paediatrics Assembly: ATS statement. Respiratory mechanics in infants: physiologic evaluation in health and disease, *Am Rev Respir Dis* 147:474, 1993.

*Weighted mean from published data.

magnitude of difference in FRC measured with gas dilution versus body plethysmograph (15% to 23%) was similar (ATS/ERS Joint Committee, 1993; Gappa et al., 1993; McCoy et al., 1995). The values for boys and girls are similar in most studies. Table 3-6 shows the average values of respiratory rate and tidal volume in infants between birth and 12 months of age based on published data (ATS/ERS Joint Committee, 1993). The average respiratory rate is high at birth (47 breaths/min) and decreases rapidly with growth (26 breaths/min at 12 months). In contrast, average tidal volume is larger in infants (9 mL/kg) than in older children and adults (7 mL/kg) but is remarkably consistent between 3 and 12 months of age, whereas the respiratory rate changes markedly.

Indications for and Interpretation of Pulmonary Function Tests

Although pulmonary function tests usually do not help in diagnosing the exact location of a pathophysiologic process (e.g., left vs. right lung), they do provide qualitative and quantitative assessments of the general type of disability (e.g., restrictive vs. obstructive, upper vs. lower airway, or central vs. peripheral airway), the extent of impairment, and the efficacy of various treatments, either medical or surgical.

Various indices of pulmonary function, as already described, are expressed in absolute terms as well as in percentage of the predicted normal values. Normal values are based usually on gender and height, because height is better correlated with lung volumes and other ventilatory parameters than is body weight or age. More complicated multiple regression formulas include all these parameters. Ideally, each pulmonary function laboratory should establish normal values based on its own sample population, using the same instruments and techniques that are used to evaluate patients with pulmonary dysfunction as recommended by the ATS/ERS Joint Committee (1993). In reality, however, laboratories usually choose values from published data. Polgar and Promadhat (1971) compiled and compared all of the predicting formulas of pulmonary function in children published by 1969. Their data are still valid and useful today. Once the “normal” values are chosen, it is important to test a sample population of healthy children to make sure that the results fall within the predicted range of values.

For most pulmonary function indices, the normal range (mean \pm 2 SDs) is within 20% to 25% of the predicted values, with the exception MEF values on MEFV curves, which go up to 40% of the mean. This does not necessarily indicate that patients with some pulmonary function indices outside of this range have lung disease. Serial pulmonary function tests in

these patients are invaluable for a better understanding of the presence or absence of disease and its progression with time.

What particular test or combination of tests is most useful? In a child who “wheezes,” it is essential to investigate lower airway function, because wheezing is most often caused by airway hyperreactivity (e.g., bronchial asthma or BPD). Wheezing is usually caused by the narrowing of relatively large intrathoracic (lower) airways (i.e., tracheal and large bronchi) and occurs during expiration. It should be kept in mind that both stridor (mostly inspiratory), coming from narrowing of the extrathoracic (laryngopharyngeal) airways, and rhonchi (both inspiratory and expiratory), usually caused by rattling of secretions in the trachea or large bronchi, are often mistaken as wheezing.

If there is considerable lower airway dysfunction, lung volume should be measured to determine the extent of dysfunction and air trapping. Evaluation of bronchial hyperresponsiveness with a bronchodilator must also be done in these patients and, if it is present, the extent of reversibility should be evaluated. Upper airway function should be examined in patients with stridor and in those in whom lower airway dysfunction is absent or mild in relation to overall respiratory symptoms.

Which children should have pulmonary function tests and pulmonology consultations preoperatively? All children with a history of severe neonatal respiratory disease, such as BPD, meconium aspiration, severe bronchiolitis, and those who wheeze (asthma) should have a consultation with a pulmonologist and have a baseline pulmonary function test performed to establish the nature of the lung dysfunction. These children often have lower airway obstruction and abnormal gas exchange with reactive airways whether or not they wheeze; infants with BPD do not wheeze, because the primary site of airway reactivity and narrowing is in relatively small airways and does not cause wheezing (Motoyama, 1988). At the minimum, oxygen saturation should be measured in room air with a pulse oximeter preoperatively as a guide for postoperative management. In addition, children with history of asthma, CF, or gastroesophageal reflux often have moderate to severe lung dysfunction, and they should be evaluated by a pulmonologist. Another condition requiring pulmonary-function testing before surgical repair is scoliosis. Adolescents with scoliosis may have a moderate to severe restrictive defect, especially those with Duchenne’s muscular dystrophy (DMD) and other forms of muscular dystrophy; some of these patients cannot generate sufficient airway pressure for effective coughing or lung expansion postoperatively. These patients, as well as surgeons, should know what to expect postoperatively, and the anesthesiologist should make sure that an intensive care unit bed is reserved for postoperative care (Finder et al., 2004; Birnkrant et al., 2007; Finder, 2010).

With advanced knowledge and new technology, the ability of a pulmonary-function laboratory to evaluate and document pulmonary dysfunction has improved considerably. Standard pulmonary-function testing is effective in identifying the site, nature, and extent of airway dysfunction, as well as changes in volume function in children. With new developments in the various noninvasive test methods, it is now possible in an increasing number of pediatric medical centers to evaluate lung function and the presence of reversible (reactive) airways disease in infants, even those experiencing respiratory failure. Pulmonary-function test results are helpful for planning the anesthetic approach and postoperative management of infants and children with known pulmonary dysfunction.

SPECIAL CONSIDERATIONS FOR PEDIATRIC LUNG DISEASE

The pathophysiology of the child with lung disease can complicate perioperative management of these children by the anesthesiologist (see Chapter 36, Systemic Disorders). Careful preoperative history taking and baseline assessment of the patient with lung disease is essential for patient safety for the perioperative and postoperative periods. Depending on the age and condition of the patient, this assessment may include, beyond the basic H&P, pulse oximetry, capnography, chest radiography, pulmonary function testing, and consultation with a pulmonologist.

Asthma

Asthma (bronchial asthma) is the most common respiratory disease of childhood and can affect up to 10% of pediatric patients. Asthma is a chronic inflammatory disease of the airways in which many cell types, but in particular, mast cells, eosinophils, neutrophils, and T lymphocytes play important roles. In susceptible individuals, the inflammation causes recurrent episodes of widespread airway constriction and obstruction with symptoms of wheezing, breathlessness, chest tightness, and cough—particularly at night or in the early morning—with or without oxygen desaturation. The airway obstruction is partly reversible either spontaneously or with pharmacologic treatments. The inflammation also causes an associated increase in airway reactivity to a variety of stimuli. The most common trigger for asthma in all age groups is respiratory viral infections, especially respiratory syncytial virus infection in infants. Other factors that can influence asthma control include environmental allergies, environmental tobacco smoke exposure, and (often unrecognized) gastroesophageal reflux. Cold, dry air can exacerbate asthma or trigger bronchospasm in susceptible individuals.

Pediatric asthma can be difficult to define in children younger than 6, but in general can be diagnosed in the setting of recurrent bronchospasm that is responsive to bronchodilators or systemic steroids. The hallmark of asthma is episodic airway obstruction that is caused by a combination of bronchospasm (increased smooth muscle tone), epithelial edema, and increased secretions in the airways. Asthma in childhood has at least two subtypes that largely fall into groups defined by the age at onset (Martinez et al., 1995). Early-onset asthma (before the third birthday) tends to be nonallergic and triggered predominantly by respiratory viral infections. The term *reactive airways disease* is often invoked, but there is no physiologic differentiation from this purported disease and childhood asthma. As a result, the term *reactive airways disease* has recently been discarded by many (Fahy et al., 1995). There is evidence that patients with early-onset asthma have reduced lung function at birth (Martinez et al. 1995). Later onset (after age 3 years) is more likely to be associated with an allergic phenotype (with positive allergy tests and most often a positive family history for allergy). Although treatment is similar, the earlier onset group is more likely to be free of asthma symptoms by the sixth birthday.

Treatment of asthma depends on severity and persistence of symptoms. The most recent guidelines document from the National Heart, Lung, and Blood Institute of the National Institutes of Health (Expert Panel Report 3) (National Asthma Education

and Prevention Program, 2007) uses a stepwise approach to asthma control by defining patients as having intermittent, mild persistent, moderate persistent, and severe persistent asthma. The “controller” therapies for these differing patient groups include low, medium, and high-dose inhaled corticosteroids, long-acting β -agonists (in conjunction with an inhaled glucocorticoid), leukotriene modifiers, mast-cell stabilizers, theophylline, and oral corticosteroids. Additional add-on therapies for poorly controlled, severe persistent asthma include a monoclonal antibody to IgE (omalizumab) in patients with documented allergies.

Management of acute exacerbations of asthma (bronchoconstriction or bronchospasm) is also managed in a step-wise approach (see Chapter 36, Systemic Disorders). β -adrenergic agonists are the mainstay of therapy, especially inhaled albuterol. Inhaled therapy can range from intermittent use of metered-dose inhaler treatments to continuous nebulized albuterol in a monitored setting in the emergency department or intensive care unit. Intravenous β -adrenergic agonists (terbutaline and others) are used in the intensive care setting. Intravenous magnesium sulfate and helium-oxygen mixture (Heliox) are also given in the intensive care setting for refractory bronchoconstriction. Anticholinergic medications have been recommended in the emergency care setting but not the hospital setting in the most recent NIH asthma guidelines.

Careful preoperative assessment for asthma control can reduce risk of intraoperative or postoperative complications from bronchoconstriction and secretions. In children aged 6 and older it is useful to have pulmonary-function testing performed before the procedure requiring general anesthesia. Normal function does not preclude the possibility of intraoperative bronchospastic episodes, but it does reduce the likelihood. Abnormal spirometry showing an obstructive pattern primarily affecting relatively large lower airways, especially with baseline responsiveness to albuterol, suggests poorly controlled asthma and therefore increased perioperative risks (Figs. 3-59 and 3-60). How the anesthesiologist deals with this information depends on the urgency of the procedure; elective procedures may have to be delayed until the child has been seen by pulmonology or allergy consultants and the asthma control has improved. Intraoperative systemic corticosteroids and inhaled bronchodilators may lessen the likelihood of perioperative bronchospasm. V/Qs imbalance may be manifest in the operating room as an increasing inspired oxygen concentration to avoid oxygen desaturation. It is important to bear in mind that with increased F_{iO_2} during general anesthesia, significant V/Q imbalance could be masked and be revealed soon after the child is extubated and brought to a lower F_{iO_2} environment in the postoperative care unit.

Bronchopulmonary Dysplasia (BPD)

BPD, or “chronic lung disease of infancy” remains a common problem in the 21st century despite significant advances in neonatology and neonatal intensive care. The term *BPD* was coined by Northway in 1967 to describe the lung disease seen in premature infants who survived the early days of positive pressure ventilatory support (with a primitive respirator by today’s standards) and with inadvertent high inspired oxygen concentrations in the neonatal period (Northway et al., 1967). They described radiographic and pathologic changes seen in this patient population. Although BPD is associated with prematurity, it can

■ **FIGURE 3-59.** Spirometry (MEFV curves) of a 15-year-old boy with mild asthma. Baseline (before treatment) flow-volume curve (blue) shows moderate flattening (decreased expiratory flows) of the entire flow-volume curve. $FEF_{25\text{ to }75\%}$ 41% pred. FVC >100%. After treatment with a bronchodilator (brown), there is a marked increase in MEF rates throughout the expiratory phase.

■ **FIGURE 3-60.** Spirometry of a 15-year-old girl with asthma with marked air trapping. Baseline (before treatment) flow-volume curve (blue) shows marked decreases in both expiratory flows and volume. After treatment with a bronchodilator (brown), both FVC and $FEF_{25\text{ to }75\%}$ increased markedly. FVC (Pre Rx), 68%, (Post Rx), 83% pred.; $FEF_{25\text{ to }75\%}$ (Pre Rx), 19%, (Post Rx), 51% pred. SpO_2 (Pre Rx), 96%, (Post Rx), 98%. FVC, Forced vital capacity; $FEF_{25\text{ to }75\%}$ maximum midexpiratory flow rate.

occur in full-term infants who receive prolonged intubation and ventilator-induced lung injury (VILI) in the neonatal period.

The lung injury originally described resulted from a combination of volutrauma and shear stress trauma from positive pressure ventilation, inadequate PEEP, and oxygen toxicity. The early descriptions of BPD included necrotizing bronchiolitis, alveolar septal fibrosis, inflammation, and increased airway smooth muscle (O’Brodoovich and Mellins, 1985). Patients with this disorder as originally described had complex pathophysiology, with a combination of noncompliant, collapsed areas side by side with compliant and overly distended areas of lung parenchyma, a combination of fixed and reversible obstructive airway disease, with resultant maldistribution of ventilation, and decreased vascular surface area with increased pulmonary vascular resistance.

The original and simplest definition of BPD was the need for oxygen at 28 days of age with characteristic chest radiographic findings. Others have recommended a definition of oxygen requirement after 36 weeks postconceptional age (Shennan et al., 1988).

Recently a differentiation between “old” and “new” BPD has been made, reflecting the changes in management of these patients: New strategies include antenatal glucocorticoids, instillation into the airway of exogenous surfactant, lower ventilator pressures with PEEP, permissive hypercapnia, and accepting lower oxygen levels or “lung protective ventilatory strategy” to minimize VILI, which predominated early BPD. These treatment strategies have resulted in a different pathology in the “new” BPD, in which the primary abnormality is a simplified alveolar architecture (fewer and larger alveoli), abnormal and reduced capillary beds, and evidence of interstitial fibrosis (Jobe, 1999; Merritt et al., 2009). The overall result appears to be an arrest in lung development, with less inflammation and fibrosis. This results in what is predominantly a restrictive rather than obstructive lung disease with a large component of vascular insufficiency (decreased vascular surface area). Modern clinical variability in lung disease seen in premature infants has prompted many clinicians to adopt the term *chronic lung disease of infancy*, because it can incorporate both the “old” and “new” forms of BPD, as well as related diseases like Wilson-Mikity syndrome.

Hypoxemia in BPD, which is one of the defining features of the disease, has numerous pathophysiologic etiologies. These include bronchobronchiolar hyperreactivity, maldistribution of ventilation and V/Q imbalance, hypoventilation (both because of respiratory insufficiency and potentially from abnormal control of breathing), and right-to-left shunting through the foramen ovale, resulting in sudden oxygen desaturation. Pulmonary artery hypertension is common in severe cases of BPD. V/Q imbalance is very common in this population, as is a baseline oxygen requirement. Hypoxia can contribute to increased pulmonary vascular resistance in an already limited vascular bed. Bronchospasm involving relatively small airways without audible wheezing is common even in the first few months of life; increased smooth muscle in the airway has been demonstrated even in very young infants (Motoyama et al. 1987; Margraf et al., 1991).

Inadequate cartilaginous support of the central airways (e.g., tracheomalacia or bronchomalacia) is also common, and it can lead to episodic complete airway obstruction with Valsalva maneuvers. Alveolar hypoxia increases pulmonary vascular resistance and can induce sudden right-to-left shunting through

the foramen ovale, resulting in profound systemic hypoxia. Anesthetic management can therefore be complicated by many factors, including bronchospasm, PA hypertension, central airway malacia, and V/Q imbalance. PEEP can be useful and essential in overcoming both large central airway collapsibility and preventing parenchymal airway closure caused by anesthesia-induced loss of inspiratory muscle tone and resultant reductions in end expiratory lung volume (FRC). Close monitoring of ventilation and end tidal CO₂ in this patient population is essential to avoid hypoventilation and hypoxemia/hypercarbia, which lead to worsened pulmonary artery hypertension, as well as to control peak inspiratory pressure (less than 20 cm H₂O) to avoid further damage to the fragile lung. Electrolyte abnormalities in patients receiving diuretic therapy for lung disease are common and therefore should be assessed before induction of anesthesia (Ramanathan, 2008).

Chronic Aspiration

Chronic aspiration is a common clinical problem in pediatric medicine. Aspiration can be viewed as falling into the categories of anterograde (“from above,” or to the result of a dysfunctional swallow) and retrograde (“from below,” or from gastroesophageal reflux disease). Patients can have both varieties simultaneously, especially in the setting of neurocognitive disabilities. Evaluation of the respiratory tract for aspiration is a common reason for bronchoscopy.

Airway protective mechanisms that occur during swallowing include cessation of breathing, adduction of the vocal cords, elevation of the soft palate and larynx in synchrony (closure of the supraglottic larynx), and a rise in intratracheal pressure during swallowing. Foreign materials are also kept out of the airway by very sensitive laryngeal and tracheal irritant receptors, which can induce cough and laryngospasm. The upper and lower esophageal sphincters also protect from reflux and penetration of gastric contents into the respiratory tract. The presence of a tracheostomy tube does not protect the airways and can reduce airway protection by anchoring the larynx and preventing rise in the larynx that helps to close the supraglottic structures during swallowing (Sasaki et al., 1977b). Thus, patients with tracheostomy tubes are at increased risk for aspiration (Finder et al., 2001). General anesthesia also reduces or abolishes airway protective reflexes.

Patients with swallowing disorders, particularly those with significant neurocognitive impairment (cerebral palsy with mental retardation) are at very high risk for airway disease and thereby perioperative anesthetic complications. Quite often children with swallowing disorders are identified early in the course of their disease as requiring gastrostomy to allow for a safe means of feeding. They are usually identified through study of their swallowing as having aspiration with thin liquids. Although the nutrition now bypasses the mouth, there remains another thin liquid—saliva in the mouth—that can be aspirated and lead to significant airway disease. Chronic aspiration of saliva leads to airway inflammation, airway hyperreactivity, airway obstruction, and eventually chronic bacterial bronchitis and bronchiectasis. This leads to a fixed airway obstruction and worsening V/Q imbalance. An important clue to V/Q mismatch in this population is low or borderline oxyhemoglobin saturation on pulse oximetry at baseline assessment in room air. Although in the setting of a hospital a saturation of 94%

may meet discharge criteria, this finding may be the only clue to silent aspiration that could complicate anesthesia and perioperative management.

In this setting, careful preoperative assessment is crucial for avoiding perioperative complications. Limiting the volume of saliva penetrating the lower airways can be achieved pharmacologically (systemic anticholinergics), surgically (excision of the submandibular salivary glands and ligation of the parotid glands), and also minimally invasively with ultrasound-guided injections of botulinum toxin into the four main saliva glands. Treatment for acquired airway reactivity (asthma) with inhaled glucocorticoids can also minimize airway inflammation, thereby reducing the likelihood of intraoperative and postoperative atelectasis, bronchospasm with hypoxemia, aspiration, and pneumonia. Children with impaired coughing mechanism and especially those whose surgery may impair coughing (e.g., scoliosis repair or major laparotomy) benefit from mechanically assisted cough therapy (CoughAssist device, Phillips Respironics; Murrysville, PA) to avoid mucus plugging and prevent postoperative pneumonia (Finder, 2010).

Tracheomalacia and Bronchomalacia

Chondromalacia of the trachea or bronchus is fairly common, occurring at an estimated 1:2100 children (Boogaard et al., 2005). The most common presentation is persistent respiratory congestion in the first 6 months of life. Airway malacia can be differentiated from more distal lower airway diseases (such as bronchial asthma or bronchiolitis) by the absence of hypoxemia and the lack of other signs of lung disease (e.g., hyperinflation, subcostal retractions, and increased work of breathing). Indeed, these patients are given the title of “happy wheezers” to describe the “wheeze” (noisy inspiratory breathing, rather than true expiratory wheeze) that occurs in the absence of distress. In general these patients do not experience airway obstruction when intubated, as the positive pressure would “stent” the collapsible central airways open.

Spirometry typically shows fixed MEF caused by large airway collapse, whereas maximum inspiratory flow is unaffected (Fig. 3-58, B). Primary tracheomalacia and bronchomalacia do not lead to V/Q imbalance and therefore are not associated with hypoxemia. Removal of the distending pressure after extubation may result in increased central-airway noises, which are perceived as a central, monophonic wheeze in the postoperative recovery room. Because β-agonists act by relaxing smooth muscle, they do not lead to improvement in wheezing from large airway malacia, and they possibly exacerbate the symptoms. Ipratropium bromide appears to be the most efficacious therapy for symptomatic relief in children with tracheomalacia and bronchomalacia (Finder, 1997).

Cystic Fibrosis (CF)

Cystic fibrosis is a primary disease of impaired mucociliary clearance caused by a mutation in the gene encoding the CF transmembrane conductance regulator (CFTR) protein (Davis, 2006). CFTR functions as a chloride channel and influences the activity of other channels, including the epithelial sodium channel. As a result, the airway surface liquid, which bathes the epithelial cells and in which the cilia function, is

reduced in volume. Ciliary beating is thereby impaired, reducing mucociliary transport, and leading to stasis of secretions, chronic infection, chronic airway inflammation, and destruction of airway elastin. This eventually leads to increasingly worsening fixed airway obstruction and to premature death from respiratory failure.

Survival in CF patients has improved dramatically since the disease was first described in 1938 and continues to increase (Davis, 2006). This can be ascribed to improved nutrition (the addition of supplemental pancreatic enzymes, vitamins, and dietary supplements), improved antibiotics (oral, intravenous, and inhaled), other inhaled therapies (nebulized recombinant human deoxyribonuclease [Dnase] or nebulized hypertonic saline), and improved attention to airway clearance (Davis, 2006). High-frequency chest-wall compression (“vest” therapy) is thought to work by rapidly and repetitively compressing the intrathoracic airways, producing “minicoughs,” which help shear airway secretions from the airway wall and aid in their clearance. This therapy has gained widespread acceptance, and it is likely responsible for the continuing rise in survival. The predicted mean survival reported by the Cystic Fibrosis Foundation was 37.4 years in 2008, which compares with 32 years in 2000 (see www.cff.org/AboutCF; Cystic Fibrosis Foundation).

CF can be viewed as a multisystem exocrinopathy that affects the sweat ducts, liver, pancreas, intestines, reproductive tract, and respiratory tract (both upper and lower airways). Indications for anesthesia and surgery are therefore diverse, ranging from vascular access (implantable ports), bronchoscopy, nasal polypectomy, and sinus surgery to lung and liver transplantations.

Because general anesthesia impedes mucociliary clearance, it is expected that even brief periods of general anesthesia in mildly affected patients can lead to accumulation of lower

airway secretions, mucus plugging, airway closure, and hypoxemia (Forbes and Gamsu, 1979). It is therefore important for the anesthesiologist to get a sense of the baseline lung function in patients with CF before planning general anesthesia. If the patient is old enough to perform pulmonary-function testing (generally 6 years and older), spirometry is a useful tool to identify those at increased risk because there are varying degrees of lower airway obstruction involving primarily smaller airways and air trapping (Fig. 3-61). Bronchiectasis is also common in CF and is associated with fixed lower airways obstruction and increased volume of bronchial secretions. This may be evident on plain chest radiographs, but it may require computed tomography (CT) for identification. The finding of bronchiectasis predicts increased bronchial secretions and a need for thorough intraoperative airway clearance (tracheal suctioning). Response to bronchodilator varies; most patients with CF do not have coexisting asthma and airway reactivity, although positive responses to bronchodilators have been documented at times in these patients—apparently to the result of acute infection and increased airway reactivity (Motoyama, personal observations).

Because of the increased risk of perioperative mucus plugging, airway closure, and atelectasis with resultant hypoxemia, elective surgery in individuals with CF should always follow a period of intensified airway clearance therapy (including antibiotic therapy when appropriate) in the intensive care settings as dictated by the pulmonologist and intensivist managing the CF lung disease for those with advanced airway obstruction and bronchiectasis. Postoperative hypoventilation and atelectasis should be anticipated and treated. Adequate pain control is key to maximizing cough clearance.

■ **FIGURE 3-61. A**, Spirometry of a 19-year-old girl with advanced cystic fibrosis. FVC is markedly decreased. Maximum expiratory flow rates are severely decreased with increasing concavity toward the volume axis as she exhales toward RV, indicating severe lower airway obstruction primarily affecting the smaller airways. There is no difference before (green) and after (red) treatment with a bronchodilator. FVC, 47% pred.; $FEF_{25\text{ to }75\%}$ 11% pred. **B**, Lung volume measurement shows severe air trapping with a marked increase in RV. SpO_2 , 95%. FVC, Forced vital capacity; $FEF_{25\text{ to }75\%}$, maximum midexpiratory flow rate; IC, inspiratory capacity; ERV, expiratory reserve volume; RV, residual volume.

Duchenne's Muscular Dystrophy (DMD) and Other Congenital Disorders of Neuromuscular Weakness

DMD is caused by a mutation in the gene coding for the protein dystrophin, which acts as a “shock absorber” for the muscle cell, connecting the cytoskeleton of the muscle cell to the membrane and extracellular matrix (Bushby et al., 2010a, 2010b). It is a critical part of a complex of proteins (referred to as the dystroglycan complex) at the cell membrane that connect the actin-myosin filament to the cell membrane. Absence of dystrophin, which is a rodlike protein, leads to a secondary loss of the rest of the dystroglycan complex. This leads to fragility of the muscle-cell membrane. Repeated injury to the muscle-cell membrane with contraction of the actin-myosin apparatus causes leak of cytosol into the plasma, inflammation, and eventual fibrosis. Skeletal muscle is most affected by this disease, but cardiac muscle is also affected quite commonly in this disease.

DMD is X-linked and therefore is almost exclusively a disease of boys. The incidence of DMD is 1:3500 boys. The muscle weakness is progressive in nature, and it may not be recognized until early childhood. Delayed walking is common, as is calf pseudo-hypertrophy. Increased falling in middle childhood can also lead to suspicion of this disease. The classic physical finding of proximal lower extremity weakness (Gower's sign), in which the patient uses his upper extremities to push his torso upright, is strongly suggestive of this diagnosis. Patients with DMD often have elevated levels of transaminases, which are mistaken as a sign of liver dysfunction, when the enzymes are leaking from the skeletal muscle. The usual screening test is the creatine kinase enzyme assay from peripheral blood, which can be extremely elevated. Diagnosis is most often confirmed by genetic testing, although muscle biopsy is occasionally performed.

Eventual involvement of the respiratory tract in DMD is the rule. This involvement does not occur until after the muscle disease has progressed to the point that the patient can no longer ambulate. The earliest respiratory involvement is the loss of an adequate cough. This is because there is loss of strength in the abdominal musculature. Weak diaphragm and glottis can also contribute to loss of an adequate cough (Finder, 2010). Patients may not realize that they have lost this function until they develop pneumonia. This stage of respiratory involvement, however, can be predicted by pulmonary-function testing (Bach et al., 1997). Management of inadequate cough includes manual and mechanically assisted coughing (Finder, 2010).

The next stage of respiratory involvement after loss of adequate cough is the development of insufficient ventilation during sleep, especially during REM sleep (Suresh et al., 2005). Signs and symptoms of this stage can be subtle, such as increasing nocturnal awakenings, morning headache (from CO₂ retention), and decreasing school performance. Current management of this stage is the institution of noninvasive ventilation (often bilevel pressure support via a nasal or face mask) (Finder et al., 2004).

When the patient with DMD begins to develop respiratory failure when awake, hypoventilation leads to hypercapnia and eventually to hemoglobin desaturation. Noninvasive measurement of CO₂ (end tidal CO₂) can be performed in the outpatient setting, along with pulse oximetry and venous measurement of blood gases—obviating the need for arterial puncture in the outpatient. Noninvasive ventilation (generally, with a ventilator attached to an angled mouthpiece for delivered breaths that are assisted and controlled) is also becoming increasingly

common for management of respiratory failure in this population (Gomez-Merino and Bach, 2002). Other management of DMD includes special attention to stretching to reduce contractures and the use of corticosteroids to slow the progression of the muscle disease (Moxley et al., 2005; Bushby et al., 2010b). Scoliosis is common in this population and often requires surgical correction. Another common surgery in the DMD population is placement of gastrostomy tubes when patients can no longer adequately chew and swallow.

Patients with DMD and other muscular dystrophies are at increased risk for life-threatening intraoperative hyperkalemia with or without hyperthermia when inhaled anesthetics or a depolarizing muscle relaxant (succinylcholine) are administered, although they are distinct from malignant hyperthermia (see Chapter 37: Malignant Hyperthermia). Although this is widely recognized, this population is also at increased risk for hypoventilation, upper airway obstruction, and impaired cough clearance. Glossomegaly is also common in boys with DMD and can obstruct the upper airway during induction of anesthesia and in the postoperative period; weakened upper airway dilator muscles contribute to airway obstruction. Limited mobility of the mandible and cervical spine limit maneuvers like a jaw thrust and may pose difficulty in visualization of the larynx and can complicate intubation.

Hypoventilation is common in patients with neuromuscular weakness, although it may not be apparent in the immediate preoperative assessment (which is largely limited to measurement of oxyhemoglobin saturation). Preoperative measurement of end tidal CO₂ is recommended, because it may reveal CO₂ retention and therefore increased risk of hypoventilation during the postoperative period. In addition, it is not uncommon for individuals with DMD to have cardiomyopathy with impaired cardiac output. This impairment is often unrecognized and untested because involved patients are nonambulatory and require relatively little cardiac output for normal activities of daily living. This impairment can be worsened by perioperative psychological and physical stresses with general anesthesia, as well as with hypoxemia and hypercapnia. It is therefore critical that any elective surgery in a patient with neuromuscular weakness be preceded by a careful assessment of both respiratory and cardiac function.

Pulmonary function testing usually shows decreased maximum inspiratory and expiratory pressures, decreased peak flows, and decreased VC (restrictive defect) caused by muscle weakness resulting in both incomplete inspiration and expiration (Fig. 3-62). Measurements of peak cough flow and of maximum inspiratory and expiratory pressures are also helpful in assessing risk for poor cough clearance postoperatively. Outpatient measurement of end tidal CO₂ (or venous blood gas) during clinical visits is useful for identifying patients at risk for hypoventilation and who might benefit from postoperative noninvasive support of ventilation. Although hemoglobin saturation may be within normal limits, the anesthesiologist should not presume that the pulmonary function is normal. An elevation in the RV/TLC ratio is not uncommon, even in those with normal minute ventilation, because of the inability to exhale forcefully to the true RV. Impaired cough clearance in the neuromuscularly weak patient should be expected.

Active postoperative involvement of the respiratory therapists and pulmonologists is essential to avoid postoperative complications of atelectasis and pneumonia. Assisted or artificial coughing using a mechanical insufflation-exsufflation

■ **FIGURE 3-62.** Spirometry of a 14-year-old boy with DMD with progressive muscle weakness. device as part of a coordinated care program along with meticulous pain control is very useful in managing these individuals in the postoperative period. The reader is referred to an excellent review of this topic (Birnkranz et al., 2007).

SUMMARY

It is apparent that the respiration of pediatric patients, especially neonates and young infants, is considerably different from that of older children and adults. Respiratory control mechanisms are not fully developed in young infants until at least 42 to 44 weeks' postconception, especially in terms of their response to hypoxia.

The lungs are immature at birth, even in full-term infants. Most alveolar formation and elastogenesis occur postnatally during the first year of life. Thoracic structure is insufficient to support the negative pleural pressure generated during the respiratory cycle, at least until the infant develops the muscle strength for upright posture toward the end of the first year. Weakness of the thoracic structure is in part compensated by

Box 3-4 Infants Are Prone to Perioperative Hypoxemia

- Immature respiratory control and irregular breathing; hypoxia does not stimulate, but rather depresses, ventilation. Trace anesthetics abolish hypoxic ventilatory response.
- Infants have small FRC and high oxygen demand.
- Anesthesia reduces FRC; airway closure and atelectasis result
- Prone to hypoxemia (SpO₂ < 94%) in PACU without O₂.
- Infants are prone to upper airway obstruction.
- High oxygen affinity (low oxygen unloading) of fetal hemoglobin.

tonic contractions of the intercostal and accessory muscles. Anesthesia diminishes or abolishes this compensatory mechanism and the end expiratory lung volume decreases to the point of airway closure, resulting in widespread alveolar collapse and atelectasis. An addition of muscle relaxants in anesthetized infants significantly decreases FRC further and collapses the thorax even more, resulting in further V/Q imbalance and hypoxemia. Infants are prone to upper airway obstruction because of anatomic and physiologic differences, as discussed in this chapter. Anesthesia preferentially depresses tonic and phasic activities of the pharyngeal and other neck muscles, which normally resist the collapsing forces in the pharynx.

Fetal hemoglobin has high oxygen affinity and limits oxygen unloading at the tissue level. These factors, unique to infants younger than 3 months of age, result in decreases in oxygen delivery to the tissues that have much higher oxygen demands than those of adults. Thus, infants and young children are prone to perioperative hypoxemia and tissue hypoxia (Box 3-4).

Pulmonary surfactant, which normally maintains the surface tension on the alveolar lining extremely low and variable during the breathing cycle, is lacking or inhibited in premature neonates and in those with IRDS, which causes alveolar collapse and atelectasis.

Lung function can be evaluated with pulmonary-function testing, even in infants, for preoperative assessment with the recent development of new technologies in certain pediatric centers. Finally, common and not so common pediatric lung diseases, which would affect anesthetic and perioperative managements, have been discussed.

Pediatric anesthesiologists are notorious for remarking that their patients are not simply small adults. This is only partially correct, because the healthy adolescent really is a small adult. At the other end of the spectrum, the statement rings most true for neonates and infants whose cardiovascular systems are profoundly different from that of an adult. All organ systems undergo a maturation process that exists as a continuum from fetal life through childhood. The immaturity of the cardiovascular system is obvious; one need only look at the heart rate and blood pressure to see that what is normal for a healthy newborn is very abnormal for an adult. Understanding the limitations of the developing cardiovascular system is one of the central challenges of pediatric anesthesia.

This chapter reviews pediatric cardiovascular physiology and begins with a thorough study of the unique anatomy and physiology of fetal circulation, as well as the remarkable changes that occur at birth. The changes at birth, termed *transitional circulation*, take on added importance in states of prematurity, congenital heart disease, or critical illness. The basic determinants of myocardial performance are the same for patients of any age, but there are important differences between the neonatal and adult hearts. Reviews of electrophysiologic development and of the maturation of the neurohumoral control of circulation comprise the first part of this chapter. With this solid foundation of knowledge, the effects of anesthetics on the developing cardiovascular system can be understood. Integrating the basic physiology with the

response to anesthetic agents allows care to be provided safely for pediatric patients across the entire spectrum of age and disease.

FETAL CIRCULATION

Current knowledge of fetal anatomy and physiology owes a great debt to the pioneering work of Rudolph and colleagues in fetal and neonatal sheep (Rudolph et al., 2001). The advent of fetal echocardiography has provided greater insight into the developing cardiovascular system. Knowledge of cardiac function and its regulation still relies on animal studies with extrapolation to the human fetus and neonate. A problem is that animals that are routinely studied are born at very differing stages of cardiovascular development. The human infant is somewhere in the middle of this developmental spectrum, with rats and rabbits less mature, and guinea pigs and sheep more mature at birth. Despite these limitations, the large body of knowledge gained from animal study has been confirmed by clinical observation in humans.

Anatomy

The organ of prenatal respiration is the placenta. It is a large, low-resistance circuit that has an enormous influence on the pattern of fetal blood flow. The lungs are almost completely excluded from fetal circulation, and three special shunts (the ductus venosus, the foramen ovale, and the ductus arteriosus) allow the most oxygenated blood to perfuse the heart and brain (Fig. 4-1). Two umbilical arteries originate from the internal iliac arteries and deliver fetal blood to the placenta. One umbilical vein carries oxygenated blood from the placenta to the fetus. When umbilical venous blood approaches the liver, it can take two pathways. It is estimated that 50% to 60% of umbilical venous blood bypasses the liver via the ductus venosus, while the remainder perfuses the left lobe of the liver. Blood flow to the right lobe of the liver is predominantly from the portal circulation. The right and left hepatic veins, along with the ductus venosus, merge into the suprahepatic inferior vena cava (IVC) (Fig. 4-2). Bypassing the high-resistance hepatic microcirculation, umbilical venous blood in the ductus venosus remains not only more oxygenated, but it also flows at a higher velocity. Within the suprahepatic IVC there are now two streams of blood. The stream of blood with higher velocity is derived from the ductus venosus and drainage from the left hepatic vein. The stream of blood with slower velocity consists of drainage from the right hepatic vein mixed with venous return from the abdominal IVC. Upon entering the right atrium, these two streams of blood diverge. The blood with higher velocity is primarily directed across the foramen ovale to the left atrium. This right-to-left shunt is possible because left atrial pressure is low due to minimal pulmonary venous return. The Eustachian valve is a flap of tissue at the junction of the IVC and the right atrium. It functions to help direct the higher-velocity stream of blood across the foramen ovale and into the left atrium (Fig. 4-3). The lower-velocity stream of blood crosses the tricuspid valve and is ejected by the right ventricle. This anatomic arrangement allows the most oxygenated blood from the umbilical vein to bypass the liver and the right side of heart.

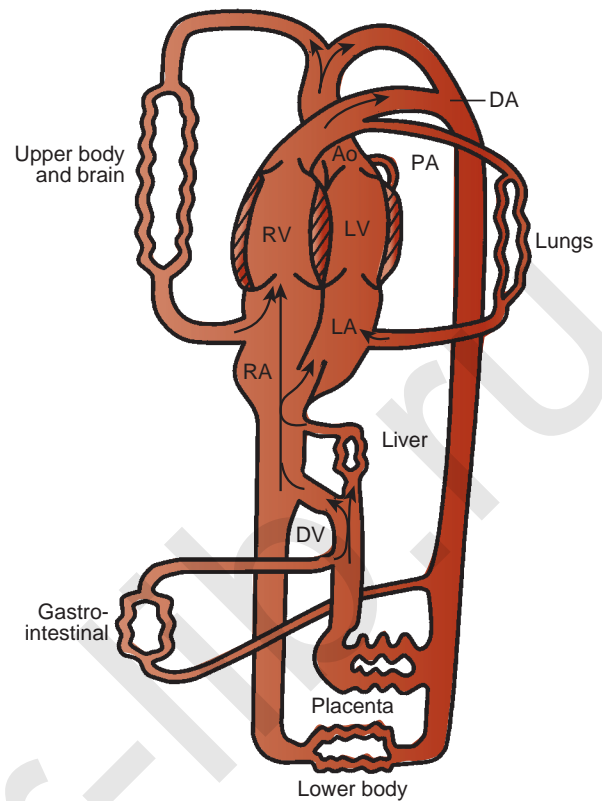

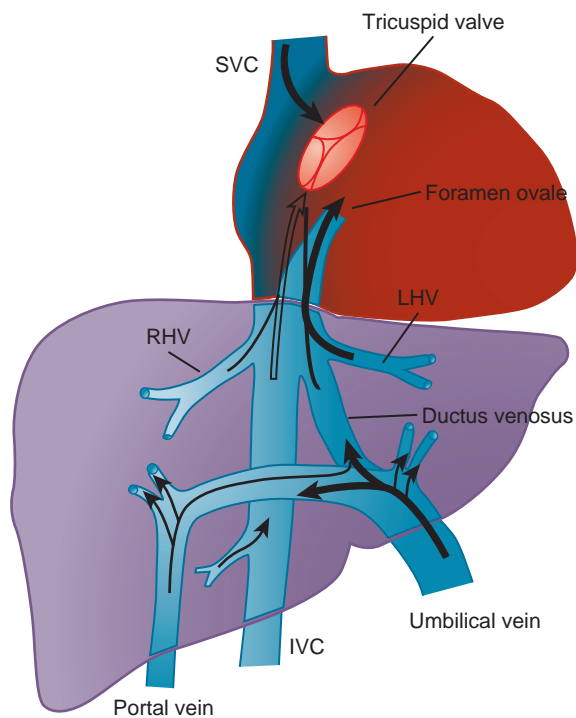

FIGURE 4-1. Fetal circulation. Ao, Aorta; DA, ductus arteriosus; DV, ductus venosus; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle. (From Rudolph AM: *The fetal circulation and postnatal adaptation*. In Rudolph AM, editor: *Congenital diseases of the heart*, ed 2, Armonk, NY, 2001, Futura.)

The majority of blood in the left atrium originates from the higher-velocity stream that crosses the foramen ovale. In the left atrium it mixes with a small amount of pulmonary venous return. The purpose of the ductus venosus and foramen ovale is to allow the most oxygenated blood from the umbilical vein to reach the left ventricle with the least drop in oxygen saturation possible. Oxygen saturation in the umbilical vein is approximately 80%. Inevitable mixing with more deoxygenated blood from the liver, IVC, and superior vena cava (SVC) results in the left ventricle ejecting blood with a saturation of 65% to 70% when the mother is breathing room air. The left ventricle pumps blood primarily to the heart and brain through the ascending aorta and great vessels of the aortic arch. SVC blood enters the right atrium and crosses the tricuspid valve into the right ventricle. Only a small amount of SVC blood and poorly oxygenated IVC blood enters the left atrium via the foramen ovale. High pulmonary vascular resistance (PVR) forces almost all of the right ventricular output to enter the systemic circulation via the ductus arteriosus. The ductus arteriosus is the continuation of the main pulmonary artery and inserts into the aorta at a point immediately distal to the origin of the left subclavian artery. The blood in the descending aorta is a mixture of left and right ventricular outputs with the right ventricle predominating. Consequently, the gut, kidneys, and lower extremities are perfused with blood that has an oxygen saturation of approximately 55%. Two umbilical arteries, branches from the internal iliac arteries, return blood to the placenta.

■ **FIGURE 4-2.** The course of umbilical venous blood as it reaches the liver. The left lobe of the liver is supplied mainly by the umbilical vein, and the right lobe of the liver is supplied by the portal circulation. IVC, Inferior vena cava; SVC, superior vena cava; LHV, left hepatic vein; RHV, right hepatic vein. (Modified from Rudolph AM: *The fetal circulation and postnatal adaptation*. In Rudolph AM, editor: *Congenital diseases of the heart*, ed 2, Armonk, NY, 2001, Futura.)

■ **FIGURE 4-3.** Transesophageal echocardiogram of an adult patient with a prominent Eustachian valve remnant (arrow). The Eustachian valve directs blood from the inferior vena cava across the foramen ovale into the left atrium. The thinnest part of the atrial septum is where the foramen ovale is during fetal life. IVC, Inferior vena cava; RA, right atrium; LA, left atrium; FO, foramen ovale. (From Sawhney N, Palakodeti V, Raisinghani A et al.: *Eustachian valve endocarditis: a case series and analysis of the literature*, J Am Soc Echocardiogr 14:11, 2001.)

The key features of fetal circulation are shown in [Figure 4-4](#) and listed below:

1. Low systemic vascular resistance (SVR) secondary to the low-resistance placenta
2. High PVR secondary to fluid-filled lungs and a hypoxic environment
3. Minimal pulmonary blood flow and low left atrial pressure
4. High pulmonary artery pressure
5. The most oxygenated blood from the umbilical vein perfuses the brain and heart, bypassing the liver via the ductus venosus and bypassing the right ventricle via the foramen ovale.
6. High PVR forces most right ventricular output across the ductus arteriosus into the descending aorta, allowing deoxygenated blood to return to the placenta.

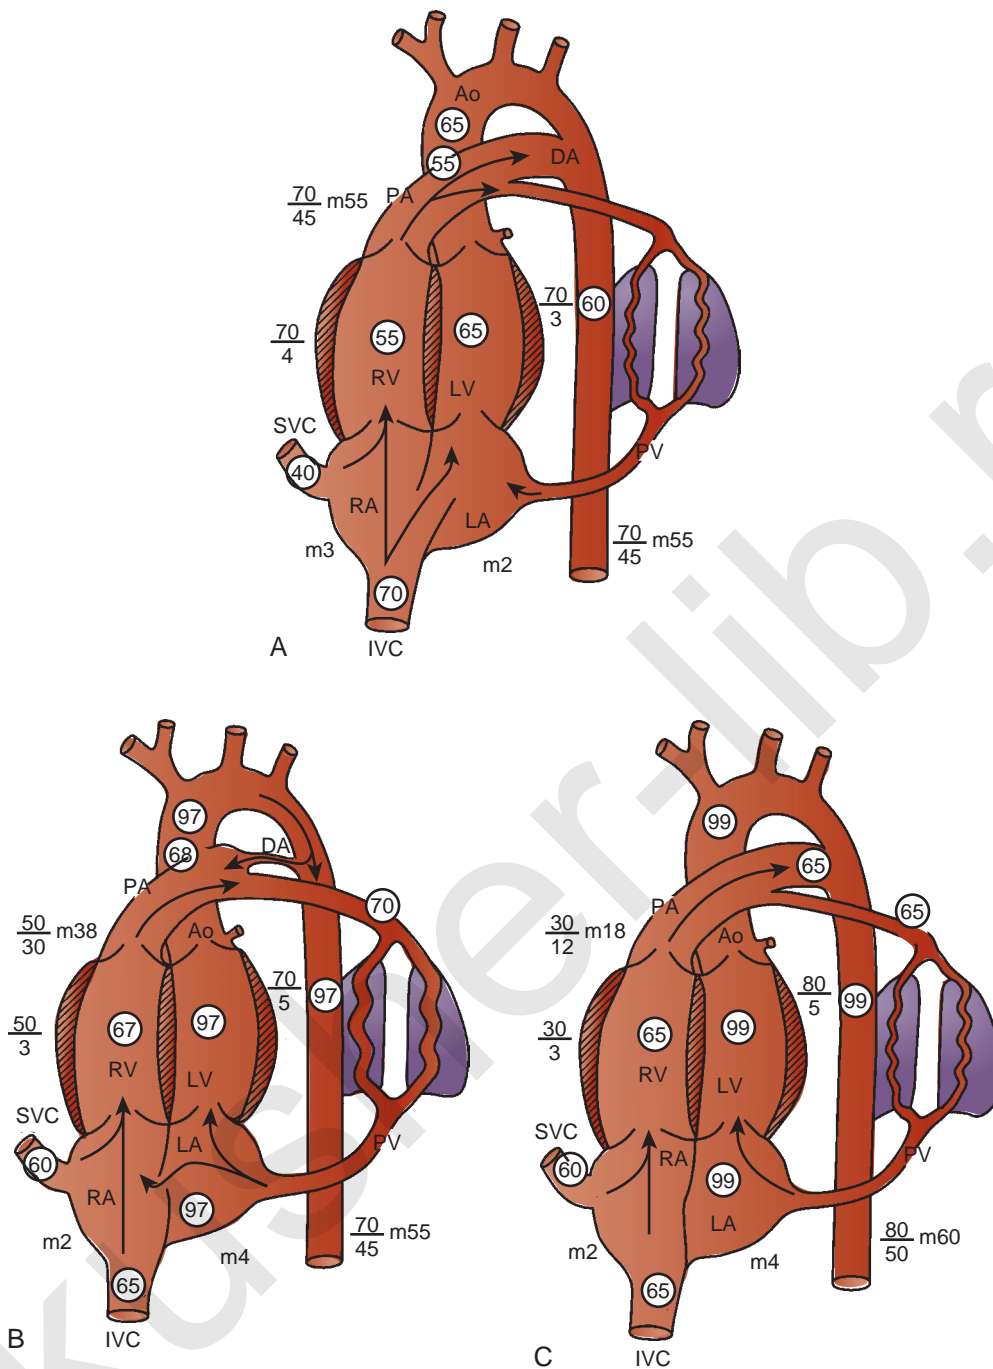

Fetal Cardiac Output

The three important fetal shunts create a circulation that is parallel rather than the more efficient postnatal series circulation. Furthermore, the shunts do not function perfectly, which increases the work of the heart. Some of the oxygenated umbilical venous blood enters the right ventricle, crosses the ductus arteriosus, and flows into the descending aorta. Delivering this highly oxygenated blood back to the placenta is the equivalent of a left-to-right shunt, which increases the myocardial work. Additionally, some deoxygenated blood from the SVC and IVC flows across the foramen ovale and is ejected by the left ventricle. This is an effective right-to-left shunt, which decreases the oxygen saturation of the blood ejected by the left ventricle. The fetus and most critically, its very metabolically active heart and brain, grow and develop in a cyanotic environment.

In the fetus, right and left ventricular outputs are not equal. The ventricles, acting in parallel, pump different amounts of blood, and organs receive blood flow from both ventricles. Thus, it is customary to refer to the combined ventricular output (CVO) of fetal circulation. The fetal CVO is estimated at 400 mL/kg per minute, a value that is similar to that of the neonate but almost threefold higher than it is in adults. The ratio of right ventricular to left ventricular output is approximately 1.3:1 (Kenny et al., 1986). The volume load borne by the right ventricle combined with the high fetal PVR results in significant hypertrophy. After birth, the right ventricle remodels over time under the influence of a series circulation and lowered PVR ([Fig. 4-5](#)). The demands of a parallel circulation result in increased myocardial work superimposed on the demands of a fetus having to grow and develop in a cyanotic milieu. Nevertheless, the fetal circulation is an efficient arrangement with adequate physiologic reserve. This is demonstrated by the full spectrum of congenital heart lesions that are well tolerated *in utero*.

Oxygen Delivery

The transfer of oxygen across the placental bed is inefficient when compared with the transfer of oxygen in the lungs. The normal alveolar-arterial gradient for oxygen is minimal for a patient with healthy lungs breathing room air. This is in contrast to the fetal state, in which maternal arterial oxygen tension (P_{aO_2}) is close to 100 mm Hg, and the partial pressure

■ **FIGURE 4-4.** Fetal and neonatal circulation. Circled values are oxygen saturation, with values for pressure (systolic, diastolic, and mean) appearing beside their respective chamber or vessel. **A,** Fetal circulation near term. **B,** Transitional circulation at younger than 1 day old. **C,** Neonatal circulation at several days old. Ao, Aorta; DA, ductus arteriosus; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary veins; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (From Rudolph AM: *The fetal circulation and Rudolph AM: Changes in the circulation after birth.* In Rudolph AM, editor: *Congenital diseases of the heart*, Chicago, 1974, Mosby.)

of oxygen (P_{O_2}) in the umbilical vein is no more than 30 to 35 mm Hg. It should be recalled that after umbilical venous blood is diluted with more poorly oxygenated blood, the P_{O_2} of the blood ejected by the left ventricle is about 25 to 30 mm Hg when the mother is breathing room air. With such a low fetal oxygen tension, any reductions in maternal oxygenation could severely impact the fetus. The large gradient for oxygen across the placenta means that when the mother is breathing 100% oxygen, maternal P_{aO_2} can be as high as 400

to 500 mm Hg, but the P_{O_2} in the umbilical vein rises to no higher than 40 mm Hg. In cases of suspected uteroplacental compromise, this small increase in umbilical vein P_{O_2} may be critical and justifies administering supplemental oxygen to the mother. The modest rise in umbilical vein P_{O_2} that occurs when the mother is breathing 100% oxygen can result in a large increase in fetal oxygen saturation. This occurs because fetal hemoglobin has a different oxygen-hemoglobin dissociation curve than adult hemoglobin.

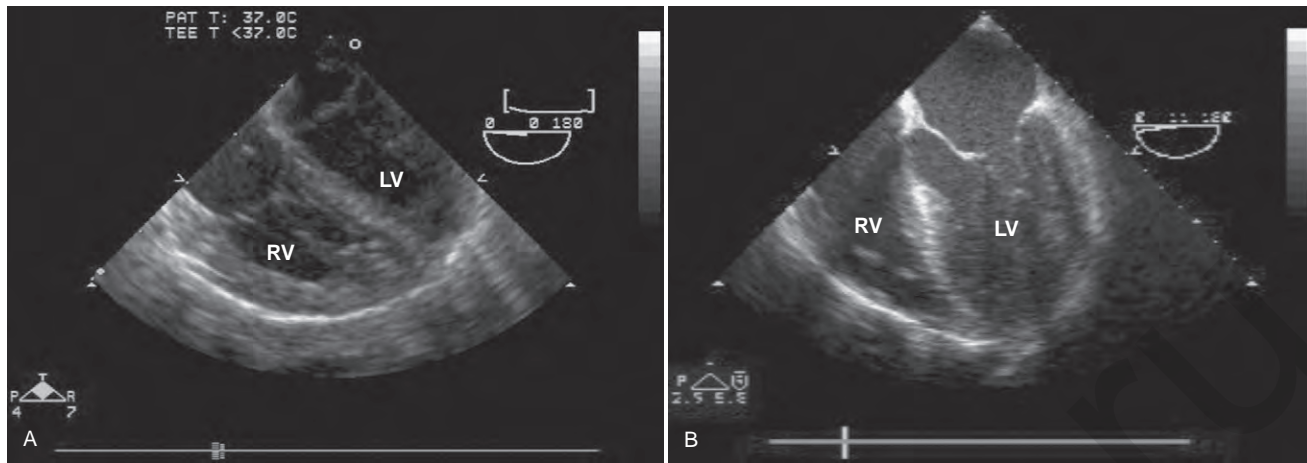

FIGURE 4-5. Transesophageal echocardiogram four-chamber view of a healthy newborn, **A**, and adult **B**. The ventricles are equal in the newborn heart. Growth of the left ventricle and remodeling of the right ventricle create the usual adult appearance.

Oxygen transport must be achieved in a relatively hypoxic environment (Lister et al., 1979). How does the fetus ensure adequate oxygen delivery? Fetal hemoglobin (HbF) has unique properties that allow the fetus to transport oxygen despite a low P_{O_2} . Approximately 80% of fetal hemoglobin is HbF compared with an adult who has over 90% adult hemoglobin (HbA). The P_{aO_2} at which Hb is 50% saturated is called the P_{50} . Fetal hemoglobin (HbF P_{50} :19 mm Hg) is shifted to the left in comparison with adult hemoglobin (HbA P_{50} :26 mm Hg). A low level of 2,3-diphosphoglycerate (2,3-DPG) and the decreased affinity of HbF for 2,3-DPG cause the leftward shift of HbF. *In vitro*, HbF has a sigmoidal oxygen dissociation curve similar to that of HbA. The result is that for any given P_{O_2} , the oxygen saturation is higher for HbF than for HbA.

Assuming a P_{aO_2} of 30 mm Hg in the blood ejected by the left ventricle, this value falls in the steepest part of the oxygen-hemoglobin dissociation curve. At a P_{aO_2} of 30 mm Hg, fetal hemoglobin would be approximately 70% saturated, and adult hemoglobin would only be 50% saturated (Fig. 4-6). Using the equation for oxygen content of the blood (C_{aO_2}) demonstrates how the fetus can achieve levels of oxygen transport that are near those of an adult. Oxygen content of blood is defined by the following equation, S_{aO_2} is the arterial oxygen saturation of hemoglobin, and Hb is the hemoglobin concentration in g/dL:

$$C_{aO_2}(\text{mL O}_2 / \text{dL}) = [S_{aO_2} / 100 \times \text{Hb} \times 1.34 \text{ mL O}_2 / \text{Hb}] + P_{aO_2} \times 0.003 \text{ mL O}_2 / \text{mm Hg}$$

At normal levels of P_{aO_2} , when an adult is breathing room air, the amount of oxygen dissolved in blood is negligible, because it is only 0.003 mL O_2 /mm Hg. Therefore, the C_{aO_2} is typically calculated by determining the amount of oxygen that is carried bound to hemoglobin. For example, an adult with a S_{aO_2} of 100% and a Hb of 11 g/dL would have the following C_{aO_2} :

$$C_{aO_2} = 1.0 \times 11 \times 1.34 = 14.7 \text{ mL O}_2 / \text{dL of blood}$$

The fetus maintains C_{aO_2} through two mechanisms. In addition to the leftward shift of HbF, the fetus is erythrocytotic compared with the adult. Using the equation for C_{aO_2} for a fetus with a Hb of 17 g/dL and an oxygen saturation of 65% yields the following:

FIGURE 4-6. Oxygen-hemoglobin dissociation curves for fetal (**A**) and adult (**B**) hemoglobin. The dashed lines represent the P_{50} for fetal and adult hemoglobin, respectively. For any given P_{O_2} , fetal hemoglobin has a higher oxygen saturation than adult hemoglobin. (From Delivoria-Papadopoulos M, McGowan JE: Oxygen transport and delivery. In Polin RA, Fox WW, Abman SH, editors: Fetal and neonatal physiology, ed 3, Philadelphia, 2004, Saunders.)

$$C_{aO_2} = 0.65 \times 17 \times 1.34 = 14.8 \text{ mL O}_2 / \text{dL of blood}$$

Fetal hemoglobin's greater affinity for oxygen improves oxygen uptake at the placenta. A greater affinity for oxygen is an advantage for uptake at the placenta but a drawback for the unloading of oxygen at the tissue level. Given that the purpose of hemoglobin is to deliver oxygen to the tissues, this poses a problem. The fetus copes with this problem with another modification to its internal milieu. Oxygen release, or rightward shifting of the oxygen-hemoglobin curve, is increased by acidosis. Fetal pH (normal values 7.25–7.35) is lower than it is in adults, facilitating oxygen release at the tissue level. It is important to realize that the preceding discussion has involved only oxygen content of the blood. Oxygen delivery,

which is the goal, can only be achieved when an adequate capacity to carry oxygen is matched with a cardiac output that is sufficient to meet metabolic needs.

TRANSITIONAL CIRCULATION

At birth, the fetus must make a transition to an adult circulatory system. The fact that the vast majority of newborns make this transition smoothly does not mean that the changes required are inconsequential. On the contrary, the events precipitating the transition from fetal to adult circulation are profound and immediate, requiring the fetus to make dramatic changes to ensure survival. The primary events that occur at birth are the clamping of the umbilical cord and initiation of breathing, with inflation of the lungs with air. These changes markedly alter the resistances in the cardiovascular system, changing the pattern of blood flow through the three vital shunts that characterize the fetal circulation. The fetus moves from a circulation that functions in parallel to one that is in a series. The lungs must now become the organs of oxygen supply and ventilation. Lung inflation and increased oxygen tension lower PVR dramatically, causing increased pulmonary blood flow and increased blood return to the left atrium. Cord clamping removes the low-resistance placenta from the circulation system and raises SVR. Left atrial pressure now exceeds right atrial pressure, closing the flap of tissue covering the foramen ovale. Normal intracardiac pressures keep the tissue flap over the foramen ovale closed, and over weeks it will completely seal. However, permanent occlusion does not occur in up to 25% of adults who retain a small defect or probe patency of the patent foramen ovale (PFO) (Hagen et al., 1984). Left atrial pressure rises for two reasons. First, left atrial volume increases significantly because of the increase in pulmonary blood flow. Second, left-sided pressures in the heart rise because of the increase in SVR. With the increase in systemic blood pressure and fall in PVR, flow through the ductus arteriosus becomes initially bidirectional and then very quickly evolves into a left-to-right shunt. Within the first hours of life the ductus arteriosus begins to close under the influence of the increased oxygen tension, loss of placental prostaglandins, and the more alkalotic environment of the newborn. Permanent closure of the ductus arteriosus takes weeks to occur.

Cardiac output *in utero* is considered to be the combined output of both ventricles and has been estimated at 400 mL/kg per minute. The right ventricle does more of this work, resulting in its hypertrophied state at birth. After birth, right ventricular work decreases because the volume load is reduced and PVR falls. In a series circulation, the cardiac output is the equal volume of blood ejected by each ventricle. Newborn cardiac output is the same as that *in utero* but by convention is calculated as 200 mL/kg per minute, which is the output of each ventricle (Lister et al., 1979). In the transition to postnatal life, it is the left ventricle that must cope with increased demands. Left ventricular output increases two- to threefold. This is accomplished by an increase in the left ventricular preload and stroke volume and heart rate. The volume load increase and rise in SVR represent a significant increase from the fetal state (Anderson, 1996). Additionally, as a result of the high beta stimulation associated with labor and delivery, heart rate increases and is near maximum. The newborn must maintain a high cardiac output because its metabolic rate ($\dot{V}O_2$: 6-7 mL O_2 /kg per

minute) is double that of an adult (Anderson, 1990). With a large surface-to-mass ratio, the newborn is at a significant disadvantage for maintaining temperature. Its compensation is to use its high metabolic rate to generate heat for temperature homeostasis (Hill and Rahimtulla, 1965). The remainder of the increased $\dot{V}O_2$ is devoted to growth and the oxygen requirement of the brain, which is proportionally much larger in newborns.

After umbilical cord clamping, flow through the ductus venosus ceases, causing it to involute. With no possibility of any flow, the ductus venosus does not play a role in problems during the state of transitional circulation. However, the foramen ovale and the ductus arteriosus have the ability to maintain fetal circulatory flow patterns under certain circumstances. The ductus arteriosus remains patent *in utero* as a result of hypoxemia, mild acidosis, and placental prostaglandins. Removal of these factors after delivery causes vasoconstriction of the ductus arteriosus. This functional closure of the ductus arteriosus is reversible until fibrosis leads to anatomic closure, which does not occur for weeks. Newborns with significant lung disease can have persistence of fetal circulation, which is defined as fetal shunting that occurs beyond the usual transition period in the absence of structural heart disease.

Persistence of fetal circulation most commonly occurs in instances of severe prematurity with respiratory distress syndrome (RDS). Hypoxemia is a potent stimulus, maintaining a patent ductus arteriosus (PDA). Flow through the ductus arteriosus remains possible as long as it is patent. The direction of that flow depends solely on the relative resistances between the systemic and pulmonary circulations. Flow through the PDA is usually left to right, adding an additional volume burden to the lung that is already coping with RDS. Significant RDS can be accompanied by elevations in PVR that are high enough to cause bidirectional or even right-to-left shunting at the PDA. The elevated PVR also raises right heart pressures, causing the same phenomenon to occur at the foramen ovale. A patent foramen ovale (PFO) provides an opportunity for intracardiac right-to-left shunting. Any other type of lung disease (e.g., meconium aspiration or pneumonia) that is severe enough can also cause persistence of the fetal circulation. Nonsteroidal antiinflammatory drugs, via their antiprostaglandin action, can be used to induce closure of a PDA. Indomethacin is the preferred agent (Giroud and Jacobs, 2007).

Reversion to fetal circulation can occur in some infants who have made a smooth transition from fetal circulation. The usual scenario is a previously healthy infant who has developed a critical illness. The cause is most often sepsis, although certain newborn surgical emergencies (such as necrotizing enterocolitis) may also be precipitants. Hypothermia, hypercarbia, acidosis, and hypoxemia can all accompany sepsis and may cause a reversion to fetal circulation. During the period before anatomic closure of the ductus arteriosus and foramen ovale, marked physiologic stresses can cause the newborn to revert to fetal circulation. This reversion is characterized by increased pulmonary vascular reactivity, raised PVR, and shunting at the PFO and PDA. The direction of shunting depends on the balance between SVR and PVR. In this scenario, vigorous resuscitation of the infant is required, and nonsteroidal antiinflammatory drugs to close the PDA do not have a role.

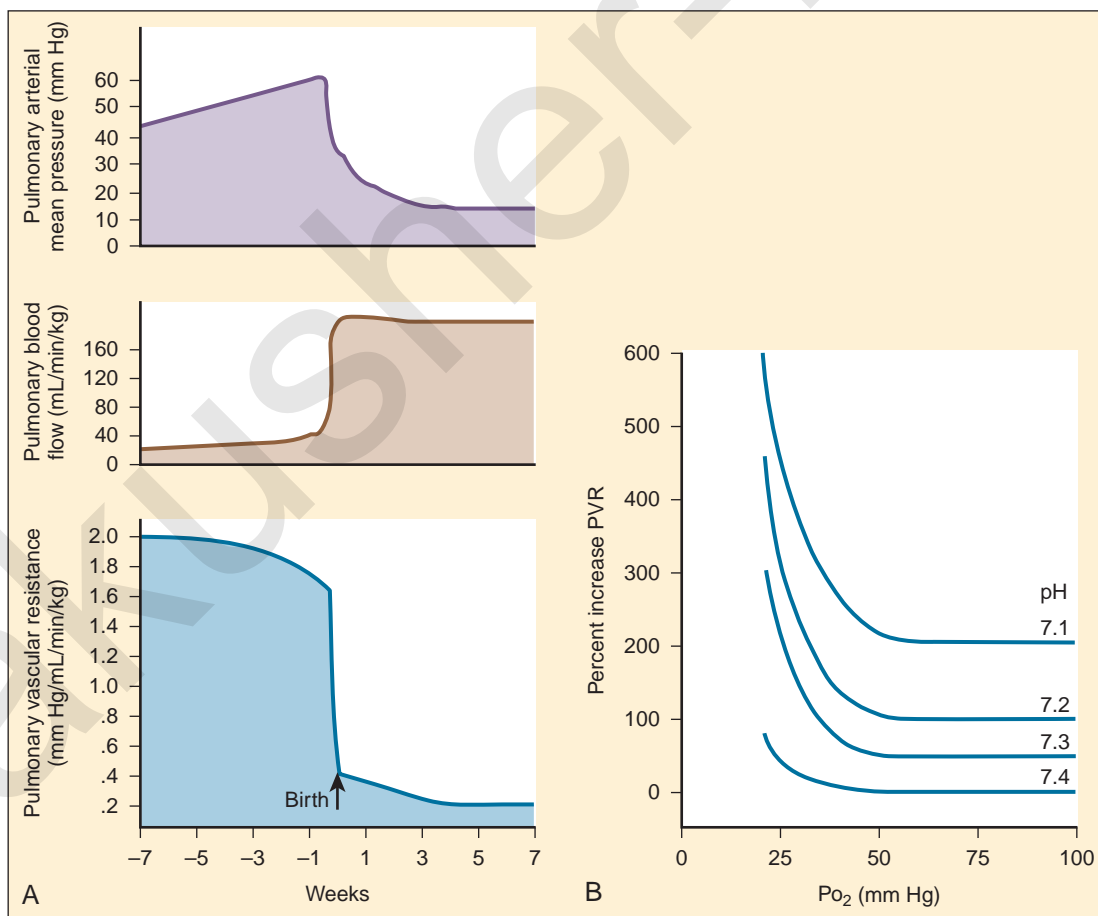

Pulmonary Blood Flow and Pulmonary Vascular Resistance

It is clear that the most fundamental and critical transition necessary for postnatal life is the establishment of breathing, accompanied by a fall in PVR. Therapeutic attempts to manipulate PVR occur in certain newborns with congenital heart disease. Deleterious changes in PVR also accompany critical neonatal disease states. Therefore, a brief discussion of pulmonary circulatory physiology is warranted.

At midgestation, PVR is estimated to be tenfold higher than it is 24 hours after an uncomplicated birth. During the last trimester, PVR decreases slightly to levels seven- to eight-fold greater than it is 24 hours after delivery (Rudolph, 1979). This reduction results from the physical growth of the pulmonary vasculature that increases the cross-sectional area by more than the corresponding increase in blood flow. Yet, PVR still remains high immediately prior to birth and must fall dramatically in the first postnatal minutes to ensure survival. Pulmonary blood flow increases by an amount corresponding to the decrease in PVR, and pulmonary blood pressure falls by 50% (Fig. 4-7). Thus, the pulmonary vasculature presents a puzzle that flies in the face of the normal principles of cardiovascular embryology. The guiding principle of cardiac and vascular development is that once normal structures form, the correct

pathway for blood flow is established. Once flow is established, normal growth ensues. The pulmonary vasculature must grow normally despite greatly reduced flow. The elevated PVR necessary for fetal existence cannot be solely the result of anatomic hypoplasia. If this were the case, the transition to postnatal life would be rocky indeed. Rather, the pulmonary vessels must be of normal size but retain the ability to markedly vasoconstrict. Even more remarkable is that the ductus arteriosus is an outgrowth of the pulmonary arterial system, yet it responds in a completely opposite fashion to the pulmonary vasculature. The very stimuli that raise PVR *in utero* cause dilation of the ductus arteriosus. The factors that govern pulmonary vasoreactivity have still not been fully elucidated, but our understanding has grown considerably in the last 20 years (Martin et al., 2006).

The primary force driving high fetal PVR is hypoxemia. The estimated Po_2 in the pulmonary arteries is less than 20 mm Hg. This phenomenon of hypoxemia-induced pulmonary vasoconstriction (HPV) persists into adulthood, where it is vital in maintaining oxygen saturation during one-lung anesthesia. *In utero*, the mechanism of HPV is not fully understood. Oxygen is a potent stimulator of endothelial-derived vasodilating substances such as nitric oxide and prostacyclin. Nitric oxide activates soluble guanylate cyclase, which increases guanylate 3'-5'-cyclic monophosphate (cGMP). Prostacyclin stimulates adenylate cyclase to

■ **FIGURE 4-7. A**, The changes in pulmonary arterial pressure, blood flow, and PVR from late gestation through the neonatal period in lambs and other species. **B**, The effect of oxygen tension and acid-base balance on PVR in newborn calves. A low Po_2 results in minimal increase in PVR if pH is maintained at 7.4. Conversely, dramatic rises in PVR occur when acidosis is combined with a low Po_2 . (From Rudolph AM: *Prenatal and postnatal pulmonary circulation*. In Rudolph AM, editor: *Congenital diseases of the heart*, ed 2, Armonk, 2001, Futura.)

increase adenylate or adenosine 3'-5'-cyclic monophosphate (cAMP). Both cGMP and cAMP initiate vasodilation in pulmonary vessels. Under conditions of low oxygen tension, the release of nitric oxide and prostacyclin is presumably attenuated, tipping the balance in favor of vasoconstriction. The specific substances inducing pulmonary vasoconstriction are not well understood. Attention is focused on arachidonic acid and its metabolites and the potent vasoconstrictor endothelin (Tod and Cassin, 1984; Hickey et al., 1985a; Ivy et al., 1996).

At delivery, mechanical and biochemical factors lead to the abrupt fall in PVR (Teitel et al., 1990). Aeration of the previously fluid-filled lungs removes the external compressive force on the pulmonary vasculature. Responding to the sudden rise in oxygen tension, the endothelium secretes potent vasodilators, nitric oxide and prostacyclin. Luminal diameter increases as endothelial and smooth muscle cells become thinner. The increase in blood flow further recruits small lumen vessels, leading to an overall increase in the cross-sectional area of the pulmonary vascular bed. Smooth muscle relaxation occurs in the larger pulmonary vessels. This first, rapid phase of pulmonary vasodilation is followed by a period of remodeling that lasts for months. During this time there is maturation of vascular smooth muscles with continuing modest declines in PVR. PVR approximates adult values by about 2 months of age, and the remodeling process is usually complete by 6 months of age. During the first few years of life, new vessels develop to supply the growing lung parenchyma (Fig. 4-8). It is important to understand that in the early postnatal period, PVR is markedly affected by hypoxia and acidosis (Rudolph and Yuan, 1966). More recently, pain has also been associated with increasing PVR.

MYOCARDIAL PERFORMANCE

At which point the newborn heart does mature is a very important issue. In this context one must distinguish between functional maturity of the heart and the state of the cardiovascular system. The histologic and physiologic changes that translate

into important clinical limitations are believed to be complete by about 6 months of age and certainly by the end of the first year of life. After this age, a child is expected to respond to changes in preload, afterload, contractility, heart rate, and calcium in a manner similar to the adult. However, the cardiovascular system is still driven by the demands of growth and will not reach adult values for blood pressure and heart rate until adolescence.

Ohm's law mathematically describes the relationship between voltage, current, and resistance in electrical circuits. The well-known adaptation of Ohm's law to the cardiovascular system states the following:

$$\text{Blood Pressure} = \text{Cardiac Output} \times \text{SVR}$$

Cardiac output is the product of stroke volume and heart rate. Heart rate is easily measured. Stroke volume, on the other hand, is not easily measured in most clinical settings. The clinician must know the factors affecting stroke volume and how they can be manipulated to optimize cardiac function. The physiologic parameters underlying myocardial performance are no different in the newborn and the adult. These parameters are preload, afterload, and contractility. Additionally, newborns and infants have an altered ability to transport calcium, which affects both diastolic relaxation and systolic contraction. Within the important areas of preload, afterload, contractility, and heart rate, pediatric patients have unique limitations. The younger the patient, the more the limitation. This section attempts to explain the key differences between the immature and adult heart.

Cardiac cells are known as myocytes. Hyperplasia, which is an increase in cell number, is responsible for growth of the myocardium during fetal life. Hyperplasia continues into the early newborn period, after which increased demands on the heart can only be met by hypertrophy (increase in myocyte size). The functional unit of each myocyte is the myofibril. Myofibrils consist of contractile proteins arranged in repeating units called sarcomeres. The immature myocyte shape is rounded compared with the rodlike appearance of the adult

■ **FIGURE 4-8.** Pulmonary angiograms at birth (A) and from an 18-month-old infant (B). Growth of existing vessels and development of intra-acinar arteries create the prominent hazy background appearance. (From Haworth SG: *Pulmonary vascular development*. In Long WA, editor: *Fetal and neonatal cardiology*, Philadelphia, 1990, Saunders.)

■ **FIGURE 4-9.** Electron micrographs of a rabbit myocyte at aged 3 weeks **(A)** and fully mature **(B)**. The infant myocyte has one myofibril. The adult myocyte has organized, repeating rows of myofibrils separated by mitochondria. (From Anderson PAW: *Myocardial development*. In Long WA, editor: *Fetal and neonatal cardiology*, Philadelphia, 1990, Saunders.)

myocyte. Immature myocytes also have a much larger surface-area to volume ratio. Adult myocytes contain multiple repeating rows of longitudinally arranged myofibrils. The newborn myocyte has fewer myofibrils in a more chaotic and scattered intracellular arrangement (Fig. 4-9). Sarcomere volume is only 30% of the newborn myocyte compared with 60% in the adult (Baum and Palmisano, 1997). The T-tubule system is a series of invaginations of the sarcolemma, or cell membrane, bringing it in close contact with the myofibrils. In this way, the action potential can rapidly disperse itself throughout the myocyte. Both the sarcolemma and T-tubule system are relatively well developed in the human newborn. The sarcoplasmic reticulum (SR) is a tubular network regulating the uptake, storage, and release of intracellular calcium. The adult heart relies on the SR to fully regulate calcium transport. Contrastingly, the newborn heart has an underdeveloped sarcoplasmic reticulum. There is more reliance on the sarcolemma and T-tubule system for the appropriate movement of calcium necessary for contraction and relaxation. The newborn has decreased contractile reserve on the basis of reduced sarcomere number and an immature system of calcium transport. The reduction in sarcomeres also reduces the compliance of the immature heart.

Preload

In 1895, the German physiologist Otto Frank published his observations on the relationship of diastolic filling of the heart and the pressure the heart was able to generate during systole (Frank, 1895). Ernest Starling, an English physiologist, conducted the classic experiment in the early 1900s that defined the length-tension relationship for cardiac muscle (Fig. 4-10). Understanding his experiment is important, because in the laboratory he was able to isolate that which is impossible to isolate

■ **FIGURE 4-10.** A schematic diagram of the classic Starling experiment. The suspended weight (afterload) is held constant, allowing the tension developed to be measured at different lengths (preload) of the muscle strip. (From Epstein D, Wetzel RC: *Cardiovascular physiology and shock*. In Nichols DG, Ungerleider RM, Spevak PS, et al., editors: *Critical heart disease in infants and children*, ed 2, Philadelphia, 2006, Mosby.)

in vivo. Using a fixed weight to keep afterload constant, he was able to prove that the tension developed was proportional to the length of the muscle strip prior to stimulation. The greater the length of the muscle strip, the greater the tension it was able to develop. The Frank-Starling mechanism, or Starling's

Law of the Heart, is taken from a famous lecture by Dr. Starling himself, in which he stated, “the energy of contraction, however measured, is a function of the length of the muscle fiber” (Starling, 1918).

The clinical correlates of length and tension are left ventricular end-diastolic volume (LVEDV) and stroke volume, respectively. In the laboratory, the length of a muscle strip is easily determined because both ends can be fixed. This is very different from the intact heart, where the ventricle is a three-dimensional structure with complex geometry that defies the simple concept of length. Nevertheless, it is clinically appropriate to regard length as LVEDV. The LVEDV represents the loading of the ventricle. It is present before contraction, and therefore has come to be called *preload*. The force of ventricular contraction increases with increasing preload until a point is reached where the ventricle is over stretched and the force of contraction decreases. This point is the apex of the well-known Starling curve. Force of contraction is not synonymous with contractility, and for all points along a Starling curve, contractility is equal. Changes in the force of contraction, however, occur when preload changes (Fig. 4-11). Laboratory evidence has shown that resting sarcomere distance is 1.6 microns, with optimal conditions occurring at 2.2 microns. Excessive stretch, causing decreased force of contraction, does not occur until sarcomere length reaches 3.5 microns (Sonnenblick, 1974). In the laboratory the force of contraction increases until the sarcomere is stretched to over twice its resting length. If this translated fully to the intact heart, any increase in preload would result in increased force of contraction, because physiologically achieving a doubling of resting sarcomere length is almost impossible. However, well before a doubling of resting sarcomere length is reached,

the patient falls on to the descending limb of the Starling curve. The reason is the relationship between volume and pressure, which is known as compliance.

The Starling curve describes the relationship between LVEDV and stroke volume. The problem is that measuring LVEDV in a way that is simple, accurate, and available in real time is not possible. Echocardiography is the best method to quantify LVEDV. However, the two-dimensional images seen echocardiographically may not faithfully represent the volume contained in a three-dimensional ventricle with its elliptical shape. The equations used to objectively measure volume are not practical in most clinical situations and certainly not in the dynamic environment of the operating room. Subjective assessments of LVEDV using echocardiography depend on the skill of the operator and will detect only the extremes of preload conditions. Given the problems in measuring volume, the clinician is forced to use a surrogate measure of LVEDV. A catheter placed in a central vein and connected to a transducer measures pressures simply, accurately and continuously. Using pressure as a guide to volume requires understanding the relationship between the two variables, defined as compliance and described by the following equation:

$$\text{Compliance} = \frac{\Delta \text{ Volume}}{\Delta \text{ Pressure}}$$

The change in pressure resulting from a change in volume is compliance. Volume is in the numerator of the equation meaning that if a large increase in volume is met by a relatively small rise in pressure, compliance is high. As a completely empty ventricle is filled, the initial rise in LVEDP is small. In this situation the ventricle is said to be compliant. When the ventricle is full, a small increase in volume results in a large increase in pressure. The ventricle is now poorly compliant or “stiff.” As with the Starling curve, it is important to note that moving to different points on the compliance curve does not mean that the intrinsic compliance of the ventricle has changed. A true intrinsic change in compliance will be reflected in a new compliance curve (Fig. 4-12). In adult cardiac medicine it is readily

■ **FIGURE 4-11.** Starling’s Law of the Heart. Contractility is the same for each curve. Moving from point A to point B requires an increase in LVEDV. Moving to point C or point D can only occur if there is a change in contractility. For the same LVEDV, the stroke volume falls progressively with impaired contractility. The figure demonstrates that the failing ventricle is dependent on preload. (Modified from Opie LH, Perlroth MG: *Ventricular function*. In Opie LH, editor: *The heart: physiology from cell to circulation*. Philadelphia, 1998, Lippincott-Raven.)

■ **FIGURE 4-12.** Diastolic-compliance curves. Each curve represents a different intrinsic compliance. Movement between points A, B, and C reflects a change in preload with no change in compliance. Movement from point A to point D can only occur when the ventricle becomes less compliant. (From Mark JB: *Atlas of cardiovascular monitoring*, New York, 1998, Churchill Livingstone.)

appreciated that ischemia, infarction, or hypertrophy result in a stiffer, or less compliant, ventricle. However, no ventricle, regardless of its intrinsic compliance, has an infinite ability to accept volume. Eventually the inflection point on the curve will be reached and pressure will climb rapidly for any given increase in volume. It is this sharp increase in pressure beyond the inflection point that is responsible for the descending limb of the Starling curve.

Decreases in the force of contraction represented by the descending limb of the Starling curve are due to the result of pressure and not volume or “overstretch.” The reason is that the rise in pressure causes an imbalance in the myocardial oxygen supply/demand ratio that results in decreased force of contraction. The left ventricle is perfused according to the following equation:

$$\begin{aligned} \text{Coronary perfusion pressure} \\ = \text{Diastolic blood pressure} - \text{LVEDP} \end{aligned}$$

When the maximum increase in blood pressure achieved by volume loading has been reached, further volume only serves to increase LVEDP at the expense of coronary perfusion pressure. Thus, myocardial oxygen supply decreases. A key determinant of myocardial oxygen demand is wall stress defined by the modified Law of Laplace:

$$\text{Wall stress} = \frac{\text{Pressure} \times \text{radius}}{\text{Ventricular wall thickness} \times 2}$$

Wall stress is usually, but erroneously, thought of as similar to afterload, because the value for pressure in the numerator is assumed to be systolic blood pressure. In fact, blood pressure is a key component of wall stress, but they are clearly not the same. Oxygen consumption increases with increasing wall stress, and wall stress has both systolic and diastolic components. During systole the value for pressure in the wall stress equation is the systolic blood pressure. In the diastole the value for pressure is LVEDP. A patient with a value on the steep part of the compliance curve has sharp increases in LVEDP disproportionate to the increase in volume. Concomitantly, the ventricular cavity is fully distended from the volume load. Thus, excessively high LVEDP combined with an enlarged ventricular radius simultaneously causes an increase in myocardial oxygen demand and a decrease in myocardial oxygen supply. This situation, if unchecked, leads to ischemia and a decrease in the force of contraction.

The response of the newborn heart to volume loading (relative insensitivity) has been the source of great confusion (Rudolph, 1974). This confusion stems from experimental work done in the 1970s and is the logical extension of the known structural differences in the newborn heart (Romero and Friedman, 1979; Gilbert, 1980). The response to preload was investigated in fetal sheep for the left and right ventricles. For either ventricle, isolated output rose only slightly with increases in filling pressures. Using a microsphere technique in fetal sheep, alterations in combined cardiac output were measured as blood volume was modulated (Gilbert, 1980). With a decrease of 10% in circulating volume, there was a significant drop in right atrial pressure, as well as in cardiac output. In contrast, cardiac output did not significantly change despite a significant change in right atrial pressure with a 10% increase in circulating blood volume from baseline. These data lead the author to conclude that the fetus operates at the upper end of the Starling curve and possesses limited cardiac reserve.

With only half the amount of sarcomere volume that is in an adult, connective tissue comprises a much greater percentage of the newborn heart. The myofibrils are fewer in number with a disorderly arrangement in the myocyte. There is much more stiff connective tissue. The sum total of these changes makes it plausible that the relatively non-compliant newborn heart does function at the upper end of its Starling curve, where the response to volume loading is blunted. In fact, the original experiments failed to account for an inevitable consequence of increases in preload. An increase in the preload leads to greater stroke volume, and if heart rate is unchanged, cardiac output must increase as well. Blood pressure must now rise unless there is a corresponding drop in SVR. Therefore, an increase in preload leads to an increase in afterload, which then acts to reduce stroke volume. This created the impression that the newborn heart could not increase stroke volume in response to volume loading. Other work, controlling for arterial pressure, shows that the newborn heart is indeed responsive to volume *within the limitations of its decreased compliance* (Fig. 4-13) (Kirkpatrick et al.; 1976, Hawkins et al., 1989). This has been shown in the laboratory with a sheep model and through echocardiography in the human fetus. The newborn can be likened to the hypertensive adult with diastolic dysfunction. This is not to suggest that the otherwise healthy newborn has diastolic dysfunction, because the newborn heart is not dysfunctional but normal for its stage of development. Rather, the lesson of diastolic dysfunction is that the ventricle is preload dependent. At the low end of the Starling curve, reduced preload is poorly tolerated. The upper end of the Starling curve is flattened, reflecting its reduced compliance. Between these two points is the steepest part of the curve, where increases in LVEDV result in significantly greater stroke volume. Clinical experience observing the response to volume infusion confirms this property of the newborn heart.

■ **FIGURE 4-13.** The response of the immature heart to changes in preload and afterload. When afterload is held constant, left ventricular stroke volume (LVSV) increases linearly with increased left atrial (LA) pressure. Increasing afterload creates an inverse linear relationship with LVSV when LA pressure is constant. (From Hawkins J, Van Hare GF, Schmid KG, et al.: *Effects of increasing afterload on left ventricular output in fetal lambs*, *Circ Res* 65:127, 1989.)

Afterload

In addition to preload, there is another loading force that influences myocardial performance. The force that resists the ejection of blood is known as afterload. In isolated muscle strip experiments, the afterload is represented by the weight against which the muscle contracts or shortens. The stretch applied to the isolated muscle strip before contraction is fixed, allowing the experiment to be conducted at a constant length, or preload. Plotting the velocity of myocardial shortening against progressively increasing afterload reveals an inverse relationship. The shape of the curve is exponential with the points of maximal and zero shortening both occurring at physiologically impossible limits. The greatest shortening velocity occurs at zero load. When the load is so great that no muscle fiber shortening can occur, isometric contraction occurs. Between these two extremes, it is intuitive that increasing afterload results in reduced velocity of muscle fiber shortening. Transferring this straightforward laboratory concept to the intact circulation is difficult (Martin et al., 2006). The force generated by the shortening of an isolated muscle strip is directed in only one plane. This is very different from the three-dimensional contraction of the left ventricle with its asymmetric geometry. Additionally, in the laboratory the force that resists the shortening of the muscle is the weight applied to the muscle strip. Physiologically, the force that resists the ejection of blood is a complex interplay between blood pressure, vascular impedance, wall stress, and inertia. Finally, blood pressure and SVR are commonly used measures of afterload, but neither is fully accurate.

In most situations, the systemic blood pressure does provide an appropriate surrogate for afterload. One common exception is in conditions in which there is obstruction to left ventricular outflow. In adults, the most common cause is aortic stenosis, but pediatric patients may also have congenital lesions that cause obstruction at the subvalvular level in the left ventricular outflow tract (LVOT) in addition to aortic valve disease. The left ventricle must generate enough pressure to overcome both the systolic blood pressure and the gradient across the valve or the LVOT obstruction. Assuming that the ventricle must only overcome the systolic blood pressure leads to a significant underestimation of afterload. The use of SVR to approximate afterload is also problematic. The concept of SVR describes resistance, which is defined as the pressure drop across a system divided by the flow across that same system. This is reflected in the equation for SVR:

$$\text{SVR} = \frac{\text{Mean arterial pressure} - \text{CVP}}{\text{Cardiac output}} \times 80$$

Multiplication by 80 converts SVR from mm Hg/L/min/m into SI units ($\text{dynes} \cdot \text{s} \cdot \text{cm}^{-5}$). The calculated SVR may be similar for patients with very different cardiovascular performance. Consider these two patients:

Patient 1: Blood pressure, 120/80; central venous pressure, 10; cardiac output, 5 L/min. The calculated SVR is 1328 $\text{dynes} \cdot \text{s} \cdot \text{cm}^{-5}$.

Patient 2: Blood pressure, 110/70; central venous pressure, 15; cardiac output, 4 L/min. The calculated SVR is 1360 $\text{dynes} \cdot \text{s} \cdot \text{cm}^{-5}$.

These two hypothetical patients are very different, yet the SVR is similar. The first patient has normal cardiovascular function and the second patient's cardiovascular function is compromised. A reduction in contractility has caused a fall in cardiac output

despite the attempts of the ventricle to compensate with a higher diastolic filling pressure. This example demonstrates how SVR in isolation does not necessarily reflect large changes in loading conditions and cardiac output. The modified Law of Laplace describes a better approximation of afterload (see Preload section p. 91). As discussed in the section on preload, wall stress was demonstrated to be a key component of myocardial oxygen demand. During left ventricular ejection, the value for pressure is the systolic blood pressure. By including the radius and accounting for the compensatory mechanism of left ventricular hypertrophy the modified Law of Laplace provides a more comprehensive view of the forces that resist ventricular ejection. Importantly, it demonstrates the concept that the dilated ventricle with an increased radius must eject blood under increased afterload conditions. Given the inability to easily measure ventricular radius and thickness, the modified Law of Laplace is not a clinical parameter to guide management. It is presented here to help the reader conceptualize afterload. It still cannot describe all the variables that account for afterload in the intact cardiovascular system.

Studies of the intact heart that assess the effect of changes in afterload on cardiac output are difficult to interpret without controlling for the other variables. The most important additional variable is preload. Preload and afterload are linked. For instance, pharmacologically increasing afterload decreases stroke volume. As the heart ejects less blood with each contraction, the end-diastolic volume must increase if venous return is held constant. With an increase in LVEDV the Starling curve dictates an enhanced ventricular force of contraction, which acts to return stroke volume to its previous level. The general inverse relationship between afterload and stroke volume holds across the spectrum from fetal life to adulthood (Friedman, 1972). The question is whether the immature myocardium is excessively sensitive to increases in afterload. In the laboratory, afterload can be assessed while strictly controlling for preload. These studies have revealed that the fetal myocardium is indeed more sensitive to increases in afterload than the adult myocardium (Friedman, 1972). Animal experiments with an intact circulation also show a decrease in ventricular output under conditions of increasing afterload (Fig. 4-13) (Gilbert, 1982; Thornburg and Morton, 1986). Van Hare and colleagues (1990) used a balloon occluder in the aortas of fetal sheep to modulate afterload while keeping preload constant. Combined ventricular output was measured by transducing aortic flow. They noted that at physiologic mean atrial pressures, there was an inverse linear relationship between mean arterial pressure and stroke volume. This exists for both right and left ventricles. Despite this, a fetus normally makes a smooth transition to postnatal life when the low-resistance placenta is removed. At birth, pulmonary blood flow dramatically increases, raising left-ventricular preload. Stroke volume increases, which leads to an increase in systemic blood pressure. Despite the rise in blood pressure and the loss of the low-resistance placenta, cardiac performance in the newborn is not compromised. The explanation is that much of the rise in afterload is secondary to increased preload. In clinical practice with newborns and young children, it is rare to encounter conditions of purely increased afterload. A more likely situation is significant hypovolemia that results in hypotension. Despite the low afterload state, overall cardiac performance is impaired, because the decrease in afterload is caused by decreased preload. The correct therapy is to restore intravascular volume.

Blood pressure improves, and the increased afterload is well tolerated. This example illustrates the interrelationship between these two variables of cardiac output.

It has been shown that when preload is held relatively constant, cardiac output moves inversely within the physiologic range of afterload. The relevance of afterload in the newborn stage might be questioned, because systemic hypertension is so rare. The right ventricle develops in an environment of raised PVR, yet after birth it is more sensitive to increases in afterload. Although there is limited ability of the systemic circulation to become hypertensive, the pulmonary circulation, under appropriately provocative conditions, can revert to its fetal state. Postnatally, the right ventricle begins to remodel in response to decreasing pulmonary artery pressures. Sustained elevations in pulmonary artery pressures decrease right ventricular output and reduce left-ventricular preload (Thornburg and Morton, 1983). Because both ventricles share the septum, the strain on the right ventricle impairs left-ventricular filling and contraction (Rein et al., 1987). Reductions in left-sided preload and contractile force demonstrate how the inability of the right ventricle to cope with increased afterload can lead to decreases in systemic cardiac output. In the newborn stage, the potential for pulmonary hypertension far exceeds that of systemic hypertension. This is the most common scenario for a significant rise in afterload while preload remains relatively unchanged. The strain on the right side of the heart and ventricular interdependence may lead to biventricular failure.

Contractility

The third parameter of myocardial performance is contractility. Seemingly intuitive, contractility is often confused with changes in stroke volume brought about by alterations in loading conditions. Contractility, synonymous with inotropy, is the intrinsic ability of the myocardium to contract *when loading conditions are held constant*. The Starling curve is the first source of confusion. As discussed in the section on preload, every point on an individual patient's Starling curve represents the same inotropic state. Movement along the curve is solely because of changing conditions of preload. In the same way, the demonstration in the laboratory of decreased myocardial shortening velocity in response to increased weight (afterload) is not evidence of a fall in contractility. Contractility has remained constant, but the force of contraction is reduced. Contractility and force of contraction are clearly not the same. The force of contraction, related to loading conditions, can vary widely. Contractility is relatively fixed. It can be increased pharmacologically but is usually either normal or reduced. Further demonstrating misconceptions about contractility, a hypertrophied ventricle is often assumed to have increased contractility. Hypertrophy is a response to increased afterload, but contractility, once corrected for the greater cross-sectional area of the ventricular muscle mass, is normal. Any disease process that injures the myocardium decreases global contractility. In adults, this most commonly occurs secondary to ischemia or infarction. In addition to these causes, pediatric patients may suffer decreased contractility on the basis of genetic disorders, infiltrative diseases, infections, or nutritional deficiencies.

The immature myocardium has a reduced sarcomere concentration combined with a transport system for calcium that is not fully developed. The myofibrillar arrangement is also

more disorganized in the infant heart when compared with the adult heart. Mitochondria, the energy powerhouse of the myocyte, are reduced in number in the immature heart (Barth et al., 1992). Based on the above differences, a reduction in contractility is expected. Contractility is measured by the tension developed in the isolated muscle strip. This expected reduction in contractility of the immature myocardium is confirmed in laboratory experiments where preload and afterload are controlled. Across the entire range of loading conditions, fetal cardiac muscle generates less tension than adult myocardium (Fig. 4-14) (Friedman, 1972; Romero et al., 1972). In an intact heart it is not possible to fully separate the influences of different loading conditions. Nevertheless, fractional area shortening of the ventricle measured echocardiographically is used as a measure of contractility. Decreased fractional area shortening has been observed in the fetal heart (St. John Sutton et al., 1984). Effecting a true increase in contractility requires either a greater number of contractile elements or more vigorous action by the contractile elements already present. Increasing the number of contractile elements (hyperplasia and hypertrophy) occurs as a normal part of development. Improving the action of the contractile elements already present requires an understanding of the singular role of calcium. Therapy to improve inotropy exerts its action at the myocyte level by affecting the levels of intracellular calcium.

Calcium and Diastolic Function

A comprehensive understanding of the excitation-contraction coupling mechanism of contraction and relaxation is important for the safe practice of pediatric anesthesia. The relevant points are included here. The formation of actin-myosin cross-bridges

■ **FIGURE 4-14.** Length-tension relationships in adult sheep compared with fetal lambs. The fetal myocardium has greater resting tension but is able to generate less active tension. This represents a state of decreased compliance or a “stiffer” ventricle combined with decreased contractility. (From Friedman WF: *The intrinsic properties of the developing heart*, Prog Cardiovasc Dis 15:87, 1972.)

occurs under the influence of calcium. Tropomyosin and troponin are inhibitory proteins that prevent the formation of actin-myosin cross-bridges. Calcium induces conformational changes in tropomyosin and troponin that remove their inhibition to actin-myosin cross-bridge formation. This is the basis of contraction and requires major changes to intracellular calcium content. It is estimated that the difference between diastolic and systolic calcium levels is 100-fold (10^{-7} M to 10^{-5} M) (Shah et al., 1994). Responsibility for these large changes in intracellular calcium concentration lies with the integrated function of the sarcolemma, the T-tubule system, and the SR. Breaking the actin-myosin cross-bridges and returning the ventricle to its baseline state is an energy-consuming process that requires adenosine triphosphate (ATP) and calcium reuptake. This is primarily accomplished by the removal of calcium into the SR and the sarcolemmal Na^+ - Ca^{2+} exchanger (Mahony, 2007). Ryanodine is an inhibitor of SR function. In the presence of ryanodine, fetal and newborn hearts are minimally affected, whereas adult hearts suffer a significant decline in contractility (Penefsky, 1974).

Experimental modulation of calcium handling has been shown to alter ventricular mechanics. In a study with mice that overexpressed the Ca^{2+} ATPase, the rate of myocardial relaxation was directly correlated with the rate of calcium uptake by the SR (He et al., 1997). In guinea pigs, ryanodine blockade of SR function caused impaired relaxation (Kaufman et al., 1990). Additionally, there were age-dependent changes in the relaxation response. In adult hearts, ryanodine blockade produced a greater impairment of relaxation compared with immature hearts. Concomitantly, there was greater density of Ca^{2+} pumps, greater calcium-dependent ATPase activity, and greater uptake of calcium in isolated SR vesicles from adult hearts as compared with those isolated from immature hearts. With decreased SR function in the immature heart, the extrusion of calcium across the cell membrane assumes greater importance. The Na^+ - Ca^{2+} exchanger provides the primary mechanism for this. The exchanger is sensitive to membrane potential as it exchanges three sodium ions for one calcium ion. Developmental changes in the exchanger function have been demonstrated, and there are differences among species in relative function (Nakanishi and Jarmakani, 1981; Artman, 1992; Boerth et al., 1994). In the rabbit, with its poorly developed SR exchanger, mRNA is significantly elevated in the neonate versus the adult (Artman, 1992). The relative contribution of calcium sequestration between the SR and the exchanger in the human is similar to that of the rabbit (Mahony, 2007). In addition to reduced calcium handling, there may be developmental changes in troponin interactions that effect calcium binding. There is differential expression of cardiac and slow skeletal-muscle isoforms. In fetal hearts, the predominant form is the slow-skeletal form. Shifts to the cardiac isoform are completed in the first year of life. This is significant in that the cardiac isoform has a decreased affinity for calcium when phosphorylated, potentially aiding the removal of calcium from troponin C.

The sum total of these events is to demonstrate that across all age ranges the intracellular handling of calcium is critical for systolic function and even more important for diastolic function. The diastolic characteristics of the immature myocardium have been studied. The immature myocardium has been described as “stiffer” when compared with the adult myocardium. Ventricular compliance increases with maturation (Friedman, 1972; Romero et al., 1972; Kaufman et al.,

1990). Measurements of rates of pressure change demonstrate decreased relaxation capabilities in neonatal hearts when compared with adult hearts (Palmisano et al., 1994). There are a number of potential factors involved. Structural and contractile protein changes, extra-cardiac structures, and maturing organelle function have been studied. The diastolic relaxation properties of the ventricle are a key determinant of the ventricle's compliance. Reductions in calcium reuptake lead to expected decreases in diastolic relaxation (Kaufman et al., 1990). Echocardiographic studies on human fetuses with normal hearts have demonstrated age-related changes in early diastolic flow that are consistent with improved relaxation (Kenny et al., 1986; Harada et al., 1997). Consequently, intracellular calcium homeostasis in the newborn is more dependent on a normal serum ionized calcium level, and the newborn tolerates hypocalcemia poorly. Immaturity of calcium transport leads to a decrease in systolic-force generation and a decrease in diastolic relaxation. The manifestation of impaired diastolic relaxation is a reduction in compliance. Clinically, these issues must be appreciated when interpreting assessments of volume based on pressure readings such as the central venous pressure (CVP).

Heart Rate

As mentioned in the section on preload, it has long been considered that the newborn's heart rate is dependent on and relatively insensitive to changes in end-diastolic volume. Assuming the maintenance of sinus rhythm, heart rate is believed to determine cardiac performance through its influence on preload and myocardial oxygen supply and demand. At very high heart rates, hypotension ensues, because diastolic filling time is severely restricted and preload markedly falls. Coronary perfusion to the left ventricle occurs during diastole, and systolic ejection time is fixed. Thus, tachycardia shortens the time for perfusion of the left ventricle and results in an increased oxygen demand combined with a decreased oxygen supply. The absence of coronary artery disease in newborns offers them some protection in accepting imbalances in myocardial oxygen supply and demand. However, extremes of heart rate are poorly tolerated by adults and newborns alike.

The question is whether the newborn who has a heart rate within normal range is fundamentally different than the adult. When corrected for weight, stroke volume is similar across all ages. The high cardiac output of newborns and infants can only be achieved with a heart rate that is significantly higher than in adults. This has created the idea that the newborn is dependent on heart rate. Here it becomes difficult to sort out the isolated effect of heart rate from its effects on loading conditions and contractility. It is not intuitive as to why changes in heart rate alter contractility. The mechanism is known as the force-frequency relationship. Experiments using atrial pacing, while controlling loading conditions, demonstrate an increase in stroke volume with an increase in heart rate (Anderson et al., 1982). With constant loading conditions, the only explanation for increased stroke volume is that contractility has increased. Thus, an increased heart rate improves contractility. The basis for the force-frequency relationship is that an increase in heart rate is accompanied by enhanced release of intracellular calcium (Parilak et al., 2009). There is a suggestion that the force-frequency relationship has minimal effect in newborns but is present during infancy (Wiegerinck et al., 2008). Spontaneous increases in heart

rate also improve cardiac output. In this scenario, the increase in heart rate is the result of a neurohumoral stimulus with an effect that cannot be isolated to producing tachycardia. Both preload and contractility can be expected to increase, as long as the increase in heart rate does not lead to deleterious changes in preload or myocardial oxygen supply and demand. The combination of these factors allows the newborn and infant to use heart rate to significantly augment cardiac output.

Integrating Preload, Afterload, and Contractility

The determinants of myocardial performance, while discussed in isolation, are actually intricately linked. Diagrammatically, the determinants of myocardial performance can be represented by ventricular pressure-volume loops (Suga et al., 1973). The loop shows the pressure and ventricular volume changes that occur during one cardiac cycle. Increases in preload while afterload is held constant result in greater stroke volume (Fig. 4-15). This simple curve does not provide any information about contractility. The end systolic pressure-volume relationship (ESPVR) is a family of curves that is generated by rapidly altering preload or afterload. The curves create a series of points that are connected to become the ESPVR line. The slope of this line represents contractility (Fig. 4-16). The pressure-volume loop illustrates the concept that movement along the ESPVR line reflects changes in loading conditions while contractility remains constant. In Figure 4-16, the increases in afterload result in a series of points that are connected to become the ESPVR line. The slope of the ESPVR line represents contractility. The two figures of ventricular pressure-volume loops represent an idealized situation where preload and afterload can be manipulated independent of each other. In the intact organism, preload and afterload are linked. The interdependence of preload and afterload is shown in a new ventricular pressure-volume loop (Fig. 4-17).

In states of decreased contractility, the ventricular pressure-volume loop displays the limitations of the failing heart. Analysis of the ventricular pressure-volume loop shows that the failing ventricle is sensitive to changes in loading conditions (Fig. 4-18). The ESPVR line has shifted down and to the right. With preload held constant, stroke volume is reduced.

■ **FIGURE 4-15.** Ventricular pressure-volume loop. As preload increases from point A to points E and F, the end-diastolic pressure-volume curve represents compliance. The increased preload results in greater stroke volume (SV) when afterload is held constant. (Modified from Braunwald E, Ross J, Sonnenblick EH: Mechanisms of contraction of the normal and failing heart, Boston, 1976, Little, Brown.)

■ **FIGURE 4-16.** Ventricular pressure-volume loop. As afterload is increased, stroke volume falls when preload is held constant. The slope of the line connecting points D, E, and F is the end-systolic pressure-volume relationship and represents contractility. Only alterations in the slope of the line represent changes in contractility. The contractility at points D, E, and F is identical. (Modified from Braunwald E, Ross J, Sonnenblick EH: Mechanisms of contraction of the normal and failing heart, Boston, 1976, Little, Brown.)

■ **FIGURE 4-17.** Ventricular pressure-volume loop. The interdependence of preload and afterload is demonstrated. The increase in preload from point 1 to point 2 results in a rise in stroke volume (SV_1 to SV_2) that is less than anticipated because the increase in preload causes a corresponding increase in afterload. (Modified from Strobeck JE, Sonnenblick EH: Myocardial contractile properties and ventricular performance. In Fozzard HA, Haber E, Jennings RB, et al., editors: The heart and cardiovascular system, New York, 1986, Raven.)

■ **FIGURE 4-18.** Ventricular-pressure volume loop with decreased contractility. The line representing contractility is shifted down and to the right. Curve 1 is the stroke volume with normal contractility. Curve 2 shows that when contractility is reduced, stroke volume can be maintained through increased preload. Curve 3 demonstrates a significant reduction in stroke volume when afterload is increased in the presence of decreased contractility. (Modified from Braunwald E, Ross J, Sonnenblick EH: Mechanisms of contraction of the normal and failing heart, Boston, 1976, Little, Brown.)

The body's response to this situation is to increase LVEDV in an attempt to preserve stroke volume. Stroke volume has improved at the expense of a higher end-diastolic pressure. The ventricular pressure-volume loop demonstrates why afterload reduction is the cornerstone of medical therapy for the failing heart. Any increases in afterload come at the expense of stroke volume, with a limited ability for compensatory changes in preload.

The reflex of the trainee when confronted with a patient with significantly decreased contractility is to withhold or restrict fluids in a well-meaning attempt to avoid pulmonary edema. The ventricular pressure-volume loop for the patient with heart failure shows the fallacy and danger of this approach. Positive pressure ventilation is associated with decreases in preload. Venous tone is decreased by most anesthetic agents. The combination of these two events means that while the patient's global volume status is unchanged, he or she has become relatively hypovolemic. He or she is below the optimum LVEDV for his or her failing heart. Far from being on the verge of pulmonary edema, this patient now requires intravascular volume to compensate for the effects of anesthesia and positive pressure ventilation. Although maintaining LVEDV is critical for patients, there are currently limited means to accurately assess preload. Central venous pressure must be interpreted in light of the altered ventricular compliance of the failing heart. Lastly, while the failing heart requires adequate preload, its ability to accept volume rapidly is limited. Cautious infusion of volume with frequent reassessment is necessary lest a rapid bolus of fluid results in pulmonary edema, which is exactly the outcome the trainee sought to avoid by restricting volume in the first place.

DEVELOPMENTAL ASPECTS OF CARDIOMYOCYTE STRUCTURE AND FUNCTION

Ultrastructural maturation of several aspects of the cardiomyocyte as it relates to calcium homeostasis has been addressed previously. This section addresses these aspects in greater detail, as well as the maturation of additional subcellular components. Most of the knowledge of ultrastructural maturation derives from animal studies, and the timing in humans is often not yet defined.

Subcellular Structures

Sarcolemmal Ion Channels

Numerous voltage-dependent and ligand-gated ion channels reside in the sarcolemma, and a full discussion far exceeds the space available in this chapter. Although developmental changes in the inward sodium current have been noted in several species, there appear to be few developmental changes in the human atrium (Sakakibara et al., 1992). A variety of inward and outward potassium channels exists. Although developmental changes have been documented, methodologic differences and differences among species do not allow application to human development (Sanchez-Chapula et al., 1994; Xie et al., 1997; Morrissey et al., 2005). $\text{Na}^+\text{,K}^+$ ATPase maintains the sodium gradient across the cell and is inhibited by the cardiac glycosides, such as digitalis. There are developmental changes in the isoform distribution of the enzyme subunits, and this enzyme has less activity in immature myocardium. Calcium handling is crucial to myocardial contraction. Calcium channel (I_{Ca}) density increases two to threefold in the developing rabbit, although the voltage sensitive activation is similar to that of humans (Osaka, 1991; Huynh et al., 1992; Wetzel et al., 1993). In one study of human atrial myocytes (presumably from ill children), younger hearts had decreased calcium channel density, and in another study, more rapid inactivation of calcium current was evident (Hatem et al., 1995; Roca et al., 1996). However, in the realm of human myocardial development, many of these hearts were fairly mature when studied. The $\text{Na}^+\text{-Ca}^+$ exchanger, which can serve to bring calcium either into or out of the cell, has higher activity in immature myocardium in a variety of species (Artman et al., 1995). This is a purported source of additional calcium entry into the contractile apparatus in immature myocardial cells that have relatively deficient sarcoplasmic reticulum. There is increased activity of the $\text{Na}^+\text{-H}^+$ exchanger in immature myocardium, and this has been implicated as a factor in the greater resistance of immature myocardium to acidosis (Downing et al., 1966; Haworth et al., 1997).

Transverse Tubules

Transverse tubules, or *T-tubules*, invaginations of the sarcolemma in ventricular, but not atrial, myocardial cells have been mentioned in the discussion of myocardial performance. They allow transmission of the action potential, with its attendant ion shifts, to all parts of the cell, which allows rapid activation of the entire cell. T-tubules are thus a required component of larger cells (Gotoh, 1983). Maturation of T-tubules is associated with the increased size of mature myocardial cells, with the sarcolemmal calcium channels

further from the contractile apparatus. Species that have a relatively mature myocardium at birth have well-developed T-tubules at birth, whereas animals with immature myocardium at birth do not. T-tubules first appear at about 30 weeks gestation in humans (Kim et al., 1992).

Mitochondria

Mitochondria increase in size, relative volume, and internal compactness and complexity during myocardial development, and their growth may continue into the postnatal period (Barth et al., 1992). In some species, maturation is postnatal. Maturation of mitochondria mirrors the shift from a primary carbohydrate energy source of immature myocardium to the primary long-chain free fatty-acid energy source of mature myocardium (Fisher et al., 1980, 1981).

Cytoskeleton

An intracellular construction of microtubules and microfilaments links the contractile elements, T-tubules, sarcolemma, mitochondria, and nucleus. This scaffolding organizes the subcellular components that participate in cell signaling and allows transmission of the force of contraction to be applied to the myocyte. Mutations in several of these can be responsible for several familial cardiomyopathic conditions. The cytoskeleton not only undergoes modification with myocardial development, but microfilaments also play a role in the adaptive response to mechanical loading of the heart (Small et al., 1992; van der Loop et al., 1995; Schroder et al., 2002). One of the most important roles of the cytoskeleton is to link the thick filaments. Titin, the largest protein in the human, extends from the Z-disc to the M-line of the sarcomere. It both aligns the thick filament and has a spring-like function that determines passive tension. Titin isoforms are under developmental regulation, with fetal myocardium having the more compliant N2BA isoform, which is then replaced with the stiffer isoforms. The conversion of isoforms is species dependent, but it correlates with the shift from the more compliant fetal myocardial cells (when studied removed from the surrounding matrix) to the less compliant cells of the adult.

Sarcoplasmic Reticulum

The tubular network of SR regulates intracytosolic calcium concentration. The ryanodine receptor is located in the SR, as are a variety of proteins and channels that regulate calcium. Calcium regulation by the SR is critically important for the release of calcium (contraction) and its re-uptake (diastole). In the mature cardiac myocyte, the SR is the primary source of calcium to the cell. The amount of SR is significantly reduced in immature myocardium, as are indices of SR function, in a variety of species (Maylie, 1982; Nakanishi et al., 1987; Nassar et al., 1987).

Contractile Proteins

These proteins compose the thin filaments of the I-band (actin, the troponin complex and tropomyosin) and the thick filaments (myosin and titin) are composed of contractile proteins. All of these proteins have developmentally regulated changes

in isoform expression. Additionally, their expression is specific to cell type (e.g., cardiac vs. noncardiac or atrial vs. ventricular) and is regulated by physiologic signaling, such as thyroid hormone or diabetes (Baum et al., 1989).

Myosin

Myosin is the most abundant contractile protein and is responsible for transducing chemical energy (ATP) into mechanical energy. It is composed of two heavy and two light chains. Different heavy-chain myosin isoforms have different ATPase activity, conferring different calcium sensitivity. Developmental changes in myosin are species specific. In humans, the V3 isoform is most common in the fetus (90% at 30 weeks, gestation), decreases in the neonate, and reaccumulates beginning in the second month of life to become predominant in the adult. The V3 isoform, consisting of two β heavy chains, has the lowest ATPase activity of the various myosin types and consumes less ATP for the same amount of force generation (Cummins et al., 1980). Atrial myosin, with its briefer contraction, is primarily the V1 isoform (consisting of two α heavy chains). Regulation of the myosin heavy chain is at the transcriptional level and appears to account, at least in part, for the rapid conditioning of a ventricle after the placement of a pulmonary artery band (Lompre et al., 1984). The myosin light chain, located near the head of the heavy chain, has a variety of subunits that regulate myosin ATPase activity and that are also under developmental regulation.

Actin

The thin filament consists of two intertwined bands of actin monomers. Both skeletal and cardiac forms of actin are present during human cardiac development. In the early embryonic heart the skeletal form predominates (more than 80%). The cardiac form is present in the early stages of heart tube development and gradually increases. The onset of rhythmic contraction coincides with the disappearance of the skeletal isoform. In humans, cardiac actin increases to approximately 50% in the first decade, but the physiologic implication of this shift is not known (Boheler et al., 1991). Skeletal actin rapidly increases after the imposition of an acute pressure load to the ventricle before declining slowly.

Tropomyosin

Tropomyosin lies in the groove between the two actin bands and, depending on its deformation by troponin, either permits or prevents the interaction of actin and myosin. There are two isomers, and the isomer distribution depends on the intrinsic heart rate (and therefore the species). In humans, the amount of β isoform increases from 5% in the fetal ventricle to 10% in the adult, but the physiologic implication of this shift is not known (Humphreys and Cummins, 1984).

Troponins

The three distinct but functionally coupled proteins of the troponin complex (troponins T, C, and I) confer calcium sensitivity to actin-myosin cross-bridge formation, and each has multiple developmental and species specificity (Anderson et al., 1991). Troponin T binds the complex to tropomyosin;

troponin C binds calcium; and troponin I regulates the interaction of the complex with tropomyosin, binding to troponin C during systole and to actin during diastole. Four forms of cardiac troponin T are present in the human as the result of alternative splicing of a single gene, and their expression is developmentally regulated (Anderson et al., 1991). All isoforms are expressed in the fetal heart, but only one (cTnT3) is expressed in the adult. In failing human hearts, including those of children, cTnT1 and cTnT4 are upregulated (Saba et al., 1996). These isoform shifts likely affect contractility, as they modify the calcium sensitivity of the contractile apparatus. Troponin I has both cardiac and slow skeletal forms. Both are found in fetal hearts. Approximately 70% of troponin I is the skeletal form, but the isoform shift to the adult form of troponin I (all cardiac) is complete in the human by 9 months of age (Sasse et al., 1993). Phosphorylation of the cardiac isoform, but not the skeletal isoform, decreases the sensitivity of troponin C and the myofilament for calcium, as well as the affinity of troponin I for troponin C, with both decreases altering contractile performance. The slow skeletal form of troponin I in neonates may contribute to the resistance of the neonatal myofilament to deactivation at acid pH, perhaps contributing to the greater recovery of neonatal myocardium from an acidotic insult (Solaro et al., 1986). Although there are several isoforms of troponin C, only the cardiac isoform is expressed in cardiac muscle.

Myocardial Energy

Newborn sheep have a higher myocardial oxygen consumption than adult sheep. These metabolic demands of the developing heart are met by a capillary network of higher density than that found in adults (Fisher et al., 1982).

The immature myocardium uses lactate as a primary energy source. This is in contrast to the mature myocardium, where fatty acids are the primary energy source. To be metabolized, fatty acids must first be transported into the mitochondria. This is accomplished by carnitine palmitoyl-CoA transferase. Activity of this enzyme is reduced in the immature myocardium, suggesting the necessity of carbohydrate as the primary energy source (Fisher et al., 1980, 1981).

Electrophysiology

The sinus node can initially be identified as a horseshoe-shaped structure at the lateral junction of the superior vena cava and the right atrium. As the heart develops, it assumes the elongated spindle shape that is seen in the mature heart. Using voltage-sensitive dyes, spontaneous cellular depolarization has been observed prior to the development of contractile function. Although spontaneous depolarization is also seen in the developing atrium and bulboventricular portion, cells that are destined to form the sinus node have a higher intrinsic rate of depolarization (Pickoff, 2007).

Discrete connections between the sinus node and the atrioventricular (AV) node are a matter for debate. The lack of an identified cell type insulated from the surrounding atrial myocardium has been considered evidence of a lack of specialized internodal conducting pathways (Anderson et al., 1981). Preferential conduction along bands of atrial myo-

cytes in the anterior septum may be to the result of a more organized cellular alignment (Racker, 1989). More recent evidence from studies of developing human hearts has demonstrated three internodal pathways identified by antibody staining (Blom et al., 1999).

Functional changes in the electrophysiologic properties of the atrium have been described. Action potential duration in human neonates is shorter than in adults. This is relevant in that it may explain the highest incidence in childhood of atrial arrhythmias in the fetus and neonate (Pickoff, 2007). Once these dysrhythmias are terminated in the newborn, there is a low incidence of recurrence.

Delay in contraction between the atrium and ventricle is seen before the development of the AV node. Action-potential recordings from the AV canal area of the developing chicken heart demonstrate characteristics that are to be expected of slowing areas of conduction—namely, a slow rate of rise and a prolonged duration. These characteristics are further linked to differential expression of acetylcholinesterase. Expression is higher in the AV canal region compared with expression in the free wall of the atrium or ventricle (Mikawa and Hurtado, 2007; Pickoff, 2007).

AV nodal cells are distinct from the other embryonic myocardial cells. They have differential expression of calcium-regulatory proteins and membrane channels (Mikawa and Hurtado, 2007). Formation of the AV node is an incompletely understood complex series of events that likely involve modulation by the gene *NK \times 2-5* (Mikawa and Hurtado, 2007; Briggs et al., 2008).

Formation of the Purkinje system is an area of active investigation. Purkinje-like function is seen after cardiac looping (Pickoff, 2007). However, the network is still developing in the fetal heart. Studies suggest a paracrine interaction between the fetal myocardium and the cardiac endothelial cells. Purkinje fiber development is seen primarily in two sites, periarterially and subendocardially. Phenotypical recruitment of a beating myocyte to a conduction fiber is thought to be modulated by endothelin-1 (ET-1). The ET-1-induced expression of conduction-tissue markers in myocytes is dependent on dosage and inhibited by ET-1 antagonists (Mikawa and Hurtado, 2007). Exposure of myocytes to ET-1 is also associated with downward regulation of markers found primarily on muscle cells.

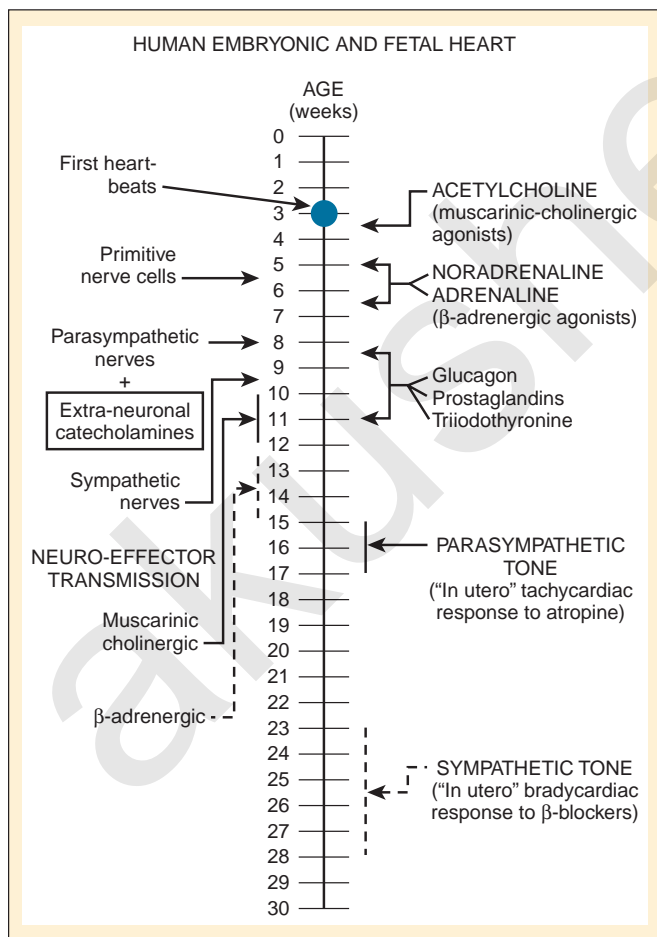

In chicken embryos, conduction velocities increase with age and are related to the emergence of fast-conducting sodium channels (Shigenobu and Sperelakis, 1971; Pickoff, 2007). Findings have been similar in mammalian systems (Rosen et al., 1981; Pickoff, 2007). Of note is the maintenance of conduction slowing from atrium to ventricle seen in the primitive heart. In a canine model, measurement of AV-nodal conduction demonstrated that conduction was faster in immature hearts, but the AV node, not the ventricular myocardium, remained the site of conduction slowing with differential atrial pacing (McCormack et al., 1988).

Through fetal magnetocardiography, conduction times have been noted to increase with gestational age (Kahler et al., 2002; Stinstra et al., 2002; van Leeuwen et al., 2004). This is thought to be related to myocardial growth (van Leeuwen et al., 2004). Intracardiac conduction times have been measured in children and compared with those in adults. There were no age-related differences in atrial, AV-nodal, or His Purkinje-conduction times (Gillette et al., 1975).

Central Nervous System Regulation of Cardiovascular Function

The regulation of cardiac output and blood flow is controlled by neural and circulation mechanisms. Neural regulation is accomplished by modulating the output through the sympathetic and parasympathetic nervous systems in response to input from receptors in the heart and vasculature. Hormonal regulation occurs by receptor stimulation by circulating molecules.

The autonomic nervous system is developed in the human by about 27 weeks' gestation. Parasympathetic innervation precedes sympathetic innervation (Fig. 4-19). In sheep, at least, the postnatal increase in contractile function with adrenergic stimulation is a consequence of higher resting adrenergic tone rather than a maturation of the myocardium (Teitel et al., 1985). The β -adrenergic/adenylate cyclase system develops during fetal life. The density of the β -adrenergic receptor density peaks at term and declines postnatally, mirroring the maturation of cardiac sympathetic innervation. Calcium channels in neonatal myocardium do, however, respond less to β -adrenergic stimulation than they do in the adult, and isoproterenol stimulation of adenylyl cyclase is blunted in the late fetus and neonate (Osaka and Joyner, 1992). In the late term fetus and the neonate, coupling of the β -receptor and adenylyl cyclase may be

■ **FIGURE 4-19.** A timeline of human fetal autonomic development. (From Papp JG: *Autonomic responses and neurohumeral control in the early antenatal heart*, Basic Res Cardiol 83:2, 1988.)

decreased, because differential β -adrenergic response to isoproterenol and forskolin, a direct activator of adenylyl cyclase, has been observed (Schumacher et al., 1982; Tanaka and Shigenobu, 1990). This finding may help explain the decreased response of calcium channels to β -adrenergic stimulation in the neonatal myocardium (Baum and Palmisano, 1997).

The sinoatrial node is sensitive to β -adrenergic stimulation in the fetus before the development of ventricular sensitivity, and this sensitivity tends to parallel the development of autonomic innervation to these regions of the heart.

Vagal myelination in humans continues through the fetal period and reaches adult levels by about 50 weeks postconceptual age (Sachis et al., 1982). In humans, parasympathetic input to the heart is from the superior, inferior, and thoracic branches of the vagus nerve (Hildreth et al., 2009). The relative balance of sympathetic and parasympathetic stimulation is reflected in the decreasing mean heart rate as a child reaches adolescence.

The aortic arch and carotid bodies have baroreceptors that provide the afferent limb of the feedback circuit. Stimulation of these receptors sends impulses to the cardioinhibitory and vasomotor centers of the medulla. In turn, the efferent signals result in decreased blood pressure, vasodilation, and slowing of the heart rate. Arterial baroreflexes are present and operational in healthy and critically ill human neonates; human neonates, even preterm neonates, have well-developed vagally mediated cardiac responses to hypoxemia and other stimuli, although the course of maturation is unclear (Thoresen et al., 1991; Buckner et al., 1993). Decreasing sensitivity in studies of awake animals suggests a decreasing role for heart rate in the control of blood pressure in aging animals (Palmisano et al., 1990).

Stretch receptors in the myocardium also provide afferent signals to the central nervous system. Within the atrium there are two types of stretch receptors. Type A receptors are sensitive to pressure and are activated by atrial systole. Type B receptors are sensitive to volume and fire during ventricular systole. They have opposing effects on the sympathetic nervous system, with Type A receptors stimulating sympathetic activity. Secretion of vasopressin is inhibited by stimulation of stretch receptors. Stretch receptors are also found in the ventricular myocardium and when activated cause hypotension and bradycardia (Teitel et al., 2007).

Pulmonary Vascular Development

The pulmonary vasculature is a unique low-flow, high-pressure system *in utero* that must convert to a high-flow, low-pressure system after birth. In the absence of shunts, the right and left sides of the heart are connected through the pulmonary vasculature, which becomes the major determinant of right-ventricular afterload and left-ventricular preload. Effective cardiopulmonary interactions are crucial for a smooth transition to postnatal life. Primary lung problems, such as severe meconium aspiration or respiratory distress syndrome, through their effects on the pulmonary vasculature, can severely stress the heart. Congenital heart disease causes abnormalities of pulmonary blood flow, which can profoundly influence the pulmonary vasculature in its transition to postnatal life. This section begins with a review of normal pulmonary vascular development and concludes with a discussion of the changes present in pulmonary arterial hypertension.

Pulmonary vessels are described by their relation to the bronchioles. Terminal bronchioles are the smallest purely conductive airways. Beyond them lie respiratory bronchioles, with dual conductive and gas-exchange functions, and then more distally, the alveolar units. Resistance in the pulmonary vasculature is at the level of the small pulmonary arteries (approximately fifth to sixth generation), which are defined as preacinar if they are proximal to the terminal bronchioles and intraacinar if they course parallel to the respiratory bronchioles and alveolar units. Conductive airways and preacinar arteries are fully present by 16 weeks' gestation (Hislop and Reid, 1973). There is a thickened muscular layer in the medial wall of preacinar vessels, most prominent at the fifth and sixth generation arteries (Hlastala et al., 1998). Beyond the preacinar arteries there is a transition zone of vessels at the level of the respiratory bronchioles with incomplete muscularization in the medial layer. The medial layer of these incompletely muscularized vessels contains pericytes (mesenchymal cells capable of differentiation) and precursor smooth muscle cells. Compared with a complete muscular layer, partial muscularization is believed necessary to aid the gas exchange function of respiratory bronchioles because alveolar development at birth is very immature. Arteries associated with immature alveoli are completely free of a muscular medial layer at birth.

The developing pulmonary vasculature must be of a caliber that can accommodate the enormous increase in postnatal blood flow without a damaging rise in pressure. In a setting of low blood flow, the pulmonary vasculature grows normally but retains a high resistance because of increased vascular tone. The increased vascular tone is primarily modulated by hypoxemia. Expansion of the lungs and a rise in alveolar oxygen tension after birth leads to the marked vasodilation of small arteries required to accept the increase in blood flow. Normal volume, low pressure pulmonary blood flow in the newborn period begins a process of regression of the muscular medial layer of the small arteries. Morphologically recognizable alveoli develop over the first 2 months of postnatal life with continued development until 18 months of age. After this, growth of existing alveoli continues until late childhood. The sparse numbers of alveoli at birth are associated with nonmuscularized intraacinar arteries. The rapid period of alveolar development is matched by growth of new intraacinar arteries. Both existing and new intraacinar arteries develop a thin, muscular medial layer. Thus, the process of normal pulmonary vascular development involves both the regression of muscularity in preacinar existing vessels and the growth of new intraacinar vessels that acquire a thin muscular layer. Disturbances of flow or pressure during this time can have profound consequences.

Diseases that affect normal pulmonary blood flow patterns have far-reaching consequences. In fetuses with abnormal restriction of pulmonary blood flow, there is often hypoplasia of the pulmonary arterial system. The degree of hypoplasia can be mild to fulminant, with atresia of all or parts of the pulmonary arterial system. For example, with tetralogy of Fallot, the level of pulmonary outflow obstruction is typically in the infundibulum of the right ventricular outflow tract. The resulting decrease in pulmonary blood flow affects the main and branch pulmonary arteries, which can be variably hypoplastic. Despite being hypoplastic, the vasculature has the ability to remodel and grow with improved blood flow. In patients who receive an early modified Blalock-Taussig shunt that provides augmentation of pulmonary blood flow, growth of the pulmonary arteries

is seen. Also, in patients with hypoplastic pulmonary arteries, patch augmentation can result in reversal of pulmonary artery hypoplasia (Agnoletti et al., 2004).

Disruption of normal pulmonary vasculature has also been observed when the perturbation to pulmonary flow is on the venous side. In hypoplastic left heart syndrome, blood returning to the left atrium must cross over to the right atrium via the foramen ovale. If the foramen ovale is widely patent, blood returning via the pulmonary veins to the left atrium is shunted across to the right atrium. Right-sided structures are often enlarged to accommodate the flow. However, if the patent foramen ovale is restrictive, pulmonary venous pressure rises and development of the pulmonary arterial vasculature is compromised. There is pressure rather than volume stress on the pulmonary vasculature. At birth, the increase in pulmonary blood flow with lung expansion leads quickly to left-atrial hypertension, compromising pulmonary blood flow and resulting in severe hypoxemia. Even if the emergent situation is optimally treated, surgical mortality remains high. At autopsy, the pulmonary veins of these infants are thickened and "arterialized" (Rychik et al., 1999). In juxtaposition to the pulmonary hypoplasia seen in patients with reduced pulmonary blood flow, patients with increased pulmonary blood flow may develop enlarged pulmonary arteries. In an uncommon variant of tetralogy of Fallot, the pulmonary valve is absent, resulting in free pulmonary insufficiency. This increased volume of blood flowing back and forth through the main and branch pulmonary arteries leads to massive dilation.

PVR decreases to near adult levels over the first 2 months of life. During these early months of life the concepts of pulmonary resistance and pulmonary reactivity are well demonstrated. Compared with the *in utero* state, resistance in young infants is low, though not quite yet at adult levels. However, the pulmonary reactivity is high, because the muscular pulmonary vasculature retains an impressive ability to increase vascular tone. By age 4 to 6 months, if the pulmonary vasculature has developed normally, both resistance and reactivity are low. The appropriate regression of the muscular layer of small pulmonary arteries leaves a healthy older infant unable to mount significant pulmonary hypertension. The contrast with the neonate is striking. Stressed by surgery that involves cardiopulmonary bypass or by pulmonary insults (such as respiratory distress syndrome or meconium aspiration) the neonate's reactive pulmonary vasculature is primed for a dangerous pulmonary hypertensive crisis.

The most common scenario of altered postnatal pulmonary blood flow occurs in patients with left-to-right shunts. Despite the increased pulmonary blood flow in the first few months of life, PVR continues to fall, leading to even greater pulmonary blood flow. The consequence of increased flow through the same cross-sectional vascular area is pulmonary hypertension. Because resistance is defined as pressure divided by flow, the diagnosis of pulmonary hypertension is not synonymous with increased PVR. The pulmonary vasculature accepts the increased blood flow at the expense of a rise in pressure. Resistance only increases when pressure remains high and pulmonary blood flow falls. Untreated, the natural result of this situation is a condition of pulmonary hypertension, elevated PVR, and fixed, irreversible pulmonary vascular disease. This is known as Eisenmenger's syndrome. In 1897, Dr. Eisenmenger described a 32-year-old male with cyanosis and exercise intolerance who died from massive hemoptysis (Eisenmenger, 1897).

The autopsy revealed a large ventricular septal defect (VSD) and overriding aorta. It was the first demonstration of congenital heart disease causing pulmonary vascular changes.

The normal process of pulmonary vascular remodeling consists of a reduction in the thickness of the muscular layer in preacinar small pulmonary arteries. Simultaneously, there is development of new intraacinar arteries and growth of existing intraacinar arteries that acquire a thin, muscular layer. The overall cross-sectional area of the pulmonary vasculature increases in concert with alveolar growth and development. Persistent high pulmonary blood flow from left-to-right shunting profoundly alters this process. The thickened muscular medial layer of small pulmonary arteries persists instead of involuting. In the transition zone of the respiratory bronchioles, precursor cells transform into vascular smooth muscle. Increased blood flow induces a shear stress in the pulmonary bed. Although felt to be a protective mechanism, this induces a reactive process that stimulates the muscularization of the pulmonary arteries and reduces the capacity for vasodilation. Development of new acinar arteries is impaired. Pulmonary artery pressure remains elevated. With persistent pulmonary hypertension, there are progressive changes in the pulmonary arteries that have been histologically characterized.

Heath and Edwards (1958) first described the following histologic changes in the pulmonary vasculature that are created by excessive blood flow and pressure:

- Stage I: Medial hypertrophy (reversible)
- Stage II: Cellular intimal hyperplasia in an abnormally muscular artery (reversible)
- Stage III: Lumen occlusion from intimal hyperplasia of fibroelastic tissue (partially reversible)
- Stage IV: Arteriolar dilation and medial thinning (irreversible)
- Stage V: Plexiform lesion, an angiomatoid formation (terminal and irreversible)
- Stage VI: Fibrinoid/necrotizing arteritis (terminal and irreversible)

Abnormal pulmonary vascular remodeling begins at birth if there is excessive pulmonary blood flow (Hall and Haworth, 1992). The Heath and Edwards scale is prognostic but limited, because pathologic stages are not correlated with clinical parameters. Rabinovitch overcame this problem by correlating pathologic severity with the hemodynamic state and assigning a simple three-stage grading system (Rabinovitch, 1999):

- Grade A: Extension of muscle into normally nonmuscularized vessels. This occurs because precursor cells in distal small pulmonary arteries differentiate into vascular smooth muscle. Pulmonary blood flow is increased but pulmonary artery pressure is not.
- Grade B: Medial hypertrophy of proximal muscular arteries. There are hyperplasia and hypertrophy of vascular smooth muscle. The mean pulmonary-artery pressure is elevated. Grade B may be further classified as mild or severe, depending on the thickness of the medial wall.
- Grade C: Reduction in the number of distal vessels. The vasculature is unable to keep up with the growth of alveolar units. There may also be loss of distal vessels due to luminal occlusion.

Grade A or mild grade B changes are histologically equivalent to Heath-Edwards Stage I. Grade C changes are associated with Heath-Edwards stage II or III and the possibility of irreversible changes in the pulmonary vasculature. Severe grade B or grade C disease is predictive of postoperative pulmonary hypertensive problems after surgery to repair the defect (Rabinovitch et al., 1984).

Any discussion of the pulmonary vasculature would be incomplete without exploring the role of the endothelium. Far from being a passive structure, modern understanding of the endothelium has evolved to recognize its singular place in the regulation of vascular tone (Rabinovitch, 1999). Exposure to high flow has multiple negative effects. Endothelial barrier function is compromised, which leads to the release of growth factors that increase vascular smooth muscle and deposition of subendothelial matrix proteins. Luminal diameter eventually decreases with superimposed increased vascular reactivity. Normally antithrombotic, damaged endothelium reacts abnormally with marginating platelets, resulting in activation of the coagulation system. The endothelium is a key source of the endogenous vasodilators prostacyclin and nitric oxide. When subjected to high flow and shear stress, the release of the endogenous vasodilators is increased, but it may not be enough of an increase to counteract the increased vascular reactivity when pulmonary blood flow is high.

ASSESSMENT OF THE CARDIOVASCULAR SYSTEM

The evaluation of a pediatric patient for anesthesia requires knowledge of age-appropriate history, physical findings, and laboratory data. Age correction is implicit in all facets of the cardiovascular examination. A heart rate of 110 beats per minute in a 6-month-old infant, for example, is normal, not “sinus tachycardia, normal for age,” as one often sees when cardiovascular data are reported by adult cardiologists. This section relates to the examination of the child with a nominally healthy and normal cardiovascular system (see Chapter 36, Systemic Disorders; issues of the child with congenital heart disease are discussed in Chapter 20, Anesthesia for Congenital Heart Surgery).

History

One of the most basic indicators of adequate cardiac function is age-appropriate exercise tolerance. In infants, heart failure is marked by a history of tachypnea and diaphoresis, particularly with feeding. A history of cyanosis may be abnormal or may be a normal finding. Many healthy infants develop acrocyanosis or perioral cyanosis with crying or cold.

Physical Examination

“Failure to thrive” is determined by plotting patient data on weight, height, and head circumference growth charts. Specific growth charts are available, for example, for children with Down’s syndrome, where normal growth may not mirror that of the population at large (Cronk et al., 1988). More important than the current position on growth charts is the child’s trajectory. The tenth percentile may be adequate for an individual patient. However, it becomes worrisome if the child’s growth had previously been recorded at the fiftieth percentile. In general, most

conditions causing failure to thrive will result first in loss of weight, followed by loss of height, preserving head circumference if at all possible. Certain metabolic disorders, however, show a preferential loss in height first.

Vital signs need to be corrected for age, as indicated above. Normal values for heart rate, respiratory rate, and blood pressure are shown in Tables 4-1 and 4-2 and Figures 4-20 and 4-21. Blood pressure cuffs need to be appropriately sized to avoid artifact. Although it was originally taught that the cuff width should be approximately two-thirds the length of the humerus, the current recommendation is now similar to that for adults. The width of the cuff should be approximately 40% to 50% of the circumference (approximately 125% to 155% of the diameter) of the limb where the pressure is being measured and long enough to approximately encircle it. The cardiovascular physical examination begins with inspection, and proceeds to palpation and then auscultation.

Inspection

Is the chest symmetric? Is there jugular venous distention? Jugular venous distention is unlikely to be observed in infants with short, fat necks. Is there cyanosis? Is there clubbing of the fingers?

TABLE 4-1. Normal Respiratory Rates in Children

Age	Respiratory Rate (min ⁻¹)
Birth-6 weeks	45-60
6 weeks-2 years	40
2-6 years	30
6-10 years	25
> 10 years	20

TABLE 4-2. Acceptable Ranges of Heart Rates (Beats/Min)

	Awake	Asleep	Exercise/Fever
Newborn	100-180	80-160	<220
1 week-3 months	100-220	80-200	<220
3 months-2 years	80-150	70-120	<200
2-10 years	70-110	60-90	<200
> 10 years	55-90	50-90	<200

Data from Adams FH, Emmanouilides GC, editors: *Moss' heart disease in infants, children, and adolescents*, ed 3, Baltimore, 1983, Williams and Wilkins.

Palpation

Is the precordium quiet? Is there a palpable thrill? Are the arterial pulses symmetric without radial-femoral delay (suggesting coarctation of the aorta)? Where is the liver palpated? The liver is normally palpable 1 to 2 cm below the right costal margin in the midclavicular line in infants, and is a window to the central venous pressure. As central venous pressure increases, the liver edge descends reliably.

Auscultation

Are the lungs clear without wheezing or rales, both of which could result from cardiac dysfunction? Are there any murmurs? Murmurs are almost universally heard in all children at some point, as heart sounds readily transmit through the thinner pediatric thorax. The differentiation between functional (innocent) murmurs and pathologic murmurs is often easy, but it can at times be challenging. A further discussion of murmurs is included in Chapter 36, Systemic Disorders. Figure 4-22 summarizes the changes in heart rate, cardiac output (CO), and stroke volume (SV) that occur in childhood.

FIGURE 4-20. Normal resting blood pressures in boys (A) and girls (B) aged 1 to 17 years. Pressures reflect those in children at the fiftieth percentile for height. Blood pressure varies slightly in children who are significantly taller (several mm Hg higher) or shorter (several mm Hg lower). Blood pressures also do not reflect normal values obtained when children are under anesthesia. (Data from National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents: The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. Available at www.nhlbi.nih.gov/guidelines/hypertension/child_tbl.htm.)

■ **FIGURE 4-21.** Systolic (A) and diastolic (B) blood pressures on the first day of life. Data are shown as the regression line and 95% confidence limits. (Data from Versmold HT, et al.: Aortic blood pressure during the first 12 hours of life in infants with birth weight 610 to 4,220 grams. *Pediatrics*, 67:607, 1981.)

■ **FIGURE 4-22.** Changes in cardiac output (CO), stroke volume (SV), and heart rate (HR) with age. (From Rudolph AM, editor: *Congenital diseases of the heart*, Chicago, 1974, Mosby.)

Chest Radiograph

Evidence of heart disease on the routine chest radiograph includes cardiomegaly (heart failure or large left-to-right shunts), decreased pulmonary blood flow (right-to-left shunts), abnormal cardiac silhouette (small pulmonary artery segment with tetralogy of Fallot), widened angle at the carina (large left atrium), pruning (decreased peripheral pulmonary arteries, as in pulmonary arterial hypertension), and rib notching (in children over about age 5 years with coarctation). Artifacts are more commonly seen in children, and the cardiac silhouette may appear artifactually large (Fig. 4-23). Although the lungs may appear abnormally small in an expiratory film, a more sensitive finding on a film taken in exhalation is buckling of the trachea. The shadow of a normal large thymus in infants can overlay the heart shadow, tempting a diagnosis of cardiomegaly. Sometimes a “sail sign” can be seen at the inferolateral border of the thymus, where it separates from the cardiac shadow, clearly identifying it as the thymus and not the heart (Fig. 4-24).

Electrocardiogram

Normal values of the electrocardiogram are dependent on age and heart rate. With development and growth, neonatal right-ventricular predominance is replaced with left ventricular predominance, the heart rate slows, and all durations and intervals lengthen. Between the ages of 3 and 8 years, the electrocardiogram of a child looks similar to that of the adult, with the exception of right precordial T waves, which are normally inverted until about age 10 years. Upright T waves over the right precordium in children younger than 10 years are an indication of right ventricular hypertrophy. Normal values for heart rate, QRS width, frontal-plane QRS axis, and PR interval are shown in Tables 4-3 and 4-4. It can be seen that the ranges of normal are fairly wide. In addition, these values are for children who are awake or resting. Heart rates in anesthetized children are likely to be somewhat lower. The QT interval (QTc), corrected by Bazett's formula ($QTc = QT / \sqrt{R - R \text{ interval}}$), has an upper limit of normal of 0.44 seconds in infants and children 6 months of age and older. The upper limit of normal is 0.47 seconds in the first week of life and 0.45 in the first 6 months.

■ **FIGURE 4-23.** **A**, Apparent cardiomegaly that is really an artifact of an expiratory film (and a large thymus). **B**, A repeat film taken shortly thereafter shows a normal cardiac size.

Cardiac Catheterization

A cardiac catheterization includes one or more of the following:

Anatomic diagnosis: This is done with a combination of hemodynamic data and angiographic evaluation. Radiographic contrast is injected through a catheter with its tip near the region of interest.

Hemodynamic data: Measures are made of oxygen saturation and pressure in the various cardiac chambers and great vessels. From these, indicators of cardiovascular function can be derived (see below).

Response to vasodilators: Hemodynamic measures are repeated in the absence and presence of a vasodilator, typically a pulmonary vasodilator such as nitric oxide or

■ **FIGURE 4-24.** A thymic sail sign (arrows). When seen, this can aid in differentiation of true cardiomegaly from a large thymic shadow. (From Keats TE, Anderson MW: Atlas of Roentgen variants that may simulate disease, Philadelphia, 2007, Mosby.)

oxygen, to evaluate the responsiveness of the pulmonary vasculature and to determine whether the patient is a surgical candidate.

Evaluation of arrhythmias: Several electrode catheters are placed in or near the right- and possibly left-sided chambers to map the locus and pathway of aberrant tracts (for example, Wolff-Parkinson-White syndrome or the site of an ectopic focus of an atrial or ventricular tachyarrhythmia). Attempts may be made to provoke the arrhythmia with electrical stimulation (a series of premature extrasystoles) or with drugs (isoproterenol).

Although major advances have been made in deriving physiologic measures of cardiac function by means of echocardiography and magnetic resonance imaging (MRI), cardiac catheterization remains the gold standard for many of these, in addition to providing images of radiologic anatomy and

TABLE 4-3. Normal Electrocardiogram Variables in Children

	Rate/min	QRS axis	QRS Duration (sec)
0-1 day	122 (94-155)	135 (59-189)	0.05 (0.02-0.07)

function (Odegard et al., 2004). In addition, the number of interventional procedures performed or proposed is expanding, while the patient population is increasingly complex. New procedures, including stenting of a variety of vessels, closure of atrial and ventricular septal defects, percutaneous placement of prosthetic valves, and hybrid repairs of defects jointly in the catheterization laboratory by both cardiac surgeon and an interventional cardiologist have expanded therapeutic options for patients (Kapoor et al., 2006; Galantowicz et al., 2008; Lurz et al., 2008). Transvascular replacement of pulmonary and aortic valves is also on the near horizon. These increasingly complex procedures require the attendance of an anesthesiologist, and the care rendered transcends beyond keeping the child from moving. The physiologic state of children undergoing such procedures can be tenuous, and the anesthetic care is provided in an environment that is foreign to many anesthesiologists (Cua et al., 2007) (See Chapter 21, Anesthesia for Children with Congenital Heart Disease Undergoing Non-Cardiac Surgery, Closed Cardiac Procedures, and Cardiac Catheterization). The environment may become increasingly foreign, because there are proposals to develop MRI suites for cardiac catheterization procedures in order to lower the radiation exposure to patients. More and more complex electrophysiologic procedures are also being done, some of which can take many hours to complete. All of these factors have contributed to a general shift from sedation toward general anesthesia in the pediatric cardiac catheterization laboratory. Additionally, transesophageal echocardiography guidance is required for many of the procedures, which requires endotracheal intubation.

Over the years, cardiac catheterization has become safer despite the increasing complexity of the procedures. Beyond routine potential anesthetic complications, complications include cardiac perforation and arrhythmias from catheter manipulation, embolization of closure devices, hypothermia (readily addressed with forced-air warming mattresses) and brachial-plexus injury from positioning (cardiologists try to extend the arms over the head to remove the upper arms from the field of the lateral x-ray tube), and vascular complications. Femoral venous injury is marked by a bluish color to the leg, whereas femoral arterial insufficiency is marked by a cold, white leg. However, these are almost always transient.

Vitiello and colleagues (1998) studied pediatric cardiac catheterization laboratory complications in a consecutive series of almost 5000 patients. One or more complications occurred in

8.8% of children. Vascular complications were most common (in 3.8%) and death occurred in 0.14%, most commonly in infants. With the large introducer sheaths needed for many newer interventional procedures, one might expect the incidence of vascular complications to increase.

Hemodynamic Assessment

A complete cardiac catheterization includes measures of oxygen saturation and pressures in all the cardiac chambers and great vessels. From these, additional hemodynamic measures such as vascular resistance and cardiac index can be derived.

Pressure

Normal intracardiac pressures are shown in Tables 4-5 and 4-6. The difference between pressures obtained on both sides of a valve, referred to as the gradient, is obtained with two separate catheters, or more commonly by withdrawing a single catheter

TABLE 4-5. Normal Values of Intracardiac Cardiac and Vascular Pressures (in mm Hg)

Location	Term Newborns	Infants and Children
Right atrium	m = 0-4	a = 5-10 v = 4-8 m = 2-6
Right ventricle	35-50/1-5	15-25/2-5
Pulmonary artery	35-80/20-50 m = 25-60	15-25/8-12 10-6
Pulmonary wedge	m = 3-6	a = 6-12 v = 8-15 m = 5-10
Left atrium	m = 3-6	a = 6-12 v = 8-15 m = 5-10
Left ventricle		80-130/5-10
Systemic artery	65-80/45-60 m = 60-65	90-130/60-80 m = 70-95

TABLE 4-6. Normal Hemodynamic Variables Beyond Infancy

Location	Average	Range
Mean right atrial pressure (CVP) (mm Hg)	3	1-5
Right ventricle pressure (mm Hg)		
Systolic	25	17-32
Diastolic	5	1-7
Pulmonary artery pressure (mm Hg)		
Systolic	25	9-19
Diastolic	10	17-32
Mean	15	4-13
Mean pulmonary wedge pressure (mm Hg)	9	6-12
Mean left atrial pressure (mm Hg)	8	2-12
Cardiac index (L/min/m ²)	3.5	2.5-4.2
Stroke volume index (mL/m ²)	45	
Oxygen consumption (mL/min/m ²)	150	110-150
Vascular resistance index		
Pulmonary (Wood units/m ²)		1-3
Pulmonary (dynes•sec•cm ⁻⁵ •m ²)		80-240
Systemic (Wood units/m ²)		10-20
Systemic (dynes•sec•cm ⁻⁵ •m ²)		800-1600

Data from Rudolph AM: *Congenital disease of the heart*, Chicago, 1974, Mosby. Pressures are in mm Hg.

across the valve. Unlike valve area that is fixed (and can be measured by echocardiography or derived from hemodynamic data), the gradient varies depending on the cardiac output—the higher the output, the higher the gradient for a specific valve area. Similarly, the gradient for a fixed lesion can decrease in the face of falling cardiac output.

Oxygen Content and Saturation

Oxygen capacity refers to the maximum amount of oxygen that can be bound to hemoglobin. Oxygen content, the amount of oxygen transported in blood, is calculated as

$$[(1.34 \times \text{oxygen saturation} \times \text{patient's hemoglobin}) + (0.003 \times \text{Po}_2)]$$

where $(0.003 \times \text{Po}_2)$ reflects the amount of oxygen dissolved in plasma. This is the oxygen content in milliliters of oxygen per 100 mL of blood. Sometimes the content is referenced in milliliters per liter, in which case everything is multiplied by 10. Because the contribution of oxygen in plasma is small, this component is typically neglected in calculations done at physiologic Po_2 . Oxygen saturation, the fraction of hemoglobin that is bound to oxygen, is readily measured in samples of blood from each cardiac chamber or vessel by oximetry.

Oxygen Consumption

Oxygen consumption is required to derive cardiac output by the Fick equation. Historically, oxygen consumption was measured by comparing the volume of oxygen in a timed sample of expiratory gas collected in a large (Douglas) bag with that inspired

over the same time (Rudolph, 2001). This is cumbersome and was replaced by a simpler method that uses a mouthpiece or a head hood, making it usable even in infants (Lister et al., 1974). In most centers, however, oxygen consumption ($\dot{V}\text{O}_2$) is simply derived from a nomogram that uses age, gender, and heart rate (LaFarge and Miettinen, 1970). In any event, after the immediate newborn period, oxygen consumption in the resting child is approximately 150 mL/min/m²; during the first 3 weeks of life, it is approximately 120-130 mL/min/m² (Rudolph, 2001). When a child is under general anesthesia, oxygen consumption reliably decreases (Table 4-7).

Cardiac Output

Cardiac output increases with increased size. Pediatric cardiologists, however, always normalize for body surface area (converting to cardiac index). Beyond the first week of life, cardiac index remains fairly constant at about 4 L/min/m². Older children and adults can have cardiac output that is readily measured in the catheterization laboratory by means of a pulmonary artery thermodilution catheter. However, small size and the presence of intracardiac shunts make this technique of less utility in pediatric cardiology. Other indicator dilution techniques, which historically preceded thermodilution, are generally obsolete and no longer used.

The method routinely used to measure cardiac output is the Fick principle, or the Fick equation. This states that in a state of equilibrium, blood flow through an organ is proportional to the amount of indicator taken up or added. In this specific modification of the indicator dilution technique, oxygen acts as the indicator. In the case of pulmonary blood flow, oxygen is added, and in the case of the systemic blood flow, oxygen is withdrawn. In a normal healthy person these must be equal, because the amount of oxygen consumed by the body must equal the amount delivered to the blood during its passage through the pulmonary circulation.

Cardiac output is derived from the Fick principle as follows:

$$\dot{Q} = \frac{I}{(C_{I_1} - C_{I_2})}$$

where \dot{Q} is the flow rate, I is the amount of indicator added and C_{I_1} and C_{I_2} are the concentrations of indicator before and after the addition (or subtraction) of indicator I. Using oxygen extraction in the systemic circulation as the indicator:

$$\dot{Q} = \frac{\dot{V}\text{O}_2}{(\text{CaO}_2 - \text{CmvO}_2)}$$

where $\dot{V}\text{O}_2$ is oxygen consumption, CaO_2 is the content of oxygen in the systemic arteries and CmvO_2 is the mixed venous oxygen content. \dot{Q} now represents cardiac output. The units of \dot{Q} are L/min, and the units of CaO_2 and CmvO_2 are mL oxygen/L blood. However, in children, $\dot{V}\text{O}_2$ is typically expressed as mL/min/m², so that the resulting number represents cardiac index rather than cardiac output. Because pulmonary flow and systemic flow are almost identical in normal individuals, oxygen uptake across the pulmonary circulation provides identical results as oxygen consumption across the systemic circulation. When the components of oxygen content are substituted, the equation becomes:

$$\dot{Q} = \frac{\dot{V}\text{O}_2}{[(1.34 \times \text{Hb} \times \text{sat}_1) + (0.003 \times \text{PaO}_2) - (1.34 \times \text{Hb} \times \text{sat}_{mv}) + (0.003 \times \text{PmvO}_2)]}$$

Data From LaFarge CG, Miettinen OS: The estimation of oxygen consumption, *Cardiovas Res* 4:23, 1970.

Hb is the hemoglobin concentration in g/dL, sat_a is the systemic arterial saturation, PaO_2 is the partial pressure of oxygen in the systemic arteries sat_{mv} is the mixed venous arterial saturation, and $PmvO_2$ is the partial pressure of oxygen in mixed venous blood. Since the amount of oxygen carried dissolved in the blood is so relatively low, this equation can be simplified to:

$$\dot{Q} = \frac{\dot{V}O_2}{[(1.34 \times Hb) \times (sat_a - sat_{mv})]}$$

Pulmonary and arterial blood flows are not similar in instances of left-to-right or right-to-left shunting, in which case both pulmonary (\dot{Q}_p) and systemic flows (\dot{Q}_s) need to be calculated independently. In these cases:

$$\dot{Q}_p = \frac{\dot{V}O_2}{[(1.34 \times Hb) \times (sat_{pv} - sat_{pa})]}$$

In the above equation, sat_{pv} is the pulmonary venous oxygen saturation, and sat_{pa} is pulmonary arterial oxygen saturation.

Shunts

Left-to-right shunting results in an increase or step up in oxygen saturation at some level of the right side of the heart. An atrial septal defect, for example, results in a step up from the systemic veins to the right ventricle and a ventricular septal defect results in a step up from the right atrium to the pulmonary

artery. Streaming patterns allow a certain amount of normal variability, and a step up may take a distance to become apparent, based on the position of the sampling catheter relative to the shunt. For example, the saturation in the inferior vena cava is typically higher than that of the superior vena cava. Thus, there can be up to a 9 mm Hg step up in P_{O_2} from the superior vena cava to the right atrium, which can be a normal finding. The step up from an atrial-septal defect may not be fully recognized from a sample drawn from the right atrium, because the tip of the catheter may be outside the stream of the shunt. The step up will not be fully recognized until a sample is drawn from the right ventricle. Similarly, a catheter tip could be directly within the streaming shunted blood before full mixing, allowing for an overestimation of the degree of shunt. Right-to-left shunts result in a step down at some level on the left side of the circulation, with the same provisos for potential artifact as for left-to-right shunts. As a general rule, samples should be obtained from the most distal chamber possible (excluding an additional level of shunt) to allow maximal mixing. The following example shows how to determine the degree of shunt (the pulmonary:systemic flow ratio, or $\dot{Q}_p : \dot{Q}_s$). This becomes somewhat more complex in the case of multiple levels of shunt or bidirectional shunting. Dividing equation 4.5 by equation 4.4 results in the pulmonary:systemic flow ratio:

$$\dot{Q}_p / \dot{Q}_s = \frac{VO_2(1.34 \times Hb) \times (\text{sat}_{pv} - \text{sat}_{pa})}{VO_2(1.34 \times Hb) \times (\text{sat}_a - 4.6 \text{sat}_{mv})}$$

Rearranging and canceling simplifies this to:

$$\dot{Q}_p : \dot{Q}_s = \frac{\text{sat}_a - \text{sat}_{mv}}{\text{sat}_{pv} - \text{sat}_{pa}}$$

This has the fortunate effect of having the term for VO_2 cancel. Thus, if only an estimation of $\dot{Q}_p : \dot{Q}_s$ is of interest, VO_2 has to be neither measured nor assumed. As an example, presume a ventricular septal defect with a left-to-right shunt. The mixed venous (right atrial) saturation is 70%, the pulmonary arterial saturation is 85%, and the pulmonary venous and systemic arterial saturations are 100%. Substituting into equation 4.7 shows that the $\dot{Q}_p : \dot{Q}_s$ is: $(100-70)/(100-85)$, or $30/15$, or 2:1. There is twice as much pulmonary blood flow as systemic.

Vascular Resistance

Measurement of the resistance across a vascular bed relates to Ohm's law. In hemodynamic terms, $I = E/R$ can be seen as $I =$ flow, $E =$ the pressure drop across the vascular bed, and $R =$ resistance. Solving for R yields $R = E/I$. Thus:

$$SVR = \frac{\text{map} - \text{cvp}}{\dot{Q}_s}$$

SVR = systemic vascular resistance, map = mean systemic arterial pressure, and cvp = central venous pressure.

By analogy:

$$PVR = \frac{\text{pap} - \text{pvp}}{\dot{Q}_p}$$

PVR = pulmonary vascular resistance, pap = mean pulmonary arterial pressure, and pvp = pulmonary venous pressure

(pulmonary arterial wedge pressure, mean left atrial pressure, or left ventricular end-diastolic pressure can be substituted for pvp).

Again, oxygen consumption must be calculated or assumed in order to calculate \dot{Q}_p and \dot{Q}_s . In general, pulmonary capillary wedge, left atrial, or left ventricular end-diastolic pressures can be substituted for pulmonary venous pressure, assuming the absence of obstructions to pulmonary venous or left atrial drainage. Pediatric cardiologists have historically expressed vascular resistance in terms of Wood units. Wood units are derived when the units are pressure in mm Hg and blood flow in L/min (or, more typically, L/min/m²) to give a resistance index. Multiplying Wood units by approximately 80 converts to SI units (dyne•cm⁻⁵/sec). Normal values (Wood units) in children are systemic vascular resistance index of 20, with a range of 15 to 30 (10 to 15 in neonates, with adult levels by 12 to 18 months of age), and pulmonary vascular resistance of 1 to 3 in infants older than 6 to 8 weeks of age, after the normal post-natal fall.

Echocardiography

For many infants and children, echocardiography has supplanted the need for cardiac catheterization, and many children now have cardiac surgery based on the results of echocardiography rather than catheterization. For some problems, such as AV valve anatomy, echocardiography is distinctly superior to catheterization (see www.expertconsult.com for further discussion). The thin chests and lack of hyperinflated lungs in children mean that echocardiographic views in children are often superior to those in adults. In common parlance, echocardiography also includes the use of Doppler to assess blood flow and to infer intracardiac pressures, shunts, and pressure gradients (see Doppler Echocardiography Basics, p. 110).

Modern echocardiography is derived from sonar used on ships. A brief electrical impulse is sent to a transducer, which converts (transduces) it and emits it as high frequency sound. As the sound wave encounters a change in density, such as a cardiac structure, some of the sound energy continues on and some is reflected. The echo transducer acts as a receiver and converts the transmitted sound to electrical energy, which is sent to an image processor and displayed on a screen. Because the speed of sound through the body is both known and constant, the distance of the structure from the transducer is easily calculated. This process occurs many times each second. The original format was A-mode echocardiography, where A stood for amplitude. The intensity of the reflected wave was shown as the height or amplitude, like a series of mountain peaks. The first clinical use was echoencephalography, where a beam was directed across the skull looking for shifts of midline structures. The next modification was B-mode echocardiography, where the intensity of the reflected wave was shown as the brightness of a dot. If the reflected waves were recorded on a rolling piece of paper, the series of dots would meld into a series of moving lines, with each line representing a separate cardiac structure with its own distinctive movement pattern. This was the M-mode echocardiograph. M-mode echocardiography was particularly useful for measuring vessel and chamber size and thickness. Although it showed only a one-dimensional representation of the heart (an "ice pick view"), ventricular function could be estimated by ventricular end-systolic and end-diastolic

dimensions or by measuring systolic time intervals. The next major advance was two-dimensional echocardiography. Several (32, then 64) separate B-mode ultrasound emitting transducers were mounted together such that a fan-shaped series of lines of light and dark was created. These were repeated rapidly and formed a real-time image of the moving heart. This was exactly analogous to a black-and-white television set, where there is not really a picture but rather a series of rapidly refreshed lines of bright dots that the eyes and brain integrate into a picture. Quality improved with the development of phased array transducers, which generated multiple B-mode lines electronically. These transducers were miniaturized so that they could be mounted onto a gastroscope, resulting in transesophageal echocardiography. Current pediatric transesophageal probes are useful down to infants who weigh approximately 3 kg. Finally, electronic manipulation has allowed the representation of three-dimensional views of the heart. This is currently available on transesophageal probes, although as of this writing, it is not available on pediatric transesophageal probes. Intraoperative transesophageal echocardiography has been shown in several studies to improve intraoperative surgical repairs in a cost-effective manner and is routine in centers with the capability (Sutherland et al., 1989; Muhiudeen et al., 1992; Bettex et al., 2005). This technique is not totally without risk, however. In addition to the risks of local pharyngeal and esophageal injury, which attend its use in both children and adults, introduction or manipulation of the probe can cause acute and massive obstruction of the easily compressible aorta or large bronchi in infants.

Cardiac shunts, particularly right-to-left shunts, can be qualitatively visualized through contrast echocardiography with extraordinary sensitivity in terms of both the presence of the shunt and the site of the shunt. A milliliter or two of air is drawn up into a syringe of saline or other fluid and vigorously agitated. The gross air is expelled and the aerated fluid rapidly injected into a systemic vein. The numerous tiny bubbles (microcavitations) appear somewhat like the snow in an agitated snow globe. Normally these transverse the right side of the heart to be eliminated via the pulmonary capillaries into the alveoli, leaving the left atrium, left ventricle, and aorta without any contrast. If there is a right-to-left shunt, these bubbles pass to the left atrium (atrial level shunt), ventricle (ventricular level shunt), or descending aorta (ductal level shunt). This technique is not helpful in determining whether there are multiple levels of shunts (unlike catheterization), and it is not particularly qualitative, also unlike catheterization.

A variety of advanced measurement techniques, such as automated (endocardial) border detection and tissue velocity measurement are available, but they are not generally used in routine intraoperative clinical management. They are useful to more fully quantitate myocardial mechanics.

Evaluation of Cardiac Function by Echocardiography

Preload

In the intact heart, pressure is easily measured and used as a surrogate for volume. The end-diastolic volume can be assessed using pulmonary arterial wedge pressure, left atrial pressure, or central venous pressure. However, given the different diastolic compliances of individual ventricles, pressure provides a crude estimate of volume—the parameter that is actually

sought. Echocardiography provides the best estimate of preload. This is readily measured either as end-diastolic dimension (M-mode), end-diastolic area (two-dimensional echocardiography), or end-diastolic volume (derived from two-dimensional echocardiography).

Afterload

Clinical measures of wall stress are difficult, leaving SVR as the typical clinical indicator. Recall the following equation.

$$SVR = \frac{\text{map} - \text{cvp}}{Q_s}$$

In normal circumstances, systemic blood flow = cardiac output (or index). Arterial and central venous pressures are obtained from indwelling catheters. Cardiac output can be derived from Doppler measures of blood flow and echo measures of valve or aortic area.

Contractility

Ejection fraction is the most common surrogate for contractility, although it suffers from being load dependent. Ejection fraction (EF), is shown in the following equation:

$$EF = \frac{(\text{End-diastolic volume}) - (\text{End-systolic volume})}{(\text{End-diastolic volume})}$$

EF is normally 65% to 80% and does not change appreciably with age. Shortening fraction (SF) is the equivalent measure in the common setting when only the ventricular diameters are known.

$$SF = \frac{(\text{End-diastolic diameter}) - (\text{End-systolic diameter})}{(\text{End-diastolic diameter})}$$

The normal value for SF is >0.28, with a range of 0.28 to 0.44 (Gutgesell et al., 1977). The concept of SF was developed when the only echocardiographic modality available was M-mode, which utilizes an echo representation in only one dimension. A variety of mathematical manipulations were derived to convert a one-dimensional measurement into three-dimensions, which would allow for expression of contractility as the already recognized concept of ejection fraction. This was particularly useful to adult cardiologists, who routinely used EF derived from other methods. However, this conversion also resulted in a cubing of any inherent error in the measurement and made these formulae somewhat less than adequate. Advances in two-dimensional echocardiography have improved the ability to generate a realistic measure of ejection fraction (three-dimensional) from echocardiography (two-dimensional); however, SF remains in common use, particularly among pediatric cardiologists. Velocity of circumferential fiber shortening (Vcf), is a somewhat outdated measure of contractility, and also suffers from being dependent on afterload. In circumferential/sec, it is:

$$Vcf = \frac{(\text{End-diastolic diameter}) - (\text{End-systolic diameter})}{(\text{End-diastolic diameter}) \times \text{Ejection time}}$$

The general increase in afterload with aging in childhood and with certain diseases limits the absolute usefulness of these measures as a pure indicator of ventricular function.

Additional measures of left-ventricular contractility can be derived from echocardiographic measures in conjunction with hemodynamic measures. These include the end-systolic pressure-volume relationship popularized by Suga and colleagues (1973). However, this is not done routinely because it requires measures of hemodynamic data and ventricular volume data at multiple levels of ventricular volume to derive the slope of the line connecting the end-systolic pressure volume points. Unlike the other measures of ventricular function, it is load independent.

Doppler Echocardiography Basics

This technique utilizes the Doppler phenomenon, the frequency shift well-known to anyone who has heard a train whistle approach with increasing frequency and then depart with decreasing frequency. In general, this technique involves insonating the heart with a high-frequency sound wave. Using fast Fourier transformation and filtering to prevent measuring the velocity of other structures, such as heart and vascular components, the velocity (and direction) of moving blood can be determined. There are three modes of Doppler in routine use. Continuous mode shows the fastest velocity along the Doppler beam, but cannot resolve distance. Pulse wave mode can resolve distance from the transducer. Thus, it can be “aimed” from the real-time two-dimensional echocardiograph image so that specific areas of the heart can be interrogated. Finally, color-flow mapping allows the color coding of specific pixels on the two-dimensional echocardiograph in essentially real time to allow superposition of blood flow and cardiac anatomy.

Data obtained from Doppler interrogation can be used to derive a wide variety of physiologic information. For example, cardiac output (or output across a specific valve or area) can be determined as follows:

$$\text{Flow} = \text{CSA} \times V_m$$

CSA = cross-sectional area, and V_m = mean flow velocity. V_m is the integral of the flow under the spectral Doppler velocity display, also known as time-velocity integral (TVI). Thus, with each beat:

$$\text{Stroke volume} = \text{CSA} \times \text{TVI}$$

and

$$\text{Cardiac output} = \text{Stroke volume} \times \text{Heart rate}$$

If flow is measured across both the aortic and pulmonary valves, the presence and degree of an intracardiac shunt can be determined.

Valve area can also be determined by Doppler examination by using the principle of continuity. This states that in the absence of shunts that either add or subtract volume, the stroke volume at any two points in the heart must be equal. The continuity principle leads to the continuity equation, where $\text{CSA}_1 \times \text{TVI}_1 = \text{CSA}_2 \times \text{TVI}_2$. Knowing three of the values in the equation allows one to rearrange the equation and solve for the fourth.

$$\text{CSA}_2 = \frac{(\text{CSA}_1 \times \text{TVI}_1)}{\text{TVI}_2}$$

Consider the example of aortic stenosis. CSA_2 is aortic valve area, CSA_1 and TVI_1 are measured in the left ventricular outflow tract, and TVI_2 is a high-velocity jet across the stenotic valve.

The continuous-wave function of Doppler echocardiography allows the calculation of pressure gradients. If the flow between the two points occurs across a narrow orifice, for example in aortic stenosis, blood-flow velocity increases. Measuring the peak velocity allows the calculation of a pressure gradient. This technique is widely used in echocardiography but has certain limitations. The angle of interrogation of the Doppler beam must be accurately aligned with the direction of blood flow. The more poorly aligned the direction of blood flow is with the Doppler beam, the greater the underestimation of the true velocity of blood flow. Mathematically, the degree of underestimation is described by the cosine of the angle theta (θ) between the direction of blood flow and the Doppler beam, the angle of incidence. The cosine function is nonlinear between 0 degrees (cosine 0 = 1) and 90 degrees (cosine 90 = 0). For example, if θ is 30 degrees, cosine 30 = 0.87. Therefore, at an angle of 30 degrees, the measured velocity is only 87% of the true blood velocity. The software of the echocardiography works on the assumption that the direction of blood flow and the Doppler beam are in perfect alignment.

The equation that relates peak velocity to pressure is known as the modified Bernoulli equation, where V is velocity in meters/sec:

$$\Delta \text{Pressure (mm Hg)} = 4V^2$$

Readers are referred to textbooks of echocardiography for a complete derivation of the modified Bernoulli equation. Assuming good alignment of the Doppler beam and the direction of blood flow, peak velocity is now easily converted into the pressure gradient across the lesion (Fig 4-25).

CARDIAC MAGNETIC RESONANCE IMAGING

The 1990s and early 2000s saw explosive growth in the use of cardiac MRI. The images produced truly bring the anatomy of the cardiovascular system to life. The use of MRI was extended to cardiac imaging when “gating” technology was developed. The beating of the heart posed a problem for MRI because it created movement artifact. Gating refers to imaging the heart in conjunction with its cardiac cycle in order to minimize artifact. It is usually linked to the electrocardiograph, but can be paired with pulse-wave plethysmography or any other modality that reflects the cardiac cycle. As a first line of investigation, MRI is generally not recommended. Echocardiography remains the initial modality for almost all pediatric patients with heart disease because of its speed and portability, as well as the information that can be obtained about cardiac anatomy and function. Nevertheless, echocardiography does have limits. Poor acoustic windows, especially in older children, may limit its usefulness. Even with good quality echocardiographic images, the major thoracic vessels, both arterial and venous, are not well visualized because of the surrounding air-filled lungs. Before the advent of MRI, the thoracic vessels could only be seen well with cardiac catheterization. MRI now provides a noninvasive method for imaging the thoracic vasculature. However, to limit the use of MRI to diagnosing abnormalities of the thoracic vessels is to underestimate its power. When it comes to imaging the cardiovascular system, MRI is only limited by the skill and expertise of the cardiologist or radiologist who is directing and interpreting the scan.

MRI has proven safe in pediatric patients. There are no known harmful effects from exposure to the magnetic field. Implanted devices containing metal can make MRI unsafe. The dangers of implanted metal exposed to a magnetic field are threefold. First,

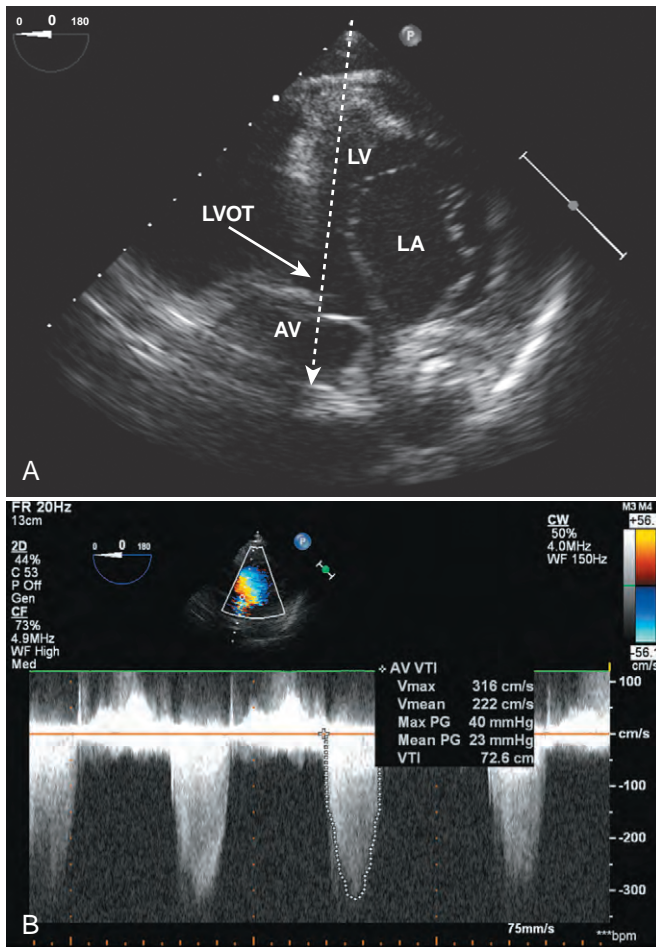

FIGURE 4-25. Transesophageal echocardiogram in aortic stenosis. **A**, Deep transgastric view with very good alignment of the Doppler beam (dashed arrow) with the left-ventricular outflow tract and aortic valve. AV, aortic valve, LA, left atrium, LV, left ventricle, LVOT, left-ventricular outflow tract. **B**, Spectral Doppler tracing of the velocity of blood as it accelerates across the stenotic aortic valve. Velocity (y axis) is plotted versus time (x axis). The peak velocity is 3.16 m/sec, which translates into a peak gradient of 40 mm Hg using the modified Bernoulli equation.

the implanted metallic devices may heat up. Second, under the influence of a magnetic field, implanted metal devices may move, causing tissue damage in the area of implantation. This is relevant to the pediatric cardiac population because patients often have various stents, coils, sternal wires, pacemakers, and other foreign material. Manufacturers attempt to make their devices “MRI compatible” but there are no hard and fast rules. The presence of a pacemaker generally contraindicates MRI imaging, although most other foreign material is safe. Foreign material implanted in pediatric cardiac patients is usually weakly ferromagnetic, which results in little heat being generated. The caveat is that the implanted device may move in the presence of a strong magnetic field. Manufacturers and clinicians often wait 4 to 6 weeks after implantation to use MRI. During this time it is believed that the device becomes fixed by surrounding fibrosis and cannot move in response to a magnetic field. The 4-to-6-week recommendation is arbitrary and not based on good data. Finally, implanted devices may pose negligible risk to the patient, but they can cause image artifacts. The discovery of possible dangerous foreign material on

preoperative questioning should delay the scan while advice is sought from the manufacturer and MRI personnel. MRI demands a still patient who is confined in a small tube. Children who have not reached adolescence require some form of sedation that covers the spectrum from “light” sedation to general anesthesia, with or without the airway being secured. The reader is referred to Chapter 33, Anesthesia and Sedation for Pediatric Procedures Outside the Operating Room, for a more complete discussion on the challenges of anesthesia and sedation in remote locations such as the MRI suite.

MRI concepts of imaging are often difficult to understand and made more so by terminology that is unfamiliar. By way of simple explanation, MRI images are created by placing a patient in a strong magnetic field that aligns the protons on hydrogen atoms. A directed pulse of radiofrequency wave is directed at the area of interest, and the hydrogen protons emit their own radiofrequency wave. These emitted radiofrequency waves are constructed into the MR image. Terms often seen on MRI reports are T1 and T2 weighting. T1 refers to the longitudinal relaxation time and is a measure of time it takes for a substance to become magnetized. T2 is transverse relaxation time and refers to how long protons remain “in phase” after the radiofrequency pulse. Depending on the molecular structure (e.g., water content, blood, soft tissue, or bone) in the anatomic area of interest, T1 and T2 images are different. These differences become important, because the pathologic abnormality being sought may be better seen on either T1 or T2 weighted images.

The lesions most commonly sought by MRI are coarctation, vascular rings, aortic arch abnormalities, and branch pulmonary artery stenosis. The common feature of these lesions is that they usually all lie beyond the reach of the echocardiography probe. The original cardiovascular imaging technique was a technique called *spin echo*, which has been improved and may now be called *fast* or *turbo-spin echo*. Flowing blood appeared black, resulting in the term “black blood imaging.” The technique was good for imaging structural abnormalities of the heart and vascular system, but it only provided still images that could not display cardiac function. After the diagnosis of a lesion on two-dimensional imaging, a three-dimensional reconstruction can display the lesion in astounding detail and clarity (Fig. 4-26). Intravenous contrast (gadolinium) can be injected rapidly to create magnetic resonance angiography and better demonstrate the pathology (Fig. 4-27). The obvious drawback to MRI for stenotic vascular lesions is that no information about the pressure gradient can be obtained. Sometimes, on visualization, the stenosis appears so severe that it demands repair. However, in cases in which even more information is needed, cardiac catheterization remains the benchmark for visualization and measurement of pressure gradients. The ability of MRI to accurately diagnose lesions of the thoracic vasculature is obvious, but a more exciting application of cardiac MRI testing is in the quantitative and qualitative assessments of cardiac function. In contrast to “black blood imaging,” gradient echo MRI produces bright blood images and is done at high speed, which allows the creation of a cine loop that displays the entire cardiac cycle in real time (Fig. 4-28). Freezing the image at end-diastole and end-systole allows the calculation of ventricular volumes. The ventricle is divided into “slices,” and the blood volume of each slice is calculated by multiplying its cross-sectional area and thickness. Knowing precisely end-diastolic and end-systolic volumes allows the calculation of stroke volume, ejection fraction, and cardiac output. Very good correlation has been made

■ **FIGURE 4-26.** Double aortic arch. **A**, Coronal MRI of the chest showing lateral tracheal compression from right and left secondary to a double aortic arch (*white arrows*). **B**, Three-dimensional reconstruction of the double aortic arch (*white arrow*) as viewed from above. The double arch encircles both the trachea and esophagus, which are not seen in this three-dimensional image.

with other methods of calculating cardiac output (Bellenger et al., 2000; Ioannidis et al., 2002). In fact, the ability of MRI to detect small changes in ventricular volume (10 mL) exceeds that of echocardiography.

In addition to static measurements of ventricular volume, MRI can also measure blood-flow velocity, which allows the calculation of blood flow. Blood flowing through a magnetic field

■ **FIGURE 4-28.** Cardiac MRI. The four-chamber view clearly shows the four cardiac chambers. A high-speed cine loop displays the four-chamber image in a real-time image, giving important information about ventricular function and valvular regurgitation. *LA*, Left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

produces a phase shift proportional to its velocity. Plotting blood-flow velocity versus time (one cardiac cycle) creates a curve. The integration of the area under the curve is stroke volume. Calculation of cardiac output by MRI compares favorably with the Fick and thermodilution methods (Hundley et al., 1995). Measuring stroke volume in the aorta and pulmonary artery simultaneously allows the measurement of pulmonary to systemic ($Q_p : Q_s$) ratio. For pediatric patients with septal defects or intracardiac mixing and single ventricle physiology, accurate noninvasive measurements of $Q_p : Q_s$ ratios can now be made. The agreement with

oximetry-based calculations obtained in the cardiac catheterization laboratory is very good (Beerbaum et al., 2001).

Although less relevant to pediatric patients, MRI can also be used to assess wall motion, diagnose ischemic heart disease, and evaluate myocardial viability. Wall motion can be assessed qualitatively by analyzing a real-time image of ventricular contraction. For these purposes, the left ventricle is divided into the same anatomic regions recommended for echocardiographic assessment (Shanewise et al., 1999). Function is graded as normal, variably hypokinetic, akinetic, or dyskinetic. Quantification of regional wall motion can be done by measuring myocardial thickening throughout the cardiac cycle, but this is time consuming. Dobutamine-stress MRI operates under the same principles as other noninvasive stress tests. Regional wall-motion abnormalities that result from coronary stenoses are unmasked by increasing the inotropic and chronotropic state of the heart. The regional wall-motion defects are assessed qualitatively. Lastly, akinetic areas of myocardium may consist of fixed scar (nonviable myocardium) or hibernating (viable myocardium) tissue, which take up and release intravenous contrast differently. Myocardial delayed enhancement is a technique that allows the differentiation of viable, chronically ischemic myocardium from that which is permanently damaged (Fig. 4-29).

EFFECTS OF ANESTHESIA ON THE CARDIOVASCULAR SYSTEM

Any use of anesthetics in young children needs to take into account the variable effects of anesthetics on the immature myocardium, recognize the time frame of myocardial development, and consider the clinical appropriateness of various anesthetic regimens for specific surgical procedures. Cardiopulmonary interactions also need to be considered, given the numerous and potentially potent effects of some anesthetics on the respiratory system. Unfortunately, many if not most, studies have been done in children, not infants, in whom myocardial maturation is essentially complete, leaving less information about the cardiac effects of anesthetics in young and premature infants. In addition, many earlier studies have not been repeated with sevoflurane or desflurane, leaving much of the available information centered on halothane and isoflurane.

Anesthetic Effects on Ion Currents

Both volatile anesthetics and several intravenous anesthetics can affect many of the voltage-dependent myocardial ion currents, although studies in immature myocardium are limited. Halothane, for example, can inhibit $I_{Ca,L}$, the L-type calcium current in fetal as well as adult myocardium (Fig. 4-30). Baum and Klitzner (1991) have shown that both halothane and isoflurane

■ **FIGURE 4-29.** Cardiac MRI. The short-axis view of the left ventricle demonstrates a scarred and akinetic segment of myocardium (white arrow). The area has delayed uptake of gadolinium contrast.

can decrease the height of the action potential in neonatal right-ventricular papillary muscle, consistent with an effect on trans-sarcolemmal calcium entry. A variety of anesthetics are known to shift the activation and inactivation kinetics of $I_{Ca,L}$. These include halothane and ketamine (Baum et al., 1994). These might decrease calcium entry via $I_{Ca,L}$ in cells with more negative resting potential, such as immature myocardial cells.

BAY K8644, a calcium-channel agonist, can only partially prevent or reverse halothane- or isoflurane-induced depression in right-ventricular papillary muscles of neonatal rabbits (Baum and Klitzner, 1993). This is consistent with the view that mechanisms other than decreased trans-sarcolemmal calcium entry contribute to anesthetic-induced myocardial depression. Halothane, even in clinically appropriate doses, reversibly inhibits $Na^+ - Ca^{2+}$ exchange in neonatal ventricular myocytes. This provides for an additional mechanism for the more pronounced volatile anesthetic-induced depression of immature myocardium, with its increased reliance on $Na^+ - Ca^{2+}$ exchange relative to adult myocardium (Baum et al., 1994).

A variety of volatile and intravenous anesthetics can affect the various K^+ channels, with implications for arrhythmia generation and anesthetic-induced myocardial preconditioning (Baum, 1993; Buljubasic et al., 1996; Stadnicka et al., 1997; Stadnicka et al., 2000; Fujimoto et al., 2002; Suzuki et al., 2003). However, there is no information on the effects in the young or

■ **FIGURE 4-30.** Calcium current ($I_{Ca,L}$) measured from a single ventricular myocyte isolated from a 28-day-old rabbit fetus (term = 31 days). Control to the left, 0.125% halothane to the right. The axes are picoamps (pA) and milliseconds (ms). (From Baum VC, Palmisano BW: *The immature heart and anesthesia*, Anesthesiology 87:1529, 1997.)

immature heart, and the phenomenon of anesthesia-induced preconditioning, mediated at least in part by potassium current, has not been fully evaluated in immature myocardium.

Anesthetic Effects on the Conduction System

In vitro, infant rabbit hearts are more resistant than adult rabbit hearts to the direct sinus-node pacemaker depression of halothane and isoflurane (Palmisano et al., 1994). Maximal depression of the sinus node is about 10%, suggesting that indirect effects rather than direct effects are primarily responsible for the bradycardia seen during clinical anesthesia. It is likely that cholinergic effects play a major role, as baseline cholinergic tone is present in neonates and infants, and under halothane and nitrous-oxide anesthesia there is a dose-related increase in heart rate with atropine (Palmisano et al., 1991b).

For both infant and adult hearts, the sinus rate is more resistant to the effects of halothane and isoflurane than are other measurements of cardiac function (Palmisano et al., 1994). These anesthetics decrease spontaneous pacemaker discharge by decreasing the rate of diastolic depolarization and increasing the action potential duration (Bosnjak and Kampine, 1983). In the adult heart, where it has been studied, halothane decreases the rate of diastolic depolarization and moves the maximal diastolic depolarization (V_m) closer to threshold potential. These two effects counterbalance with little effect on sinus rate (Hauswirth and Schaer, 1967).

Halothane prolongs AV conduction time more than isoflurane, and the effect in infants is greater than it is in adults (Palmisano et al., 1994). The age difference for isoflurane is much less marked than for halothane. There has been little information evaluating the effects of the newer inhalational agents on sinus-node function in healthy children. Sevoflurane and isoflurane have little effects on sinus node function or AV conduction in children with pre-excitation conditions such as Wolff-Parkinson-White syndrome, suggesting they have little if any effects on normal tissue (Chang et al., 1996; Sharpe et al., 1999). In a study of *in vitro* rabbit hearts, propofol had no effects on atrial or AV conduction, although it did prolong AV conduction in adult hearts of rabbits (Wu et al., 1997).

Anesthetic Effects on Myocardial Metabolism

Reactivity of the coronary vasculature to a variety of physiologic and pharmacologic stimuli has been shown to be present in newborn animals of a variety of species (Toma et al., 1985; Downing and Chen, 1986; Buss et al., 1987; Hickey et al., 1988; Ascuitto et al., 1992). In infant rabbit and *in vitro* fetal lamb hearts, both halothane and isoflurane vasodilate coronary arteries and result in increased coronary flow, and these effects are similar to those in adult hearts of those animals (Palmisano et al., 1994; Davis et al., 1995). Isoflurane decreases oxygen consumption, which coupled with increased coronary flow, results in relative overperfusion (Hickey et al., 1988; Stowe et al., 1991; Palmisano et al., 1994). Because isoflurane causes a greater decrease in heart rate in adults, the decrement in oxygen consumption is more pronounced in adult hearts than in neonatal hearts (Palmisano et al., 1994). However, when heart rates are kept similar, there are no age differences. In the hypoxic, stressed, neonatal lamb, neither halothane nor isoflurane alter

redistribution of blood flow to vital organs, including the heart (Cameron et al., 1985; Brett et al., 1989).

Myocardial flow in the neonatal lamb decreases at 1 MAC isoflurane (from 250 to 88 mL/100g per minute), but this fall is in exact proportion to the decrease in myocardial oxygen consumption, resulting in unchanged myocardial oxygen extraction and endocardial-to-epicardial flow ratios (Brett et al., 1987). Consistent with this, 1.5% halothane was not found to affect steady state levels of myocardial high energy phosphates or intracellular pH in neonatal myocardium, despite a decrement in myocardial performance (McAuliffe and Hickey, 1987). This indicates that uncoupling of oxidative phosphorylation does not account for volatile anesthetics' depressant effect on myocardial function.

Anesthetic Effects on Systolic Function

Young hearts show an increased susceptibility to myocardial depression from the volatile anesthetics (Cook et al., 1981). Although it has been suggested that the apparent increased hemodynamic depression in the young human heart may be the result of differences in anesthetic uptake and distribution, several studies have indicated that the increased hemodynamic effects of the volatile anesthetics are a result of increased direct action on the myocardium in the immature heart (Barash et al., 1978; Boudreaux et al., 1984; Schieber et al., 1986; Murray et al., 1992).

A major effect on myocardial contractility is via limitation of calcium availability to the contractile apparatus. Transsarcolemmal and sarcoplasmic reticular calcium flux are altered with the net effect of depleting intracellular stores (Nakao et al., 1989; Wilde et al., 1991; Frazer and Lynch, 1992; Schmidt et al., 1993; Wilde et al., 1993). Halothane depresses contractility more than isoflurane does (Lynch, 1986; Krane and Su, 1987; Baum and Klitzner, 1991; Palmisano et al., 1994). Halothane decreases peak intracellular calcium concentration more than isoflurane does and is a more potent depressant of contractile function *in vitro* in both neonatal and adult hearts (Komai and Rusy, 1987; Krane and Su, 1989; Lynch, 1990; Bosnjak et al., 1992; Pan and Potter, 1992; Palmisano et al., 1994). Although there were no age effects of isoflurane, halothane was more depressant to neonatal hearts than adult hearts. However, there may be some dependence on species, because a study in isolated rat atrium did not find that the depression was dependent on age (Rao et al., 1986).

Studies in neonatal lambs have shown that both halothane and isoflurane decrease cardiac output to the same degree that they decrease myocardial oxygen consumption (Cameron et al., 1985; Brett et al., 1987; Brett et al., 1989). Isoflurane at 1 MAC decreased blood pressure primarily by decreasing cardiac output rather than by affecting vascular resistance (Brett et al., 1987). Results in human neonates, infants, and children are more variable, probably because of differing techniques and the confounders of changes in heart rate and afterload. Nicodemus, in an early study, showed increased hypotension in neonates and less hypotension in older children (Nicodemus et al., 1969).

Murray et al. (1992), using echocardiographic indexes of cardiac function, could show no difference between halothane and isoflurane at equipotent concentrations. Sevoflurane has been shown to cause less myocardial depression in young children than halothane, although very young infants were not studied (Holzman et al., 1996).

Anesthetic Effects on Diastolic Function

Anesthetic effects of calcium flux that might impair systolic function could also affect diastolic function, which requires temporary reuptake of released calcium into stores. Indexes of diastolic relaxation show a more depressant effect of halothane than isoflurane, and the effects are greater in infant rabbit hearts than in adult rabbit hearts (Palmisano et al., 1994). There was no age effect seen with isoflurane. This prominent effect of halothane may be a reflection of immature myocardium's limited capacity to remove calcium from the contractile proteins. The principle mechanism for relaxation in adult myocardium is sequestration of calcium in the sarcoplasmic reticulum, and this is relatively undeveloped in immature myocardium; thus, these hearts may depend more on removal via $\text{Na}^+\text{-Ca}^{2+}$ exchange (Hoerter et al., 1981; Bers and Bridge, 1989; Fisher and Tate, 1992). It is possible that developmental changes in the actin-regulatory proteins could also affect anesthetic mediation of relaxation.

Anesthetic Effects on Autonomic Control

Halothane, isoflurane, fentanyl, sevoflurane, and nitrous oxide all depress baroreceptor control of heart rate through the central nervous system, autonomic ganglia, and the heart (Biscoe and Millar, 1966; Duke et al., 1977; Duncan et al., 1981; Seagard et al., 1982; Seagard et al., 1983; Kotrly et al., 1984; Murat et al., 1988; Murat et al., 1989). The effect of halothane is more pronounced in younger animals when animals are made pharmacologically hypertensive, but there does not seem to be an age effect when animals are made pharmacologically hypotensive (Wear et al., 1982; Dise et al., 1991; Palmisano et al., 1991a). In (anesthetized) infants undergoing ligation of a patent ductus arteriosus, a heart rate change is typically not seen with acute alterations in blood pressure (Gregory, 1982). Constant showed that while halothane preserves cardiac vagal activity in children, it does not preserve baroreceptor activity any better than sevoflurane (Constant et al., 1999; Constant et al., 2004). Murat showed that isoflurane-mediated tachycardia may be less pronounced in neonates (Murat et al., 1989). Although acute increases in the inspiratory concentration of desflurane or isoflurane can cause an abrupt increase in heart rate and systemic blood pressure from stimulation of the tracheobronchial tree, this effect is not seen with acute increases in sevoflurane concentration (Ebert et al., 1995).

Hemodynamic Effects of Specific Agents

Preanesthetic Medications

Appropriate preanesthetic management of pediatric patients has been an area of much interest for quite a few years. Preoperative education, parental presence, and pharmacologic agents have all been used and all have a place in providing a smoother and safer induction. These are considered in Chapter 9 (Preoperative Preparation) and only cardiac effects of pharmacologic agents will be considered here. Although numerous oral, intramuscular, and intranasal drugs have been proposed as pediatric premedicants, the current most popular agent is oral midazolam. Intravenous midazolam can decrease cardiac output when it is combined with intravenous morphine (Shekerdemian et al., 1997). Midazolam in routine oral doses of 0.5 to 1.0 mg/kg is

well tolerated hemodynamically, even in children with cardiac disease. In a study by Masue and colleagues (2003), larger doses of 1.5 mg/kg did not cause any overall decrease in blood pressure, heart rate, or oxygen saturation, although a small number of patients did have a decrease in blood pressure or saturation (6% and 4%, respectively). This was likely related to baseline agitation or underlying cyanotic heart disease confounding the measurements (Masue et al., 2003). If used for sedation in the intensive care unit, abrupt cessation after several days of use can result in cardiovascular withdrawal phenomena. Audenaert et al. (1995) used Doppler echocardiography to compare three premedication regimens in children. They compared oral premedication (meperidine, 3 mg/kg + pentobarbital 4 mg/kg), nasal premedication (ketamine, 5 mg/kg + midazolam, 0.2 mg/kg), and rectal premedication (methohexital, 30 mg/kg). All had relatively modest effects if any. Meperidine + pentobarbital decreased heart rate, mean arterial pressure, and cardiac index. Ketamine + midazolam had no significant cardiovascular effects, and methohexital increased heart rate with a consequent decrease in stroke volume, but without additional effects.

Inhalational Anesthetics

To some extent, all the currently used volatile anesthetics are myocardial depressants. Many studies in humans suffer from studying relatively older children, where differences in myocardial function from adults would be expected to be limited if at all. In general, halothane decreases blood pressure by decreasing myocardial contractility without a compensatory rise in heart rate. Thus, cardiac output decreases. Isoflurane, desflurane, and sevoflurane decrease blood pressure by decreasing left-ventricular afterload. Cardiac output is also maintained by these three agents because they preserve autonomic function and baroreceptor-mediated tachycardia. Children older than age 3 years will have an increase in heart rate with sevoflurane but no change in cardiac output, whereas halothane results in a lower blood pressure and no change in heart rate (Piat et al., 1994; Sarner et al., 1995; Kern et al., 1997). The greatest decrease in blood pressure and the least increase in heart rate with sevoflurane occur in infants younger than 6 months of age (Lerman et al., 1994). The myocardial effects of volatile anesthetics may be more pronounced in the myopathic heart, which mirrors clinical experience (Hetricks et al., 1997).

Ejection fraction and cardiac index are decreased at 1.25 MAC by both isoflurane and halothane (Murray et al., 1987). Halothane has a more pronounced effect on contractility than isoflurane or sevoflurane. In a group of children (not neonates) with congenital heart disease, sevoflurane and isoflurane maintained cardiac output with minimal effect on contractility. Sevoflurane decreased contractility less than halothane. Isoflurane, as it did in other studies, increased heart rate and lowered systemic vascular resistance. Halothane depressed contractility, cardiac output, mean arterial pressure, and systemic vascular resistance (Rivenes et al., 2001). The addition of nitrous oxide to halothane or isoflurane at 1.0 MAC does not seem to change contractility, although it may decrease heart rate, blood pressure, and cardiac index (Murray et al., 1988). Cardiac output has been shown to improve, particularly with halothane, with the administration of atropine in several studies (Miller and Friesen, 1988; Murray et al., 1989). The effect of atropine on cardiac output was because of its effect on heart rate.

Sevoflurane has gained widespread acceptance in the practice of pediatric anesthesia. It produces less tachycardia than isoflurane, as well as less myocardial depression and fewer arrhythmias than halothane (Lerman et al., 1990; Frink et al., 1992; Holzman et al., 1996; Paris et al., 1997; Wodey et al., 1997). Sevoflurane does not cause heart rate or cardiac output to change appreciably; however, it does lower systemic vascular resistance and blood pressure compared with those values of awake patients.

Desflurane has been shown to either decrease or increase heart rate before an incision is made (Taylor and Lerman, 1991; Zwass et al., 1992).

Nitrous oxide is a direct myocardial depressant; however, this is likely offset by an increase in sympathetic tone (Ebert and Kampine, 1989). In the intact animal, it is a very mild cardiac depressant, and its effects are similar to its effects in infants and adults. Its use in infants does not result in an increase in pulmonary vascular resistance (Hickey et al., 1986). The effects of sympathetic stimulation that can be seen with nitrous oxide in adults are absent in young children (Murray et al., 1988).

Xenon has significant potential as a general anesthetic, and it has been shown to not have significant cardiac effects *in vitro*, however both clinical and pediatric uses are very limited (Stowe et al., 2000).

Opioids

Opioids have long been used in the field of pediatric cardiac anesthesia for their cardiovascular stability, and even a high dose of an opioid has minimal or no effect on heart rate, cardiac output, PVR, mean arterial pressure, and SVR (Robinson and Gregory, 1981; Hickey et al., 1985c; Hansen and Hickey, 1986). As when they are used in adults, opioids used in pediatric patients can blunt the increases in PVR that are associated with tracheal suctioning. The effects of high-dose sufentanil are qualitatively similar to those of high-dose fentanyl (Hickey and Hansen, 1984; Davis et al., 1987). Other opioids have not been studied as intensively in infants and young children. However, given their similar effects in adults, similar findings can be expected in children.

Propofol

Propofol can cause decrease in blood pressure and heart rate, even in healthy children (Short and Aun, 1991). Hannallah and coworkers, however, noted no significant hemodynamic differences when induction/maintenance was done with propofol/propofol infusion, propofol/halothane, thiopentone/halothane, or halothane/halothane (1994). Intracardiac hemodynamic values, including shunts, measured in the catheterization laboratory tend to remain unchanged with propofol (Gozal et al., 2001).

Ketamine

Ketamine has long history of use in the arena of pediatric anesthesia. It can be given orally or intramuscularly as a premedication, or it can be given intravenously to induce or maintain anesthesia. Ketamine's benefits particularly concern its hemodynamic stability. Although it is a direct myocardial depressant, possibly related to its effects on I_{CaL} (Baum et al., 1991b; Baum et al., 1994), its actions as a sympathomimetic preserve myocardial function. However, in hearts that are depleted of catecholamine or beta-blocked, one would expect to see a more prominent depressant effect. In the pediatric cardiac catheterization laboratory, ketamine has been shown

to have little hemodynamic effects if given as a 2 mg/kg bolus or as an infusion of 50 to 75 mcg/kg per minute (Murray et al., 1984; Oklu et al., 2003). Compared with an infusion of propofol, ketamine causes an increase in systemic arterial pressure and has fewer effects on shunting, because PVR and SVR were unchanged. After cardiac surgery, ketamine at a dose of 2 mg/kg has also been shown to cause no change in heart rate, cardiac output, PVR, or SVR (Hickey et al., 1985b). This statement, however, presumes adequate ventilation. That said, a study in children with pulmonary hypertension showed that even with sevoflurane and spontaneous ventilation, ketamine did not change pulmonary arterial pressure or PVR (Williams et al., 2007). Two studies in children have evaluated the effects of ketamine at altitude (Denver and Albuquerque) and found significant increases in pulmonary vascular resistance with ketamine (Berman et al., 1990; Wolfe et al., 1991).

Regional Anesthetics

Regional anesthesia is discussed more fully in Chapter 16 (Regional Anesthesia). Both spinal and epidural anesthesia with local anesthetics in children have minimal hemodynamic effects compared with the vasodilation noted in adults. Routine prophylactic fluid loading is not required in pediatric practice. A caudal and thoracic epidural block with local anesthetic and fentanyl had no effect unless epinephrine (5 mcg/mL) was added, when it was associated with increased cardiac output accompanied by decreased arterial blood pressure and SVR (Raux et al., 2004). There are no hemodynamic differences noted between spinal or epidural anesthesia (combined with general anesthesia) when used for pediatric cardiac anesthesia (Hammer et al., 2000). Regional anesthesia has such a negligible hemodynamic effect in children that high or even total spinal anesthesia has in fact been suggested by some groups for use in pediatric cardiac anesthesia (Finkel et al., 2003).

SUMMARY

The developmental stage of myocardium at the time of birth is dependent on species, and much of the knowledge of myocardial development derives from animal studies, leaving the specifics in humans unclear. For most purposes, human myocardium can certainly be considered mature by 12 months of age and to a good extent by 6 months of age. Developmental changes in myocardial maturation are apparent in numerous extracellular and intracellular components of heart muscle, and many have to do with calcium handling and excitation-contraction coupling. Current clinically useful anesthetics have multiple sites of interaction with the myocardium and its neural regulation, but are generally safe. Noninvasive evaluation of the heart by echo-Doppler and MRI have supplanted many of the indications for cardiac catheterization in evaluating both cardiac anatomy and cardiac physiology.

Concentrations of minerals and electrolytes in extracellular fluid (ECF) are maintained nearly constant, despite large day-to-day variations in the dietary intake of salt and water. Such homeostasis is governed primarily by the kidneys through an array of intricate processes that may be influenced by intrarenal and extrarenal vasoactive substances and hormones. Although the basic tenants governing nephron function and homeostasis of body fluid composition have changed little over the past decade, major advances stemming from genetic research have greatly elucidated the structure and function of many renal tubular electrolyte transporters during both health and disease. A major objective of this chapter is to enhance the understanding of electrolyte (and fluid) pathophysiology based on newer information.

OVERVIEW OF ANATOMY AND PHYSIOLOGY

Anatomy

The kidneys are retroperitoneal paired organs located on each side of the vertebral column. A normal adult kidney measures

11 to 12 cm in length, 5 to 7.5 cm in width, and 2.5 to 3.0 cm in thickness. In the adult male, it weighs 125 to 170 g, and in the adult female, it weighs 115 to 155 g. Beneath its fibrous capsule lies the cortex, which contains the glomeruli, the convoluted proximal tubules, the distal tubules, and the early portions of the collecting tubules. The remainder of the tissue, the medulla, contains the pars recta, the loop of Henle, and the middle and distal portions of the collecting duct. The inner medulla borders the renal pelvis, where urine is received from the collecting ducts. The ducts and loops are arranged into cone-shaped bundles called *pyramids*, which have tips that project into the renal pelvis and form papillae. The pelvis drains into the ureters, which in the adult human descend a distance of 28 to 34 cm to open into the fundus of the bladder. The walls of the pelvis and ureters contain smooth muscles that contract in a peristaltic manner to propel urine to the bladder.

Renal Blood Flow

Despite accounting for only 0.5% of body weight, the kidneys receive about 25% of the cardiac output, with a blood flow

of approximately 4 mL/min per gram of kidney tissue. Renal plasma flow (RPF) in women is slightly lower than it is in men, even when normalized for body surface area, averaging 592 ± 153 mL/min per 1.73 m^2 and 654 ± 163 mL/min per 1.73 m^2 , respectively (Smith, 1943). In children between the ages of 6 months and 1 year, normalized RPF is half that of adults but increases progressively to reach adult levels at about 3 years of age (McCrary, 1972). After the age of 30 years, renal blood flow (RBF) decreases progressively; by the age of 90 years, it is approximately half of the value present at 20 years (Davies and Shock, 1950). This generous supply provides not only for the basal metabolic needs of the kidneys but also for the high demands of ultrafiltration.

The basic arterial supply of the kidneys is a single renal artery that divides into large anterior and posterior branches and subsequently into segmental or interlobar arteries. The latter form the arcuate and interlobular arteries. These blood vessels are end-arteries and therefore predisposed to tissue infarction in the presence of emboli. The arcuate arteries are short, large-caliber vessels that supply blood to the afferent arterioles of the glomeruli at a mean pressure of 45 mm Hg, which is higher than that found in most capillary beds. This high hydraulic pressure and large endothelial pore size lead to enhanced glomerular filtration (Brenner and Beeuwkes, 1978).

Glomerular capillaries have many anastomoses but recombine to form the efferent arteriole. The latter subdivide into an extensive peritubular capillary network. This arrangement allows solute and water to move between the tubular lumen and blood. These networks rejoin to form the venous channels, through which blood exits the kidneys.

Ninety percent of RBF goes to the cortex, which accounts for 75% of the renal weight, whereas the medulla and the rest of the kidneys receive 25% of the RBF. Although cortical blood flow is 5 to 6 mL/g per minute, outer medullary blood flow decreases to 1.3 to 2.3 mL/g per minute, and the flow to the papilla is as low as 0.22 to 0.42 mL/g per minute (Dorkin and Brenner, 1991). The unevenness in the distribution of RBF between the cortex and the medulla is necessary to develop and maintain the medullary gradient of osmotically active solutes that drive the countercurrent exchange/multiplier, which is essential for the elaboration of concentrated urine. Outer medullary blood flow may preferentially supply the loop of Henle, thereby accounting for the striking influence of loop diuretics in that region. Furthermore, papillary blood flow is far greater than the metabolic needs of the renal parenchyma and is well adapted to the countercurrent concentrating mechanism characteristic of this region.

RBF remains almost constant over a range of systolic blood pressures from 80 to 180 mm Hg, a phenomenon known as autoregulation. Consequently, glomerular filtration is also constant over this range of pressures as a result of adaptations in the renal vascular resistance (Selkurt et al., 1949, Gertz et al., 1966). Because the changes in resistance that accompany graded reductions in renal perfusion pressure occur in both denervated and isolated perfused kidneys, autoregulation appears not to depend on extrinsic neural or hormonal factors (Thurau, 1964). According to the "myogenic hypothesis" first proposed by Bayliss (1902), the stimulus for vascular smooth muscle contraction in response to increasing intraluminal pressure is either the transmural pressure itself or the increase in the tension of the vascular wall. An increase in perfusion pressure, which initially distends the vascular wall, is followed by a contraction of the resistance vessels and a return of blood flow to basal levels.

There are only a few studies of autoregulation of RBF in developing animals. Aortic constriction in adult animals reduces renal perfusion by 30% but has minimal effects on RBF and glomerular filtration rate, compared with the significant changes observed in 4- to 5-week-old rats (Yared and Yoskioka, 1989). Furthermore, it has been demonstrated that autoregulation of RBF in young rats occurs at renal perfusion pressures between 70 and 100 mm Hg, compared with pressures of 100 to 130 mm Hg in adult rats (Chevalier and Kaiser, 1985). A similar increase in the pressure set point for autoregulation has been found in dogs (Jose et al., 1975). It appears that autoregulation of RBF occurs in the very young and is sufficient to maintain blood flow constant over a wide range of perfusion pressures that are physiologically adequate for the age. No such human studies are available.

Several substances have been proposed to participate in the autoregulation of RBF, including vasoconstrictor and vasodilator prostaglandins, kinins, adenosine, vasopressin, the renin-angiotensin-aldosterone system, endothelin, and endopeptidases (Herbacznaska-Cedro and Vane, 1973, Osswald et al., 1978, Maier et al., 1981, Schnermann et al., 1984). Nitric oxide (NO), previously known as endothelium-derived relaxing factor (EDRF), has also been shown to play an important role in regulating renal vascular tone through its vasodilatory action. Bradykinin, thrombin, histamine, serotonin, and acetylcholine act on endothelial receptors to activate phospholipase C, which in turn results in the formation of inositol triphosphate and diacylglycerol, resulting in the release of intracellular calcium (Marsden and Brenner, 1991, Luscher et al., 1992). This in turn stimulates the synthesis of NO from L-arginine. Other factors that stimulate the formation of NO include hypoxia, calcium ionophores, and mechanical stimuli to the endothelium. NO increases RBF by decreasing efferent arteriolar vascular resistance, while glomerular filtration remains unchanged (Marsden and Brenner, 1991).

Because in mature kidneys, autoregulation is lost at arterial pressures less than 80 mm Hg, the lower physiologic pressures prevailing in the newborn period may be expected to limit this important control mechanism. There is evidence both to support and to refute this conclusion (Kleinman and Lubbe, 1972, Jose et al., 1975).

Renal Physiology

The glomerulus is a specialized capillary cluster arranged in loops that functions as a filtering unit. The capillary walls may be viewed as a basement membrane lined by a single layer of cells on either side. In contact with blood are endothelial cells, which contain many fenestrations; podocytes, with their foot processes, line the other side of the basement membrane.

The route by which water and other solutes are filtered from the blood is not fully understood, but it appears that plasma ultrafiltrate traverses the large fenestrations of the glomerular capillary endothelium and penetrates the basement membrane and the slit pores located between the podocyte foot processes. Filtration of large molecules is greatly influenced by the size and charge of the specific molecule, as well as by the integrity and charge of the glomerular basement membrane. Abnormalities in various structural proteins of the slit-pore diaphragm such as nephrin, podocin, and α -actinin may be responsible for several proteinuric disorders (Mundel and Shankland,

2002). In general, the endothelium and the *lamina rara interna* of the glomerular basement membrane slow the filtration of circulating polyanions such as albumin (Ryan and Karnovsky, 1976). The *lamina rara externa* and the slit pores slow the filtration of cationic macromolecules such as lactoperoxidase (Graham and Kellermeyer, 1968). Neutral polymers such as ferritin are not filtered because of their large molecular size and shape (Farauhar et al., 1961). Molecules with a radius of 4.2 nm or more are excluded from the glomerular filtrate. In practical terms, red cells, white cells, platelets, and most proteins are restricted to the circulation.

Glomerular Filtration

Among the main functions performed by the kidneys is the process of glomerular filtration. The glomerulus is primarily responsible for the filtration of plasma. The glomerular filtration rate (GFR) is the product of the filtration rate in a single nephron and the number of such nephrons, which range from 0.7 to 1.4 million in each kidney (Keller et al., 2003). Clearance, which is defined as the volume of plasma cleared of a substance within a given time, provides only an estimate or approximation of GFR.

Although tubular reabsorption and tubular secretion may influence the blood level of numerous medications and endogenously-produced substances such as urea, creatinine, and uric acid, the degree of elimination of such substances depends largely on GFR. Hence, in individuals with renal impairment, estimation or measurement of GFR is crucial in determining the dosage adjustment and choice of medications needed to achieve effectiveness while avoiding toxicity. GFR is also a major factor that affects electrolyte composition and volume of body fluids, as well as acid-base homeostasis.

Glomerular filtration is driven by hydrostatic pressure, which forces water and small solutes across the filtration barrier. In healthy individuals, changes in hydrostatic pressure rarely affect single-nephron GFR because autoregulatory mechanisms sustain or maintain a constant glomerular capillary pressure over a large range of systemic blood pressure (Robertson et al., 1972). Hydrostatic pressure is opposed by the oncotic pressure produced by plasma proteins and the hydrostatic pressure within Bowman's capsule. Mathematically, this relation can be expressed by the following equation:

$$\text{SNGFR} = K_f \times (P - p) = K_f \times P_{\text{UF}}$$

SNGFR is the single-nephron glomerular filtration rate; K_f is the glomerular ultrafiltration coefficient; P and p are the average hydraulic and osmotic pressure differences, respectively; and P_{UF} is the net ultrafiltration pressure. As plasma water is filtered, the proteins within the capillaries become more concentrated, so oncotic pressure increases at the distal end of the glomerular capillary loop and the rate of filtration ceases at the efferent capillary (Blantz, 1977). Under normal conditions, about 20% of the plasma water that enters the glomerular capillary bed is filtered; this quantity is referred to as the filtration fraction

RBF has the greatest influence on GFR. Renal parenchymal disorders interfere with autoregulation of RBF, such that GFR may fall, even with low-normal mean arterial blood pressure (MABP). Still more pronounced changes in GFR may occur with hypotension or hypertension, which may accelerate

ischemic or hypertensive injury. Clearance of a molecule may serve as an indicator of GFR only if the assayed molecule is biologically inert and freely permeable across the glomerular capillary, if it remains unchanged after filtration, and if it is neither reabsorbed nor secreted by the tubule. The exogenous-filtration marker inulin (a fructose polymer) has all of these attributes and is the ideal standard for measuring GFR. However, inulin-clearance measurement is rarely used clinically because it is an expensive and cumbersome method. Instead, measurement of an endogenous small molecule such as serum creatinine (molecular weight, 0.113 kDa), which is derived from muscle metabolism at a relatively constant rate and is freely filtered at the glomerulus, is a practical, rapid, and inexpensive means for estimating GFR, thereby aiding clinical decisions. Thus, in the steady state, creatinine production and urinary creatinine excretion are equal even when GFR is reduced.

Serum-creatinine concentrations vary by age and gender. In 1-year-old girls values are 0.35 ± 0.05 mg/dL (mean \pm SD) and rise gradually to 0.7 ± 0.02 mg/dL (mean \pm SD) by 17 years of age; boys have corresponding mean values that are 0.05 mg/dL higher until 15 years of age and 0.1 mg/dL higher subsequently (Schwartz et al., 1987). Expected creatinine-excretion rates in 24-hour urine collections are often used to validate such collections. Values range from 8 to 14 mg/kg per day in neonates and in infants younger than 1 year of age, with an increase to about 22 ± 7 mg/kg per day (mean \pm SD) in preadolescent children of either gender (Hellerstein et al., 2001). Subsequently, creatinine excretion in boys is 27 ± 3.4 mg/kg per day.

In healthy children with proportional height and weight, GFR can be estimated by creatinine clearance (CrCl) as calculated by Schwartz's formula, which does not rely on measurement of urinary creatinine or timed urine collections:

$$\text{CrCl (mL/min per } 1.73 \text{ m}^2) = (\text{Height} / P_{\text{CR}}) \times k,$$

where height is in centimeters, P_{CR} is the plasma-creatinine concentration in mg/dL, and k is a constant proportion to muscle mass. The value of k is 0.45 in full-term newborns and until 1 year of age, 0.55 in children 2 years of age and older and in adolescent girls, and 0.70 in adolescent boys (Schwartz et al., 1987). Normal CrCl ranges from 90 to 143 mL/min per 1.73 m^2 , with a mean of 120 mL/min per 1.73 m^2

Although more cumbersome, calculation of CrCl based on values obtained in 12- or 24-hour urine collections provide a better estimate of GFR. Once the completeness of such collections is validated based on expected creatinine excretion, CrCl is calculated using the following formula:

$$\text{CrCl (mL/min/1.73 m}^2) = \frac{U \times V \times \text{SA m}^2}{\text{min} \times P_{\text{CR}} \times 1.73 \text{ m}^2}$$

U is the urinary concentration of creatinine in mg/dL, V is the total urine volume in mL, min is the time of collection in minutes, and P_{CR} is the serum concentration of creatinine in mg/dL. To standardize the clearance of children of different sizes, the calculated result is multiplied by 1.73 m^2 (surface area of a standard man in meters squared) and divided by the surface area of the child in meters squared

In children with impaired renal function, GFR estimates based on creatinine methods may grossly overestimate the true GFR, because tubular and gastrointestinal secretion of creatinine increases disproportionately. Hence, serum creatinine concentrations are less reflective of filtration at the glomerulus.

For example, Schwartz’s formulas overestimate GFR by 10% ± 3% when GFR is greater than 50 mL/min per 1.73 m² but by 90% ± 15% when GFR is less than 50 mL/min per 1.73 m². Other limitations of creatinine-based GFR determinations stem from variations of analytical assays, reference values ranging from 0.1 to 0.6 mg/dL in children younger than 9 years of age, diurnal variation in serum creatinine levels resulting from high intake of cooked meat or intense exercise, influence of body mass index, and inaccurate urine collections—all of which make comparisons of GFR difficult over time, especially in growing children (Levey et al., 1988). Using cimetidine to block tubular secretion of creatinine before measuring CrCl in urine collections may improve such measurements (Hellerstein et al., 1998).

Measurement of cystatin-C, a 13-kDa serine proteinase produced at a constant rate by all nucleated cells, is purported to be a superior endogenous marker of filtration, because cystatin-C is less susceptible to variation than is plasma creatinine. A meta-analysis compared the correlation between GFR measured by inulin clearance, radiolabeled methods, nonlabeled iothalamate or iohexol, and either plasma creatinine or cystatin-C concentrations measured nephelometrically (Dharnidharka et al., 2002). The correlation between GFR and cystatin-C was significantly higher compared with plasma creatinine (0.846 versus 0.742, P < 0.001). Thus, cystatin-C measurements are becoming increasingly popular in clinical practice, and reference ranges have been generated in children up to 16 years of age (Table 5-1) (Bokenkamp et al., 1998; Finney et al., 2000; Harmoinen et al., 2000).

Studies in renal transplant donors and in individuals with various renal disorders have shown that plasma-creatinine concentration changes minimally as GFR falls to about 50 mL/min per 1.73 m² (Fig. 5-1) (Shemesh, 1985). This compensation is largely the result of hypertrophy and hyperfiltration of the remaining nephrons. When more than 50% of the nephrons cease to function and “renal reserve” is outstripped, serum creatinine may rise rapidly in a parabolic fashion (Fig. 5-1). Thus, when a more accurate clinical assessment of GFR is desirable for research purposes, radiolabeled methods with an identity exceeding 97% give a better approximation of GFR relative to inulin clearance and may be more useful in aiding clinical decisions. In multicenter investigations conducted in the United States using a uniform method for GFR measurement, ¹²⁵I-iothalamate is often used because this isotope has low radiation exposure and long isotope half-life and can be assayed

■ FIGURE 5-1. Relationship of serum creatinine to GFR. (From Shemesh O, Golbetz H, Kriss JP, et al.: Limitation of creatinine as a filtration marker in glomerulopathic patients, *Kidney Int* 28:830, 1985.)

at a central laboratory (Bajaj et al., 1996). Otherwise, ^{99m}Tc-diethylenetriaminepenta-acetic acid (Tc-DTPA) is commonly used to estimate GFR for routine clinical purposes. In other countries, ⁵¹Cr-ethylenediaminetetra-acetic acid (Cr-EDTA), which delivers a greater radiation dosage, is also popular, as are nonlabeled iothalamate and iohexol methods.

Although GFR may fluctuate, the kidneys retain the ability to regulate the rate of solute and water excretion according to changes in intake. This regulation is achieved by changes in tubular reabsorption rates—a phenomenon known as glomerular-tubular balance (Tucker and Blantz, 1977). The end result is preservation of ECF volume and chemical composition. Glomerular-tubular balance can be disturbed by several factors, including volume expansion, loop diuretics, and inappropriate secretion of antidiuretic hormone (ADH).

TABLE 5-1. Nonparametric 95% Reference Intervals for Cystatin C in Different Age Groups

Age Group	n	Reference Interval	90% Confidence Limits		P*
			Lower Limit	Upper Limit	
Preterm infants	58	1.34-2.57	1.07-1.42	2.47-2.86	0.000
Full-term infants	50	1.36-2.23	1.24-1.44	2.03-2.32	0.000
>8 days to 1 yr	65	0.75-1.87	0.71-0.86	1.78-1.91	0.000
>1 to 3 yr	72	0.68-1.60	0.65-0.79	1.39-1.67	0.011
>3 to 16 yr	162	0.51-1.31	0.48-0.68	1.26-1.35	—

Modified from Harmoinen A, Ylinen E, Ala-Houhala M, et al.: Reference intervals for cystatin C in pre- and full-term infants and children, *Pediatr Nephrol* 15:105-108, 2000, p 107, Table 1. (With permission of Springer Science and Business Media.)

Overview of Tubular Function

The proximal tubule is the site of reabsorption of large quantities of solute and filtered fluid (Fig. 5-2). Many transporters subserving tubular electrolyte transport have been characterized at the genetic level, and various pathologic disorders have been elucidated (Epstein, 1999). Under physiologic conditions, the proximal convoluted tubule isototically reabsorbs 50% to 60% of the glomerular filtrate (Berry and Rector, 1991). The initial portion of the proximal convoluted tubule reabsorbs most of the filtered glucose, amino acids, and bicarbonate. Glucose and amino acids are absorbed actively, whereby they are transported against their electrochemical gradient, coupled to sodium (Na^+). Active Na^+ transport at the peritubular membrane provides the driving force that ultimately is responsible for other transport processes. The system is driven by sodium, Na^+ , K^+ , (activated) adenosine triphosphatase (Na^+ -, K^+ -ATPase), or the Na^+ "pump," which requires the presence of K^+ in the peritubular fluid and is inhibited by ouabain. Micropuncture studies show that around 50% to 70% of the filtered Na^+ is reabsorbed in this segment, mostly by a process of active cotransport.

The major fraction of filtered bicarbonate (HCO_3^-) is absorbed early in the proximal convoluted tubule. Hydrogen (H^+) gains access to luminal fluid via an Na^+/H^+ electroneutral exchange mechanism and forms carbonic acid. The latter is dehydrated to H_2O and CO_2 under the influence of carbonic anhydrase. CO_2 diffuses into the cell, and HCO_3^- is re-formed and ultimately absorbed into the bloodstream. In general, the concentration of HCO_3^- is maintained at 26 mmol/L, which is slightly below the renal threshold of approximately 28 mmol/L (Pitts and Lotspeich, 1946).

The renal clearance of glucose is exceedingly low, even after complete maturation of glomerular filtration. The amount filtered increases linearly as plasma glucose increases. Initially, all filtered glucose is reabsorbed until the renal threshold has been exceeded (at around 180 mg/dL), at which point filtered glucose appears in the urine. However, maximal tubular glucose (T_{mC}) reabsorption is attained at a filtrate glucose concentration of about 350 mg/mL (Pitts, 1974). The reabsorption of glucose in the proximal tubule occurs via a carrier-mediated, Na^+ /glucose cotransport process across the apical membrane, followed by passive facilitated diffusion and active Na^+ extrusion across the basolateral membrane.

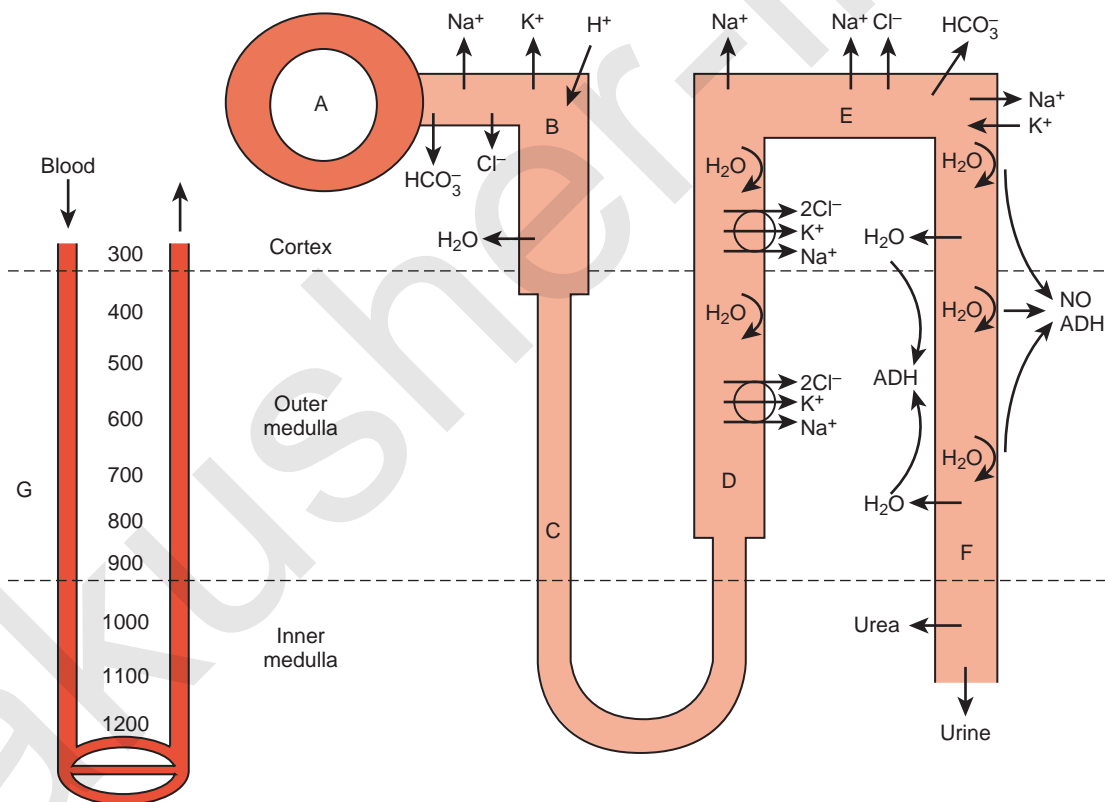

FIGURE 5-2. Sodium and water handling by the nephron. A, Glomerulus. B, Proximal tubule, the major site for the reabsorption of Na^+ (70%), Cl^- , K^+ (80%), HCO_3^- (80% to 90%), and water. The reabsorptive process is isotonic, regardless of whether the kidneys are concentrating or diluting urine. C, Thin descending loop of Henle. D, Thick ascending loop of Henle. It is always impermeable to water. The medullary portion is important for the generation of free water. There is active Na^+ , K^+ , and Cl^- (20% to 25%) reabsorption, which is responsible for driving the countercurrent multiplier and creating increased medullary tonicity. The cortical thick ascending limb and the early distal tubule (E) are responsible for the reabsorption of the remaining HCO_3^- , as well as 5% of the filtered Na^+ and Cl^- . These segments are impermeable to water and are unaffected by ADH. In the late distal tubule and the cortical collecting duct (F), aldosterone action controls Na^+ and K^+ reabsorption and excretion. The medullary portion of the collecting duct is the major site for ADH-dependent water reabsorption. This segment is permeable to water in the presence of ADH. The vasa recta (G) is important in maintaining a concentrated medullary interstitium.

Apart from Na^+ , other solutes reabsorbed in the proximal tubule include K^+ , Ca^{2+} , P^{2-} , Mg^{2+} , and amino acids. These are discussed in detail in other sections of this chapter.

The loop of Henle makes the formation of concentrated urine possible and contributes to the formation of dilute urine (Kokko, 1979). This dual function is achieved through the unique membrane properties of the loop, the postglomerular capillaries, and the hypertonicity of the interstitium. The proximity of the descending and ascending portions of loop allows it to function as a countercurrent multiplier, whereas the capillaries serve as countercurrent exchangers (Fig. 5-2). The descending loop of Henle abstracts water from tubular fluid, increasing the intraluminal concentrations of NaCl and other solutes. However, the intraluminal osmolality remains in equilibrium with the interstitium, where 50% of the osmolality results from urea. In the thin ascending limb of the loop of Henle, there is passive efflux of NaCl and urea into the interstitium. The thick ascending limb of the loop of Henle, by being impermeable to water, contributes to the formation of dilute urine.

The final creation of hypotonic or hypertonic urine depends on the distal tubules and collecting ducts and their interaction with ADH. In the distal convoluted tubule, Na^+ reabsorption occurs against a steep gradient, largely under the influence of aldosterone. K^+ is secreted by the distal tubule in association with Na^+ reabsorption and H^+ secretion. Moreover, this segment of the nephron acidifies the urine and is the only site of new bicarbonate formation. At the end of the collecting duct, about 1% of the filtered water and about 0.5% of the filtered Na^+ appear in the final urine.

The Kidneys and Antidiuretic Hormone

ADH plays a pivotal role in water homeostasis by acting on the most distal portion of the nephron. ADH is a cyclic octapeptide that, along with its carrier protein, neurophysin, is synthesized in the supraoptic and paraventricular nuclei of the hypothalamus (Zimmerman and Defendini, 1977). The prohormone migrates along the nerve axons to the posterior pituitary gland, where it is stored as arginine vasopressin. It is released through exocytosis (Douglas, 1973).

Several variables affect ADH secretion. Physiologically, the most important factor is plasma osmolality. A very small rise in plasma osmolality is sufficient to trigger a response from the sensitive osmoreceptors located in and around the hypothalamic nuclei, leading to ADH secretion. Conversely, plasma ADH concentrations are less than 1 pg/mL at a physiologic plasma osmolality of less than 280 mOsm/kg water. The antidiuretic activity of ADH is maximal at plasma osmolality of greater than 295 mOsm/kg water, when plasma ADH exceeds 5 pg/mL (Robertson, 2001). Once plasma osmolality exceeds this limit—thus surpassing the capacity of the ADH system to affect maximal fluid retention—the organism depends on thirst to defend against dehydration. Intracerebral synthesis of angiotensin II largely mediates this thirst response and the oropharyngeal reflex. Atrial natriuretic peptide (ANP) opposes the release of ADH and of angiotensin II. In summary, plasma osmolality and Na^+ are maintained within a narrow range. The upper limit of this range is determined by the sensitivity of the thirst mechanism located in the hypothalamus, whereas its lower range is affected by ADH release.

Nonosmolar factors also influence ADH secretion and may be the key stimuli of ADH secretion in pathologic disorders, leading to hypovolemia and hypotension. These changes are mediated by low-pressure (located in the left atrium) and high-pressure (located in the carotid sinus) baroreceptors. Experimental studies suggest that this nonosmotic pathway of ADH release is less sensitive than the osmotic pathway and is triggered by a 5% to 10% fall in blood volume, whereas a 1% to 2% increase in ECF osmolality can trigger ADH release.

Nonhypovolemic conditions that stimulate ADH release often result in diminished urine volume, hyponatremia, fractional excretion of uric acid greater than 10%, low serum uric acid level (<4 mg/dL), and urinary sodium greater than 20 mEq/L (Albanese et al., 2001). These conditions result in hyponatremia. Conversely, inhibitors of ADH release or primary or acquired nephropathies may result in the inability to respond to ADH or to conserve water, and these inhibitors are often accompanied by polyuria with U_{osm} of less than 150 mOsm/kg, dehydration, and hypernatremia.

ADH has a major effect on the medullary thick ascending limb and thereby influences the countercurrent multiplier mechanism and urinary concentration. More directly, ADH binds to V_2 receptors in the basolateral membrane of the collecting duct, causing the activation of adenylate cyclase and the formation of cyclic 3',5'-adenosine monophosphate (cAMP) (Dorisa and Valtin, 1976; Schwartz et al., 1974). This results in insertion of aquaporin-2 water channels in apical membranes and in the activation of apical Na^+ channels, which causes water conservation (Andreoli, 2001). These effects are counterbalanced by prostaglandin E_2 (PGE_2) and the calcium-sensing receptor in cells of the medullary thick ascending limb that mediate saluresis and diuresis.

Polyuric syndromes can be separated on the basis of urine osmolality and generally consist of water diuresis, solute diuresis, or a mixed water-solute diuresis with typical U_{osm} of less than 150 mOsm/kg, 300 to 500 mOsm/kg, and 150 to 300 mOsm/kg, respectively (Oster et al., 1997). The etiology of polyuria may be facilitated by obtaining a urinalysis; a measurement of urine pH; and measurements of electrolytes, creatinine, osmolality, glucose, urea nitrogen, and bicarbonate, preferably in a timed urine collection together with the corresponding serum values. Such assessment may serve to prevent dehydration, acid-base disturbances, hypokalemia, or hypernatremia, which often accompany such polyuric disorders (Table 5-2) (Oster et al., 1997). Proper correction of acute hypernatremia is needed to prevent brain demyelination. Normal saline infusion may be the agent of choice in polyuric conditions associated with solute diuresis, whereas ADH and electrolyte-free fluid administration may be appropriate in cases of “pure” water diuresis. The recommended rate of correction of hypernatremia is about 10 mEq/L per 24 hours, amounting to a fall in plasma osmolality of about 20 mOsm/kg H_2O per day (Adrogué and Madias, 2000b).

Renin-Angiotensin-Aldosterone System

The renin-angiotensin-aldosterone axis plays a key role in control of vascular tone, Na^+ and K^+ homeostasis, and, ultimately, circulatory volume and cardiovascular and renal function. Renin is an enzyme with a molecular weight of 40 kDa that is synthesized and stored in the juxtaglomerular apparatus

TABLE 5-2. Studies Used in the Evaluation of Polyuria

Abbreviation (Term)	Definition	Formula*	Comment
C_{osm} (osmolal clearance)	Urine flow (volume/unit time) necessary to excrete the urinary solution isototically (i.e., at osmolality of the plasma)	$\frac{(U_{\text{osm}})V}{P_{\text{osm}}}$	Classic clearance formula applied to solute
$C_{\text{osm(E)}}$ (electrolyte osmolal clearance)	Urine flow (volume/unit time) necessary to excrete urinary electrolytes at concentration of plasma Na	$\frac{(U_{\text{Na}} + U_{\text{K}})V}{P_{\text{Na}}}$	Assumes that contribution of P_{K} is negligible compared with P_{Na}
$C_{\text{osm(NE)}}$ (nonelectrolyte osmolal clearance)	Urine flow (volume/unit time) necessary to excrete urinary nonelectrolytes isototically (i.e., at osmolality of plasma)	$C_{\text{osm}} - C_{\text{osm(E)}}$	—
Ch_2O (free water clearance)	Volume of urinary solute-free water excreted per unit time	$V - C_{\text{osm}}$	—
$\text{Ch}_2\text{O(e)}$ (electrolyte-free water clearance)	Volume of urinary electrolyte-free water excreted per unit time	$V - C_{\text{osm(E)}}$	$\text{Ch}_2\text{O(e)}$, rather than Ch_2O , influences S_{Na}
U_{TS} (urine total solute)	Measured total amount of urinary solute in 24 hr	$(U_{\text{osm}})(TV)$	—
U_{E} (urine electrolyte solute)	Estimated total amount of urinary solute in 24 hr accounted for by electrolytes	$(2)(U_{\text{Na}} + U_{\text{K}})(TV)^{\dagger}$	—
U_{NE} (urine nonelectrolyte solute)	Estimated total amount of urinary solute in 24 hr not accounted for by electrolytes	$U_{\text{TS}} - U_{\text{E}}$	—
UAG (urinary anion gap)	Difference (in mEq/L) between sum of urinary concentrations of Na and K, and that of Cl	$U_{\text{Na}} + U_{\text{K}} - U_{\text{Cl}}$	A large (positive) value usually implies a large concentration of anions other than Cl
PS (principal solute)	Principal urinary solute in millimoles per 24 hr	—	If PS is a monovalent ion such as Na^+ or Cl^- , PS is calculated as twice its total excretion
PS% (percent principal solute)	Contribution of principal solute to total solute excretion	$\frac{(100)(PS)}{(U_{\text{osm}})(TV)}$	The solute with the highest osmolal concentration in a 24-hr urine collection, expressed as a percentage of total solute excretion

surrounding the afferent arterioles of the glomeruli (Davis and Freeman, 1976). The primary stimuli for renal renin release are reductions in renal-perfusion pressure, Na^+ restriction, and Na^+ loss as detected by the specialized *macula densa* cells located in the distal tubule. Mechanical (stretch of the afferent glomerular arterioles), neural (sympathetic nervous system), and hormonal (PGE_2 and prostacyclin) stimuli act in an integrated fashion to regulate the rate of renin secretion (Fig. 5-3).

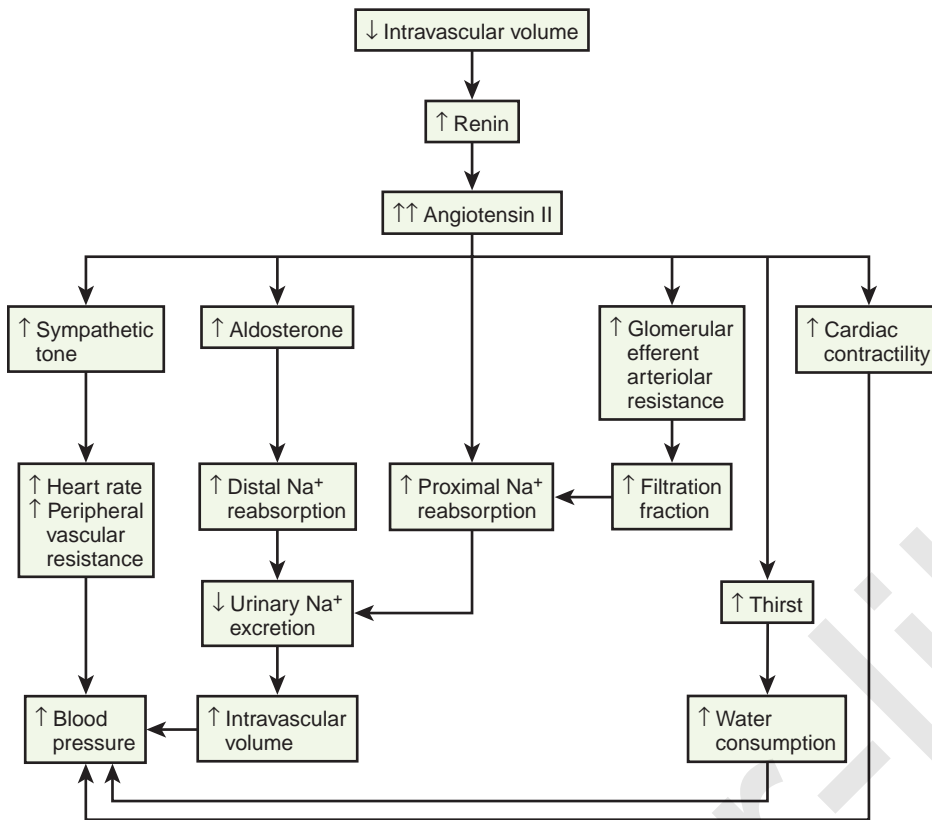

Once released into the circulation, renin cleaves the leucine-valine bond of angiotensinogen, forming angiotensin I. Angiotensin-converting enzyme that is present in the lungs, as well as in the kidneys, large caliber vessels, and other tissues, cleaves the carboxyl terminal (histidine-leucine dipeptide) from angiotensin I to form the biologically active angiotensin II (Ng and Vane, 1967).

Angiotensin II has numerous important hemodynamic functions that are mediated largely by binding to angiotensin-II T1-receptors in endothelial cells, tubular epithelial cells, and smooth muscle (Box 5-1) (Burnier and Brunner, 2000). It plays a key role in regulating blood volume and long-term blood pressure through stimulation of several tubular transporters of Na^+ -concentration that are mainly located in the proximal tubule, as well as through its effects in enhancing aldosterone secretion

and Na^+ reabsorption in the distal tubule. As a potent direct smooth-muscle vasoconstrictor and as an enhancer of ADH and sympathetic nervous system activity, angiotensin II also participates in short-term blood-pressure regulation in disorders associated with volume depletion or circulatory depression. Research has uncovered multiple nonhemodynamic functions that are primarily mediated by binding to T1 receptors of angiotensin II, which are particularly important in the pathophysiology of progressive renal injury (Hall et al., 1999).

A rise in plasma aldosterone concentration stimulates urinary K^+ secretion, thus allowing maintenance of K^+ balance. Aldosterone also increases the excretion of ammonium (NH_4^+) and magnesium (Mg^{2+}) and increases the absorption of Na^+ in the distal tubule, both by increasing the permeability of the apical membrane and by increasing the activity of Na^+ , K^+ -adenosine triphosphatase (ATPase) (Marver and Kokko, 1983). The net effect is to generate more negative potential in the lumen, a driving force for increased K^+ secretion. In addition, aldosterone enhances reabsorption of sodium in the cortical collecting duct through activation of the epithelial sodium-specific channel, ENaC (Greger, 2000). In performing these functions, aldosterone plays a key role in regulating fluid and electrolyte balance. Long-term aldosterone administration to

FIGURE 5-3. Effects of decreased intravascular volume on the renin-angiotensin-aldosterone system.

Box 5-1 Effects of Angiotensin II Mediated via AT₁ and AT₂ Receptor Stimulation

AT₁ RECEPTOR STIMULATION

- Vasoconstriction (preferentially coronary, renal, cerebral)
- Sodium retention (angiotensin, aldosterone production)
- Water retention (vasopressin release)
- Renin suppression (negative feedback)
- Myocyte and smooth muscle cell hypertrophy
- Stimulation of vascular and myocardial fibrosis
- Inotropic/contractile (cardiomyocytes)
- Chronotropic/arrhythmogenic (cardiomyocytes)
- Stimulation of plasminogen activator inhibitor-1
- Stimulation of superoxide formation
- Activation of sympathetic nervous system
- Increased endothelin secretion

AT₂ RECEPTOR STIMULATION

- Antiproliferation/inhibition of cell growth
- Cell differentiation
- Tissue repair
- Apoptosis
- Possible vasodilation
- Kidney and urinary-tract development

The Kidneys and Atrial Natriuretic Peptide

ANP is secreted by atrial monocytes in response to local stretching of the atrial wall in cases of hypervolemia (e.g., congestive heart failure or renal failure) and ultimately results in the reduction of intravascular volume and systemic blood pressure (Brenner et al., 1990). In the kidneys, ANP acts in the medullary collecting duct to inhibit sodium reabsorption during ECF expansion. ANP induces hyperfiltration, natriuresis, and suppression of renin release, and it inhibits receptor-mediated aldosterone biosynthesis (Greger, 2000). In the cardiovascular system, it diminishes cardiac output and stroke volume and reduces peripheral vascular resistance. Some of these effects are mediated through the influence of ANP on vagal and sympathetic nerve activity.

Body Fluid Compartments

The internal environment of the body consists of fluids contained within compartments. Water accounts for 50% to 80% of the human body by weight. The variation in water content depends on tissue type: adipose tissue contains only 10% water, whereas muscle contains 75% water. Total body water (TBW) decreases with age, mainly as a result of loss of water in ECF. For clinical purposes, TBW is estimated at 60% of body weight in infants older than age 6 months, as well as in children and adolescents. This value is very inaccurate for low-birth-weight premature infants in whom TBW comprises as much as 80% of total body weight (Friis-Hensen, 1971; Kagan et al., 1972). In term infants younger than 6 months of age, TBW may be approximated as 75% of total body weight (Hill, 1990). Newer formulas that consider the height (cm) and weight (kg), but

healthy volunteers increases the ECF volume. Clinical edema does not occur, however, because after several days the kidneys “escape” from the Na⁺-retaining effect while maintaining the K⁺-secretory effect (August et al., 1958).

■ **FIGURE 5-4.** Total body water (TBW) plotted against the parameter ($Ht \times Wt$) for children from 3 months to 13 years of age. The 10th, 50th, and 90th percentile curves, generated from the equations in the text, are shown. The curves for both males and females are presented. (From Morgenstern BZ, Mahoney DW, Warady BA: Estimating total body water in children on the basis of height and weight: a reevaluation of the formulas of Mellits and Cheek, *J Am Soc Nephrol* 13:1884-1888, 2002.)

not the degree of adiposity or the child's surface area, have improved the estimation of TBW, particularly in healthy children between 3 months and 13 years of age (Fig. 5-4) (Mellits and Cheek, 1970; Morgenstern, 2002). TBW can be determined as follows:

$$\text{0 to 3 Months: TBW} = 0.887 \times (Wt)^{0.83}$$

$$\text{Children 4 to 13 years: TBW} = 0.0846 \times 0.95^{\text{[if female]}} \times (Ht \times Wt)^{0.65}$$

$$\text{Children over 13 years: TBW} = 0.0758 \times 0.84^{\text{[if female]}} \times (Ht \times Wt)^{0.69}$$

Intracellular Fluid

Intracellular fluid (ICF) represents about two thirds of the TBW, which is equivalent to 30% to 40% of total body weight. However, the proportion of ECF is much greater than that of ICF in preterm infants and reaches 60% of TBW at term. The membranes retaining this fluid allow the passive diffusion of water, whereas active transport mechanisms maintain an internal solute milieu different from that found outside the cells. K^+ , P^{2-} , and Mg^{2+} are intracellular ions, and Na^+ and Cl^- are predominantly extracellular.

Extracellular Fluid

ECF accounts for about one third of TBW and is made up of two compartments: plasma and interstitial fluid. Plasma water represents 4% to 5% of body weight and 10% of TBW. It is the milieu in which blood cells, platelets, and proteins are suspended. Blood volume is usually estimated as a changing proportion with respect to body weight. When expressed as milliliters per kilogram of body weight, it decreases with age from 80 mL/kg at birth to 60 mL/kg in adulthood.

Interstitial Fluid

Interstitial fluid accounts for 16% of body weight and has a solute composition almost identical to that of intravascular fluid, except for a lower protein concentration. In general, the bulk distribution of ions and fluids between these two compartments is determined by the Donnan effect and Starling forces.

Transcellular Fluid

The transcellular fluid compartment (1% to 3% of body weight) is a specialized subdivision of the ECF compartment. Separated from blood by endothelium and epithelium, it represents fluid collections such as cerebrospinal fluid, aqueous and vitreous humors of the eyes, synovial fluid, pleural fluid, and peritoneal fluid.

MATURATION OF RENAL FUNCTION

Although all nephrons of the mature kidneys are formed by 36 weeks' gestation during healthy intrauterine life, hyperplasia continues until the sixth postnatal month; thereafter, cell hypertrophy is responsible for increases in renal size. Growth in the size of the kidney tends to be directly proportional to increase in height (Schultz et al., 1962).

While the fetal kidney receives 3% to 7% of cardiac output, RBF increases gradually after birth (Rudolph et al., 1971). RBF, as measured by paraaminohippuric acid (PAH) clearance (C_{PAH}), correlates with gestational age. For example, C_{PAH} is 10 mL/min per square meter at 28 weeks of gestation and 35 mL/min per square meter at 35 weeks of gestation (Fawer et al., 1979). C_{PAH} corrected for body surface area doubles by 2 weeks of age and reaches adult levels at 2 years. Furthermore, changes in RBF are associated with considerable increases in the relative RBF to the outer cortex, where most glomeruli are located (Olbing et al., 1973).

Selected renal functions measured at different ages are summarized in Table 5-3. The GFR in the full-term newborn infant averages 40.6 ± 14.8 mL/min per 1.73 m^2 and increases to 65.8 ± 24.8 mL/min per 1.73 m^2 by the end of the second postnatal week (Schwartz et al., 1987). GFR reaches adult levels after 2 years of age. Premature newborns have a lower GFR that increases more slowly than that in full-term infants. The low GFR at birth is attributed to the low systemic arterial blood pressure, high renal-vascular resistance, and low ultrafiltration pressure, together with decreased capillary surface area for filtration.

Despite a low GFR, full-term infants are able to conserve Na^+ (Spitzer, 1982). This is explained by the existence of glomerulotubular balance, such that as GFR and the filtered load of Na^+ increase, so does the ability of the proximal tubule to reabsorb Na^+ . In contrast, preterm infants have a prolonged glomerulotubular imbalance, so that GFR is high relative to tubular capacity to reabsorb Na^+ . The glomerulotubular imbalance is caused by structural immaturity of the proximal convoluted tubule and the incomplete development of the transport system responsible for conserving Na^+ . This, together with poor response of the distal tubule to mineralocorticoids in preterm infants, results in Na^+ wastage and susceptibility to hyponatremia.

TABLE 5-3. Maturation of Renal Function with Age

Measurement	Premature Newborn	Full-term Newborn	1 to 2 weeks	6 Months to 1 Year	1 to 3 Years	Adult
GFR (mL/min /1.73 m ²)*	14 ± 3	40.6 ± 14.8	65.8 ± 24.8	77 ± 14	96 ± 22	Male: 125 ± 15 Female: 110 ± 15
RBF (mL/min /1.73 m ²)	40 ± 6	88 ± 4	220 ± 40	352 ± 73	540 ± 118	620 ± 92
Tm _{PAH} (mg/min/ 1.73 m ²)	10 ± 2	16 ± 5	38 ± 8	51 ± 20	66 ± 19	79 ± 12
Maximal concentration ability (mOsm/kg)	480	700	900	1200	1400	1400
Serum creatinine (mg/dL)	1.3	1.1	0.4	0.2	0.4	0.8-1.5
Tm _p /GFR (mg/dL)	—	7.39 ± 0.37	—	5.58 ± 0.28	5.71 ± 0.28	3.55 ± 19
Fractional excretion of sodium (%)	2% to 6%	<1	<1	<1	<1	<1
Tm _c (mg/min /1.73 m ²)	—	—	71 ± 20	—	—	339 ± 51

*GFR, Glomerular filtration rate; RBF, renal blood flow; Tm_{PAH}, tubular maximum for para-aminohippuric acid; Tm_p, tubular maximum for phosphorus; Tm_c, tubular maximum for reabsorption of glucose.

The tubular mechanisms involved in the excretion of organic acids are poorly developed in neonates. The tubular transport of PAH, which is a weak acid, is around 16 ± 5 mg/min per 1.73 m² in full-term infants and about half this value in premature babies. It increases with age and reaches adult rates, ranging from 55 to 104 mg/min per 1.73 m² by 12 to 18 months (Spitzer, 1978). PAH excretion is limited by a number of factors, including low GFR, immaturity of the systems providing energy for transport, and a low number of transporter molecules. This is further accentuated by a low extraction ratio for PAH and other organic acids caused by the predominance of juxtamedullary circulation in the immature kidney, a phenomenon that allows increased shunting of blood through the *vasa recta* and exclusion of postglomerular blood from the proximal tubular excretory surface (Calcagno and Rubin, 1963).

The kidneys' ability to concentrate urine is lower at birth, especially in premature infants. After water deprivation in the full-term newborn, urine concentrates to only 600 to 700 mOsm/kg, or 50% to 60% of maximum adult levels. Healthy children ranging from 6 months to 3 years of age who were given 20 mcg of desmopressin intranasally demonstrated a gradual rise in urinary concentration, starting from a mean value of 525 mOsm/kg to reach a mean maximum plateau of 825 mOsm/kg (Marild et al., 1992). The major cause for the reduced concentration of urine in the neonate is the hypotonicity of the renal medulla (Aperia and Zetterstrom, 1982). Several mechanisms that contribute to interstitial hypertonicity are not well developed, including urea accumulation in the medulla, length of the loop of Henle and the collecting ducts within the medulla, and Na⁺ reabsorption in the ascending, water-impermeable loop (Trimble, 1970; Horster, 1978; Edwards, 1981). In addition, the collecting duct cells in immature kidneys may be less sensitive to ADH than those of mature nephrons (Schlondorff et al., 1978).

A water-loaded infant can excrete diluted urine with osmolality as low as 50 mOsm/kg. In the first 24 hours of life, however, the infant may be unable to increase water excretion to approximate water intake (Aperia and Zetterstrom, 1982). The diluting capacity becomes mature by 3 to 5 weeks of postnatal life.

FLUID AND ELECTROLYTE NEEDS IN HEALTHY INFANTS AND CHILDREN

The normal need for fluids varies markedly in low-birth-weight and full-term neonates, as well as during infancy and later childhood. This variability in fluid needs is caused by differences in the rate of caloric expenditure and growth, the ratio of evaporative surface area to body weight, the degree of renal functional maturation and reserve, and the amount of TBW at different ages. For instance, compared with older children and adults, infants have greater fluid needs because of higher rates of metabolism and growth; a surface area-to-weight ratio that is about three times greater, resulting in higher insensible fluid loss; and greater urinary excretion of solutes combined with lower tubular concentrating ability, which increases obligatory fluid loss. On the other hand, as previously noted, low-birth-weight and full-term neonates have a greater percentage of TBW compared with older children and adults (Friis-Hensen, 1971; Kagan et al., 1972). This increase in TBW results mainly from expansion of the ECF compartment, which at birth may comprise as much as 50% of the TBW. During the first 3 postnatal days, when this "extra fluid" is eliminated by the kidneys, full-term neonates require less fluid intake (Silverman, 1961; Oh, 1980; Winters, 1982).

The needs of low-birth-weight infants are more variable and may be markedly altered by relatively minor changes in ambient temperature or by phototherapy (Table 5-4) (Fanaroff et al., 1972; Oh and Karecki, 1972; Wu and Hodgman, 1974). In contrast to more mature infants, the immature skin in very low-birth-weight infants (<1500 g) allows disproportionate evaporative heat loss relative to basal metabolic rate (Levine et al., 1929; Levinson et al., 1966). This greater evaporative heat loss, together with a large body surface area, accounts for the much greater insensible fluid needs in infants with very low birth weight.

Parenteral and Oral Fluids and Electrolytes

Except for the first 3 postnatal days when full-term neonates require only 40 to 60 mL/kg fluid per day, in general, 100 mL

TABLE 5-4. Average Fluid Needs of Low-Birth-Weight Infants (mL/kg per 24 hr) During First Week of Life*

Age (days)	Component	Body Weight (g)			
		751 to 1000	1001 to 1250	1251 to 1500	1501 to 2000

*Allowances for increased metabolic rate (cold stress, increased activity) are not included; these infants are in an incubator and naked.

[†]Insensible water loss.

[‡]Volume required to achieve a urine osmolarity of 250 mOsm/kg of renal solute load during the first day (no sodium and protein added), 10 mOsm/kg per day on the second and third days, and 15 mOsm/kg per day on the fourth to seventh days.

of water is needed for each 100 kcal expended. Notably, an additional 15 mL of water is generated endogenously for each 100 kcal used (water of oxidation), which is also available for body functions. In preterm infants, fluid intake may be gradually increased to 150 mL/kg per day, whereas 100 to 125 mL/kg per day generally suffices for infants weighing less than 10 kg. The fluid requirement decreases to 50 mL/kg per day for those weighing 11 to 20 kg and to 20 mL/kg per day for those with body weights above 20 kg. These fluid volumes are sufficient to allow excretion of dietary solute load, as well as to replace insensible fluid loss through the skin, lungs, and intestines (Table 5-5) (Winters, 1982). It should be noted that energy expenditure and, therefore, fluid intake may be significantly increased with stress (Table 5-6) (Holliday et al., 1994).

The high fractional excretion of Na⁺ (FE_{Na+}) in premature infants can lead to negative Na⁺ balance, hyponatremia, neurologic disturbances, and poor growth unless an Na⁺ intake of 3 to 5 mmol/kg per day is given; in full-term infants and older children, 2 to 3 mmol/kg per day is sufficient (Drukker et al., 1980). Premature infants have a lower renal threshold for bicarbonate. In addition, several functional and anatomic factors combine to limit tubular excretion of weak organic acids (Avner et al., 1990). Consequently, premature infants may need small supplements of base. Sodium bicarbonate at 1 to 2 mmol/kg per day is generally recommended for the very small premature infant. Clinically important disturbances in acid-base status are unusual in full-term neonates unless they consume excessive amounts of protein.

DEHYDRATION IN INFANTS AND CHILDREN

Because premature infants and mature neonates have a greater TBW-to-body weight ratio than older infants and children, they tolerate a greater degree of dehydration before manifesting

clinical symptoms. A 10% fluid deficit in such patients may produce symptoms consistent with moderate dehydration, whereas a similar deficit in adults produces severe symptoms. However, dehydration can occur very quickly in infants because disorders such as vomiting or diarrhea very rapidly produce deficits of 50 to 100 mL/kg. Dehydration can also develop in healthy premature infants if insensible water losses are underestimated and are not adequately replaced. This situation may result from use of an open radiant warmer without appropriate plastic shields; forced convection in nonhumidified incubators; skin immaturity, resulting in greater transcutaneous evaporative fluid loss; use of phototherapy, causing insensible fluid loss; hyperthermia; or tachypnea. In older infants and children, gastrointestinal disorders are the major causes of dehydration.

Assessment of Dehydration

Assessment of the extent and type of dehydration is important for formulating a therapeutic strategy. Table 5-7 provides guidelines for the clinical assessment of the severity of dehydration in children (Ellis and Avner, 1985). Laboratory measurements should include hematocrit, blood gases, glucose, calcium, blood urea nitrogen, and albumin, as well as serum and urinary creatinine, osmolality, and electrolytes. A urinalysis should be done to detect cellular elements and to measure specific gravity. Urinary osmolality and specific gravity are of minimal value in assessing dehydration in premature infants with tubular immaturity and in infants with reduced urinary concentrating ability

caused by low protein intake. In general, however, such data, together with a careful medical history, physical examination, and assessment of fluid input and loss, aid in the diagnosis of dehydration and guide adjustment of the amount and composition of fluid administration during various phases of therapy.

Treatment of Dehydration

Severely dehydrated infants and children should be cared for in the intensive care unit with constant monitoring of central venous pressure and serial measurements of the initial laboratory studies. Box 5-2 shows a stepwise approach to the treatment of isotonic, hypotonic, and hypertonic dehydration (Ellis and Avner, 1985). Particular attention should be given to hypernatremic dehydration and brain injury. The initial measures for fluid resuscitation are to stabilize the vital signs by administering crystalloid or colloid solutions and to correct severe acid-base imbalance, hypoglycemia, and other metabolic disturbances. The objective of subsequent measures is to assess further the kind of dehydration and to plan a time course for administration of the appropriate fluid volume and chemical composition needed to correct previous deficits and to replace ongoing losses.

The composition of select parenteral and oral rehydration solutions are shown in Tables 5-8 and 5-9. In most infants and children receiving parenteral solutions for brief periods, the normal fluid and electrolyte needs can be easily satisfied. The caloric needs, however, are not readily met. It is customary

TABLE 5-7. Clinical and Laboratory Assessments of the Severity of Dehydration in Children*

Signs and Symptoms	Mild Dehydration	Moderate Dehydration	Severe Dehydration
Weight loss (%)	5	10	15
Fluid deficit (mL/kg)	50	100	150
Vital Signs			
Pulse	Normal	Increased; weak	Greatly increased; feeble
Blood pressure	Normal	Normal to low	Reduced and orthostatic
Respiration	Normal	Deep	Deep and rapid
General Appearance			
Infants	Thirsty, restless, alert	Thirsty, restless, or lethargic, but arousable	Drowsy to comatose; limp, cold, sweaty; gray color
Older children	Thirsty, restless, alert	Thirsty, alert, postural hypotension	Usually comatose; apprehensive, cyanotic, cold
Skin turgor [†]	Normal	Decreased	Greatly decreased
Anterior fontanel	Normal	Sunken	Markedly depressed
Eyes	Normal	Sunken	Markedly sunken
Mucous membranes	Moist	Dry	Very dry
Urine			
Flow (mL/kg/hr)	<2	<1	<0.5
Specific gravity	1.020	1.020-1.030	>1.030

*When hypernatremia is present, the severity of dehydration may be clinically underestimated because of the relative preservation of extracellular fluid volume (ECFV) at the expense of intracellular fluid volume (ICFV). In such states, neurologic symptoms (lethargy alternating with hyperexcitability, progressing to focal or generalized seizures) may predominate.

[†]With hypernatremia, the skin may have a thick, "doughy" consistency or a soft, velvety texture.

Box 5-2 Stepwise Approach to Fluid Therapy in Infants and Young Children with Moderate (100 mL/kg) to Severe (150 mL/kg) Dehydration*

PHASE I (0 TO 4 HOURS)

1. Assess vital signs and body weight, approximate fluid deficit, and begin fluid balance sheet.
2. Obtain blood for immediate chemical and acid-base analysis, and if possible, obtain a urine sample for chemical and microscopic determinations.
3. Regardless of the type of dehydration (see p ***), begin immediately with 0.9% NaCl at 20 to 30 mL/kg given over 1 hr or faster, depending on the severity of circulatory compromise. If the major cause of dehydration is diarrhea, a mixture of 0.45% NaCl and 0.45% NaHCO₃ is preferred as the initial hydrating solution. If shock is present, administer 5% salt-poor albumin (10 mL/kg).
4. Stabilize vital signs by repeating Step 3 if needed, and continue fluid administration at 10 mL/kg per hour until urine output is established.
5. On the basis of serum electrolyte values, determine the type of dehydration. Also, make a more precise assessment of the total fluid deficit and proceed to phase II.

PHASE II (4 HOURS TO 2 DAYS)

1. Repeat Phase I, Steps 1 and 2.
2. Isotonic dehydration (serum [Na⁺] = 130 to 150 mmol/L).
 - a. Replace 60% to 70% of the remaining fluid deficit over the next 24 hours using a solution containing 0.45% NaCl with 20 mmol/L KCl and 50 g/L dextrose; add 20 mmol NaHCO₃/L if serum pH is <7.25. Replace maintenance fluid plus continued fluid loss using the same solution.
 - b. Replace remainder of fluid deficit over the subsequent 24 hours, in addition to maintenance fluid and ongoing fluid loss, with solution containing 0.2% NaCl with 20 mmol KCl and 50 g/L dextrose.
 - c. Additional dextrose, K⁺, or HCO₃⁻ may be needed and may be added according to serial serum measurements.
3. Hypotonic dehydration (serum [Na⁺] < 130 mmol/L).
 - a. Estimate Na⁺ deficit as follows: [Na⁺] deficit (mmol) = (135 - Serum [Na⁺]) × Total body water (L). Replace 60%

of fluid deficit over the next 24 hours using a similar choice of solution as in Phase I, Step 3, plus 5% to 10% dextrose. If serum [Na⁺] is <120 mmol/L or symptoms of water intoxication are present, give 12 mL/kg of 3% saline solution over 1 hour. During this time, replace maintenance fluid and ongoing fluid loss with the solution noted in Phase II, Step 2b.

- b. Same as for Phase II, Step 2b.
 - c. Same as for Phase II, Step 2c.
4. Hypertonic dehydration (serum [Na⁺] > 150 mmol/L).
 - a. Add fluid deficit, 48 hours of maintenance water, and estimate of continued fluid loss to determine total volume of fluid to be administered initially at a constant rate over 48 hours.
 - b. Use a solution containing 0.2% NaCl with 40 mmol KCl/L and 25 g/L dextrose.
 - c. Add 20 mmol lactate or acetate if plasma pH is <7.25. (Do not use NaHCO₃, because calcium may need to be added to the fluid.)
 - d. If serum calcium level is <8.5 mg/dL, add 1 g calcium gluconate to every 500 mL of administered fluid. Additional calcium is administered as required by serial serum values or clinical symptoms of hypocalcemia. Discontinue when serum calcium level equals 9.0 mg/dL.
 - e. If serum [Na⁺] is decreasing at 0.50 mmol/L per hour, decrease rate of administration by 30% to 50%. If serum [Na⁺] is decreasing at <0.25 mmol/L per hour, increase rate of fluid administration by 30% to 50%.

PHASE III (3 TO 6 DAYS)

1. Same as for Phase I, Steps 1 and 2.
2. Replace any residual fluid or solute deficits over the next 2 to 4 days using the solution described in Phase II, Step 2b.
3. For severe hypertonic dehydration (serum [Na⁺] > 175 mmol/L), Phase II therapy is continued for 3 to 4 days and subsequently may be switched to Phase III therapy, Step 2, when serum [Na⁺] is <145 mmol/L.

*For mild dehydration (50 mL/kg) that requires parenteral fluid therapy, start therapy with phase II.

*Na⁺, K⁺, Cl⁻, and base levels are measured in mmol/L.

to provide 5% dextrose in parenteral solutions. Although this concentration provides only a fraction of the optimal number of calories (20% of total kilocalories needed by infants younger than 1 year of age), it is sufficient to prevent ketosis. In less mature neonates, higher infusion rates of 5% dextrose generally suffice to maintain blood glucose concentrations between 50 to 90 mg/dL (Roy and Sinclair, 1975; Winters, 1982).

Provided that infants and children are less than 10% dehydrated and have minimal electrolyte abnormalities, a good level of consciousness, adequate bowel sounds, and absence of signs of hypovolemia, oral rehydration may be used to replace deficits and maintain fluid volume. Commercially available preparations, such as Pedialyte RS (Ross) with a Na⁺ content of 45 mmol/L may be used. In children with diarrhea in developing countries, the World Health Organization (WHO) has recommended the use of an inexpensive and effective oral rehydration solution consisting of 90 mmol/L Na⁺ and 111 mmol/L of glucose (total osmolality, 311 mOsmol/L). However, glucose-based solutions with a lower osmolality may further optimize fluid and glucose-sodium coupled absorption in the small intestine (Hahn et al., 2001).

PERIOPERATIVE PARENTERAL GUIDELINES OF FLUIDS AND ELECTROLYTES

The optimal perioperative fluid volume and composition requirements in infants and children have not been adequately investigated. The formulas provided by Berry in Table 5-10 are widely used to determine the hourly rates of intraoperative fluid volume administration, which consists of four major components (1986):

1. Maintenance fluid established by Holliday and Segar based on calorie expenditure at different ages (1957).
2. Estimated volume deficit incurred during preoperative fasting or gastrointestinal or by other fluid deficits. One third of such deficits may be replaced during the first hour of surgery, while the remaining volume may be spread over the duration of the surgery.
3. Severity of surgical and nonsurgical trauma. This may comprise the largest volume of fluid loss or fluid redistribution, which derives largely from the ECF compartment.

TABLE 5-10. Guidelines for Fluids for Newborn and Children during the Perioperative Period*

Age (yr)	Hydrating Solution During First Hour (mL/kg)	Hydrating Solution During Following Hours
Neonates		Maintenance fluid: 4 mL/kg/hr 5% to 10% dextrose in 0.75 normal saline plus 20 mEq sodium bicarbonate/L Trauma: 6 to 10 mL/kg/hr for intra-abdominal or 4 to 7 mL/kg/hr for intrathoracic surgery replaced with Ringer's lactate
<3	25	Maintenance fluid: 4 mL/kg/hr 5% Dextrose in normal saline
3 to 4	20	Maintenance and trauma: basic hourly fluid 4 mL/kg 5% Dextrose in normal saline + If mild trauma 2 mL/kg = 6 mL/kg/hr
>4	15	+ If moderate trauma 4 mL/kg = 8 mL/kg/hr + If maximal trauma 6 mL/kg = 10 mL/kg/hr

Modified from Berry FA: Practical aspects of fluid and electrolyte therapy. In Berry FA, editor: *Anesthetic management of difficult and routine pediatric patients*, New York, 1986, Churchill Livingstone.

*Plus blood replacement with blood or 3:1 volume replacement with crystalloid. Replace blood loss in excess of 20 mL/kg with equal volume of packed red blood cells.

4. Blood losses and fluids needed to support systemic blood pressure.

A key goal of perioperative fluid management is to maintain an adequate intravascular volume without the development of hyponatremia. Perioperative patients are at risk for developing hyponatremia because of multiple factors, including prehydration with hypotonic fluid, and nausea, pain, and stress associated with surgery that may result in nonhypovolemic stimulation of ADH release during and after surgery (that is, the inappropriate secretion of ADH) (Burrows et al., 1983; Arieff, 1998). The limited ability of such individuals to excrete a large water load may be influenced by any preexisting edema-forming disorder, obstructive uropathy, or the use of thiazide diuretics or other drugs such as narcotics and antiemetics. However, hypotonic fluid infusion is the most important cause of acute hyponatremia developing in the intraoperative period. Acute hyponatremia results in increased water content in neurons (brain edema) without a change in solute content. This may cause subclinical symptoms such as headache, nausea, vomiting, or muscle weakness in any age group. Younger children are more susceptible to more severe hyponatremic encephalopathy because of their larger brain-to-skull ratio (Moritz and Ayus, 2002). Unless there is a free water deficit, isotonic fluid infusion is recommended during the perioperative period. The need for potassium, calcium, chloride, and bicarbonate (or lactate or citrate, which may be converted to bicarbonate in individuals without hepatic failure) is more controversial. Such components are contained in lactated Ringer's solution, which is nearly isonatremic ($\text{Na}^+ = 130 \text{ mEq/L}$) and isotonic but also

contains K^+ (4 mEq/L), Ca^{2+} (0.9 mmol/L), Cl^- (109 mEq/L), and lactate (27.7 mmol/L).

The amount of dextrose commonly used is 5% (equals 5000 mg/dL or 278 mmol/L). Although this is more than 50 times more concentrated than normal plasma glucose concentration (90 to 100 mg/dL or $\approx 5 \text{ mmol/L}$), the energy delivery based on the volume of fluid given to an infant weighing 10 kg amounts to 50 kcal for the first hour of surgery. Such energy supply is particularly important in preventing hypoglycemia in premature and full-term neonates, who have greater energy requirements than older children, but it may lead to hyperglycemia in 0.5% to 2% of pediatric patients. This disorder may be less common in children receiving regional anesthesia, which reduces the hyperglycemic effects of surgery. Although such transient hyperglycemia is purported to have various potential deleterious consequences, these have not been well substantiated. A review suggests that a solution of lactated Ringer's solution with 1% dextrose is sufficient to prevent both hypoglycemia and hyperglycemia in most children, excluding premature and full-term neonates (Berleur et al., 2003). This practice, however, is not yet widely used.

Perioperative Fluid Management of Premature and Full-Term Neonates

Guidelines for the intraoperative fluid and electrolyte management of premature and full-term neonates are largely based on available knowledge of renal physiology rather than on data obtained from clinical investigations. The physiology of the healthy neonate is influenced by the short tubular length and is characterized by immature reabsorption mechanisms, an activated renin-angiotensin-aldosterone system, and low circulating ADH concentrations (Avner et al., 1990; El-Dahr and Chevalier, 1990). Thus, healthy preterm neonates weighing less than 1300 g, or of fewer than 32 weeks' gestation, have FE_{Na^+} rates that range from 8.2% to 2.1% between 28 and 32 weeks' gestation, with further gradual decrease to less than 1% at term; such rates may increase to 15% with stress (Arant, 1978; Delgado et al., 2003). The high FE_{Na^+} in preterm infants is ascribed to decreased Na^+ reabsorption in the proximal tubule, together with hyporesponsiveness of the distal tubule to aldosterone (Sulyok et al., 1979). When combined with a negative Na^+ balance that results from inadequate Na^+ supplementation as well as decreased sensitivity of the collecting duct to ADH, up to one third of such infants develop significant hyponatremia ($\text{Na}^+ < 130 \text{ mEq/L}$), often manifesting with neurologic disturbances during the first 6 weeks of life (Roy and Sinclair, 1975).

Both premature and term neonates have a limited capacity to excrete K^+ , possibly because of distal tubular insensitivity to aldosterone. Hence, baseline reference plasma K^+ concentrations range from 3.9 to 5.9 mEq/L. Moreover, both preterm and term neonates are capable of producing maximally diluted urine while concentrating capacity is limited. Yet, hyponatremia may develop after administration of large volumes of hypotonic fluids, because fluid excretion may be limited mainly because of low GFR. Stress may cause profound reduction in GFR in premature and term neonates through release of various extrarenal vasoactive and hormonal substances that modify the response of "immature kidneys," thereby further disturbing fluid and electrolyte homeostasis. The higher body content of water and the higher metabolic rate, as well as a propensity to

metabolic acidosis and hypocalcemia in premature newborns, are other important factors in deciding the volume and composition of intraoperative fluids.

Such considerations support the avoidance of boluses of hypotonic fluids while keeping in mind the lower age- and size-appropriate circulatory pressures that may serve as the goal of fluid management. In the absence of the expected physiologic fluid loss, which may range from 5% to 15% of body weight during the first 3 days of postnatal life, fluid volume during this time period may be limited to 60 mL/kg per day, whereas blood pressure support may be sustained with small infusions (5 mL/kg) of 5% albumin or other blood products as needed. Beyond 3 days of life, maintenance fluid volume is gradually increased to 150 mL/kg per day. Deficits beyond the expected physiologic losses and ongoing losses and allowance for surgical trauma may be replaced by a similar fluid composition, but the volume replacement may be more gradual or less rapid than outlined for older infants and children (Table 5-10). Na⁺ bicarbonate and calcium may be supplemented, while K⁺ should be limited. Also, a higher glucose concentration is generally desirable in premature infants. A recommended fluid composition is 0.75 normal saline with 20 mEq sodium bicarbonate/L (total Na⁺ = 135 mmol/L) in 5% to 10% dextrose, as well as 20 mEq/L KCl if plasma K⁺ falls below 3.5 mEq/L. Close attention to change in body weight and urine output and serial measurements of plasma electrolytes are essential in guiding the perioperative fluid management of the sick premature and full-term neonate.

Fluid Management of Children Undergoing Renal Transplantation

The key goal of intraoperative management is to expand the circulatory volume and to maintain systemic blood pressure between the 90th and 95th percentiles for age, gender, and height percentile, so as to allow for adequate perfusion of the renal allograft (Update on the 1987 Task Force Report on High Blood Pressure in Children and Adolescents, 1996). An adult kidney may sequester up to 250 mL of blood, and in infants nearly 50% of the cardiac output may be directed toward perfusion of the allograft. To ensure adequate perfusion of the allograft, the anesthesiologist actually needs to maximize the circulatory volume of the recipient, mainly with crystalloid or packed cytomegalovirus-safe, leukocyte-poor red blood cells if hemoglobin is below 9 g/dL, while closely monitoring the central venous pressure (CVP) and systemic MABP during vessel anastomosis. Near the completion of the vascular anastomoses, 20% mannitol (0.5 to 1.0 g/kg) and intravenous furosemide, 1 mg/kg, may be given before the cross-clamps are released. Before cross-clamp release, CVP should be maintained at 8 to 12 cm H₂O, and the systolic blood pressure and MABP should be kept above 120 mm and 70 mm Hg, respectively. If the MABP is inadequate to achieve good renal perfusion of the adult kidneys, a constant dopamine infusion of up to 5 mcg/kg per minute may be started. Intraoperative blood gases may be monitored frequently, because clamping of the aorta and accumulation of lactic acid can result in metabolic acidosis and vasoconstriction. The critical goal is to obtain immediate allograft function; hypotension after cross-clamp release in an infant with inadequate circulatory volume and an underperfused allograft is a potential catastrophe.

Intravenous furosemide (1 to 2 mg/kg per dose), 25% salt-poor albumin (0.5 g/kg per dose), 20% mannitol (0.3 to 0.5 g/kg per dose), or 0.9 normal saline solution (10 mL/kg bolus) may be given to help promote urine output in the immediate postoperative period.

The volume and composition of intravenous fluid administered during the first 48 postoperative hours are essential to ensure continued renal function. The urine output often exceeds 5 mL/kg per hour. Thus, insensible losses are quantitatively less important. In children with such high urine output, the concentration of dextrose to 1% is routinely reduced to prevent hyperglycemia, which may compound osmotic diuresis because of high preoperative blood urea nitrogen concentrations. Urine output is replaced on a milliliter-for-milliliter basis. In infants and children with body weight below 30 kg, the CVP should be maintained in the range of 5 to 10 cm H₂O, and the MABP should be at greater than 70 mm Hg. One fluid solution that may be used during the first 24 to 48 hours consists of 1% dextrose, 0.45 mEq/L NaCl solution, and 10 to 20 mEq sodium bicarbonate per liter. During the first 24 to 36 hours, additional fluid boluses of 10 mL/kg of normal saline or a 5% albumin solution may be given if CVP falls below 5 cm H₂O, with the goal of maintaining a urine output above certain arbitrary limits (5, 4, and 3 mL/kg per hour for body weight <10 kg, <20 kg, and <30 kg, respectively). In conjunction with such fluid boluses, intravenous furosemide (1 mg/kg) is also administered because renal allografts tend to be dependent on diuretics in the early perioperative setting.

Serum electrolytes (Na⁺, K⁺, Cl⁻, HCO₃⁻, Ca²⁺, P²⁻, Mg²⁺) may be monitored at 8- to 12-hour intervals during the first 2 postoperative days. Potassium chloride is given separately as needed when the plasma K⁺ falls below 3.5 mEq/L. In infants and young children, close monitoring of fluid balance and cardiovascular examination are essential to prevent electrolyte imbalance and fluid overload, which may result in severe hypertension or pulmonary edema, or, in reduction of intravascular volume and acute tubular necrosis (ATN). A bladder catheter inserted intraoperatively is necessary for accurate measurement of urine volume. Unless there are specific urologic indications, the catheter is removed after 4 to 5 days.

Immediate measures must be undertaken to improve postoperative oliguria. Beside the most easily correctable causes of oliguria, such as hypovolemia or a malfunctioning catheter, other potential causes include vascular bleeding or occlusion, ATN caused by prolonged cold ischemia storage, hyperacute rejection, or urinary extravasation or obstruction. In patients with oxalosis, precipitation of calcium oxalate crystals in the graft may cause acute allograft failure. Children with delayed graft function, congestive heart failure, or marked electrolyte abnormalities may require removal of fluid by hemodialysis or peritoneal dialysis. Fluid removal should be performed cautiously to avoid allograft hypoperfusion.

DISORDERS OF SODIUM METABOLISM

Among the many kidney functions, sodium homeostasis via multiple or redundant systems is paramount (Greger, 2000). About 75% of the filtered Na⁺ is reabsorbed in the proximal tubule by the luminal Na⁺/H⁺ exchanger and by the basolateral Na⁺, K⁺-ATPase. Such reabsorption is increased by the action of angiotensin II, which preferentially constricts the efferent

arteriole, thereby increasing filtration fraction and limiting fluid reentry into the peritubular capillaries. Dopamine has an opposing effect in this tubule segment, causing natriuresis. About 20% of NaCl reabsorption occurs in the ascending loop of Henle via the electroneutral $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ transporter (NKCC2), causing the formation of dilute urine. Vasopressin and loop diuretics inhibit such reabsorption. In the distal tubule, Na^+ is reabsorbed by a thiazide-sensitive Na^+/Cl^- cotransporter. In the connecting tubule and in the cortical collecting duct, Na^+ is reabsorbed by the sodium-specific amiloride-sensitive ENaC. The ENaC is activated by aldosterone. In the medullary collecting duct, Na^+ reabsorption is under the influence of ANP.

Much experimental evidence suggests that regulation of ECF volume and maintenance of systemic blood pressure prevail over Na^+ homeostasis; plasma Na^+ concentration and plasma osmolality are secondary regulators (Bricker, 1982; Rees et al., 1984; Gennari, 1998a; Kumar and Berl, 1998; Scheinman et al., 1999). Thus, virtually all of the conditions associated with hyponatremia are primarily disorders of ADH excess with an impaired ability to excrete free water. Disturbances in serum Na^+ concentration may be associated with hypervolemia, normovolemia, or hypovolemia.

Hyponatremia (Plasma $\text{Na}^+ < 135 \text{ mmol/L}$)

In infants and children, hyponatremia occurs much more often than hypernatremia. Although premature and full-term infants are capable of producing hypotonic urine, large, hypotonic fluid loads cannot be excreted, especially during the first 6 weeks of postnatal life. This is most evident during the first week of life, when only 10% to 50%, rather than 80%, of an intravenous challenge of 5% dextrose in water is excreted within 4 hours. The major factor limiting the response to a fluid challenge, especially in preterm infants during the first 5 weeks of postnatal life, is the physiologically low GFR and low urinary flow rate (Svenningsen and Aronson, 1974; Leake et al., 1976). Moreover, high urinary Na^+ excretion and negative Na^+ balance may contribute to the hyponatremia found in about one third of low-birth-weight premature infants (Engelke et al., 1978). This Na^+ wasting has been attributed to deficient proximal and distal tubular reabsorption of Na^+ in such infants (Sulyok et al., 1979).

A positive water balance, rather than Na^+ wasting, has also been implicated in the hyponatremia of healthy premature infants (Rees et al., 1984; Sulyok et al., 1985). Low serum albumin concentrations and reduced plasma oncotic pressure may also bring about fluid retention and “late hyponatremia” in preterm infants (Menon et al., 1986). Thus, independent of the specific pathologic process, preterm infants are at high risk of developing hyponatremia. Therefore, electrolytes should be monitored frequently during the first 4 to 6 weeks of life, especially in infants of fewer than 34 weeks’ gestation. Other causes of hyponatremia in neonates are shown in Table 5-11. In older infants and children, hyponatremia may occur with dehydration, edema-forming states, and syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Such conditions may be differentiated clinically at the bedside. In addition, the simple laboratory studies described in the section on dehydration may reveal urinary hypotonicity, suggesting water intoxication or the dilutional hyponatremia associated with renal failure.

TABLE 5-11. Causes of Hyponatremia

Neonates	Infants and Children
Drugs	
Prolonged use of diuretics in mother or infant	Diuretics (thiazides, osmotic diuretics)
Oxytocin for labor	Arginine vasopressin
Dopamine >5 mcg/kg/min	Carbamazepine
Prostaglandin infusion	Vincristine
Excessive administration of electrolyte-free solutions	Theophylline Cyclophosphamide Morphine Estrogen Barbiturates Nonsteroidal antiinflammatory agents Mannitol Hypotonic 1.5% glycine irrigant Ecstasy Selective serotonin reuptake inhibitors All conditions listed for neonates

TABLE 5-11. Causes of Hyponatremia—cont'd

Neonates	Infants and Children
Miscellaneous	
Negative Na ⁺ balance caused by high FE _{Na⁺} in infants ≤34 weeks gestation	Congestive heart failure
Hypoalbuminemia and decreased oncotic pressure	“Third-space” from burns, peritonitis, or severe muscle injury
Osmotic diuresis caused by hyperalimentation and low TmG	Water intoxication (psychogenic polydipsia, dilute formulas)
Ketonuria	Physical and emotional stress
Congestive heart failure	Cystic fibrosis
Hydrops fetalis	Pain
Congenital nephrotic syndrome	Postoperative
Surgery	Porphyria
Infection	Rickettsial disease
Pulmonary disorders	Fresh-water drowning Pseudohyponatremia in patients with hypoproteinemia, hyperglycemia, or hyperlipidemia Prolonged exercise

FE_{Na⁺}, Excreted fraction of filtered sodium; SIADH, syndrome of inappropriate antidiuretic hormone; TmG, tubular maximum for glucose reabsorption.

Surgery and anesthesia stimulate ADH release. This may persist for 2 or more days and may result in acute hypotonic hyponatremia, particularly when hypotonic fluids are also administered. Even isotonic fluid administration may not prevent hyponatremia caused by ADH release, because such individuals often excrete urine with sodium and potassium concentrations higher than plasma. This is partly because of high ANP concentrations that may coexist in this setting. The syndrome of SIADH is discussed in a later section of this chapter.

Several causes of hyponatremia require special emphasis. Pseudohyponatremia is associated with normal plasma osmolality and occurs in the setting of severe hyperlipidemia, hyperproteinemia, or disorders in which solutes other than sodium such as glucose, mannitol, or sorbitol result in high plasma osmolality. Administration of thiazide diuretics to individuals with cardiac failure may impair distal tubular dilution of urine and the ability to excrete a water load. Finally, large amounts of hypotonic fluid intake during prolonged exercise can cause acute symptomatic hyponatremia and noncardiogenic pulmonary edema, particularly under high ambient temperatures when sweat sodium and chloride are high or when nonsteroidal antiinflammatory agents are administered.

In hyponatremic patients who require parenteral fluids, the decision to correct the plasma Na⁺ level may be based both on clinical symptoms and signs and on the rapidity with which the disorder developed. Children are especially prone to neurologic symptoms (Laureno and Karp, 1997; Lauriat and Berl, 1997; Albanese et al., 2001). In clinical practice, the most important prophylactic measure for preventing hyponatremia is to avoid the infusion of hypotonic fluids. Common symptoms and signs of hyponatremia include headache, fatigue,

nausea, and vomiting; seizures and respiratory arrest are more severe and sometimes delayed manifestations. Guidelines for replacing such sodium deficits may be based on the following formula:

$$\text{Na}^+ \text{ Deficit (mmol)} = \text{TBW} \times (\text{Desired} - \text{Actual plasma Na}^+)$$

For example, the amount of 3% saline solution needed to raise the plasma Na⁺ to 125 mmol/L in a 10-kg infant with a plasma Na⁺ concentration of 115 mmol/L (assuming that TBW is 65% of body weight) may be calculated as follows:

$$\text{TBW} = 0.65 \text{ TBW} \times 10 \text{ kg} = 6.5 \text{ L}$$

$$\text{Na}^+ \text{ Deficit} = 6.5 \text{ L} (125 \text{ mmol/L} - 115 \text{ mmol/L}) = 65 \text{ mmol}$$

In asymptomatic children, the Na⁺ deficit of 65 mmol may be replaced by 422 mL of normal saline (154 mmol/L) given over 24 hours; symptomatic children may receive 127 mL of 3% saline solution (513 mmol/L) given at a rate of about 5 mL/kg per hour, that is, 2.5 mmol/kg per hour

With chronic hyponatremia (over 48 hours in duration), adaptive increases in neuronal osmolytes (glutamine, taurine, phosphocreatinine, myoinositol) diminish cellular uptake of water, thereby preventing brain edema (Gullans and Verbalis, 1993). Thus, in contrast to acute hyponatremia, in which brain edema combined with noncardiogenic pulmonary edema and hypoxia can disrupt neuronal function, such events are uncommon with chronic hyponatremia. Edema-forming disorders such as nephrosis, liver failure, or congestive heart failure are commonly associated with chronic hyponatremia in children. Although physiologic mechanisms stimulate both sodium and fluid retention aimed at preventing hypovolemia, hypovolemic stimuli for ADH release result in free-fluid retention and hyponatremia. Treatment includes the possible correction of the primary disorder, the elimination of diuretics and other offending agents, and limitation of electrolyte-free water intake. Because most individuals with chronic hyponatremia are asymptomatic, and because slow recovery of brain osmolytes coupled with iatrogenic correction of chronic hyponatremia can result in fatal or serious pontine and extrapontine myelinolysis, the rate of correction of serum sodium should be slow (about 0.3 mEq/L per hour) (Ayus et al., 1987; Adrogué and Madias, 2000a).

Syndrome of Inappropriate Secretion of Antidiuretic Hormone

SIADH is a diagnosis by exclusion. It is a hypo-osmolar, saline-resistant form of hyponatremia that occurs in the absence of dehydration, hypoadrenalism, renal failure, hypothyroidism, or myxedema. The nonhypovolemic and nonhypotonic release of ADH impairs the ability of the kidneys to excrete free water.

The main causes of SIADH in infants and children are shown in Box 5-3. Hyponatremia attributable to SIADH is uncommon in premature and full-term infants younger than 4 to 6 weeks old because of factors that limit the urinary concentrating ability to values below 600 mOsm/kg. These factors include a low dietary-solute intake, low circulating levels of ADH, and tubular hyporesponsiveness to endogenous ADH (Svenningsen and Aronson, 1974; Godard et al., 1979). Because of these circumstances, it is indeed difficult to establish the diagnosis of SIADH in such infants. In children with bacterial meningitis,

Box 5-3 Disorders Associated with Syndrome of Inappropriate Secretion of Antidiuretic Hormone

CENTRAL NERVOUS SYSTEM DISORDERS

Asphyxia in newborns: Intraventricular hemorrhage in neonates, mask ventilation
 Encephalitis
 Meningitis (viral, bacterial, tuberculous)
 Cerebrovascular accident (stroke)

MEDICATIONS

Vincristine
 Cyclophosphamide
 Carbamazepine
 Selected serotonin reuptake inhibitors

ADH may be directly released through leaky, inflamed vessels, with secondary alterations in the blood-brain barrier. Despite the hyponatremia, mean plasma ADH levels are relatively high rather than suppressed in such children (3.3 U/mL versus 1 U/mL), and SIADH develops in about 50% of them (Kaplan and Feigin, 1978).

The diagnosis of SIADH should be suspected in any child who has or has had asphyxia, meningitis, a brain tumor, trauma, surgery, or pulmonary disease, as well as in any child who does not appear dehydrated but has hyponatremia, hypochloremia, persistent natriuresis, decreased plasma osmolality (<270 mOsm/kg), and urine that is not maximally dilute (>100 mOsm/kg). The blood urea nitrogen (BUN) and plasma uric acid levels are often reduced.

Na⁺ excretion in SIADH may vary according to the extent of ECF expansion, which may raise the GFR and suppress aldosterone release. In addition, intravascular volume expansion stimulates the secretion of ANP, which enhances the renal excretion of Na⁺. Moreover, Na⁺ excretion matches or exceeds Na⁺ intake.

The initial treatment of children with SIADH who have few or no symptoms may consist of restricting fluid intake to between one half and two thirds of the maintenance rate, or 800 to 1000 mL/m²/day. For severely symptomatic children, 3% saline may be given at a rate of 2.5 mmol/kg per hour, or 5 mL/kg per hour to maintain serum Na⁺ concentrations at or above 125 mmol/L. In patients with urinary osmolality greater than 500 mOsm/kg, an alternative method for faster correction

of severe hyponatremia is to use loop diuretics to inhibit reabsorption of free water while replacing measured urinary Na⁺ losses. In young children, such treatment must be monitored especially closely to prevent volume contraction, hypokalemia, or acid-base imbalance. Furosemide at a dose of 1 mg/kg may be given intravenously one or two times daily. Other therapies used to manage adults with SIADH, such as osmotically active agents, dimethyl chlortetracycline, and lithium carbonate, are generally not used in children with this condition. V_{1a} and V₂ receptor blockers are newer agents that may soon become available and may be more effective in managing this disorder (Palm et al., 2001).

Hypernatremia (Plasma Na⁺ >145 mmol/L)

The causes of hypernatremia in infants and children are listed in Box 5-4. Hypernatremia commonly results from excessive water loss and inadequate water intake and occurs most often in individuals who are unable to communicate or satisfy their own thirst by accessing water. Thus, infants and debilitated individuals of any age are particularly susceptible to this disorder. A primary lack of thirst sensation is a rare cause of this disorder in children. The condition has been caused by improper mixing of formulas and is also increasingly reported with inadequate breastfeeding (Manganaro et al., 2001; Oddie et al., 2001). It is also increasingly recognized as a complication in hospitalized individuals who are very ill and have edema in association with renal failure, heart failure, hypotension, or liver failure, resulting in impaired sodium excretion and sodium overload (Kahn, 1999; Adrogo and Madias, 2000b). Administration of isotonic saline to maintain systemic blood pressure, together with associated hyperglycemia, may promote hypernatremia in these settings. Also, the deliberate use of hypertonic saline for the treatment of brain edema has occasionally resulted in severe hypernatremia (Peterson et al., 2000).

Premature infants and full-term neonates are also prone to hypernatremia because, in addition to an inability to excrete a water load, they are unable to excrete a large solute load (Aperia et al., 1975a, 1975b, 1977). The renal response to an Na⁺ load improves gradually, so that by the end of the first year of life, Na⁺ excretion reaches maximal levels of 16 mmol/hr per 1.73 m² (Aperia et al., 1975b). The limited ability to excrete an Na⁺ load appears to result from a reduced GFR and tubular inability to significantly increase the FE_{Na+} because of the effect of aldosterone in increasing distal tubular Na⁺ reabsorption.

Signs and symptoms associated with hypernatremia in infants include muscle weakness, hyperpnea, apnea, bradycardia, restlessness, a high-pitched cry, lethargy, insomnia or coma, and muscular hypertonicity (Finberg and Harrison, 1955). Older children may exhibit thirst, lethargy, confusion, muscle irritability, rhabdomyolysis, respiratory arrest, seizures, or coma. Tachycardia and hypotension are symptoms of hypovolemia, which is an ominous sign suggestive of extreme dehydration. Because of hypertonicity, fluid shift from the intracellular compartment may result in brain shrinkage, subarachnoid hemorrhage, and permanent brain injury when chronic adaptive solute gain fails to maintain cell volume. Even with such correction, the ensuing neuronal hyperosmolality may predispose a patient to cerebral edema and serious neurologic consequences when rehydration with hypotonic fluid is used aggressively.

Box 5-4 Causes of Hypernatremia**HYPERNATREMIA CAUSED BY PURE WATER LOSS**

Inadequate water replacement of mucocutaneous fluid losses, especially in low-birth-weight infants or young children with fever and lack of access to water; phototherapy; or use of radiant warmers.

Central diabetes insipidus: Low plasma ADH concentration
 Congenital thalamic/pituitary disorders
 Acquired: Trauma or tumor involving the thalamic/pituitary areas

Nephrogenic diabetes insipidus with failure of thirst response:
 High plasma ADH concentration
 Congenital distal tubular and collecting duct unresponsiveness to ADH

Biochemical: Hypercalcemia, hypokalemia

Dietary: Severe protein malnutrition or marked restriction in NaCl intake

Drug-induced: Lithium carbonate, demeclocycline, amphotericin B

Anesthetic-induced: Methoxyflurane
 Hyperventilation

HYPERNATREMIA CAUSED BY WATER LOSS IN EXCESS OF SODIUM LOSS

Lactation failure: Breastfeeding

Overdressing of neonates and infants

Neonates receiving phototherapy or kept in incubators without normothermic control

Diarrhea or colitis

Vomiting

Profuse sweating

Hyperosmolar nonketotic coma

Hypertonic dialysis

Renal disorders with partial diabetes insipidus or limited concentrating ability, including chronic renal failure, polycystic kidney disease, medullary cystic disease, pyelonephritis, obstructive uropathy, amyloidosis, and sickle-cell nephropathy

High protein intake with high urea appearance rate

Diuretics: Mannitol, furosemide

HYPERNATREMIA CAUSED BY SODIUM EXCESS

Excess NaCl intake secondary to improper preparation of oral formulas or electrolyte solutions

Excessive administration of NaHCO_3

Ingestion of NaCl tablets, sea water, or near-drowning in sea water

Inadequate free fluid relative to NaCl intake because of defective thirst mechanism or unconsciousness

Cushing's syndrome or excessive administration of glucocorticoids
 Hyperaldosteronism or excessive administration of mineralocorticoids

The initial laboratory investigation of hypernatremia is similar to that noted in the section on dehydration. In the absence of dehydration, the treatment of hypernatremia depends largely on the underlying disorder. The judicious administration of insulin and avoidance of colloids may be needed in patients with hyperosmolar nonketotic hyperglycemic coma. On the other hand, the administration of free water, together with appropriate replacement of arginine vasopressin, is useful for the treatment of central diabetes insipidus. Surgery may be used to treat several endocrinopathic conditions, whereas thiazides and a diet low in osmotic activity may be of benefit in nephrogenic diabetes insipidus.

In children with acute hypernatremia resulting from pure water loss, such as those with nephrogenic diabetes insipidus, a hypotonic fluid may be given at a rate that decreases plasma osmolality by no more than 2 mOsmol/kg per hour. The rate can be calculated using the following formula:

$$\text{Current TBW} = 65\% \text{ of body weight (kg)}$$

$$\text{Former TBW} = \frac{\text{Current Na}^+ \times \text{Current TBW}}{\text{Desired Na}^+}$$

$$\text{Water deficit (L)} = \text{Former TBW} - \text{Current TBW}$$

For example, to calculate the water deficit in a 10-kg infant with diabetes insipidus, a current serum- Na^+ concentration of 160 mmol/L, and a desired plasma- Na^+ concentration of 140 mmol/L, the following applies:

$$\text{Current TBW} = 0.65 \times 10 \text{ kg} = 6.5 \text{ L}$$

$$\text{Former TBW} = \frac{160 \text{ mmol/L} \times 6.5 \text{ L}}{140 \text{ mmol/L}} = 7.43 \text{ L}$$

$$\text{Water deficit} = 7.43 \text{ L} - 6.5 \text{ L} = 0.93 \text{ L}$$

In children with hypotonic sodium loss, this fluid deficit, together with ongoing fluid losses that occurring during replacement of such a deficit, may be infused as $\frac{1}{8}$ or $\frac{1}{4}$ saline with 1% to 2% dextrose

With chronic hypernatremia, correction of plasma osmolality may occur at a rate of less than 1 mOsmol/kg per hour, or a reduction in serum sodium of less than 0.5 mEq/L. Hypotonic fluids given at a low rate are the most suitable for this purpose. In individuals with accidental sodium loading, furosemide combined with adequate replacement of urine volume with 5% dextrose in water, is usually effective unless renal failure is present, in which case dialysis may be of benefit.

Hypernatremic Dehydration

This disorder is relatively common in premature infants of fewer than 27 weeks' gestation (Baumgart, 1982; Baumgart et al., 1982). Its typical presentation, however, is in infants younger than 12 months of age, with diarrhea being the usual predisposing cause. Such infants have inadequate access to free water, increased insensible water loss, proportionally greater water loss than Na^+ loss from the gastrointestinal tract, and at times, a positive solute balance from the improper use of electrolyte solutions used to manage the diarrhea (Paneth, 1980). Patients with hypertonic dehydration often do not have dehydration of the interstitial fluid compartment and thus may not manifest the poor skin turgor, dryness of mucous membranes, and postural changes in pulse and blood pressure that are often associated with isotonic or hypotonic dehydration. Muscular hypertonicity may result in nuchal rigidity. Other potential complications include brain hemorrhage and edema after rehydration because of fluid shifting into the brain. Because of impaired insulin secretion, initial serum glucose

concentrations often exceed 130 mg/dL in 50% and 200 mg/dL in 25% of children with hypernatremia. Hence, the amount of dextrose administered to such individuals may be limited, or insulin may be given to prevent further hyperglycemia, osmotic diuresis, and hypernatremia. Hypocalcemia also occurs in 10% to 20% of patients with hypertonic dehydration. The management of this disorder is outlined in [Box 5-2](#).

DISORDERS OF POTASSIUM METABOLISM

Potassium (K^+) is the principal cation in the ICF, ranging in concentration from 140 to 160 mmol/L; the normal K^+ concentration in ECF varies between 3.5 and 5.5 mmol/L (same as 3.5 and 5.5 mEq/L). The low proportion of ECF K^+ to ICF K^+ is necessary to maintain transmembrane electrical potential, which is essential for proper functioning of muscle and neural tissue (Suki, 1976).

Potassium Homeostasis

Total body K^+ content correlates with body weight and height and depends on muscle mass (Pierson et al., 1974; Patrick, 1977). In a healthy 20-year-old adult, total body K^+ approximates 58 mmol/kg, a value that decreases progressively with age as muscle mass decreases and body fat increases. In children, the total body K^+ is 38 mmol/kg or less (Pierson et al., 1974). More than 90% of body K^+ is intracellular, and most of that is in muscle tissue. Of the extracellular K^+ , only 1.4% is contained within the ECF, whereas the remaining 8.6% is contained in the bone matrix.

The daily need for K^+ is about 2 mmol/100 kcal of expended energy. The daily intake from a standard Western diet is estimated to be 0.75 to 1.5 mmol/kg of body weight. Typically, approximately 90% of the K^+ ingested each day is eliminated in the urine. Less than 15% is eliminated in the stool, while a negligible amount is lost through the skin. The amount of K^+ eliminated in stool increases, however, with a significant degree of renal failure, reaching 34% of dietary intake at a GFR of less than 5 mL/min per 1.73 m² (Hayes et al., 1967).

The renal tubular mechanisms involved in K^+ homeostasis have been extensively reviewed (Halperin and Kamel, 1998). Nearly 85% of the filtered K^+ is reabsorbed in the proximal tubule and the ascending thick limb of the loop of Henle. The amount of K^+ in the final urine depends on the amount of intake and on the tubular secretion of K^+ .

Two key hormones lower ECF K^+ acutely through redistribution in various tissues. Insulin causes Na^+ to enter and H^+ to exit cells through the electroneutral Na^+/H^+ exchanger, and epinephrine (and β_2 -adrenergic agonists) activates the Na^+ , K^+ -ATPase, which exports three Na^+ ions for each two K^+ ions that enter the cell. Although epinephrine possesses both α - and β -adrenergic properties, it first causes a hyperkalemic response (during the first 1 to 3 minutes) and then a sustained decrease in plasma K^+ concentration through trapping of K^+ in cells by maintenance of an intracellular net negative charge that is essential in determining the electronegative resting membrane potential. By contrast, α -adrenergic agonists raise plasma K^+ concentration by modifying muscle K^+ uptake (Rosa et al., 1980).

Chronic K^+ homeostasis is largely regulated by secretion of K^+ by principal cells that predominate in the renal cortical collecting

duct and are located in smaller numbers in the connecting tubule. The main mechanisms of K^+ secretion are depicted in [Figure 5-5](#). Secretion is aided by the following factors:

1. The plasma aldosterone level that is stimulated by angiotensin II and by high plasma K^+ concentrations. Aldosterone activates the ENaC. This results in Na^+ reabsorption and the development of an electronegative lumen voltage that favors K^+ secretion. An ATP-sensitive ROMK channel aids the efflux of K^+ into the tubular lumen. Many primary adrenal disorders or renal disorders associated with high circulating levels of renin and angiotensin II may lead to secondary stimulation of aldosterone and result in hypokalemia.
2. The peritubular-fluid K^+ concentration directly stimulates Na^+/K^+ -ATPase and may be the most important mediator of K^+ secretion.
3. High urinary flow rates.
4. Hypomagnesemia, possibly through inactivation of the Na^+/K^+ -ATPase pump.
5. Higher pH in the lumen of the cortical collecting duct.
6. Reabsorption of bicarbonate and Na^+ that influences the electronegativity in the lumen of the cortical collecting duct.

FIGURE 5-5. Major factors that regulate K^+ secretion in principal cells. Sodium is reabsorbed across the luminal membrane through ENaC Na^+ channels, with the resultant cellular depolarization increasing the electrical driving force for K^+ secretion through ROMK K^+ channels. 1, Elevation of peritubular $[K^+]$ (oval arrowheads) increases the density of luminal ENaC and ROMK channels, which promote both K^+ secretion by increasing the electrical driving force and K^+ permeability, respectively. Increases in peritubular $[K^+]$ also activate the Na^+ , K^+ -ATPase pump in the basolateral membrane and stimulate aldosterone release. 2, Aldosterone (diamond arrowheads) increases the density of ENaC (but not ROMK) channels and activates the Na^+ , K^+ -ATPase pump, both of which increase the driving force for K^+ secretion. The surface area of the BLM containing the Na^+ , K^+ -ATPase pump undergoes amplification during prolonged exposure to either increased peritubular $[K^+]$ or aldosterone. 3, Kaliuretic factors, including K^+ itself, have been proposed to somehow directly increase K^+ secretion. For example, high luminal $[K^+]$ may directly increase the activity of ROMK channels. (From Gennari FJ, Segal AS: *Hyperkalemia: An adaptive response in chronic renal insufficiency*, *Kidney Int* 62:1-9, 2002.)

Understanding such mechanisms provides physiologic explanations for plasma K^+ alterations and for therapeutic rationale. An example is the individual with hypovolemia and hyperkalemia. The kidneys guard against extracellular volume contraction by raising angiotensin II levels. The latter increases bicarbonate reabsorption in the proximal and distal tubules such that the cortical collecting duct lumen becomes less electronegative and favors $NaCl$ retention but reduced K^+ secretion despite elevated aldosterone levels. In this clinical setting, low urinary flow rate also contributes to hyperkalemia. This is in contrast to individuals with euvoemia or hypervolemia, in whom a high plasma K^+ concentration inhibits proximal tubular bicarbonate reabsorption while it directly stimulates aldosterone release, thereby promoting K^+ secretion (along with Cl^- and HCO_3^-) in the cortical collecting duct. In this setting Na^+ is reabsorbed through the important effect of aldosterone in activating the specific ENaC at the apical membrane of principal cells (Halperin and Kamel, 1998). When ENaC is blocked by trimethoprim, amiloride, or triamterene, kaliuresis is inhibited.

Hypokalemia (Plasma K^+ <3.5 mmol/L or <3.5 mEq/L)

Although hypokalemia usually implies total body K^+ depletion, it can also be caused by transcellular shifts of K^+ without extrarenal losses. Several classifications of hypokalemia have been devised according to whether the condition is acute or chronic, with or without K^+ shift, renal or extrarenal. One classification

is shown in [Box 5-5](#). Because the etiology of renal K^+ wasting is extensive, it may be facilitated by further subclassification on the basis of systemic blood pressure ([Box 5-6](#)).

Hypokalemia without Potassium Depletion

Pseudohypokalemia can result from increased uptake of K^+ when large numbers of leukemic cells (white blood cell count of 100,000 to 250,000 mm^3) are allowed to stand at room temperature (Adams et al., 1981). This confounding effect is eliminated by rapid separation of plasma or by cold storage of blood samples at 4°C.

Hypokalemia caused by intracellular shift of K^+ is particularly common in metabolic or respiratory alkalosis, and approximates a 0.6-mmol/L fall for every 0.1-unit increase in blood pH (Kim and Brown, 1968; Adroque and Madias, 1981). Endogenous or exogenous β -adrenergic agonists such as albuterol, dopamine, dobutamine, and theophylline mediate transcellular shifts of K^+ . Barium poisoning or toluene intoxication resulting from the inhalation of paint or glue vapors can produce hypokalemia by trapping K^+ within the cells (Roza and Berman, 1971; Streicher et al., 1981). Insulin administration activates the Na^+ , K^+ -ATPase, resulting in active K^+ uptake and hypokalemia. This is commonly encountered during the treatment of diabetic ketoacidosis.

Hypokalemic periodic paralysis is a rare autosomal dominant disorder characterized by recurrent episodes of flaccid paralysis of the trunk and limbs that lasts 6 to 24 hours. Paralysis may be accompanied by cardiac arrhythmias, which may be provoked by high carbohydrate intake, exertion, and a

high Na⁺ diet (Griggs et al., 1970). This condition is more common in the Asian population and is characterized by low urinary K⁺ excretion, low transtubular potassium gradient (TTKG), and no acid-base disturbances (Lin et al., 2001). Dietary restriction of salt and carbohydrates together with spironolactone may help prevent such attacks. Intravenous K⁺ infusion should be avoided, because rebound hyperkalemia can occur. Potassium-sparing diuretics and the ingestion of foods rich in K⁺ are of limited benefit in treating or in preventing the disorder. Notably, affected individuals are susceptible to malignant hyperthermia with administration of general anesthesia.

Potassium Depletion

K⁺ depletion accounts for most cases of hypokalemia. Three basic disturbances can affect total body K⁺ balance and result in cellular depletion: poor nutritional intake, extrarenal loss of K⁺, and renal loss of K⁺.

Nutritional Causes

A deficient diet alone is seldom the only cause of symptomatic hypokalemia, because K⁺ is ubiquitous in foodstuffs. In adults, a

reduction in K⁺ intake to less than 10 mmol/day for 7 to 10 days does cause a relative total body K⁺ deficit of 250 to 300 mmol, or a decrement of 7% to 8% (Wormersley and Darragh, 1955). Occasionally K⁺ depletion occurs in hospitalized patients maintained on K⁺-free intravenous fluids. In these instances, the kidney responds by appropriately decreasing K⁺ excretion, although it cannot produce K⁺-free urine.

Extrarenal Causes

Diarrhea, vomiting, and abuse of laxatives result in hypokalemia via a complex process. In addition to K⁺ loss (through vomit and stool), these conditions cause intravascular volume contraction, secondary hyperaldosteronism, and enhanced urinary excretion of K⁺. In children, diarrhea is often accompanied by hyperchloremic metabolic acidosis, whereas laxative abuse is associated with normal acid-base status or mild metabolic alkalosis (Welfare et al., 2002).

Copious perspiration from intense physical exertion in a hot environment causes K⁺ depletion (Knochel et al., 1972). This condition is characterized by normal plasma K⁺ concentration with total body K⁺ depletion and a high rate of urinary K⁺ excretion. Loss of K⁺ via sweat and secondary hyperaldosteronism explains the depletion state and the urinary loss; the sustained normal plasma K⁺ level, however, is not adequately explained. The human colon responds to aldosterone in a similar fashion, resulting in an increase in the renal collecting duct transepithelial potential difference followed by an increase in Na⁺, K⁺-ATPase activity (Thompson and Edmonds, 1971). Glucocorticoids are kaliuretic, and evidence suggests that their effect is independent of any action on the mineralocorticoid receptor (Bia et al., 1982). Furthermore, glucocorticoids appear to cause an increase in K⁺ and a decrease in Na⁺ stool concentration that can be associated with increased Na⁺, K⁺-ATPase activity (Charney et al., 1975).

Renal Causes

Renal wastage of K⁺ occurs by several different but interrelated mechanisms. First, an increased Na⁺/K⁺ exchange may occur in the distal tubule in conditions associated with increased circulating mineralocorticoid or glucocorticoid concentrations, resulting in circulatory volume expansion and suppression of plasma renin and aldosterone levels. Hypokalemia often occurs in Conn's syndrome (Ganguly and Donohue, 1983). It also occurs in 30% of patients with adrenal hyperplasia (Cushing's syndrome) (Prunty et al., 1963). The ingestion of certain foods and the use of glucocorticoids or other drugs that possess mineralocorticoid activity can also result in hypokalemia. Licorice, for example, contains large amounts of glycyrrhizic acid, which impairs adrenal 11 β -hydroxysteroid dehydrogenase action. This impairs the degradation of endogenous glucocorticoids, resulting in a mineralocorticoid-like response (Brem, 2001).

Second, increased delivery of Na⁺ to the distal tubule, which occurs in various proximal tubulopathic conditions (including proximal renal tubular acidosis and Fanconi's syndrome) may enhance K⁺ secretion. Similarly, thiazides and loop diuretics increase the delivery of Na⁺ to the distal nephron, thus promoting K⁺ excretion (Kassirer and Harrington, 1977). This effect by diuretics is augmented by concomitant Cl⁻ depletion and by contraction alkalosis (Seldin and Rector, 1972; Kassirer and Harrington, 1977).

Third, large concentrations of nonabsorbable anions in the distal tubules, such as penicillins, increase the electronegativity of tubular fluid and induce kaliuresis and hydrogen ion secretion (Lipner et al., 1975). Carbenicillin is particularly notorious for causing hypokalemia, because it is secreted actively in the proximal tubule, and high concentrations of the anion are delivered to the distal nephron (Stapleton et al., 1976).

Fourth, kaliuresis may occur secondary to direct damage to the renal epithelium. Conditions such as pyelonephritis and other interstitial nephritides may be associated with hypokalemia. Similarly, antibiotics such as amphotericin B, polymyxin, and outdated tetracycline can lead to K^+ depletion through their direct toxic effects on the renal tubules (Chesney, 1976). Aminoglycosides result in magnesium and K^+ wasting, probably because of a change in the permeability of the renal epithelium to these cations (Humes et al., 1982). Experimentally, hypokalemia tends to occur within the first 7 days of aminoglycoside administration and often occurs in the absence of overt acute tubular necrosis and renal failure. This tubular defect and the risk of hypokalemia usually resolve within 1 to 2 weeks after discontinuation of the drug.

Fifth, several genetic disorders are known to cause K^+ depletion. Box 5-6 characterizes such disorders of hypokalemia based on the presence or absence of hypertension. Hypertensive disorders may be associated with high peripheral renin activity (renovascular disorders comprise the majority of such causes in children) or low renin states that are then associated with either increased plasma mineralocorticoid or glucocorticoid levels, or with more direct activation of the principal cell amiloride-sensitive ENaC in the cortical collecting duct. The result may be salt retention, chronic volume expansion, renin and aldosterone suppression (hence “pseudoaldosteronism”), and hypertension as exemplified in Liddle’s syndrome. In Liddle’s syndrome, treatment that consists of blocking the mineralocorticoid receptor with spironolactone, or blocking the aldosterone receptor with amiloride, is less effective than the combination of triamterene and a low-salt diet.

Manifestations of Potassium Depletion

Hypokalemia results in multiple biochemical and neurophysiologic disturbances (Box 5-7) (Weiner and Wingo, 1997). Chronic hypokalemia and moderate degrees of acute K^+ depletion (5% to 10% of total body K^+) are generally well tolerated. More profound deficits result in clinical manifestations that are independent of the underlying cause of hypokalemia.

Biochemical consequences of hypokalemia include impairment in insulin release and insulin end-organ sensitivity, thereby increasing the risk of hyperglycemia or precipitation of frank diabetes mellitus (Rowe et al., 1980). Metabolic alkalosis results from direct stimulation of proximal tubular bicarbonate reabsorption and ammonia genesis by increased proton secretion via H^+ , K^+ -ATPase located in the collecting duct and by decreasing citrate excretion. Inadequate ADH response and increased synthesis of angiotensin II in the central nervous system may cause polyuria. Hypokalemia may raise plasma ammonia levels in patients with reduced hepatic function. Also, chronic renal K^+ wasting may predispose to formation of renal cysts and interstitial fibrosis (Torres et al., 1990).

Many of the symptoms of acute hypokalemia relate to disturbed neuromuscular functions. Skeletal muscle weakness

Box 5-7 Pathophysiologic Consequences of Hypokalemia

NEUROMUSCULAR

Peripheral nerves: Paresthesias
Skeletal muscle: Fatigue, weakness, cramps, flaccid paralysis, rhabdomyolysis, myoglobinuria
Smooth muscle: Paralytic ileus, increased vascular pressor resistance

RENAL

Concentration defect: Polyuria, nocturia
Sodium retention
Increased ammonia production, enhanced bicarbonate reabsorption
Reduced renal blood flow, decreased GFR
Predisposition to urinary tract infection
Interstitial fibrosis
Cyst formation

METABOLIC

Metabolic alkalosis
Impaired hepatic glycogen storage
Impaired protein metabolism
Insulin resistance
Increased plasma ammonia
Growth retardation

HORMONAL

Impaired growth hormone release
Impaired insulin secretion
Decreased aldosterone secretion
Increased renin release
Increased synthesis of prostaglandins

Gill JR, Santos F, Chan JCM: Disorders of potassium metabolism. In Chan JCM, Gill JR, editors: *Kidney electrolyte disorders*, New York, 1990, Churchill Livingstone.

caused by cell hyperpolarization is the earliest manifestation of K^+ depletion. Plasma K^+ concentrations below 3.0 mEq/L lower the resting cell membrane potential and thereby increase the voltage needed to reach the threshold and initiate an action potential (Fig. 5-6). The symptoms include restless legs syndrome, fatigue, muscle cramps, paralysis, and rhabdomyolysis. Frank muscle necrosis may occur with serum K^+ concentrations below 2.0 mEq/L (Knochel, 1982). Cardiac manifestations of hypokalemia include abnormalities in rhythm as a result of slowed repolarization (Helfant, 1986). The presence of electrocardiographic changes helps to exclude spurious hypokalemia and may aid the decision to manage the hypokalemia urgently (see Fig. 5-6). Abnormalities include depression of the ST segment, lower T-wave voltage, and appearance of U waves. Patients receiving cardiac glycosides are especially at risk of developing such abnormalities. Hypokalemia also impairs the cardiovascular responses to norepinephrine and angiotensin II.

K^+ depletion may lead to several functional and structural abnormalities in the kidneys, including reduced RBF and GFR, renal hypertrophy, tubuloepithelial dilation, vacuolization, and sclerosis (Relman and Schwartz, 1956). Functionally, patients develop urinary acidification and concentration defects and polyuria.

■ **FIGURE 5-6.** Typical action potential profile. Normal threshold is influenced by Ca²⁺ concentrations, whereas K⁺ concentrations affect the resting potential. (From Leaf A, Cotran RS: Renal pathophysiology, ed 2, New York, 1980, Oxford University Press.)

Diagnosis of Hypokalemia

When hypokalemia is diagnosed, the underlying pathophysiologic cause may not be apparent. Measurement of urinary K⁺ levels may be helpful. A urinary concentration of less than 10 mEq/L suggests nearly maximal conservation and usually implies extrarenal loss of K⁺. Urinary K⁺ concentrations exceeding 30 mEq/L suggest the kidneys are a likely route for the depletion. In patients maintained on diuretics, the caveat is that within hours of discontinuation of these agents, the kidneys respond by conserving K⁺.

Treatment of Hypokalemia

The treatment of hypokalemia requires extreme caution, as the magnitude of loss is difficult to measure clinically. In the absence of cellular shifts, the percent of total body K⁺ deficit may be grossly estimated from the plasma concentration and intracellular K⁺ content ($0.40 \times \text{body weight} \times 145 \text{ mEq/L}$) as follows:

$$\begin{aligned} \text{Plasma K}^+ 2.6 \text{ to } 3.5 \text{ mEq/L} &= 5\% \text{ to } 10\% \\ \text{Plasma K}^+ 1.8 \text{ to } 2.5 \text{ mEq/L} &= 10\% \text{ to } 20\% \\ \text{Plasma K}^+ < 1.8 \text{ mEq/L} &= >20\% \end{aligned}$$

The concurrence of hypokalemia and metabolic acidosis suggests an even greater K⁺ depletion. In such children the correction of the acidosis should follow, rather than precede, the correction of hypokalemia. Guidelines for potassium supplementation in dietary or medication forms are available for adults but not for children (Cohn et al., 2000). Such supplements should be given with close monitoring of blood levels, particularly when combined with potassium-sparing diuretics such as amiloride and spironolactone. Providing details of managing children with specific disorders associated with chronic hypokalemia is beyond the scope of this chapter. Supplemental K⁺ at a dosage of 3 to 5 mEq/kg per day (plus maintenance amounts) may be given orally as the chloride salt, because most disorders are associated with chloride depletion. Several liquid and salt preparations are available. Microencapsulated

salt preparations are associated with a lower rate of gastrointestinal bleeding and hemorrhage. In patients with combined K⁺ and phosphate depletion, the phosphate salt is recommended. Magnesium correction may help improve the hypokalemia, especially in refractory states such as appears in Gitelman's syndrome (Whang et al., 1992). High K⁺-containing foods are useful in individuals whose conditions are managed with laxatives and diuretics.

Intravenous K⁺ repletion is often desirable for the management of acute hyperkalemia, particularly when neuromuscular or electrocardiographic alterations are clinically evident. Concentrations as high as 40 mEq/L may be given peripherally. Higher concentrations should be administered in large veins to prevent phlebitis. Concentrations exceeding 60 mEq/L generally are not recommended. In special clinical situations, higher K⁺ concentrations may be delivered in limited fluid volumes by diluting 20 mEq of KCl in 100 mL in a Soluset with a microdrip and infusing it at a rate not to exceed 0.5 mEq/kg per hour (maximum, 30 to 40 mEq/hr). Such higher infusion rates, although reserved for life-threatening situations, can be given perioperatively in hypokalemic children with close cardiac monitoring and frequent measurement of plasma K⁺ concentrations.

Hyperkalemia (Plasma K⁺ >5.5 mEq/L in Infants and Children, or >6 mmol/L in Neonates)

Conditions causing hyperkalemia are listed in Box 5-8. Hyperkalemia may result from a surprisingly small increase in total body K⁺ or may result rapidly from transcellular shift. Normally, the kidneys provide the crucial defense against slight elevations in serum K⁺ level. Thus, with a few exceptions, hyperkalemia commonly occurs in conditions characterized by decreased urine flow rates or marked reduction in GFR. In the absence of renal insufficiency, drugs are responsible for most cases of hyperkalemia. Several agents may cause hyperkalemia by increasing the K⁺ load, by facilitating transcellular K⁺ efflux, or by impairing renal excretion of K⁺ (Table 5-12) (Perazella, 2000).

Box 5-8 Causes of Hyperkalemia**PSEUDOHYPERKALEMIA**

Ischemic blood drawing
 Hemolysis
 Thrombocytosis ($>1,000,000/\text{mm}^3$)
 Leukocytosis ($>500,000/\text{mm}^3$)
 Familial “leaky red blood cell”
 Infectious mononucleosis

TRANSCELLULAR SHIFTS

Metabolic acidosis
 Hyperglycemia with insulin insufficiency
 Extracellular hypertonicity
 Tissue damage: Trauma, exercise, burns, rhabdomyolysis, asphyxia, catabolic states, sepsis, rejection of transplanted organs (such as liver, kidney)
 Drugs (see Table 5-12)
 Familial hyperkalemic periodic paralysis

INCREASED POTASSIUM LOAD

Dietary excess, oral or intravenous K^+ supplementation
 Use of aged bank blood/hemolysis
 Geophagia
 High doses of K^+ -containing medications (such as potassium penicillin)

DECREASED RENAL EXCRETION OF POTASSIUM

Acute renal failure
 Chronic renal failure
 Low-birth-weight infants
 Spitzer-Weinstein syndrome
 Drugs (see Table 5-12)
 Hyporeninemic hypoaldosteronism
 Type I and type II pseudohypoaldosteronism
 Addison’s disease (hypoaldosteronism)
 Obstructive uropathy
 Impaired steroidogenesis: Congenital adrenal hyperplasia, mitochondrial disorders, Smith-Lemli-Opitz syndrome

Transcellular Shift

Among the conditions associated with altered K^+ distribution across cell membranes is poorly controlled insulin-dependent diabetes mellitus. The mechanism is twofold: hyperglycemia causes hypertonicity with resultant extrusion of K^+ from cells, whereas insulin deficiency does not promote K^+ entry into the cells (Ammon et al., 1978). These effects are independent of aldosterone response and level of renal function.

Cellular damage from rhabdomyolysis, burns, tissue necrosis, or fulminant rejection of a grafted organ may release large quantities of K^+ into the extracellular space. In patients with normal renal function, most of the excess K^+ is easily excreted. In those with large tumor lysis after induction of chemotherapy or those with renal impairment, however, hyperkalemia may occur (Araseneau et al., 1973).

During metabolic acidosis, part of the H^+ load is buffered within cells in exchange for K^+ . It has been noted that for every 0.1-U decrease in blood pH, serum K^+ changes by 0.6 mEq/L. Changes in plasma HCO_3^- concentration may influence K^+ concentration independent of changes in pH. Clinically, serum K^+ can be decreased with bicarbonate administration in the absence of metabolic acidosis (Fraley and Adler, 1977).

TABLE 5-12. Medications That Can Cause Hyperkalemia and Their Mechanisms of Action

Medication	Mechanism
Increased Potassium Input	
Potassium supplements and salt substitutes	Potassium ingestion
Nutritional and herbal supplements	Potassium ingestion
Stored packed red blood cells	Potassium infusion
Penicillin G potassium	Potassium ingestion
Transcellular Potassium Shifts	
β -Blockers	Decrease β -driven potassium uptake
Intravenous amino acids (lysine, arginine, and ϵ -aminocaproic acid)	Release of potassium from cells
Succinylcholine	Depolarize cell membranes
Digoxin intoxication	Decrease Na^+ , K^+ -ATPase activity
Impaired Renal Excretion	
Potassium-sparing diuretics	
Spironolactone	Aldosterone antagonism
Triamterene	Block Na^+ channels in principal cells
Amiloride	Block Na^+ channels in principal cells
Nonsteroidal antiinflammatory drugs	Decrease aldosterone synthesis Decrease renal blood flow and glomerular filtration rate
ACE Inhibitors and Angiotensin II Receptor Blockers	
	Decrease aldosterone synthesis
	Decrease renal blood flow and glomerular filtration rate
Trimethoprim and pentamidine	Block Na^+ channels in principal cells
Cyclosporine and tacrolimus	Decrease aldosterone synthesis Decrease Na^+ , K^+ -ATPase activity Decrease K^+ channel activity
Heparin	Decrease aldosterone synthesis

 ACE, Angiotensin-converting enzyme.

Pseudohyperkalemia

Ischemic blood drawing is a very common cause of pseudo-hyperkalemia, especially in infants and young children who undergo blood sampling by lancing and squeezing the finger or heel, or because of hemolysis from prolonged application of tourniquets. Several conditions cause false elevations in plasma K^+ concentrations, including thrombocytosis, leukocytosis, hemolysis, and sampling of ischemic blood (Chumbley, 1970; Ingram and Seki, 1962). In general, immediate determination of K^+ in plasma instead of in serum minimizes the release of K^+ from the cellular components and avoids the development of pseudohyperkalemia.

High Potassium Intake

An oral intake of as little as 50 mmol of K^+ (<2% of normal body K^+ content) by an adult can cause a transient increase in plasma K^+ of 0.5 to 1.0 mmol/L. From 70% to 90% of this load is sequestered intracellularly within 15 to 30 minutes and ultimately excreted in the urine. Thus, when renal function is normal, large amounts of K^+ may be ingested without adverse sequelae. However, the intravenous administration of K^+ at a rate higher than 0.5 mmol/kg per hour may result in life-threatening hyperkalemia. In patients with renal insufficiency, hyperkalemia may occur because of increased excretory burden associated with large doses of potassium penicillin (10^6 units contain 1.7 mEq K^+), juices with high K^+ content, overuse of salt substitutes (1 g contains 10 to 13 mEq of K^+), and the administration of banked stored blood (1 L contains 15 to 20 mEq of K^+) (Bostic and Duvernoy, 1972).

Decreased Potassium Excretory Capacity

Regardless of the underlying cause, impaired renal function predisposes a patient to K^+ retention and hyperkalemia. However, hyperkalemia is uncommon even in advanced renal failure unless endogenous or exogenous loads are excessive. Nonoliguric individuals with impaired GFR can excrete ordinary dietary intakes of K^+ until GFR decreases to as low as 5 mL/min per 1.73 m² (Gonick et al., 1971). An increase in K^+ secretion per nephron, as well as increased colonic secretion, helps to prevent hyperkalemia in severe renal failure (van Ypersele de Strihou, 1977). If hyperkalemia occurs with a GFR above 10% of normal, other causes should be sought, such as worsening metabolic acidosis, increased catabolism, cell injury, hemorrhage, or use of potassium-sparing diuretics.

The most common clinical setting in which hyperkalemia occurs is acute oliguric renal failure of any etiology. In addition to the decreased excretory capacity, an increased K^+ burden is imposed by an increased catabolic rate. The daily increase in K^+ concentration averages 0.3 to 0.5 mmol/L in oliguric acute renal failure under optimal conditions of nutrition, whereas the increase exceeds 0.7 mmol/L in patients with trauma, a high rate of catabolism, or both (Schrier, 1979).

Hyporeninemic hypoaldosteronism accounts for more than 50% of adults or older children with unexplained hyperkalemia accompanying adequate, albeit decreased, GFR (Schambelan et al., 1980). Most such patients have a component of chronic interstitial renal disease, and more than half have diabetes mellitus.

Obstructive uropathy may be associated with a defect in K^+ excretion associated with a mild hyperchloremic acidosis, decreased fractional excretion of K^+ , and mild hyperkalemia (Battle et al., 1981) because of end-organ resistance to the action of aldosterone or because of hypoaldosteronism by itself.

Many drugs or drug combinations can cause hyperkalemia, particularly when KCl supplements are coadministered (Table 5-12) (Perazella, 2000). For example, a potassium-sparing diuretic and an angiotensin-converting enzyme inhibitor can result in life-threatening hyperkalemia-induced arrhythmia, especially in diabetic patients with renal insufficiency or other high-risk groups. The mechanisms may involve one or more of the following:

- Lowered aldosterone synthesis caused by angiotensin-converting enzyme inhibitors
- Inhibition of Na^+ , K^+ -ATPase and other transporters in principal cells by digitalis, trimethoprim, cyclosporine, or tacrolimus. Succinylcholine increases plasma K^+ concentration by increasing the permeability of muscle membranes during depolarization (Gronert and Theye, 1975).

Adrenal destruction brought on by hemorrhage, tumor, infection, autoimmune polyglandular syndrome, or adrenoleukodystrophy can cause an Addison-like presentation with fatigue, muscle weakness, hypotension, and hyponatremia. Congenital disorders associated with reduced steroidogenesis may have a similar clinical presentation (Ten et al., 2001; Bonny and Rossier, 2002). Hereditary disorders that exhibit similar sodium wasting and hyperkalemia, but that show increased, rather than low, plasma renin and aldosterone levels, include the autosomal dominant (self-limited) and autosomal recessive (permanent) forms of pseudohypoaldosteronism I. In these disorders, a defective mineralocorticoid receptor is responsible for hyponatremia, hyperkalemia, and metabolic acidosis (Ten et al., 2001; Bonny and Rossier, 2002). In contrast, pseudohypoaldosteronism Type II (Gordon's syndrome) is a sporadic or autosomal dominant condition associated with hypertension, suppressed plasma renin activity, normal plasma aldosterone concentration, and mild hyperchloremic acidosis that respond well to thiazide diuretics (Milford, 1999).

Manifestations of Hyperkalemia

The clinical manifestations of hyperkalemia relate to interference with the electrophysiologic activities of muscle. Under the influence of hyperkalemia, the ratio of intracellular to extracellular K^+ is decreased, resulting in delayed depolarization, hastened repolarization, and slow conduction velocity (Knochel, 1982). The most important effect involves the heart. Diagnostic electrocardiographic alterations include tenting or symmetric peaking of the T wave in the precordial leads and depression of the ST wave (Fig. 5-7). In severe hyperkalemia, there is widening of the QRS complex, lengthening of the PR interval, first-degree or second-degree heart block, disappearance of the P wave, and, finally, atrial standstill. Ventricular fibrillation or asystole follows the development of a sinusoid wave. Although the magnitudes of hyperkalemia and of cardiotoxicity correlate well, arrhythmias may develop with even mild hyperkalemia when other metabolic abnormalities such as hyponatremia, acidosis, or calcium disorders coexist.

Hyperkalemia affects electrical activities in noncardiac muscle as well. Such manifestations as paresthesias, weakness, and flaccid paralysis that spare the head and trunk are not rare.

Clinical Evaluation of Dyskalemia

The initial step involves a clinical assessment of circulatory volume (Halperin and Kamel, 1998; Rodriguez-Soriano et al., 1990). Assuming that Na^+ and fluid conservation mechanisms are intact, the next step is to determine whether the excretion of K^+ is appropriate relative to expected values in healthy children (Rodriguez-Soriano et al., 1990). If K^+ excretion is abnormal, urinary flow rate and K^+ excretion rate are measured separately. The flow rate in the terminal portion of the cortical collecting duct (CCD) is proportional to the osmolar particles in urine,

- Direct suppression of renin release by β -blockers or by prostaglandin synthetase inhibitors leading to secondary hypoaldosteronism

■ **FIGURE 5-7.** The relationship between plasma potassium concentration and electrocardiographic changes. (From Winters RW: *The body fluids in pediatrics*, Boston, 1973, Little, Brown.)

which consist primarily of urea derived from protein metabolism, with Na^+ and Cl^- contributing to a lesser extent. This is derived as follows:

$$\text{Flow rate in CCD} = (U_{\text{osm}} \times U_{\text{vol}}) / P_{\text{osm}}$$

where U refers to urine and P refers to plasma. Under the influence of ADH, a minimum flow rate in the CCD is 1L for each 300 mOsmol excreted, which is approximately the osmolality of plasma. Thus, a lesser osmolality in the CCD would result in a lower flow rate and reduced net K^+ secretion

If the flow rate in the CCD is adequate, then the ability of principal cells to secrete K^+ depends largely on the appropriate activity and secretion of K^+ by ENaC and ROMK channels (see Fig. 5-5). This is assessed by measurement of urinary chloride excretion and by estimation of the transtubular $[\text{K}^+]$ gradient, or, TTKG:

$$\text{TTKG} = ([\text{K}^+]_{\text{U}}) \div (U_{\text{osm}} / P_{\text{osm}}) \div [\text{K}^+]_{\text{P}}$$

This equation provides an estimate of the K^+ concentration in the CCD relative to plasma K^+ concentration after correcting for further water reabsorption past the CCD, in the medullary collecting duct, under the influence of ADH. TTKG values under 4.9 in infants or under 4.1 in children indicate a reduced ability to secrete K^+ as a result of hypoaldosteronism or pseudohypoaldosteronism, and the situation requires further investigation of renal and adrenal disorders (Rodriguez-Soriano, 1990). Such evaluation may consist of venous blood gas measurements; electrolyte measurement of gastric fluids,

urinary nitrogen, plasma renin, aldosterone, and cortisol and corticosterone concentrations; and, possibly, identification of mutated genes.

Treatment of Hyperkalemia

The strategy of managing hyperkalemia depends on the plasma K^+ concentration, renal function, and cardiac manifestations (Box 5-9). Mild to moderate hyperkalemia without major electrocardiographic changes responds to a simultaneous decrease in K^+ intake and increase in Na^+ intake. In certain instances, loop diuretics may be used to increase K^+ excretion.

The fastest means of reversing cardiotoxicity is to antagonize the membrane effects of high plasma K^+ concentration. Calcium decreases the threshold potential of excitable tissue, thus restoring the normal differences between threshold and transmembrane potentials (see Fig. 5-6).

Calcium gluconate, infused intravenously at 100 to 200 mg/kg per dose, is an effective initial measure even in the absence of hypocalcemia.

If the clinical setting permits administration of a high fluid volume rate, a solution consisting of glucose and insulin added to 0.9N NaCl is the most effective means for lowering plasma K^+ concentration (10% glucose solution, with insulin added at a ratio of 1 unit per 4 or 5 g of glucose). In children with metabolic acidosis, K^+ can be driven intracellularly by intravenous NaHCO_3 , given at 1 to 2 mEq/kg per dose. Both treatment measures decrease plasma K^+ levels within minutes and are effective regardless of acid-base or insulin status. Hyperventilation (with resultant hypocapnia and respiratory alkalosis) abruptly increases the urinary excretion of K^+ . Its effect, however, is not sustained beyond 24 hours (Gennari and Segal, 2002).

Sodium polystyrene sulfonate (Kayexalate), a cation-exchange resin, can be administered at a dose of 1 g/kg, in

Box 5-9 Treatment of Hyperkalemia

TREATMENT OF MILD HYPERKALEMIA

Decrease dietary K^+ burden
Discontinue K^+ -containing medications or K^+ -sparing diuretics
Eliminate conditions that favor hyperkalemia: Acidosis, sodium restriction

TREATMENT OF MODERATE TO SEVERE HYPERKALEMIA To Reverse Membrane Effects

Calcium gluconate, 100 to 200 mg/kg per dose

To Produce Transcellular Shifts

Sodium bicarbonate, 1 to 2 mmol/kg per dose
Glucose, 0.3 to 0.5 g/kg as 10% glucose solution with insulin, 1 unit per 4 to 5 g glucose IV
Albuterol by nebulizer
Hyperventilation

To Remove Potassium

Kayexalate, 1 g/kg per dose PO or enema
Furosemide, 1 mg/kg per dose IV
Dialysis (hemodialysis or peritoneal dialysis)
Hemofiltration (continuous arteriovenous hemofiltration or continuous venovenous hemofiltration with or without dialysis)

sorbitol for oral use, or in mineral oil for rectal instillation. This dosage may be repeated every 2 to 4 hours. Typically, plasma K^+ concentration decreases by 1 mEq/L per dose. The onset of action for the oral route is 1 to 4 hours, whereas an enema removes K^+ within 30 to 60 minutes. In patients with renal failure, repeated administration of sodium polystyrene sulfonate may impose a high Na^+ load with resultant hypertension and edema.

Dialysis may be useful in the treatment of hyperkalemia, especially in patients with renal failure. Hemodialysis can remove 1 mEq K^+ /kg per hour. The duration of this effect depends on the rate of ongoing endogenous release of K^+ . Peritoneal dialysis is less efficient than hemodialysis, but it can be performed more safely in small infants and children.

DIURETIC THERAPY

Pharmacologic agents that promote diuresis represent a major advance in the treatment of edema and hypertension. The principal therapeutic purpose of these agents is to induce a negative Na^+ and fluid balance. The increase in urine output merely reflects the linkage of salt and water transport in the kidneys: solute reabsorption limits the osmotic reabsorption of water, and diuresis ensues.

Classification of Diuretics and Site of Action

In this section diuretics are classified according to the site of action in the nephron. This system is oversimplified, because

several agents have pharmacologic effects that are not localized to a single tubular site (Table 5-13).

Proximal Tubule Diuretics

Mannitol

This is a nonmetabolizable sugar that is osmotically active. Mannitol is freely filtered at the glomerulus, but it is poorly reabsorbed and therefore obligates the renal excretion of water (Warren and Blantz, 1981). It limits water reabsorption in segments of the nephron that are freely permeable to water, namely, the proximal tubule, the descending limb of Henle's loop, and the collecting tubule. This results in a decreased gradient for $NaCl$ reabsorption in the late proximal and distal tubule, which, together with a mannitol-induced washout of the hypertonic medullary interstitium brought about by increased blood flow, potentiates natriuresis. The magnitude of the natriuresis depends on the pretreatment intravascular volume status and on RBF.

Mannitol has limited use when GFR is severely compromised and may aggravate congestive heart failure or other conditions in which intravascular volume is often increased.

In nonedematous oliguric conditions, mannitol may be used to increase water excretion rather than natriuresis. It is also useful in the prophylaxis of acute renal failure because of its ability to expand the extracellular volume, increase tubular-fluid flow, redistribute blood to hypoxic inner cortical and outer medullary regions, and scavenge free radicals (Warren and Blantz, 1981). The rationale for using mannitol in oliguric acute renal failure is to convert the condition into a nonoliguric

TABLE 5-13. Site, Mechanism, Duration of Action, and Dose of Diuretics

Site of Action	Diuretic	Mechanism of Action*	Action (hr)			Dose (mg/kg/day)	Potency
			Onset	Peak	Duration		
Proximal tubule	Acetazolamide (Diamox)	Carbonic anhydrase inhibitor	1-2	2	4-6	5-7	Mild
	Mannitol	Osmotic diuretic	1-2	2	Variable	0.5-1.0 g/kg per dose	Moderate
Ascending loop of Henle	Furosemide (Lasix)	Inhibition of chloride reabsorption	0.5-1	2-4	6-8	2-6 (oral), 1-6 (IV)	Very potent
	Bumetanide (Bumex)		0.25-0.5	0.45	5-8	0.08-0.6 (oral), 0.04-0.4 (IV)	Very potent
	Ethacrynic acid (Edecrin)		0.5-1	2-4	6-8	1-2	Very potent
Distal convoluted tubule (early)	Hydrochlorothiazide (HydroDiuril)	Inhibition of sodium reabsorption	1-2	4-6	12-24	2-3.5	Moderate
	Chlorothiazide (Diuril)		1-2	4-6	12-24	20-40	Moderate
	Metolazone [†] (Zaroxolyn)		2	6	24-6	0.5-5.0 mg/day	Moderate to potent
Distal convoluted tubule (late) and collecting duct	Spironolactone (Aldactone)	Competitive inhibitor of aldosterone	8-24	24-48	48-72	1-2	Mild
	Triamterene (Dyrenium)	Direct effect by reducing electrical potential between cell and lumen	2-4	6-8	19-24	3	Mild

*See text for details of mechanisms of action.

[†]Metolazone acts at the proximal tubule (as a carbonic anhydrase inhibitor) and unlike the other thiazides, can be used in patients with renal failure. It is only available in oral form.

one, thereby permitting easier management of fluids, nutritional support, and electrolytes. In addition, mannitol has been reported to decrease the incidence of acute renal failure in cardiopulmonary bypass surgery, myoglobinuria, transfusion of mismatched blood, and contrast nephropathy (in patients with chronic renal failure) (Byrne, 1966; Eneas et al., 1979; Anto et al., 1981, Rigden et al., 1984). The usual dose is 0.5 g/kg given intravenously as a 12.5% solution. A good response is usually observed within 2 hours and consists of a urine output of at least three times the volume injected (10 to 12 mL/kg). In oliguric conditions, however, loop diuretics may be used initially because these may be effective without risking further intravascular volume expansion.

Because osmotic diuretics such as mannitol reduce TBW and intracellular volume, they help to decrease intracranial pressure in neurosurgical conditions associated with brain edema and to decrease intraocular pressure in ophthalmologic procedures. They also ameliorate symptoms associated with dialysis-related disequilibrium syndrome (Arieff, 1982).

Acetazolamide

This carbonic anhydrase inhibitor causes sodium bicarbonate diuresis and a reduction in total body bicarbonate stores. Its effectiveness is limited by the development of hyperchloremic metabolic acidosis. The bicarbonaturia induces phosphaturia, whereas the metabolic acidosis increases calcium excretion (Lemman et al., 1967; Beck and Goldberg, 1973). Both factors are responsible for renal stone formation and nephrocalcinosis during prolonged use of acetazolamide. It can cause severe K^+ wasting, especially during the acute bicarbonaturic phase.

Therapeutically, acetazolamide may be effective in the chronic treatment of glaucoma, in alkalinization of the urine, in the treatment of acute mountain sickness, to stimulate ventilation in central sleep apnea, to reduce endolymph formation in Meniere's disease, and in the treatment of refractory hydrocephalus (Conger and Falk, 1977; Vogh, 1980; Greene et al., 1981; Brookes et al., 1982; White et al., 1982; Maren, 1987).

Loop Diuretics

These agents are rapidly absorbed from the gastrointestinal tract and are excreted by glomerular filtration and by tubular secretion (Rane et al., 1978). Diuretic response is usually very rapid after intravenous administration and greatly exceeds that produced by most other diuretic agents.

Loop diuretics inhibit the NKCC2 electroneutral cotransport system in the luminal membrane of both the medullary and the cortical segments of the ascending limb of the loop of Henle, where 20% of the filtered Na^+ and Cl^- are reabsorbed (Burg et al., 1973). They also inhibit NaCl transport at the level of the proximal and distal tubules and are known to possess weak carbonic anhydrase inhibitory properties (Radtko et al., 1972; Imbs et al., 1987). Loop diuretics tend to increase RBF without increasing GFR, especially after intravenous administration. Increased RBF is associated with a redistribution of blood flow from the medulla to the cortex and within the cortex (Higashio et al., 1978). The hemodynamic effects appear to involve the renin-angiotensin system and vasodilatory prostaglandins (Gerger, 1983). These hemodynamic effects have not been linked to the diuretic response, however, and tend to be short-lived.

By markedly increasing the movement of solute in the distal segments of the nephron, loop diuretics induce potent diuresis and natriuresis. The large Na^+ load presented to the distal tubule is associated with increased K^+ and H^+ ion secretion. Thus, hypokalemia and metabolic alkalosis may ensue. The hypercalciuric action of loop diuretics makes them suitable agents for treatment of hypercalcemia, but their use in newborns with chronic respiratory disorders has been implicated in the development of nephrocalcinosis (Dirks, 1979; Schell-Feith et al., 2000).

In addition to inducing rapid diuresis, loop diuretics appear to improve cardiac function before the onset of diuresis by increasing venous capacitance (Dikshit et al., 1973). These drugs are also effective in the treatment of refractory edema as long as interstitial fluid can be mobilized without compromising intravascular volume. Because furosemide, ethacrynic acid, and bumetanide are effective with GFR as low as 10 mL/min per 1.73 m², they are useful for the management of edema in patients with chronic renal failure. Despite the obvious benefits of high-dose furosemide in certain experimental models of acute renal failure (deTorrente et al., 1978), its use in humans for conversion of oliguric acute renal failure to a nonoliguric state is controversial (Brown et al., 1981). All loop diuretics are ototoxic when given in large dosages to patients with severe renal failure (Gallagher and Jones, 1979). Unique to the loop diuretics, ototoxicity has been ascribed to drug-induced changes in the electrolyte composition of endolymph.

Finally, furosemide must be used cautiously in infants with hyperbilirubinemia because it is highly protein bound (Prandota and Pruitt, 1975) and thus capable of displacing bilirubin from albumin (Wenneberg et al., 1977). This phenomenon usually occurs with repeated dosages exceeding 1 mg/kg (Aranda et al., 1978).

Distal Convoluted Tubule Diuretics

The diuretic action of thiazides depends on the direct inhibition of the Na^+/Cl^- cotransporter in the distal convoluted tubule, which is accompanied by enhanced excretion of K^+ and hypokalemia (Kunau et al., 1975). By increasing Na^+ delivery to the cortical collecting duct, thiazides induce a kaliuresis that rivals that of loop diuretics, whereas the natriuresis of furosemide is 5 to 10 times greater than that produced by thiazides.

Apart from their use in managing edema and hypertension, thiazides have also been used successfully for treatment of hypercalciuria because they augment the reabsorption of calcium in the distal tubule (Sutton, 1986). Thiazides can also reduce polyuria and polydipsia in nephrogenic diabetes insipidus (Shirley et al., 1982). Such beneficial effect probably results from plasma volume depletion with an attendant decrease in GFR, which promotes NaCl and obligatory fluid reabsorption in the proximal tubule. This effect of thiazides is augmented by dietary salt restriction. Finally, thiazides are useful in the treatment of proximal renal tubular acidosis, characterized by marked bicarbonaturia. Depletion of intravascular volume is necessary to increase proximal bicarbonate reabsorption, an effect that is also promoted by restricting dietary Na^+ (Donckerwolke et al., 1970).

Combined therapy with thiazides and loop diuretics can be used to manage refractory edema that is caused by cirrhosis, nephrotic syndrome, or severe cardiac dysfunction. Synergy

occurs when these classes of diuretics are administered together. NaCl delivery out of the proximal tubule is increased, whereas Na⁺ reabsorption is inhibited in the loop of Henle and distal tubule. Thus, the resulting diuretic action is greater than that achieved with either agent alone (Ghose and Gupta, 1981). Similarly, metolazone, a thiazide-like diuretic, is particularly useful in the management of edema that accompanies congestive heart failure, renal disorders such as nephrotic syndrome, and states of decreased renal function. While other thiazides lose their diuretic effectiveness at a CrCl of about 30 to 40 mL/min, metolazone retains its effectiveness, especially when used in conjunction with loop diuretics. This is attributed to its action on the proximal tubule in addition to its action on the distal diluting tubular segments. A limiting factor to the use of metolazone is its availability in tablet form, which may preclude its use in patients whose gastrointestinal tract cannot be used. In such instances, chlorothiazide may be used intravenously in conjunction with loop diuretics.

Adverse effects of thiazides include hypokalemia, metabolic alkalosis, carbohydrate intolerance, hyperuricemia, hyponatremia in the presence of severe restriction of dietary Na⁺, and hypercalcemia (Manuel and Steele, 1974; Popovtzer et al., 1975; Hoskins and Jackson, 1978). In general, the hypercalcemia resolves within a few days.

Late Distal Tubule Diuretic

These diuretics are primarily K⁺-sparing diuretics. Because of their distal site of action, they are not potent when they are used alone. Their major use is as adjuncts to thiazide or loop diuretics. Spironolactone competitively antagonizes aldosterone, whereas triamterene and amiloride inhibit the ENaC in the cortical collecting duct and thereby limit kaliuresis (Stoner et al., 1974; Corvol et al., 1981). In addition, triamterene may depress the GFR through its effect on urinary prostaglandin E₂ excretion (Favre et al., 1982). In general, these agents should be used cautiously in children with renal failure because of the danger of hyperkalemia. Furthermore, concurrent use of K⁺-sparing diuretics and K⁺ supplements is hazardous.

ANESTHETIC AGENTS AND THE KIDNEYS

Inhalational and intravenous anesthetics and many intravenous and oral analgesics and sedatives may influence renal function through their hemodynamic, cardiovascular, autonomic, and neuroendocrine effects. The trauma of surgery and possible accompanying dehydration are more likely, however, to result in renal dysfunction through elevations in plasma renin, aldosterone, and ADH that accompany surgery. These perturbations are reduced by morphine or halothane anesthesia (Philbin and Coggins, 1978). Prolonged release of ADH associated with surgical stress and use of anesthetics, combined with high infusions of hypotonic fluids, may result in hyponatremia. Moreover, well-hydrated patients may not experience reductions in glomerular filtration and may actually experience increases in RBF with subsequent increases in urine output and sodium excretion (Bastron et al., 1981; Philbin et al., 1981).

More direct nephrotoxic acute renal failure was common before discontinued use of the fluorinated anesthetic methoxyflurane (Pezzi et al., 1966; Halpren et al., 1973). Inhaled anesthetics in current use, such as sevoflurane and halothane,

result in fewer metabolic byproducts composed of inorganic fluoride, as well as oxalic acid; hence renal dysfunction is rare with these agents. Fluoride, in particular, may decrease ATP availability and thereby impair the action of the Na⁺, K⁺-ATPase in the loop of Henle and in the collecting duct. This may result in a salt-losing, vasopressin-resistant high-urine-output renal dysfunction (Whitford and Taves, 1973). Conversely, a preexisting reduction in GFR may prolong the pharmacologic half-life of many agents that have significant renal elimination, such as morphine, and thereby exacerbate their hemodynamic and other systemic adverse effects. Moreover, because of short tubular length and enzymatically immature secretory mechanisms, proximal tubular secretion of propofol metabolites and of other substances may be limited in infants under 6 months of age. Awareness of the previously discussed developmental differences in GFR and tubular function in preterm and term neonates and early infancy is essential in determining the choice and dosage modification of many such agents.

DISORDERS OF DIVALENT ION METABOLISM

Calcium

Calcium plays many vital physiologic roles, not the least of which is to maintain the health of bones. It is essential for the stability of cellular membranes and regular neuromuscular excitation-contraction coupling, blood coagulation, and transport and secretory functions of the cell. Furthermore, Ca²⁺ acts as a “second messenger” in the signal transduction of extracellular hormones and other substances that affect numerous cellular functions.

Calcium Homeostasis

A typical adult diet contains about 800 mg of elemental Ca²⁺, of which only 20%, or about 4 mmol (160 mg), is absorbed principally in the duodenum and jejunum. This net Ca²⁺ absorption is closely matched by renal excretion such that all but 4 mmol of the 270 mmol of Ca²⁺ filtered by the kidneys is excreted in the urine. This contrasts with a net Ca²⁺ absorption of 40% to 45% in infants and a rate as high as 80% in low-birth-weight infants and breastfed babies (Liu et al., 1989; Matkovic and Heaney, 1992). Normal daily bone turnover in adults accounts for 14 mmol of Ca²⁺ and comprises only a small proportion of the bone reservoir consisting of about 20 mmol, or 800 g.

Plasma Ca²⁺ is maintained at a concentration of 9 to 10.5 mg/dL (2.2 to 2.4 mmol/L) as total calcium, with approximately 40% of this value comprising the protein-bound nonfiltratable fraction, and 10% is chelated. Ionized calcium accounts for 47% of the total circulating Ca²⁺ and ranges from 4 to 5 mg/dL (1.0 to 1.25 mmol/L) (Moore, 1970).

The extent of protein binding per deciliter of plasma is approximately 0.8 mg of Ca²⁺ for every 1 g of albumin and 0.16 mg for each 1 g of globulin. Furthermore, a threefold increase in serum phosphate or sulfate concentration results in a 10% decrease in serum Ca²⁺ concentration. In addition, the binding of Ca²⁺ to albumin is pH-dependent between pH 7 and 9. An acute increase or decrease in the pH by 0.1 units results in an increase or a decrease, respectively, of protein-bound Ca²⁺ of 0.2 mg/dL (0.05 mmol/L). Thus, infusion of blood

products, rapid correction of metabolic acidosis by infusion of sodium bicarbonate, or acute alkalosis caused by hyperventilation in the presence of hypocalcemia may all precipitate tetany and/or seizures because of increased binding of Ca^{2+} to albumin. Calcium homeostasis is complex and occurs at three main levels, often involving similar calcitropic hormones, receptors, and transporters.

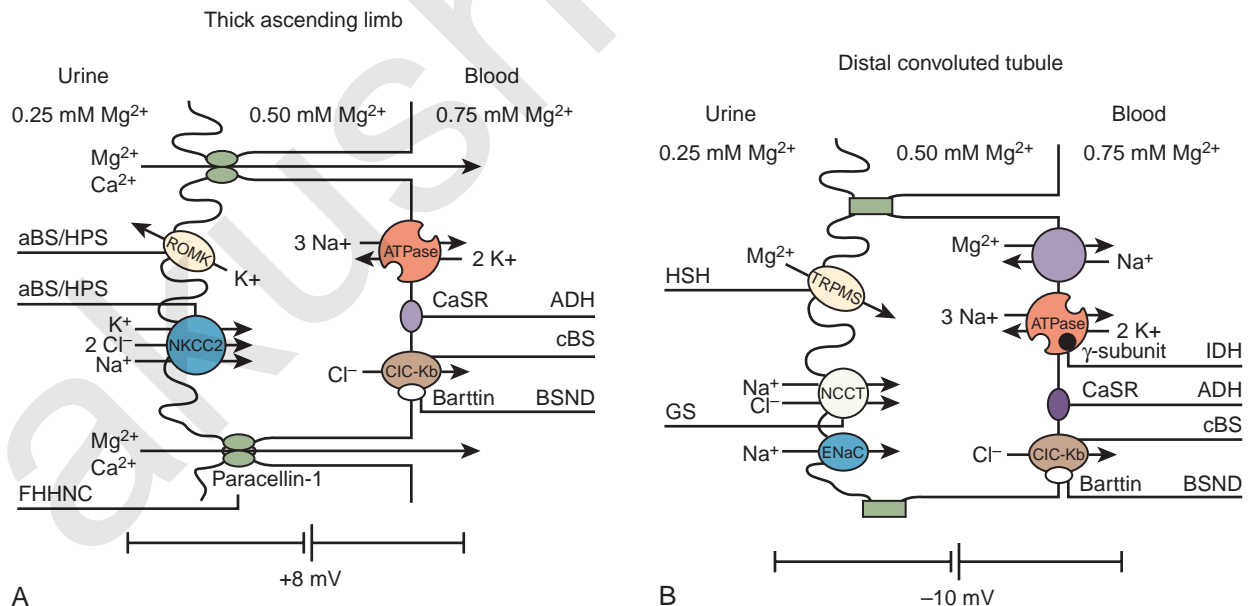

In the small intestine, Ca^{2+} is absorbed via two mechanisms: a nonsaturable passive paracellular pathway such that a high Ca^{2+} intake results in higher Ca^{2+} absorption, and an active energy-dependent intracellular pathway that predominates when calcium intake is low. This latter mechanism is highly influenced by 1,25-dihydroxyvitamin D_3 [$1,25(\text{OH})_2\text{D}_3$ or calcitriol], which stimulates the synthesis and/or activity of enterocyte apical Ca^{2+} transporters known as CaT1 and ECaC . Calcium crosses the cytoplasm bound to calbindin- D_{9k} and then is extruded against an electrochemical gradient at the basolateral side by plasma membrane Ca^{2+} -ATPase (PMCA). Disorders leading to hypersensitivity or increased synthesis of $1,25(\text{OH})_2\text{D}_3$ can result in increased intestinal absorption and hypercalciuria. Lactose stimulates calcium absorption even in the absence of vitamin D via an effect that may involve 25-hydroxylase (Lester et al., 1982). This may explain the higher plasma Ca^{2+} levels seen in infants. The efficiency of intestinal Ca^{2+} absorption depends on needs, age, gender, dietary intake, pregnancy, and vitamin D status.

The kidneys play a major role in Ca^{2+} homeostasis. The mechanisms of renal transport have been reviewed extensively by Suki and Rouse (1991), Bushinsky (2001), and Frick and Bushinsky (2003) and are reviewed here briefly. Only the fraction of Ca^{2+} not bound to protein is filtered, accounting for 60% of the plasma concentration. About 70% of the filtered

Ca^{2+} is reabsorbed in the proximal convoluted tubule through a paracellular pathway involving solvent drag of salt and water (convection). It is then returned to the circulation from the interstitium. About 20% of the filtered Ca^{2+} is reabsorbed in the thick ascending limb of the loop of Henle via both paracellular and transcellular processes. Paracellin is the major protein component of the paracellular tight junction. Similar to the pathway of magnesium reabsorption, the Ca^{2+} -sensing receptor (CaSR) detects small changes in interstitial Ca^{2+} concentrations and regulates the apical ROMK channel, thereby producing a lumen-positive voltage that drives Ca^{2+} through the tight junctions (Fig. 5-8, A and B). In this tubular segment mutations in paracellin, NKCC2 transporter, ROMK, CaSR, or inhibition of the NKCC2 transporter by loop diuretics can result in significant hypercalciuria, nephrocalcinosis, and osteopenia. The distal convoluted tubule reabsorbs 8% of the filtered calcium mainly via an active transcellular transport. This mechanism is similar to that found in enterocytes, except that intracellular calcium transport occurs through binding to calbindin- D_{28k} and extrusion takes place mainly through a $\text{Na}^+/\text{Ca}^{2+}$ exchanger and less by PMCA. This mechanism is influenced by parathyroid hormone (PTH) and perhaps by other calcitropic hormones.

Bone reabsorption and formation also contribute to calcium homeostasis. The mechanisms by which osteoclasts and osteoblasts affect these processes are less well understood, but several hormonal regulators and transport processes are thought to resemble those found in the intestine and kidneys.

PTH is a major regulator of serum Ca^{2+} homeostasis. PTH acts via cAMP to increase proximal tubular Ca^{2+} excretion while it increases reabsorption in the distal and collecting ducts, so that the net effect is conservation of Ca^{2+} (Suki and Rouse, 1991). PTH also resorbs Ca^{2+} from the vast skeletal reservoir

■ **FIGURE 5-8. A**, Magnesium reabsorption in the thick ascending limb of the loop of Henle. Driving force for the paracellular reabsorption of magnesium and calcium is the lumen-positive electrochemical gradient generated by the transcellular reabsorption of NaCl . **B**, Magnesium reabsorption in the distal convoluted tubule. In this segment, magnesium is reabsorbed by an active transcellular pathway involving an apical entry step probably via a magnesium permeable ion channel and a basolateral exchange mechanism, presumably an $\text{Na}^+/\text{Mg}^{2+}$ exchanger. The molecular identity of this exchanger is still unknown. See text for details. *ADH*, Autosomal dominant hypocalcemia. (From Konrad M, Weber S: Recent advances in molecular genetics of hereditary magnesium-losing disorders, *J Am Soc Nephrol* 14:249-260, 2003.)

of Ca^{2+} and increases intestinal Ca^{2+} absorption by stimulating 1α -hydroxylase and calcitriol synthesis by proximal tubular epithelium, thereby guarding against hypocalcemia. High plasma phosphorus concentrations directly stimulate PTH release. This causes phosphaturia and raises serum Ca^{2+} concentration by the body's tendency to maintain a constant $\text{Ca}^{2+} \times \text{P}^{2-}$ product. Conversely, preterm infants who are fed diets low in phosphorus develop hypophosphatemia and are susceptible to hypercalcemia through direct stimulation of calcitriol synthesis.

Calcitriol is another major independent homeostatic factor. It increases intestinal absorption of Ca^{2+} , and in concert with PTH, it stimulates osteoclast-mediated resorption of bone. High serum calcium concentrations, on the other hand, interact with the parathyroid cell Ca^{2+} -sensing receptors to inhibit PTH secretion. High calcitriol levels also exert a negative feedback role on PTH secretion.

Other endogenous or exogenous substances play a lesser role in Ca^{2+} homeostasis. A hypercalcemic substance produced in several malignant or paraneoplastic syndromes is known as PTH-related peptide (PTHrP). The N-terminal of PTHrP functions like PTH and often contributes to humoral or tumoral hypercalcemia. Increased synthesis of other hypercalcemic cytokines, such as interleukins-1, -6, and -11, as well as tumor necrosis factor- α and prostaglandins, may also be released in various malignancies (Mundy and Guise, 1997). Macrophages may be an important source of such factors that act synergistically to produce significant osteolysis. Glucocorticoids lower calcium levels by reducing its intestinal absorption. Excessive thyroid hormone accelerates bone turnover, and calcitonin lowers serum calcium by increasing its excretion at the medullary portion of the thick ascending limb of the loop of Henle while inhibiting bone turnover. Immobilization may raise serum calcium levels by lowering the inflow of calcium into bone hydroxyapatite. Hypervitaminosis D, or a combination of vitamin A administration and decreased vitamin A catabolism in individuals with reduced renal function, may cause hypercalcemia by stimulating intestinal absorption.

Hypocalcemia (Plasma Ionized Calcium <1.0 mmol/L, or Total Calcium <7.0, 8.0, and 8.8 mg/dL, or <1.7, 2.0, and 2.2 mmol/L in Preterm, Term Newborns, and Children, Respectively)

The causes of hypocalcemia in neonates and children are listed in [Box 5-10](#), and the biochemical features of these disorders are shown in [Table 5-14](#) (Umpaichitra et al., 2001). "Early neonatal hypocalcemia" develops within the first 48 hours after birth in about 33% of infants of fewer than 37 weeks' gestation, in 50% of infants of insulin-dependent diabetic mothers, and in 30% of infants with neonatal asphyxia. In this disorder, there appears to be a significant correlation between gestational age and serum calcium levels. Plasma PTH concentrations are usually normal. Hence, the mechanism for the hypocalcemia may involve decreased calcium intake associated with increased P^{2-} loading and possibly resistance to the action of PTH (Linarelli et al., 1972; Tsang et al., 1973). Elevated calcitonin levels have been recently suggested as a cause of early hypocalcemia, particularly in neonatal asphyxia (Venkataraman et al., 1987).

In term infants, hypocalcemia may occur 5 to 7 days after birth and is often associated with the ingestion of cow's milk

Box 5-10 Causes of Hypocalcemia* in Neonates and Children

EARLY NEONATAL HYPOCALCEMIA

Preterm: Related to decreased PTH secretion
 Neonates with asphyxia: Limitation of calcium intake
 Infants of mothers with diabetes: Related to maternal urinary magnesium loss because of glycosuria, which results in hypomagnesemia

LATE NEONATAL HYPOCALCEMIA (END OF THE FIRST WEEK OF LIFE)

Dietary phosphate loading
 Hypoparathyroidism
 Hypomagnesemia

CHILDHOOD HYPOCALCEMIA

Vitamin D-related: Vitamin D-deficient rickets, vitamin D-dependent rickets type I (1β -hydroxylase deficiency), and type II (end-organ resistance to calcitriol)
 Parathyroid hormone-related: Hypoparathyroidism, pseudohypoparathyroidism type I and type II
 Calcium/phosphorus-related: Malabsorption, hyperphosphatemia
 Organ-related: Hepatic rickets, acute pancreatitis, renal osteodystrophy
 Miscellaneous: Drugs, such as calcitonin, phosphate, and bisphosphonates; magnesium deficiency; calcium-sensing receptor defect

Modified from Umpaichitra V, Bastian W, Castells S: Hypocalcemia in children: pathogenesis and management, *Clin Pediatr* 40:305-312, 2001.
 *Causes, at different ages at onset, can overlap.

(Root and Harrison, 1976). Maternal vitamin D status may also play an important role in late neonatal hypocalcemia (Cockburn et al., 1980). Nutritional deficiency of vitamin D, inadequate photoconversion of vitamin D, and decreased calcium intake are currently uncommon causes of hypocalcemia and rickets in infants. In neonates with micrognathia, hypertelorism, fishmouth, low-set posteriorly rotated ears, cardiac disease, branchial dysembryogenesis, or DiGeorge's anomaly, must be considered. In this disorder, there is aplasia or hypoplasia of the parathyroid glands in association with diverse genetic deletions that can be detected by fluorescent in situ hybridization (FISH) DNA probes (Hong, 1998).

In children, autoimmune disorders that are either isolated or associated with other polyglandular syndromes comprise the majority of causes of acquired hypoparathyroidism and are often diagnosed by detection of specific autoantibodies directed against various endocrine tissues. Pseudohypoparathyroidism is associated with mutations in the PTH receptor, which is a G protein-coupled receptor. Circulating PTH levels are high, but there is PTH resistance in bone and the kidneys or in the kidneys alone (Farfel et al., 1999). In the first subtype (Ia), the phenotype consists of hereditary osteodystrophy (Albright's dystrophy), short fingers, short stature, mental retardation, and subcutaneous calcifications, whereas in subtype Ib, the phenotype is normal. Pseudohypoparathyroidism type II is caused by disturbances in the pathway past the PTH receptor. Plasma PTH levels are also increased in this disorder.

Hypocalcemia is a common complication of hypomagnesemia. Three mechanisms have been suggested: resistance to the action of PTH; subnormal secretion of PTH; and defective

Ca²⁺/Mg²⁺ exchange in bone (Estep et al., 1969; Suh et al., 1973; Chase and Slatopolsky, 1974). Correction of hypomagnesemia has been shown to restore calcium homeostasis.

Hepatic disorders that interfere with vitamin D and other fat-soluble vitamin absorption and conversion to 25-vitamin D₃ or calcidiol, can cause hypocalcemia, particularly in debilitated or immobilized individuals. In children with renal failure resulting from a variety of chronic renal disorders, impaired conversion of calcitriol by proximal tubular α -hydroxylase to the active calcitriol form, along with phosphate retention, impaired intestinal absorption of Ca²⁺, and high circulating PTH concentrations that impair osteoclastic activity all combine to cause hypocalcemia (Slatopolski and Delmez, 1992). Mutations in 1α -hydroxylase lead to vitamin D-resistant rickets, an autosomal dominant disorder that appears at 4 to 12 months of age with low serum Ca²⁺ but normal 25-vitamin D₃ levels. If calcitriol levels are normal, hypocalcemia can be the result of mutations in the vitamin (calcitriol) D receptor (VDR), which is also an autosomal dominant, vitamin D-resistant condition that appears at 3 to 12 months with rickets and alopecia (Levine and Carpenter, 1999).

Manifestations of Hypocalcemia

Many of the symptoms associated with hypocalcemia are attributed to increased neuromuscular excitability. These symptoms include numbness and tingling of the hands, toes, and lips; irritability, anxiety, and depression; a prolonged QT interval; cardiac arrhythmias; and congestive heart failure. In the neonatal period, jitteriness, twitching, and seizures are more common. The seizures may be generalized or focal and usually are short-lived but repetitive, with very little postictal depression. Chvostek's and Trousseau's signs and a high-pitched cry are useful indications, especially in the older infant and child. Infants may have cyanosis, vomiting, or feeding intolerance, whereas older children may experience laryngospasm. With prolonged hypocalcemia, cataracts can develop because of the increased intake of Na⁺ and water by the lens (Ireland et al., 1968).

Treatment of Hypocalcemia

If hypocalcemia is not life threatening, it is preferable to administer a calcium-containing solution amounting to 15 mg of elemental calcium/kg body weight infused over a period of 4 to 6 hours. For clinical emergencies (seizures, tetany), 10% calcium gluconate is infused, preferably in a large vein or central venous catheter, to provide an elemental Ca²⁺ dosage of 2 to 4 mg/kg body weight in newborns and 2 to 3 mg/kg body weight in children, given over 5 to 10 minutes under constant electrocardiographic monitoring. Subsequently, 25 to 50 mg of intravenous elemental Ca²⁺/kg per day may be used until hypocalcemia resolves. If hypomagnesemia is also present, 50% magnesium sulfate (48 mg elemental Mg²⁺/mL) at a dosage of 6 mg of elemental Mg²⁺/kg body weight may be infused over 1 hour.

Hypoparathyroidism requires the use of calcitriol at an initial dosage of 0.01 mcg/kg body weight daily to maintain plasma Ca²⁺ concentrations between 8.5 and 9.0 mg/dL. Monitoring of plasma levels and urinary Ca²⁺ excretion may limit the risk of hypercalcemia, hypercalciuria, and nephrocalcinosis (evident on renal ultrasound). In vitamin D-dependent rickets type I, the dose of calcitriol is 10 to 15 ng/kg per day combined with elemental calcium of 500 to 1000 mg/day. Children with vitamin D-deficient rickets may receive vitamin D (ergocalciferol, 8000 units/mL = 0.2 mg/mL) at 2000 to 10,000 IU/day orally for 4 to 8 weeks, or a single oral megadose of 200,000 to 600,000 IU (Strosstherapy), which is safe and more effective, particularly when compliance is in question. Oral or intravenous calcitriol may be used in pseudohypoparathyroidism or in children with chronic renal failure to increase intestinal absorption Ca²⁺ and suppress PTH secretion.

Hypercalcemia (Plasma Ionized Calcium >1.35 mmol/L or >5.4 mg/dL, or Total Calcium >10.5 mg/dL, or 2.6 mmol/L)

It is important to exclude pseudohypercalcemia as a cause of hypercalcemia in individuals with essential thrombocytosis after clotting of phlebotomized blood. The causes of

CHILDREN

Primary hyperparathyroidism
Tertiary hyperparathyroidism
Ectopic secretion of PTH by tumors
Neoplasms (bony metastases)
Neoplastic production of $1,25(\text{OH})_2\text{D}_3$
Phosphate depletion with hypophosphatemia
Sarcoidosis, tuberculosis, and other granulomatous disorders
Immobilization
Milk-alkali syndrome
Medications: Thiazide diuretics, theophylline, lithium, salicylate intoxication, vitamin D or vitamin A intoxication
Thyrotoxicosis
Exsiccosis
Acquired immunodeficiency syndrome (AIDS)
Multiple fractures
Acute renal failure
PTH, PTHrP

hypercalcemia vary by age (Box 5-11) (Rodd and Goodyer, 1999; Ziegler, 2001). Although hypercalcemia is uncommon in newborns, the most common cause is iatrogenic, resulting from excessive administration of calcium salts. Other causes in this age group include idiopathic infantile hypercalcemia, which is usually mild; more severe hypercalcemia occurs in Williams' syndrome. Primary neonatal hyperparathyroidism is a rare disorder caused by homozygous inheritance of mutations in the Ca^{2+} -sensing receptor that result in familial hypocalciuric hypercalcemia (FHH). Although these patients' heterozygous parents are often asymptomatic, the condition may be life threatening in the offspring because of plasma calcium 15 to 30 mg/dL, unexplained anemia, hepatosplenomegaly, and nephrocalcinosis. Primary hyperparathyroidism is extremely rare in childhood but may occur in the multiple endocrine adenoma syndrome, in which hypercalcemia, hypercalciuria, and nephrolithiasis relate to elevated levels of $1,25(\text{OH})_2\text{D}_3$ (Broadus et al., 1980).

Box 5-12 Evaluation of Infants with Persistent Hypercalcemia

Blood-total and ionized calcium, pH, phosphorus, alkaline phosphatase, creatinine, intact PTH, 25-hydroxyvitamin D, 1,25-dihydroxyvitamin D
Urine-calcium/creatinine ratio, tubular reabsorption of phosphate

Diagnostic Studies

Diagnostic studies to consider in newborns and in children with hypocalcemia or hypercalcemia are shown in Box 5-12 (Rodd and Goodyer, 1999). In general, PTHrP and calcitrophic cytokines need not be measured unless plasma PTH levels are normal or suppressed and the cause of hypercalcemia is cryptic. If PTHrP is measured, the blood tube should contain a proteinase inhibitor.

Manifestations of Hypercalcemia

Newborns and infants with hypercalcemia have nonspecific symptoms, such as failure to thrive because of anorexia and vomiting. Irritability, lethargy, hypotonia, and seizures are common with more severe hypercalcemia. Bradycardia, a short QT interval, and hypertension are other findings. In older children, nausea, vomiting, constipation, and vague central nervous system symptoms of headaches and fatigue may be apparent. Renal function may be markedly decreased because of diminished RBF caused by hypercalcemia-induced vasoconstriction and by circulatory volume depletion resulting from acquired nephrogenic diabetes insipidus. Nephrocalcinosis, nephrolithiasis, hematuria, and sterile pyuria may occur secondary to hypercalciuria. An inability to concentrate the urine because of resistance to the action of ADH may result in polyuria, polydipsia, and dehydration. Hypokalemia may occur secondary to diuresis. The development of rapid and severe hypercalcemia ($>17\text{ mg/dL}$) can result in dehydration, azotemia, coma, and death.

Management of Hypercalcemia

The first step in the management of acute hypercalcemia is to discontinue all of the sources of calcium and vitamin D. In neonates, a formula with low calcium and vitamin D content may be used, as well as immediate provision of hydration consisting of normal saline at 20 mL/kg per hour for 4 hours. Excretion of calcium may be further promoted by intravenous furosemide at a dosage of 0.5 to 1.0 mg/kg body weight given every 6 hours with frequent monitoring of plasma ionized Ca^{2+} , Na^+ , K^+ , Cl^- , and Mg^{2+} concentrations. Supplementation with such ions is essential. Thiazides are anticalciuric and are contraindicated. Calcitonin given at 4 to 8 IU/kg body weight subcutaneously

every 6 hours is particularly useful if there is concurrent renal insufficiency. Methylprednisolone at 1 mg/kg per 24 hours may be useful in this setting. Biphosphonates inhibit macrophage and osteoclast activity and are increasingly used to treat hypercalcemia but also to prevent osteoporosis, osteopathy, or calcinosis. Pamidronate at a single dose of 0.5 mg/kg intravenously (may be repeated daily as needed for 3 days) is the agent of choice in tumoral hypercalcemia, vitamin D intoxication, resistant hypercalcemia, or in newborns with subcutaneous fat necrosis and elevated plasma $1,25(\text{OH})_2\text{D}_3$ concentrations. Etidronate at an oral dosage of 5 mg/kg given twice daily along with sodium supplementation at 3 mmol/kg per day is also effective for managing chronic disorders. In severe hypercalcemia or when oliguria or renal insufficiency is present, dialysis with a low calcium dialysate concentration (1.25 mmol/L) is recommended. In cases of severe neonatal hyperparathyroidism resulting from homozygous FHH or other forms of primary hyperparathyroidism, expeditious parathyroidectomy may be lifesaving.

Magnesium

Magnesium is the fourth most abundant cation in the body, and it is largely located intracellularly. Its principal role is to stabilize electrically excitable membranes. Magnesium is also an important co-factor of numerous important enzymes, including Na^+ , K^+ -ATPase, alkaline phosphatase, and adenylate cyclase (Gums, 1987). It is essential in oxidative phosphorylation, protein synthesis, and DNA metabolism.

Magnesium Homeostasis

Normal plasma magnesium levels range from 1.7 to 2.5 mg/dL or 0.7 to 1.0 mmol/L. In general, plasma levels of Mg^{2+} correlate well with tissue levels; such correlation is poor, however, in circumstances such as renal failure or hepatic cirrhosis (Cohen and Kitzes, 1982).

Despite being very abundant in the body, defense against hypomagnesemia is limited by the following factors:

- An inappropriately low parathyroid secretion when plasma levels are below 1.0 mg/dL
- PTH resistance at the skeletal level, and
- Decreased calcitriol levels predisposing to combined hypocalcemia (Agus, 1999)

Hypomagnesemia is common in hospitalized individuals, particularly when nutritional intake is low for 3 or more days.

An average Western diet provides 400 mg of Mg^{2+} (16 mmol) per day, of which 30% to 50% is absorbed in the jejunum and ileum (Brannan et al., 1976). Intestinal absorption can increase to 80% in the presence of mild hypomagnesemia (plasma Mg^{2+} <1.2 mg/dL, <1.0 mEq/L, or <0.5 mmol/L). In the blood, 30% of Mg^{2+} is bound to proteins and is not filtered at the glomerulus. Of the filtered Mg^{2+} , about 3% is excreted in the urine.

Once filtered, Mg^{2+} is reabsorbed in the proximal tubule (15% to 20%), in the thick ascending limb of the loop of Henle (65% to 76%), and in the distal convoluted tubule (5% to 10%). As with Ca^{2+} , the bulk of Mg^{2+} reabsorption occurs in the thick ascending limb of the loop of Henle via a passive paracellular mechanism. This mechanism is facilitated by the positive transepithelial voltage that is generated by apical Na^+ entry and by diffusion of K^+ into the lumen that is generated by the inter-

play of the apical NKCC2 cotransporter, the basolateral Na^+ - K^+ -ATPase, and the return of K^+ into the tubular lumen via the action of ROMK (Fig. 5-8, A) (Konrad and Weber, 2003). The resultant change in luminal charge affects the configuration of structural proteins, especially that of paracellin-1 (also known as *claudin 16*) present in tight junctions. Mutations in paracellin-1 become manifest in early childhood and are often accompanied by familial hypomagnesemia, hypercalciuria, hematuria, and nephrocalcinosis, and they can cause polyuria and progressive decline in GFR, such that one third of these children develop renal failure by age 15 years (Weber et al., 2001).

Interference with NKCC2 cotransport by loop diuretics diminishes the luminal voltage and leads to Mg^{2+} wasting, hypomagnesemia, and hypocalcemia. Metabolic acidosis, K^+ depletion, and hypophosphatemia may cause magnesuria by affecting the transepithelial voltage. In contrast, Mg^{2+} transport in the distal convoluted tubule is active and transcellular (Fig. 5-8, B). Specific, but not well-characterized, Mg^{2+} channels transport Mg^{2+} in and out of the cells in this region and are influenced by multiple agents, including the Mg^{2+} -sparing diuretics amiloride and chlorothiazide (Cole and Quamme, 2000, Konrad and Weber, 2003). Mutations in these channels or in the Ca^{2+} / Mg^{2+} -sensing receptor (CaSR), which inhibits Na^+ , Ca^{2+} , and Mg^{2+} absorption at the basolateral membrane, are responsible for several inherited disorders that are often present in infancy and childhood with symptoms related to hypomagnesemia (Box 5-13) (DiStefano et al., 1997).

Cole D, Quamme GA: Inherited disorders of renal magnesium handling. *J Am Soc Nephrol* 11:1937-1947, 2000, p 1940, Table 2. (With permission of Springer Science and Business Media.)

Etiology and Manifestations of Dysmagnesemia

Hypomagnesemia (Plasma Concentration <1.7 mg/dL, or <0.7 mmol/L)

Hypomagnesemia is far more common and more clinically relevant than hypermagnesemia (>2.5 mg/dL, or >1.0 mmol/L). Genetic disorders resulting in renal Mg^{2+} wasting are highlighted in [Box 5-13](#), and noninheritable or acquired causes of hypomagnesemia and its clinical manifestations are shown in [Boxes 5-14](#) and [5-15](#) (Elin, 1988). Pediatric transplant recipients maintained on cyclosporine or tacrolimus are particularly susceptible to hypomagnesemia. This disorder is associated with an increase in the fractional excretion of Mg^{2+} (Barton et al., 1987). Experimental studies demonstrate that cyclosporine leads to a decrease in the serum magnesium concentration that is associated with renal Mg^{2+} wasting and Mg^{2+} shift into tissue compartments with no effect on intestinal absorption of Mg^{2+} (Barton et al., 1989).

Because of the type of clinical conditions that cause hypomagnesemia and because hypomagnesemia itself may contribute to refractory hypokalemia and hypocalcemia, it is common to find concurrent hypokalemia, hypocalcemia, and metabolic alkalosis. Symptoms may be exclusively attributed to hypomagnesemia only after excluding these other electrolyte disturbances. Patients with renal wasting of magnesium have nephrocalcinosis, nephrolithiasis, and decreased GFR. Neurologic symptoms resemble those of hypocalcemia and may include personality changes, tremors, seizures, and carpopedal spasm.

Hypermagnesemia

Hypermagnesemia often occurs in individuals with acute renal failure who also consume a high level of dietary Mg^{2+} or who experience cellular efflux in association with acute ketoacidosis or pheochromocytoma crisis. Although individuals with plasma Mg^{2+} concentrations below 10 mg/dL are usually asymptomatic,

Box 5-14 Causes of Hypomagnesemia

GASTROINTESTINAL

Chronic diarrhea
Bowel bypass or resection
Congenital inflammatory bowel disease
Malabsorption syndromes
Tropical sprue
Gluten enteropathy
Laxative abuse
Pancreatitis
Specific magnesium malabsorption
Prolonged nasogastric suctioning
Caloric malnutrition

RENAL EXCRETION

Gitelman's syndrome
Acute renal failure
Renal tubular acidosis
Chronic pyelonephritis
Postobstructive diuresis
Primary renal tubular magnesium wasting
Drugs

Acetazolamide
Alcohol
Aminoglycosides
Amphotericin B
Bumetanide
Capreomycin
Carbenicillin
Chlorthalidone
Cisplatin
Cyclosporine
Digoxin
Ethacrynic acid
Furosemide
Mannitol
Methotrexate
Osmotic agents
Pentamidine
Tacrolimus

Theophylline
Thiazides
Torsemide
Viomycin

NUTRITIONAL DEFICIENCIES

Malnutrition or eating disorders
Magnesium-free parenteral feedings
Long-term alcohol abuse

ENDOCRINE DISORDERS

Hyperaldosteronism
Hypocalcemia
Hyperparathyroidism
Hyperthyroidism
Diabetes mellitus
Ketoacidosis
Diabetic
Alcoholic
Hypoparathyroidism
SIADH
Excessive lactation

REDISTRIBUTION

Insulin treatment for diabetic ketoacidosis
High-catecholamine states
Major trauma or stress
Hungry-bone syndrome

MULTIPLE MECHANISMS

Chronic alcoholism
Alcohol withdrawal
Major burns
Liquid-protein diet
Acute porphyria

NEONATES

Gestational diabetes
Gestational hyperparathyroidism
Gestational hypoparathyroidism
Exchange transfusion (citrate)

METABOLIC

Hypokalemia
Hypocalcemia

Modified from Elin RJ: Magnesium metabolism in health and disease, *Dis Mon* 34:161-218, 1988.

hypermagnesemia may cause central nervous system depression, decreased deep-tenon reflexes, muscle weakness, respiratory muscle paralysis, hypotension, bradycardia, heart block, and other arrhythmias.

Etiology and Management of Dysmagnesemia

Diagnosis of Dysmagnesemia

In individuals with normal renal function and absence of renal Mg^{2+} wasting, a fractional excretion of Mg^{2+} ($FE_{Mg^{2+}}$) below 0.5% indicates low dietary intake or gastrointestinal losses of Mg^{2+} , whereas an $FE_{Mg^{2+}}$ over 2% suggests renal Mg^{2+} wasting.

$$FE_{Mg^{2+}} = \frac{U_{Mg^{2+}} \times Pcr}{(0.7 \times P_{Mg^{2+}}) \times Ucr} \times 100$$

$U_{Mg^{2+}}$ and $P_{Mg^{2+}}$ and Ucr and Pcr are the urinary and plasma concentrations of Mg^{2+} and creatinine, respectively. In this equation, plasma Mg^{2+} concentration is multiplied by 0.7 because only 70% of plasma Mg^{2+} is free. This implies that administration of albumin or blood products may further lower the ionized form of Mg^{2+} and precipitate symptoms. In individuals with low normal plasma Mg^{2+} concentrations, total body Mg^{2+} depletion may be confirmed by an Mg^{2+} excretion in a 24-hour urine collection amounting to less than 80% after an intravenous or intramuscular load of 2.4 mg/kg of lean body mass (this may be administered over 4 hours as the chloride or the sulfate solution in 5% dextrose in water or normal saline) (Gullestad et al., 1994)

Management of Dysmagnesemia

The first steps in the management of dysmagnesemia are to discontinue offending medications and to attempt to correct the primary cause of hypomagnesemia (Box 5-16). In individuals with tetany or cardiac arrhythmias, intravenous Mg^{2+} may be infused slowly to avoid hypotension. The usual dosage is 0.2 mEq/kg (0.1 mmol/kg or 2.4 mg/kg) every 4 to 6 hours until blood levels exceed 1.0 mg/dL (0.4 mmol/L or 0.8 mEq/L). The intravenous or intramuscular administration of 25 to 50 mg/kg body weight of magnesium sulfate solution, or 0.2 to 0.4 mEq/kg body weight of elemental Mg^{2+} , is also preferred in symptomatic individuals with normomagnesemia who exhibit refractory hypokalemia or hypocalcemia. Amiloride may be used to reduce renal Mg^{2+} wasting by stimulating reabsorption in the cortical collecting duct. Because Mg^{2+} has a low renal tubular threshold (1.3 to 1.7 mEq/L), intravenous infusions or large single oral loads of Mg^{2+} are quickly excreted in the urine. Thus, smaller, more frequent doses or use of oral sustained-release preparations are more effective. Symptomatic hypermagnesemia may be acutely managed by dialysis using a dialysate Mg^{2+} concentration of 0.2 mmol/L, as well as calcium infusion or anticholinesterase administration.

Phosphorus

Most total body P^{2-} exists in the form of the inorganic phosphate, but it also exists in an organic intracellular form, where it is the major anion. Phosphorus is an integral component of intracellular nucleic acids and cell membrane phospholipids and it is involved in phosphorylation of proteins and lipids. Severe hypophosphatemia (<1 mg/mL) may have profound effects on all body functions by limiting 2,3-diphosphoglycerate and oxygen dissociation from hemoglobin and by reducing phosphate available for synthesis of high-energy bonds in the form of ATP, which is involved in virtually all energy-requiring processes (Knochel, 1977). Phosphorus, along with Ca^{2+} , is a major constituent of bone.

Phosphorus Homeostasis

Approximately 85% of the total body P^{2-} is in bone (hydroxyapatite, octacalcium phosphate, and amorphous calcium phosphate) and teeth, whereas 15% is a constituent of carbohydrate, lipid, and protein in soft tissues, and 0.1% is in the ECF (Raisz, 1977).

Serum P^{2-} concentration is maintained between 3.0 and 8.5 mg/dL, depending on age (Parfitt and Kleerekoper, 1980). It is highest in infants (4.5 to 8.5 mg/dL) and relatively high in children (3.7 to 5.9 mg/dL), presumably because of increased concentrations of growth hormone and reduced levels of gonadal hormones until the completion of adolescence.

About 50% to 60% of dietary P^{2-} is absorbed in the small intestine, especially in the duodenum and jejunum, through an active vitamin D-dependent process that is also dependent on Na^+ , and by passive diffusional flux through paracellular pathways (Harrison and Harrison, 1961). The absorption of P^{2-} depends on the availability of adequate glucose, Na^+ , P^{2-} , and Ca^{2+} . Absorption is decreased by the ingestion of antacids such as aluminum hydroxide, which binds phosphorus in the gut and thereby inhibits gastrointestinal absorption.

Box 5-16 Treatment of Magnesium Depletion

The following guidelines are suggested for the treatment of magnesium deficiency regardless of etiology:

1. It is important to know that the kidneys are producing urine and that the blood urea nitrogen (BUN) and/or creatinine is normal. Magnesium may be needed and may be administered even in an instance of renal insufficiency, but the treatment must be monitored by frequent serum or plasma level assays.
2. On the first day of therapy, at least 1 mEq mg/kg per day should be given parenterally. Subsequently, at least 0.5 mEq mg/kg per day should be given for 3 to 5 days. If parenteral fluid therapy continues, at least 0.2 mEq/kg per day should be given.
3. Give the above in intravenous infusions if such infusions are being given anyway; otherwise, intramuscular administration is satisfactory.
4. The following schedule for an average adult is safe and effective.
 - a. Intramuscular route: [ampules of 1 g $\text{MgSO}_4(\text{H}_2\text{O})_7$, 50% solution = 8.13 mEq Mg^{2+}]. Day 1: 2.0 g (16.3 mEq) every 4 hours for six doses. Days 2-5: 1.0 g (9.1 mEq) every 6 hours.
 - b. Intravenous route (same ampules) Day 1: 6 g (41 mEq) in each liter of fluid and at least 2 L of 83 mEq. Days 2 to 5: A total of 6 g (49 mEq) distributed equally in total fluids of the day.

If the patient's condition requires continued intravenous infusions, 2 g of MgSO_4 should be given daily in the infusion as

long as infusions are necessary. When a patient who has a reason to have magnesium deficiency is convulsing, 2.0 g of MgSO_4 solution may be administered intravenously in a 10-minute period. For infants and children with symptoms, such doses may be 0.025 g MgSO_4/kg , or 0.2-0.3 mEq/kg per dose of elemental mg^{2+} , in 10 minutes.

5. Oral preparations

Magnesium oxide	(Uro-Mg) 50 mEq magnesium per g of salt
	(Mag-Ox) 50 mEq magnesium per g of salt
Magnesium chloride	(Slo-Mag) 9.75 mEq magnesium per g of salt
Magnesium lactate	(MagTab) 7.6 mEq magnesium per g of salt

- Note: 50% solution of $\text{MgSO}_4 = 500 \text{ mg/mL}$ (1 g/2 mL), or 49.3 mg elemental Mg^{2+}/mL , or 98.6 mg elemental $\text{Mg}^{2+}/2 \text{ mL}$. Given an atomic gram weight of 24.3 and a valence of 2 for Mg^{2+} , $98.6 \text{ mg} = 4.058 \text{ mmol}$ or 8.13 mEq elemental Mg^{2+}/g salt.

- Example: A 10-kg infant with seizures, hypomagnesemia, and an adequate serum calcium level may receive 2.0 mEq elemental Mg^{2+} (0.2 mEq/kg \cdot 10 kg). This may be accomplished by diluting 0.5 mL of the 50% MgSO_4 in 9.5 mL of dextrose and infusing over 2 to 10 minutes.

Adapted from Flink EB, et al.: Magnesium deficiency and magnesium toxicity in man. In Prasad AS, Oberleas D, editors: *Trace elements in human health and disease*. New York, 1976, Academic Press, p 13.

At least 90% of plasma P^{2-} appears in the glomerular ultrafiltrate. Most of the filtered P^{2-} is reabsorbed in the proximal tubule. The process is active and Na^+ dependent, and it occurs against an electrochemical gradient (Suki and Rouse, 1991). The amount of P^{2-} in the urine closely parallels the amount absorbed by the intestine. Normally the kidney excretes 10% to 20% of the filtered P^{2-} , suggesting that the maximal capacity of the tubules to reabsorb P^{2-} is met or exceeded. Saline expansion causes phosphaturia, which can be blocked by total parathyroidectomy. In the absence of PTH, the reabsorption of P^{2-} by the *pars recta* and the distal nephron is complete and accounts for the hyperphosphatemia in hypoparathyroidism (Knox et al., 1977).

The urinary excretion of P^{2-} depends on the oral intake of P^{2-} (high intake causes increased excretion), the oral intake of Ca^{2+} (high intake causes hypophosphaturia), the presence of catabolism (high catabolic rates cause hyperphosphatemia and hyperphosphaturia), acid-base status (chronic metabolic acidosis decreases the tubular reabsorption of P^{2-} by decreasing the V_{max} of $\text{Na}^+/\text{P}^{2-}$ cotransport in the brush border membrane of the proximal tubule), and the levels of PTH and calcitriol (Kempson, 1982). Severe respiratory alkalosis stimulates glycolysis and carbohydrate phosphorylation, resulting in secondary intracellular shift of phosphate. Untreated diabetes causes hypophosphatemia through volume expansion, osmotic diuresis, or ketonuria, and also through extracellular shift after insulin administration.

Phosphate transport at the proximal tubule is the main means for regulating total body phosphate balance. The latter process is largely mediated by a type IIa $\text{Na}^+/\text{P}^{2-}$ electrogenic cotransporter (NPT2a) in the proximal tubule (Murer et al., 2000; Kronenberg, 2002; Tenenhouse and Murer, 2003). An increase or a decrease in the number of NPT2a in the brush

border cell membrane is associated with either an increase or a decrease in P^{2-} reabsorption. Modulators of NPT2a endocytosis, internalization, recycling, and lysosomal degradation include PTH, fibroblast growth factor 23 (FGF-23), and several proteins that interact with this phosphate transporter. High levels of PTH or FGF-23 increase NPT2a endocytosis and breakdown and cause phosphaturia. Reduction in dietary phosphate lowers PTH levels while concurrently promoting insertion of NPT2a at the apical membrane, thereby promoting phosphate reabsorption (Fig. 5-9).

Human disorders of phosphate transport may relate to aberrations in these phosphate-regulating genes. Certain tumors can cause oncogenic hypophosphatemic osteomalacia (OHO) by stimulating mRNA encoding for FGF-23, whereas activating mutations of FGF-23 can cause autosomal dominant hypophosphatemic rickets (ADHR). Another phosphate-regulating gene is named the *phosphate-regulating gene with homology to endopeptidases on the X chromosome (PHEX)*. Many mutations in this gene that are largely expressed in osteoblasts, osteoclasts, and odontoblasts, lead to decreased degradation of FGF-23, which may be the key defect in X-linked hypophosphatemic rickets (XLH). However, the mechanism by which PHEX dysfunction leads to renal phosphate wasting is unclear (Kronenberg, 2002).

Regulation of phosphate shifts in and out of bone is principally mediated by PTH and calcitriol that is synthesized mainly by proximal tubular epithelial cells. Several plasma proteins prevent precipitation of calcium phosphate in vessels and soft tissues, whereas alkaline phosphatase aids deposition of such minerals in bone. Other hormones that may affect the renal handling of P^{2-} include vasopressin, thyroxin, glucagon, insu-

■ **FIGURE 5-9.** Regulation of the NPT2a sodium-phosphate cotransporter and synthesis of 1,25-dihydroxyvitamin D_3 in the renal proximal tubule. PTH and fibroblast growth factor 23 (FGF-23) both lead to rapid internalization and subsequent lysosomal destruction of NPT2a. A low-phosphate diet causes the insertion of NPT2a into the plasma membrane. PTH and a low-phosphate diet both stimulate production of 25-hydroxyvitamin D 1α -hydroxylase messenger RNA (mRNA), whereas FGF-23 lowers mRNA levels. (From Kronenberg HM: *NPT2a—The key to phosphate homeostasis*, *N Engl J Med* 347:1022-1024, 2002.)

lin, and glucocorticoids (Ritz et al., 1980). The antiphosphaturic action of growth hormone is believed to occur via mechanisms involving increased reabsorption of Na^+ , release of insulin, or increased synthesis of $1,25(OH)_2D_3$.

Hypophosphatemia stimulates calcitriol synthesis. The adaptive increases in plasma calcitriol concentrations on bone and intestine raise serum phosphate levels and cause hypercalciuria. This is evident in hereditary hypophosphatemic rickets (HHPR) but not in the disorders involving excessive amounts or activating mutations of FGF-23 (XLH, ADHR, or OHO), in which calcitriol expression is suppressed. The transporter abnormality in HHPR remains elusive.

Hypophosphatemia (Plasma Concentration <2.5 mg/dL)

The etiologies of hypophosphatemia are summarized in [Box 5-17](#). Because it is found in most foods, particularly in dairy

products, and because intestinal absorption is efficient and minimally regulated, phosphorus depletion is rare except in patients with hyperparathyroidism. Hypophosphatemia usually coexists with total body P^{2-} depletion, which is defined precisely as P^{2-} content in lean muscle below 0.28 mol/g dry weight. One may occur without the other, however, particularly when the decrease in serum P^{2-} results from intracellular shifts (Popovtzer and Knochel, 1986).

Clinical manifestations of hypophosphatemia are quite diverse and may be attributable to the underlying disorder (for example, pseudofractures and osteopenia in chronic hypoparathyroidism) or because of hypoxic effects on any and all body processes resulting in hemolysis, rhabdomyolysis, respiratory muscle paralysis, myocardial failure, encephalopathy, or neuropsychiatric symptoms and in secondary disturbances in renal tubular bicarbonate, magnesium, calcium, and glucose reabsorption. Plasma Ca^{2+} concentration may increase as a result of stimulation of calcitriol and from mobilization of bone Ca^{2+} caused by reduction in the blood $Ca^{2+} \times P^{2-}$ product. Glucose intolerance may occur with severe P^{2-} depletion (Marshall et al., 1978). Osteomalacia, rickets, hypercalcemia, hypercalciuria, and distal tubular acidification

Box 5-17 Causes of Hypophosphatemia

EXCESSIVE RENAL LOSSES AS PRIMARY CAUSE

Drugs: Cyclosporine, tacrolimus, diuretics, salicylates, carbonic anhydrase inhibitors
 Primary hypophosphatemic rickets
 Hereditary hypophosphatemic rickets with hypercalciuria
 Postobstructive diuresis
 Renal tubular acidosis
 Postrenal transplantation
 Fanconi's syndrome
 Recovery from acute tubular necrosis
 Potassium deficiency
 Oncogenic osteomalacia or rickets
 Vitamin D deficiency and dependency (also related to decreased intestinal absorption)
 Volume expansion or osmotic diuresis (hyperglycemia)

NEGATIVE INTESTINAL BALANCE AS PRIMARY CAUSE

Breastfed premature infants
 Term infants fed with low phosphate source
 Use of phosphate-binding antacids
 Decreased dietary intake (rare) especially with dialysis and phosphate binders
 Vomiting or gastric suction
 Glucocorticoids

ACUTE FLUX OF PLASMA PHOSPHATE TO INTRACELLULAR AND SKELETAL POOLS*

Nutritional recovery, usually TPN associated
 Therapy of diabetic ketoacidosis
 Salicylate intoxication
 Alkalosis (especially respiratory)
 Androgen therapy
 Burn therapy
 Hungry-bone phenomenon
 Increased tumor burden (uptake by tumor cells)

*The serum phosphate is maintained but total body pools are depressed. In many of these conditions, recovery results in restoration of intracellular phosphate, precipitating acute hypophosphatemia.

defects are known to occur in chronic hypophosphatemia of any cause (Kurtz and Hsu, 1978). Chronic administration of antacids (such as calcium carbonate or aluminum hydroxide) combined with inadequate P^{2-} intake may result in severe hypophosphatemia. In addition to acting as P^{2-} binders, antacids can induce net P^{2-} secretion in the gut and create a negative P^{2-} balance.

Many genetic disorders causing hypophosphatemia are characterized by an abnormal response to PTH, alteration in the structure and function of renal tubular transporters, or defective regulatory proteins within the proximal tubular epithelium. Several of these disorders are inherited and are associated with other metabolic disturbances such as aminoaciduria, glucosuria, hypocalcemia, rickets, and growth failure.

Hypophosphatemia is commonly seen after successful renal transplantation. Contributory factors include the persistence of preexisting parathyroid hyperplasia, volume expansion and osmotic diuresis in the immediate postoperative period, glucocorticoid administration (which increases the renal excretion of P^{2-} and inhibits the gastrointestinal absorption of this ion), ingestion of antacids (which also function as phosphate binders), and an inherent renal tubular defect for P^{2-} reabsorption that is independent of all other hormonal and metabolic factors (Parfitt et al., 1986).

Moderate hypophosphatemia (plasma concentrations of 1.0 to 2.5 mg/dL) generally results in few symptoms and can be managed with oral rather than intravenous phosphate salts. Whenever possible, this may be accomplished through dietary supplements. One quart of milk provides about 1 g of elemental phosphorus (≈ 32 mmol). The dosage of oral salt supplements ranges from 1.0 to 3.0 mmol/kg per day, with the larger dosages given to infants. Children with hypophosphatemia after renal transplantation may temporarily require phosphate replacement with calcitriol supplements. This drug combination is also effective in the management of children with hypophosphatemic rickets.

Children who show symptoms, those with profound hypophosphatemia (plasma concentration <1.0 mg/dL), or children requiring parenteral nutrition may be treated with intravenous phosphate at about 50% of the oral dosage. The choice of the preparation, including sodium phosphate or potassium phosphate, of either oral or intravenous phosphate preparations (Table 5-12), depends on plasma K^+ concentrations and level of renal function.

Hyperphosphatemia

The pathogenesis of hyperphosphatemia is related to the redistribution of P^{2-} from the intracellular compartment, P^{2-} overdose, or decreased renal clearance of P^{2-} (Box 5-18). Symptoms result from the reciprocal decrease in serum calcium. Convulsions, cardiac arrhythmias, laryngospasm, and tetany may reflect hypocalcemia. Also, hyperphosphatemia can produce, contribute to, or be associated with acute renal failure. Conditions such as crush injury, tumor lysis syndrome, rhabdomyolysis, and hemolysis are often associated with oliguria and acute renal failure. The most serious side effect of

Box 5-18 Causes of Hyperphosphatemia

DECREASED GLOMERULAR FILTRATION RATE

Acute and chronic renal failure

INCREASED TUBULAR REABSORPTION OF PHOSPHATE

Parathyroid Dysfunction

Hypoparathyroidism (transient hypoparathyroidism of infancy, pseudohypoparathyroidism; transient parathyroid resistance of infancy)

Other Endocrine Causes

Hyperthyroidism, tumoral calcinosis, growth hormone excess; juvenile hypogonadism
High ambient temperature

INCREASED PHOSPHATE LOADS

Exogenous Loads

Enemas and laxatives; vitamin D intoxication; parenteral phosphate; blood transfusions; white phosphorus burns; phosphorus-rich cow's milk

Endogenous Loads

Cellular shift in diabetic ketoacidosis; lactic acidosis; tissue hypoxia; rhabdomyolysis; cytotoxic therapy of neoplasms; hemolysis; malignant hyperthermia

Miscellaneous

Familial intermittent hyperphosphatemia

hyperphosphatemia relates to calcium-phosphorus precipitation in the form of hydroxyapatite crystals in nonosseous tissue, including the cornea, lungs, kidneys, pancreas, blood vessels, and brain.

SUMMARY

Elucidation of nephron transporters and their interacting substrates has greatly enhanced our understanding of fluid and electrolyte regulation in children and in adults. However, unlike in adults, anatomic, metabolic, and physiologic differences stemming from the evolving aspects of development (ranging from prematurity to adolescence) result in a spectrum of responses of the nephron to perturbations in fluid and electrolyte balance. This treatise provides the guidelines for fluid and electrolyte management based on an understanding of renal function and tubular transporter physiology in health and disease and during various periods of childhood.

One of the many physiologic adaptations required for the survival of homeothermic species is the ability to maintain constant core body temperature within narrow limits. The significance of thermal regulation for neonates was first appreciated by two French obstetricians, Tarnier and later Budin, who in 1907 published the finding of significantly higher survival rates in normothermic versus hypothermic neonates (Budin, 1907). Several other investigators later confirmed the importance of thermal stability in the adaptive process and further elucidated the mechanisms by which neonates, infants, and children are able to behave as homeotherms (Silverman and Blanc, 1957; Cross et al., 1958; Silverman et al., 1958; Bruck, 1961). A homeothermic organism is characterized by its ability to maintain constant (or central) body temperature despite changes in the ambient temperature. Not many physiologic parameters are as vigorously and effectively controlled as the core temperature. In humans, the central body temperature refers to the temperature of the vessel-rich group organs (i.e., brain, heart, lungs, liver, and kidneys) and is normally maintained within $\pm 0.2^\circ\text{C}$ of its set point of 37.0°C . This so-called interthreshold range defines the limits within which no thermoregulatory effector responses are

triggered and the human organism behaves poikilothermically. The musculoskeletal system makes up the major part of the peripheral compartment, which is considered to be a dynamic buffer in the thermoregulatory system. The skin, representing the shell compartment, acts as a barrier to the environment.

Temperature control is subjected to circadian rhythms, some of which begin in the first days of life. The circadian rhythm of body temperature is generally age dependent (less pronounced at very young and very old ages) and generally closely associated with the sleep-wake cycle. In fertile women, a monthly rhythm in body temperature exists because of a higher set-point temperature in the luteal phase of the menstrual cycle (Hardy, 1961). Despite the fluctuations of body temperature within these rhythms, temperature control is tight and is accomplished by a sophisticated system that balances heat production and heat loss.

However, despite this effective regulatory system, the body's ability to dissipate or generate heat by means of skin-blood-flow regulation, sweat production, changes in minute ventilation, and metabolism, it can easily be overwhelmed by external factors.

Anesthesia and surgery have a powerful effect on thermoregulation, and otherwise minor changes in body temperature may result in cellular and tissue dysfunction, thus explaining the need not only for tight temperature regulation within narrow limits, but also for perioperative temperature monitoring.

Accidental hypothermia occurs commonly in patients of any age who are undergoing anesthesia and surgery, and it has often been accepted as an unfortunate but unavoidable consequence of the surgical procedure. This high rate of hypothermia led Pickering to his famous statement, "The practical difficulty in cooling men is to break through the defenses of the body; the most effective means is to give an anesthetic..." (Pickering, 1958).

This chapter discusses the relative merits of different anatomic sites of temperature monitoring; the principles and physiology of thermoregulation in adults and children of all ages; and reviews the influence of anesthetic agents on thermoregulation, the physiologic consequences of hypothermia and hyperthermia, and the techniques used to prevent perioperative hypothermia.

TEMPERATURE MONITORING

Temperature is one of the seven base quantities as defined in the International System of Units (Système Internationale, SI). The unit is Kelvin (K; not "degrees Kelvin"), where $0\text{ K} = -273.15^\circ\text{ C}$. Most countries measure temperature in degrees Celsius ($^\circ\text{C}$), whereas a few use degrees Fahrenheit ($^\circ\text{F}$). Normal body temperature is 37.0° C , 98.6° F , or 310.15 K . The following formulas can be used to easily convert from one unit into the other:

$$^\circ\text{Celsius} = [(\text{Fahrenheit} - 32) \times 5] \div 9$$

$$^\circ\text{Fahrenheit} = (9 \times \text{Celsius} \div 5) \times 32$$

$$\text{Kelvin} = \text{Celsius} + 273.15$$

Perioperative detection of changes in body temperature requires appropriate monitoring and monitoring sites. Most national anesthetic societies now have guidelines that require that one method for measuring body temperature during anesthesia be available (La Société Française d'Anesthésie et de Réanimation, 1994; American Society of Anesthesiologists, 2005; Australian and New Zealand College of Anaesthetists, 2006; Canadian Anesthesiologists' Society, 2007).

Although mercury-in-glass thermometers were standard for decades, the most common thermometers used in the perioperative setting are thermocouples and thermistors.

A thermocouple consists of two different metals, often copper and constantan (an alloy of copper, nickel, manganese, and iron). At the junction of any two different metals from the thermoelectric series, a small current is produced. The voltage magnitude of the current depends on the temperature and can therefore be used to measure the temperature. This principle is named *Seebeck's effect* after the physicist, Thomas Johann Seebeck, who discovered it.

The fact that electrical resistance changes exponentially with different temperatures forms the basis of the thermistor type of thermometer, which consists of a semiconductor resistor made of a tiny piece of metal (copper, nickel, manganese, or cobalt). The change in resistance is analyzed to measure

temperature. Both thermocouple and thermistor probes are inexpensive and considered sufficiently accurate for clinical purposes.

Infrared thermometers (thermopiles) are quite popular in postanesthesia care units and on hospital wards; however, for continuous temperature monitoring during anesthesia they are not suitable. Despite a fast response time, their accuracy in clinical practice has not been confirmed (particularly when they are not used properly) (Craig et al., 2002; Heusch and McCarthy, 2005; Leon et al., 2005; Dodd et al., 2006).

Temperature-sensitive liquid crystals have been used to measure skin temperature. Although these devices are easy and convenient to handle, they generally do not meet the accuracy criteria required for clinical use. Their readouts can easily be affected by changes that are related not only to body temperature but also to skin blood flow (Leon et al., 1990; MacKenzie and Asbury, 1994). The suggestion of simply adding a constant correcting value (e.g., 2.2° C) to an arbitrary skin temperature to estimate central temperature has been shown to be unreliable (Burgess et al., 1978; Leon et al., 1990).

Body temperature varies widely within the body. Because of their high perfusion rates, core tissues tend to maintain a constant temperature, whereas peripheral tissues usually have significantly lower and less uniform temperatures that may differ by several degrees within a short distance from each other (Colin et al., 1971).

It has been suggested that hypothalamic temperature reflects core temperature, although there is no physiologic evidence that hypothalamic temperature precisely represents central temperature (Benzinger, 1969). Core-temperature measuring sites recommended for clinical use are the tympanic membrane, nasopharynx, distal esophagus, pulmonary artery, and, with some limitations, bladder and rectum. These sites usually provide equal readings in humans who are awake and in those who are anesthetized and undergoing noncardiac surgery (Cork et al., 1983). However, different temperatures may be measured at different monitoring sites and under certain clinical conditions, and the physiologic and clinical significance of these differences may vary.

The precision and accuracy of measurements at different body sites have been studied, and each site has its advantages and disadvantages (Cork et al., 1983; Bissonnette et al., 1989b). Ideally, the temperature-monitoring site reflects core temperature and is associated with only minimal or no morbidity.

Skin temperature measurements offer little as a reflection of core temperature (Lacoumenta and Hall, 1984; Bissonnette et al., 1989b). Because there is a wide variation in skin temperature, depending on the site of monitoring, several investigators have suggested monitoring between 4 and 15 sites, using different formulas to accurately describe the mean skin temperature (Shanks, 1975; Puhakka et al., 1994; Ram et al., 2002). For skin temperature to be of clinical value, it must closely reflect central temperature in the perioperative setting so that mild hypothermia and early signs of malignant hyperthermia (MH) can be detected. Beside the fact that increased body temperature is a late sign of MH, it is unlikely that skin temperature correlates well with central temperature during the early stages of MH, because circulating catecholamine concentrations may be up to 20 times higher than normal and result in significant changes of skin perfusion (Sessler, 1986; Sessler and Moayeri, 1990).

Tympanic-membrane temperature has been suggested as the most ideal temperature-monitoring site. Although it is not necessary for the temperature probe to be in direct contact with the tympanic membrane to accurately reflect tympanic temperature, the external auditory canal needs to be sealed by the probe to allow the air column trapped between the probe and the tympanic membrane to reach a steady-state temperature. During the initial postoperative period after infants and children have had cardiac reconstructive surgery, tympanic temperature does not correlate well with brain temperature and therefore does not provide a reliable estimate of central body temperature (Muma et al., 1991; Bissonnette et al., 2000). Because of difficulties associated with obtaining appropriate-sized thermistors and reports of tympanic membrane perforation, the clinical use of continuous intraoperative temperature measurement has been discouraged.

For a nasopharyngeal temperature probe to accurately reflect core temperature, its tip needs to be placed in the posterior nasopharynx close to the soft palate. This should provide a good estimate of the core temperature. However, using the probe with an uncuffed endotracheal tube that has a moderate to large air leak may lead to falsely low readings. Slight and self-limited bleeding from the nose may occur (especially in children with large adenoids), and its impracticability with mask anesthesia has limited its routine use. Nevertheless, because of the ease of its application and its reliability, this mode of temperature monitoring has been widely accepted in clinical practice.

In contrast, oral temperature is generally considered less adequate and is therefore not recommended as an accurate site for intraoperative temperature-monitoring (Cork et al., 1983).

Esophageal temperature probes are often combined with an esophageal stethoscope, which makes this site particularly attractive for the pediatric population. In infants and children, and in patients who are cachectic, the thermal insulation between the tracheobronchial tree and the esophagus is minimal. Therefore, the respiratory gas flow may result in erroneous temperature readings, particularly when the fresh gas flow is high and its temperature differs significantly from body temperature (Bissonnette et al., 1989b). Furthermore, central temperature is measured only if the tip of the probe is placed in the distal third of the esophagus at the point where the heart sounds are the loudest (Bissonnette et al., 1989b; Stoen and Sessler, 1990). In patients with endotracheal tubes, monitoring of esophageal temperature is more reliable than rectal temperature and more practical than tympanic temperature.

Axillary temperature is not only the most commonly used method of measuring temperature, but it is also the most convenient site for temperature monitoring. It has been reported to be as accurate in measuring central temperature as tympanic membrane, esophageal, and rectal temperature sites. However, this accuracy is only achieved when the tip of the thermometer is carefully placed over the axillary artery and the arm is closely adducted (Bissonnette et al., 1989b). Unfortunately, malpositioning of the probe may result in unreliable estimates of core temperature. Infusion of cool solutions at high flow rates in small children on the ipsilateral side of the thermometer probe may result in falsely low temperature readings.

Rectal temperature monitoring can provide a central temperature reading; it is associated with minimal morbidity and its ease of insertion confers major advantages (Bissonnette et al., 1989b). Problems to be considered with its use pertain to the probe's insulation by feces, its exposure to cooler blood

returning from the legs, the influence of an open abdominal cavity during laparotomy, or irrigations of the bladder or the abdomen with either cold or warm solutions. Relative contraindications for rectal temperature probe insertion are inflammatory bowel disease, neutropenia and/or thrombocytopenia, and the need to irrigate the bowel or bladder.

Bladder-temperature monitoring is considered to be one of the most accurate methods of measuring core temperature. Its precision has been demonstrated to be identical to pulmonary-artery-temperature monitoring as long as urinary output is high; however, when urinary output is normal or less than normal, this site may become inaccurate in reflecting central temperature (Horrow and Rosenberg, 1988; Brauer et al., 2000).

A pulmonary artery catheter with a distal-tip thermistor represents the gold standard for core temperature measurement in noncardiac surgery. Because of its invasive nature, its use—particularly in the pediatric population—has been limited to special situations, such as in critically ill children.

The site or sites for temperature monitoring are often guided by the surgical procedure. For patients undergoing cardiac surgery, in whom temperatures from different body sites convey useful information, temperature is usually measured in at least two sites (e.g., the rectum, bladder, esophagus, nasopharynx, or tympanic membrane).

For pediatric patients undergoing a short surgical procedure that does not require endotracheal intubation, either rectal or axillary temperature monitoring can be used safely. If the child is intubated, an additional option includes the use of a distal esophageal temperature probe.

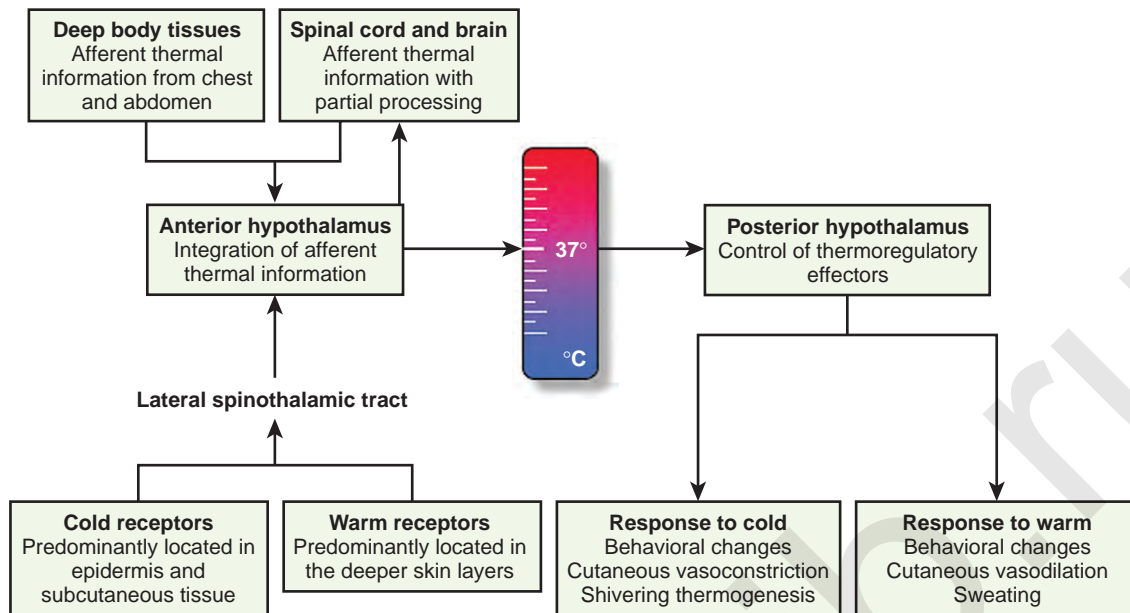

PHYSIOLOGY OF THERMAL REGULATION

Survival from body temperatures as low as 13.7° C has been reported, whereas death resulting from protein denaturation occurs within 7° C above normality at approximately 44° C (Gilbert et al., 2000). This illustrates a tolerance for cold that is more than three times higher than that for heat, which explains why the system for heat dissipation needs to be much more effective than the system for defense against cold.

The thermoregulatory system is similar to other physiologic control systems in the sense that the brain uses negative feedback mechanisms to keep temperature variations from normal values minimal. The principal site of temperature regulation is the hypothalamus, which integrates afferent signals from temperature-sensitive cells found in most tissues, including other parts of the brain, spinal cord, central core tissues, respiratory tract, gastrointestinal tract, and the skin's surface. The processing and regulation of thermoregulatory information occurs in three stages: afferent thermal sensing, central regulation, and efferent response (Fig. 6-1).

Afferent Thermal Sensing

Anatomically distinct warm and cold receptors in the body periphery sense the ambient temperature. The skin contains about 10 times more cold receptors than warm receptors, acknowledging the important function of the skin in the detection of cold (Poulos, 1981). Thermosensitive receptors are also located in close proximity to the great vessels, the viscera, and the abdominal wall, as well as in the brain and in the spinal

■ **FIGURE 6-1.** Illustration of the thermoregulatory pathways with afferent thermal information from various body parts being integrated in the anterior hypothalamus and triggering efferent responses in the posterior hypothalamus.

cord. Each receptor type transmits its information through an afferent-nerve-conduction pathway. Although information originates from anatomically different nerve fibers, the speed of transmission is mainly influenced by the intensity of the stimulus rather than the type of nerve fiber. It is well established that the rate of change in skin temperature alters the apparent importance of the change. Rapid changes contribute up to five times as much to the central regulatory system as slower changes with comparable intensity (Wyss et al., 1975). However, other than in patients undergoing cardiopulmonary bypass surgery (where rapid temperature changes are common), the rate of change in core temperature does not appear to substantially influence the magnitude of the provoked regulatory responses.

The thermal information from cold-sensitive receptors, which have their maximal discharge rate of impulses at a temperature between 25° and 30° C, is transmitted to the preoptic area of the hypothalamus by A-delta fibers.

Thermal information gathered from peripheral warm receptors, whose maximal discharge rate is between 45° and 50° C, is carried by unmyelinated C fibers. These C fibers also convey pain sensations, which explains why intense heat cannot be distinguished from severe pain (Pierau and Wurster, 1981; Poulos, 1981). Although most ascending thermal information travels along the spinothalamic tracts in the anterolateral spinal cord, no single spinal tract is solely responsible for conveying thermal information (Hellon, 1981).

Central Regulation

Integration of afferent thermal information takes place in the anterior hypothalamus, whereas the posterior hypothalamus controls the descending pathways to the effectors. Thermal inputs from the skin's surface, spinal cord, and deep body tissues are integrated in the preoptic area of the anterior hypothalamus and compared with the threshold temperatures, triggering heat gain or loss. Once the threshold has been reached, the

hypothalamus then carefully orchestrates the mechanisms for heat generation and dissipation in order to maintain body temperature within the narrow limits of its set point (interthreshold range).

The preoptic area of the hypothalamus contains cold- and heat-sensitive neurons, with the latter predominating by a ratio of 4:1 (Boulant and Bignall, 1973). However, the vast majority of the neurons in this area are insensitive to temperature (Nakayama et al., 1963). This area also receives and processes nonthermic afferent information, which seems to be important in controlling the adaptive mechanisms and the behavior of the organism (Hori and Katafuchi, 1998).

Direct heat stimulation of this area results in increased discharge rates from the heat-sensitive neurons and activation of heat-loss mechanisms. Conversely, hypothalamic cold-sensitive neurons respond with increased discharge rates to direct cooling of the preoptic area of the hypothalamus (Boulant, 1974; Boulant and Demieville, 1977). Other centers involved in thermoregulation include the dorsomedial hypothalamus, periaqueductal gray matter, the *nucleus raphe pallidus* in the medulla oblongata, and the spinal cord, although their functions are not yet fully elucidated (Guieu and Hardy, 1970; Simon, 1974; Cabanac, 1975; Dickenson, 1977).

The contribution of the central thermoreceptors to thermal regulation under normal conditions is limited by the marked predominance of thermal input from peripheral receptors (Downey et al., 1964). These central receptors take over thermoregulation if the sensory input from peripheral sensors is disrupted (e.g., through central neuraxial anesthesia or spinal cord transection), but they are less efficient when compared with peripheral thermoreceptors (Downey et al., 1967).

The threshold temperature defines the central temperature at which a particular regulatory effector is activated (Box 6-1). When the integrated input from all sources is signaling that the interthreshold range is exceeded on either side, efferent responses are initiated from the hypothalamus to maintain normal body temperature.

Box 6-1 Definition of Temperature Regulation Terms

Threshold temperature: Central temperature that elicits a regulating effect to maintain normothermia, e.g., vasoconstriction, vasodilation, shivering, sweating, or nonshivering thermogenesis

Interthreshold range: Temperature range over which no regulatory response occurs

Gain: Intensity of regulatory response

Mean body temperature: Physiologically weighted average temperature from various tissues

Nonshivering heat production: Metabolic thermogenesis above basal metabolism not associated with muscle activity

Shivering: Heat production through voluntary muscle activity

Dietary thermogenesis: Heat production through metabolism of nutrients

The slope of the response intensity plotted against the difference between the thermal input temperature and the threshold temperature is called the *gain* of that response (i.e., the intensity of the response).

The difference between the lowest temperature at which warm responses are triggered and the highest temperature at which cold responses are triggered indicates the thermal sensitivity of the system. As previously stated, the interthreshold range defines the temperature range over which no regulatory responses occur (although the brain presumably detects these temperature changes). This range changes from approximately 0.4° C in the awake state to approximately 3.5° C during general anesthesia. Compared with normal body temperature (37.0° ± 0.2° C), the interthreshold range during general anesthesia expands further into the hypothermic than into the hyperthermic range. This physiologic system acts as an “all-or-none” phenomenon. The mechanism by which the body determines the absolute threshold temperatures is not known, but it appears that the thresholds are influenced by multiple factors, including plasma concentrations of sodium, calcium, thyroid hormones, tryptophan, general anesthetics, and other drugs; circadian rhythm; exercise; pyrogens; food intake; and adaptation to cold and warm environments. Central regulation is already fully functional in neonates, but it may be impaired in the premature, elderly, or critically ill patient. It is now known that regulatory responses are based on mean body temperature.

Efferent Response

Mean body temperature (MBT) is a physiologically weighted average temperature that reflects the thermoregulatory importance of various tissues, but in particular that of the central compartment. In unanesthetized humans, the MBT can be calculated as follows:

$$MBT = 0.85 \times (\text{Central T}) + 0.15 \times (\text{Skin T})$$

where T denotes the temperature measured in °C. Other formulas do exist (Ramanathan, 1964; Colin et al., 1971; Shanks, 1975; Puhakka et al., 1994). See the following example:

$$MBT = 0.66 \times (\text{Rectal T} + 0.34 \text{ MSK})$$

where MSK reflects the mean skin temperature (in °C), which then equals:

$$MSK = 0.3 \times (\text{Chest T} + \text{Arm T}) + 0.2 \times (\text{Thigh T} + \text{Calf T})$$

From that it follows:

$$MBT = 0.66 \times \text{Rectal T} + 0.34 \times (0.3 \times [\text{Chest T} + \text{Forearm T}] + 0.2 \times [\text{Thigh T} + \text{Calf T}])$$

Skin temperature is the most important parameter in triggering behavioral changes; however, in terms of impact on the thermoregulatory autonomic response, the thermal input from the skin contributes only about 20% (Cheung and Mekjavic, 1995; Lenhardt et al., 1999). The main part of this autonomic response depends on afferent information from the central core, which includes the brain (parts other than the hypothalamus), the spinal cord, and deep abdominal and thoracic tissues, with each of them contributing about 20% to the central thermoregulatory control (Jessen and Mayer, 1971; Simon, 1974; Mercer and Jessen, 1978; Jessen et al., 1984).

The thermal steady state is actively defended by the hypothalamus responding to thermal changes, that is, temperatures exceeding the interthreshold range to either side. Thus, thermal deviations from the threshold temperature initiate efferent responses that either increase metabolic heat production (shivering or nonshivering thermogenesis) and decrease environmental heat loss (active vasoconstriction and behavioral changes) or increase heat loss (active vasodilation, sweating, and behavioral maneuvers).

Efferent responses (behavioral changes, cutaneous vasoconstriction or vasodilation, nonshivering thermogenesis, shivering, and sweating) appear to be mediated according to the central interpretation of the afferent input.

The most commonly described thermoregulatory model is a set-point system in which hypothalamic integration of thermal information indicates a body temperature above or below a predetermined threshold and then triggers warm or cold defenses. This set-point model, borrowed from engineering models, provides an easy way to explain how the thermoregulatory system functions and how temperature is regulated. In this model, the body compares its actual central temperature against a set reference temperature and then balances heat loss and heat-generating mechanisms to keep the temperature at this set reference point. However, while convenient, this model may not be accurate. More recent research suggests that peripheral and central thermoreceptors are connected through several other neurons to a thermoregulatory effector cell to form a thermoeffector loop (Kobayashi, 1989). In this set-up, once the temperature reaches the range for which the particular thermosensitive neuron has its highest sensitivity, its firing rate increases significantly and—independent of a central nervous system controller—triggers a response in the thermoregulatory effector. Central body temperature in this model is then the averaged result of all the thermoeffector loop actions combined, basically making a central controller (i.e., the hypothalamus) redundant (Kobayashi, 1989; Romanovsky, 2004). Although this more recent model has received a fair amount of attention, it has not yet been widely accepted in clinical practice.

Regardless of the actual model used, if an effective thermoregulatory system is in place, behavioral responses (e.g., heating the home, looking for shelter, or putting on a jacket) to environmental temperatures outside the thermoneutral range (approximately 28° C for an unclothed adult) remain the quantitatively most important thermoregulatory effectors in humans and are far more efficient than all of the autonomic responses combined. Cutaneous vasoconstriction is the first and most consistent thermoregulatory response to hypothermia. Total digital skin blood flow can be divided into nutritional (capillaries) and thermoregulatory (arteriovenous shunts) components. Cold-mediated decreases in cutaneous blood flow are most pronounced (down to 1% of the normal blood flow seen in a thermoneutral environment) in arteriovenous shunts of the hands, feet, ears, lips, and nose (Grant and Bland, 1931; Hillman et al., 1982). These shunts are typically 100 μm in diameter, which means that one can divert 10,000 times as much blood as a capillary with a 10 μm diameter under otherwise unchanged conditions (i.e., same length and pressure gradient) (Hales, 1985).

Neuronal regulation of blood flow in cutaneous arteriovenous shunts is different in glabrous (nonhairy) and nonglabrous (hairy) skin. In glabrous skin, blood flow is controlled by norepinephrine, whereas nonglabrous arteriovenous shunt flow is controlled by the opposing actions of noradrenergic vasoconstriction and cholinergic vasodilation.

Flow changes not only in the arteriovenous shunts, but also in the far more numerous capillaries (Coffman and Cohen, 1971). The impressive decrease in cutaneous perfusion secondary to thermoregulatory vasoconstriction results in a heat-loss reduction of 50% from the hands and feet, but only of 17% from the trunk, resulting in an overall heat-loss reduction of only 25% (Sessler et al., 1991).

Voluntary muscle activity, nonshivering thermogenesis, and shivering are the efferent mechanisms that lead to heat generation.

In contrast, exposure to warmth initially results in sweating, which triggers massive precapillary vasodilation with marked increase in skin blood flow. This allows for huge amounts of heat to be transported to the skin, from where it then dissipates to the environment, mainly by evaporation because of the pre-conditioning by sweat.

THERMAL REGULATION IN THE NEWBORN

Premature infants, infants who are small for gestational age, and even full-term neonates have an exceptionally large skin surface area compared with their body mass (assuming a normal ratio for a full-term neonate of 1, then the ratio for an adult is approximately 0.40). Heat loss is further increased because there is only a thin layer of subcutaneous fat and reduced keratin content of the infant's skin, which results in increased thermal conductance and increased evaporative heat loss. (Therefore, when compared with adults, neonates lose proportionately more heat through their skin in similar environments). In contrast to adults, the capabilities and the functional range of the neonate's thermoregulatory system are significantly limited and easily overwhelmed by environmental factors. The lower ambient temperature limit of thermal regulation in adults is

0° C, whereas that in newborns is 22° C. The combination of increased heat loss and a diminished efficacy of the thermoregulatory response with a reduced ability to generate heat puts these infants at high risk for hypothermia. The same anatomic properties that are responsible for the increased risk of hypothermia also allow for rewarming that is three to four times faster in infants and children compared with adults (Szmuk et al., 2001).

The neutral temperature (or the thermoneutral zone) is defined as the ambient temperature range, at which the oxygen demand (as a reflection of metabolic heat production) is minimal and temperature regulation is achieved through nonevaporative physical processes only (i.e., vasoconstriction or vasodilation). The upper limit of this range is called the *upper critical temperature* and marks the ambient temperature at which evaporative heat losses are triggered. Similarly, the lower critical temperature defines the ambient temperature below which metabolic heat generation is activated (nonshivering and/or shivering thermogenesis). Depending on the neonate's weight, this neutral temperature zone is in the range of 32° to 35° C (unclothed in a draft-free environment with uniform temperature and moderate humidity), whereas for an unclothed adult it is approximately 28° C (Hey, 1975). In a thermoneutral environment, the cutaneous arteriovenous shunts are open and skin blood flow is maximal.

Maintaining core temperature in a cool environment results in increased oxygen consumption and potentially metabolic acidosis. It was demonstrated long ago that oxygen consumption does not correlate with rectal temperature in full-term neonates, but rather it increases directly with the skin surface-to-environment temperature gradient (Adamson et al., 1965). Oxygen consumption is minimal at gradients of 2° to 4° C. Thus, at environmental temperatures of 32° to 34° C and an abdominal skin temperature of 36° C, the resting newborn infant is in a state of minimal oxygen consumption (i.e., in a neutral thermal state). Normal rectal temperature, therefore, does not necessarily imply a state of minimal oxygen consumption in this age group, because the baby could activate all its physiologic defense mechanisms to maintain normal rectal temperature (Fig. 6-2).

Of particular concern in view of thermoregulation in the newborn is the head, which comprises up to 20% of the skin's total surface area and shows the highest regional heat flux ability (Anttonen et al., 1995). In neonates and infants, the head may account for up to 85% of body-heat losses, which can be explained by the thin skull bones and the usually sparse scalp hair in combination with the close proximity to the highly perfused brain (core temperature) (Fleming et al., 1992). Facial cooling may increase oxygen requirements in the term and preterm infant by up to 23% and 36%, respectively, thereby further demonstrating the effectiveness of protecting the infant from heat loss by covering the head (Sinclair, 1972).

Thermoregulatory vasoconstriction and vasodilation are already present during the first day of life in both the premature and the full-term infant (Bruck, 1961; Lyons et al., 1996). With vasoconstriction, cutaneous blood flow decreases and the effect of tissue insulation increases, which results in an overall reduction in conductive and convective heat losses.

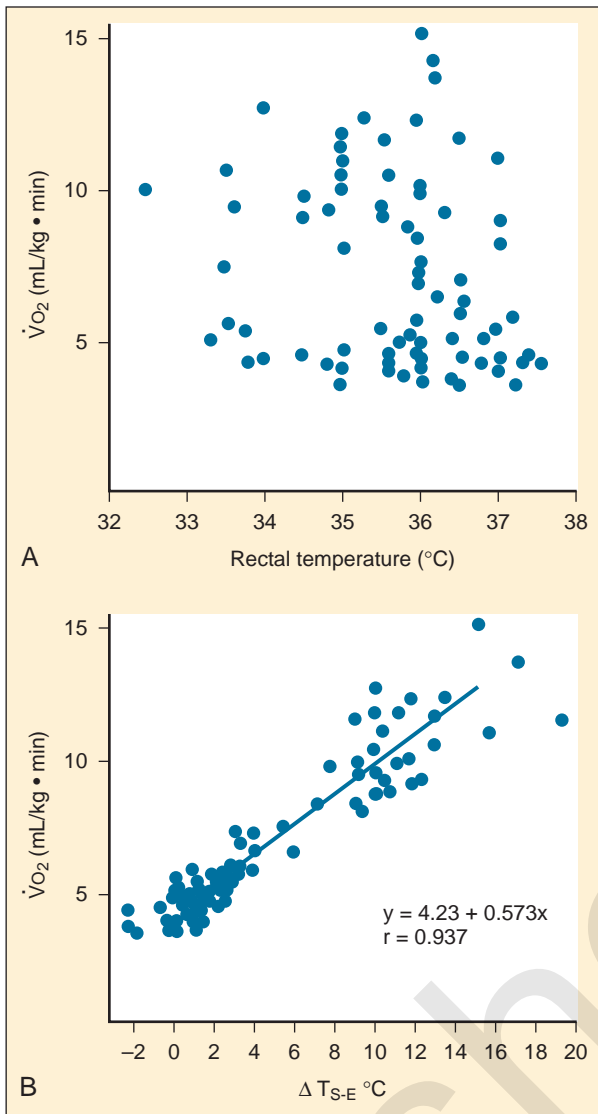

FIGURE 6-2. **A**, Relation of oxygen consumption ($\dot{V}O_2$) to rectal temperature. Note complete lack of correlation. **B**, Relationship between oxygen consumption and temperature gradient between skin temperature and environment (ΔT_{S-E}) in full-term human newborns with varying deep body and skin temperatures. (From Adamson KJ, Jr, Gandy GM, James LS: *The influence of thermal factors upon oxygen consumption of the newborn human infant.* J Pediatr 66:495, 1965.)

Heat loss for the premature infant or the infant who is small for gestational age represents the extreme of thermal regulation. The small size and decreased subcutaneous insulation tissue result in increased thermal transfer coefficients, thereby challenging the thermoregulatory capacity of these infants. The anatomic disadvantages further narrow the temperature range for thermoregulatory stability. In small-for-gestational-age infants, a slightly lower skin surface area-to-volume ratio and an increased motor tone offer some (although minor) protection, compared with the premature infant with regard to heat loss or transfer. In addition to the physical limitations of heat conservation in infants and children, surgery can further increase heat loss and fluid requirements by exposing the visceral surfaces of the abdomen and thorax, thereby exacerbating evaporative heat and water losses.

HEAT LOSS MECHANISMS

The abilities to produce and dissipate heat are fundamental for a homeothermic organism. Controlled heat loss in homeotherms is accomplished in two stages, both governed by the physical laws of conduction, radiation, convection, and evaporation (Box 6-2) (Swyer, 1973). The second law of thermodynamics states that heat can be transferred from a warmer to a cooler object but never from a cooler to a warmer object. What this means is that the warmer object (in the operating room setting, this is almost exclusively the patient) is used to warm up the surrounding cooler objects (e.g., the operating room walls, tables, and instruments). Although most anesthesiologists consider heat loss to be a nuisance, without any heat loss to the environment (i.e., perfect insulation), the body of an awake adult at rest (assuming a metabolic rate of 75 W) would warm up by at least $1^{\circ}C$ per hour. (Keep in mind that during exercise, metabolic heat generation can increase up to tenfold.) This can be calculated with the following formula:

$$HSR = mk \, dT_B / dt$$

where HSR is the heat storage rate (W), m is the body mass (kg), k is the specific heat coefficient of the human body ($3.5 \cdot 10^3$ J/ $^{\circ}C$), dT_B is the change in body temperature ($^{\circ}C$), and dt is the time interval (sec) (Burton, 1935).

The first stage of heat loss during anesthesia occurs with the transfer of heat from the body core (central compartment) to the periphery and the skin's surface, which is referred to as the concept of internal redistribution of heat. In the second stage, heat is dissipated from the skin's surface to the environment (see "Anesthesia and Hypothermia," p. 168). Physiologic manipulations of regional blood flow and changes in the thermal conductance properties of the insulation tissue can influence both gradients. Most studies of thermal regulation in infants and children have quantified the relative contributions of radiation, convection, evaporation, and conduction to heat loss. A study in newborns in a thermoneutral environment found radiation, convection, evaporation, and conduction to account for 39%, 34%, 24%, and 3%, respectively, of total heat loss (Hey, 1973). However, the conditions in the operating room rarely meet the criteria for thermoneutrality and the relative contributions of each of these four physical components to total heat loss can vary significantly. Figure 6-3 gives an overview of the heat loss mechanisms involved in the operating room setting.

Conduction

Conduction describes heat transfer between two surfaces in direct contact. The amount of heat transferred (C) depends on the temperature difference between the two objects in contact ($T_1 - T_2$), the surface area of the objects in contact (A), and the

Box 6-2 Mechanisms (by Percent) of Heat Loss for a Neonate in a Thermoneutral Environment

Radiation	39%	Evaporation	24%
Convection	34%	Conduction	3%

■ **FIGURE 6-3.** Schematic illustration of the four mechanisms contributing to perioperative hypothermia: (1) conduction, (2) evaporation, (3) convection, and (4) radiation. (Modified from Gurtner C, Paul O, Bissonette B: *Temperature regulation: physiology and pharmacology*. In Bissonette B, Dalens B, editors: *Pediatric anesthesia: principles and practice*, New York, 2002, McGraw-Hill.)

conductive heat transfer coefficient (h_k) of the materials and can be calculated as follows:

$$C = h_k A(T_1 - T_2)$$

The coefficient h_k is a property of the material or interface between the two objects that determines the rate of heat transfer per unit area per unit temperature difference ($W/m^2 \cdot ^\circ C$). During surgery, relatively little heat should be lost to the environment via conduction, because the patient is supposed to be well insulated from surrounding objects (Allen, 1987). However, conduction is also responsible for heat loss created by warming up cool intravenous fluids and irrigation solutions, which have the potential to significantly and quickly reduce body temperature. Attention should also be paid to ensure that the patient's skin is not in contact with any metallic surfaces, because metals have a high thermal conductivity, thereby facilitating heat transfer. (In addition, contact with metallic surfaces during surgery must be avoided to prevent skin burns from electrocautery.) The physiologic factors controlling conductive heat loss are cutaneous blood flow and the thickness of the subcutaneous tissue (insulation).

Radiation

Radiant heat loss refers to transfer of heat between two objects of different temperatures that are not in contact with each other (e.g., radiation is the mechanism by which the sun warms the earth). The emitted radiation carries the energy from the warmer object to the cooler object, thereby causing the warmer object to cool and the cooler object to warm. This heat transfer occurs in the infrared light spectrum. Heat exchange by radiation depends on the difference of the fourth power of the absolute temperatures of the two objects:

$$R = e s A (T_{sk}^4 - T_r^4)$$

where R is heat transfer by radiation (W), e is the emissivity (a material property with a value between 0 and 1), s is the Stefan Boltzmann constant ($5.67 \cdot 10^{-8} J/sec \cdot m^2 \cdot K^4$), A denotes the

surface area of the object (m^2), T_{sk} is the skin temperature, and T_r is the temperature of the second object (both temperature values in K).

Because the temperature differences for clinical purposes are rather small, it is acceptable to use a first-power relationship for T_{sk} and T_r , which then allows the calculation of radiation heat exchange as follows:

$$R = h_r A (T_{sk} - T_r)$$

where h_r denotes the radiation coefficient, an integration of emissivity and the Stefan Boltzmann constant. Heat transfer by radiation principally depends on the temperatures of the two surfaces concerned and is unaffected by air movement or the distance between the surfaces, and it can take place even across a vacuum (Allen, 1987).

As previously stated, newborns and infants have a large surface area-to-mass ratio, thus radiant heat loss is proportionally greater the smaller the infant. In both the infant who is awake and the infant who is anesthetized, radiation is the major factor for heat loss under normal conditions. The human body is an excellent emitter of energy at wavelengths relevant to heat transfer, and the probability of photon reflection in the standard operating room is almost zero. Radiant heat loss in the operating room is therefore a function of the temperature difference between the patient's body and the room (i.e., the floor, walls, and ceiling) and all the objects in it. Warming up the operating room (and its contents) reduces not only the temperature gradient between the patient and the environment but also radiant heat losses. However, as long as a temperature gradient exists, the patient continues to warm up the surrounding environment. At a room temperature of $22^\circ C$, about 70% of the total heat loss is a result of radiation (Hardy et al., 1941). A simple single-layer covering of the body dramatically reduces the heat loss by convection and radiation; thus, a thin shirt (e.g., a silk blouse, although it provides only negligible insulation) already results in considerably increased thermal comfort.

Convection

Convective heat loss describes the transfer of heat to moving molecules, such as air or liquids. The thin layer of air directly adjacent to the skin is warmed by conduction from the body, from which heat is then lost by convection. Changes in body posture and minute ventilation may also affect convective heat loss. In the case of an unclothed individual who is exposed to air, the rate and direction of convective heat exchange depend on airflow velocity ("wind speed") and the temperature difference between air and the skin's surface. The situation is more complex for a clothed individual. Convective heat transfer may be calculated as follows:

$$Q = h_c A (T_{sk} - T_a)$$

where Q is the heat exchange by convection (W), A is the surface area (m^2), h_c is the convective heat transfer coefficient ($W/m^2 \cdot ^\circ C$), T_{sk} is the mean skin temperature ($^\circ C$), and T_a is the ambient temperature ($^\circ C$). The convective heat exchange coefficient h_c is not a constant and depends on the rate of air movement (or fluid current), the shape of the body, and the surrounding medium (i.e., gas or liquid). Thus, convective heat loss increases in proportion to the temperature difference

between the body surface and the surrounding gas (or liquid) and the square root of the flow velocity of the gas (or liquid) in contact with the patient. Convective loss is best experienced outdoors in the form of the wind chill factor.

Evaporation

Evaporative heat loss occurs through the skin and the respiratory system. Under conditions of thermal neutrality, evaporation accounts for 10% to 25% of heat loss. Physical factors governing evaporative heat loss include relative humidity of the ambient air, velocity of airflow, and lung minute ventilation. The driving force behind evaporation is the vapor pressure difference between the body surface and the environment. Evaporative losses include mainly three components: sweat (sensible water loss); insensible water loss from the skin, respiratory tract, and open surgical wounds; and evaporation of liquids applied to the skin, such as antibacterial solutions. The evaporation of water from a surface is dependent on energy that is absorbed from the surface during the transition from a liquid to a gaseous state. This energy is called the *latent heat of vaporization*, and in the case of sweat, it has a value of 2.5×10^6 J/kg. This figure emphasizes the extraordinary power of the human sweating mechanism as a means of dissipating heat, especially considering that an adult in excellent physical condition can produce up to 2 or 3 liters of sweat per hour (Armstrong et al., 1986; Godek et al., 2008). In an environment where the air temperature is equal to or higher than the skin temperature, sweating is the only mechanism available for dissipation of heat that originates from metabolic production. In this situation, anything that limits evaporation, such as high ambient humidity or impermeable clothing, may easily lead to heat storage and a potentially fatal rise in body temperature. Evaporative heat loss can be calculated as follows:

$$E = h_e A_{\text{wet}} (P_{\text{sk}} - P_a)$$

where E is the evaporative heat loss (W); h_e is the evaporative heat transfer coefficient ($\text{W}/\text{m}^2 \cdot \text{kPa}$); P_{sk} is the water vapor pressure at the skin's surface; and P_a is the ambient water vapor pressure (both pressure values in kPa). The coefficient for evaporative heat exchange (h_e) incorporates the latent heat of vaporization of water and the paramount effect of air movement on evaporation. For practical purposes, h_e may be calculated from the following formula:

$$h_e = 124V^{0.5} (\text{W}/\text{m}^2 \cdot \text{kPa})$$

where V is the airflow velocity (m/sec). The important point to note is that evaporation is determined by the vapor pressure gradient between the exposed body surface and the ambient air and the rate of airflow across the surface (Allen, 1987).

Physiologic factors affecting evaporative losses relate to an infant's ability to sweat and to increase the minute ventilation. Although the physical characteristics of the newborn predispose him or her to heat loss, it has been demonstrated that neonates are capable of sweating in a warm environment (Bruck, 1961). Full-term neonates begin to sweat when rectal temperature reaches 37.5° to 37.9° C and ambient temperature exceeds 35° C. Although the onset of sweat production in infants who are small for gestational age is slower than it is in full-term infants, the maximum rates of sweat production are comparable (Sulyok et al., 1973). However, premature infants with a gesta-

tional age below 30 weeks show no sweating response because the lumen of their sweat glands are not yet fully developed.

Only a small amount of heat is lost when dry, inspired respiratory gases are humidified by water evaporating from the tracheobronchial epithelium. In adults, respiratory losses account for only 5% to 10% of total heat loss during anesthesia and surgery, and total insensible losses account for approximately 25% of the total heat dissipated (Bickler and Sessler, 1990). Minute ventilation on a per-kilogram basis in infants and children is significantly higher than in adults; thus, respiratory heat loss represents about one third of the total heat loss. Obviously, respiratory heat loss increases if the patient breathes cool, dry air as opposed to warm, moisturized air (Bissonnette et al., 1989a, 1989b).

Evaporative heat loss from a large surgical incision may equal all other sources of intraoperative heat loss combined (Roe, 1971). Because of increased evaporative heat loss, hypothermia is also more likely to occur if the skin of the patient is wet or comes in contact with wet drapes.

HEAT GENERATION

The ability to produce heat by increasing the metabolic rate and oxygen consumption is the other prerequisite of thermal regulation for a homeothermic organism (Hull and Smales, 1978). Beside the fact that three of the physical mechanisms leading to heat loss (i.e., conduction, radiation, and convection) can theoretically also be used to passively warm up a patient, the body has the ability to actively produce heat. Heat generation can be achieved through four mechanisms:

1. Voluntary muscle activity
2. Nonshivering thermogenesis
3. Involuntary muscle activity (shivering)
4. Dietary thermogenesis

The behavioral aspect of heat production (voluntary muscle activity) is usually not functional in the perioperative period and therefore its role in heat production will not be discussed further here. Of the three remaining mechanisms for heat production, nonshivering thermogenesis is the major component in the newborn, whereas shivering thermogenesis is the main mechanism for heat production in older children and adults. The contribution of nonshivering thermogenesis in adults is debatable (Jessen, 1980a).

Although both the time course and the relationship between nonshivering and shivering thermogenesis in infants have been described, the exact time sequence and factors involved in the developmental aspects of switching on shivering thermogenesis and nonshivering thermogenesis off remain to be elucidated (Hull and Smales, 1978). The importance of nonshivering thermogenesis seems to decrease rapidly after the first year of life, while at the same time shivering thermogenesis is becoming more and more effective (Fig. 6-4B). Under normal conditions, dietary thermogenesis will not contribute significantly to thermogenesis during anesthesia. It only affects temperature if the patient is given food with a high protein or fructose content before or during anesthesia, which is normally not the case.

Nonshivering Thermogenesis

Nonshivering thermogenesis is defined as an increase in metabolic heat production (above the basal metabolism) that is not associated with muscle activity. It occurs mainly through

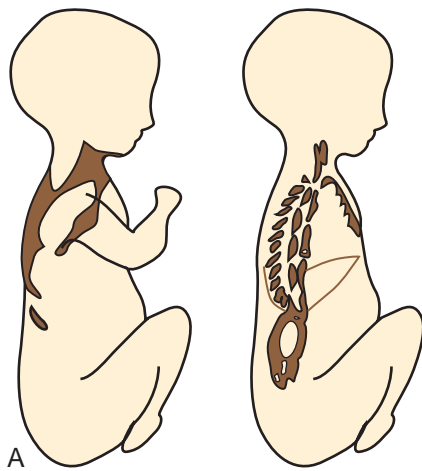

FIGURE 6-4. **A**, Brown adipose tissue in superficial (*left*) and deep (*right*) sites in the newborn. **B**, Relation of shivering thermogenesis to nonshivering thermogenesis as it appears in certain newborn animals. The time scale represents human development. (**A**, From *Aherne W, Hull D: The site of heat production in the newborn infant. Proc R Soc Med 57:1172, 1964.* **B**, From *Hull D, Smales ORC: Heat production in the newborn. In Sinclair JC, editor: Temperature regulation and energy metabolism in the newborn, New York, 1978, Grune and Stratton.*)

metabolism in brown fat and to a lesser degree also in skeletal muscle, liver, brain, and white fat.

Brown fat differentiates in the human fetus between 20 and 30 weeks of gestational age (Lean et al., 1986a). It comprises only 2% to 6% of the infant's total body weight and is found in six main locations: between the scapulae, in small masses around blood vessels of the neck, in large deposits in the axillae, in medium-size masses in the mediastinum, around the internal mammary vessels, and around the adrenal glands or kidneys (Fig. 6-4A).

Brown fat is a highly specialized tissue; the brown color is secondary to the abundant content of mitochondria in the cytoplasm of its multinucleated cells. These mitochondria are densely packed with cristae and have an increased content of respiratory-chain components (Himms-Hagen, 1976). They are unique in their ability to uncouple oxidative phosphorylation, resulting in heat production instead of generating adenosine triphosphate. This uncoupling process is mediated by the presence of the uncoupling protein 1 (UCP-1, or thermogenin) that is located on the inner mitochondrial membrane (Himms-Hagen, 1976; Ricquier and Kader, 1976).

Brown fat is highly vascularized and has a rich sympathetic innervation, which appears to be primarily β -sympathetic in

origin and responsible for the uncoupling of oxidative phosphorylation (Karlberg et al., 1962, 1965). In respect to nonshivering thermogenesis, mature brown fat cells mainly rely on activation by β_3 -receptors. Cold stress increases sympathetic nervous system activity and norepinephrine release, which causes increased lipase activity in the brown fat tissue (Schiff et al., 1966). As a consequence, hydroxylation of triglycerides and release of free fatty acids occur. These free fatty acids act on UCP-1 and thereby increase the protein conductance across the mitochondrial membrane. In addition to norepinephrine, glucocorticoids and thyroxin have been implicated as factors that trigger nonshivering thermogenesis (Gale, 1973; Jessen, 1980b, 1980c). The heat produced by nonshivering thermogenesis is mainly a by-product of fatty acid metabolism, but to a minor degree it can also result from glucose metabolism. The activation of brown fat metabolism results in an increased proportion of the cardiac output being diverted through the brown fat. This proportion may reach as much as 25% of the cardiac output, which facilitates the direct warming of the blood.

Pharmacologic inhibition of nonshivering thermogenesis can be achieved with ganglionic and β -receptor blockade, inhalational anesthetics, and surgically by sympathectomy (Silverman et al., 1964; Stern et al., 1965; Ohlson et al., 1994). Inhibition of nonshivering thermogenesis by inhalational anesthetics starts as early as 5 minutes after turning on the vapor and starts to wean off within approximately 15 minutes after discontinuation of the inhalational anesthetic (Ohlson et al., 1994). Nonshivering thermogenesis is also inhibited in infants who have been anesthetized with fentanyl and propofol (Plattner et al., 1997).

In general, nonshivering thermogenesis seems to be quite variable in adults, but most often it does not appear to be functional or relevant (Ohlson et al., 1994; van Marken Lichtenbelt and Daanen, 2003). This assumption is supported by the fact that oxygen consumption does not increase significantly when patients exhibit thermoregulatory vasoconstriction (Mestyan et al., 1964; Dawkins and Scopes, 1965). However, it seems that adults have the potential to regenerate brown fat tissue under certain pathologic conditions, such as pheochromocytoma (secondary to high and sustained sympathetic stimulation), Chagas' disease, hibernoma (a benign brown-fat tissue tumor), or marked cold acclimatization (Garruti and Ricquier, 1992; Lean et al., 1986b; Vybiral et al., 2000).

In contrast, premature and full-term neonates, as well as infants, are able to double their metabolic heat production during cold exposure (Mestyan et al., 1964; Dawkins and Scopes, 1965; Hey and Katz, 1969). Clinically significant nonshivering thermogenesis is possible within hours after birth and may persist up to the age of 2 years (Fig. 6-4, B) (Oya et al., 1997). Despite the fact that nonshivering thermogenesis is the main source of thermoregulatory heat production in infants, it should be kept in mind that its effect and sustainability are limited and do not compensate for the decreased ability of newborns and infants to effectively reduce heat loss through cutaneous vasoconstriction or the lack of heat production through shivering.

Core hypothermia or exposure to cold during general anesthesia with propofol and fentanyl do not trigger nonshivering thermogenesis in children; therefore, nonshivering thermogenesis seems to be nonfunctional (Plattner et al., 1997). Halothane anesthesia has been shown to block nonshivering thermogenesis

in children (Ohlson et al., 1994; Dicker et al., 1995). It has been demonstrated in animal studies that pharmacologic inhibition of nonshivering thermogenesis by β -blockade also affects shivering thermogenesis (Bruck and Wunnenberg, 1965). In the animals studied, shivering did not fully compensate for the lack of heat produced by nonshivering thermogenesis. The magnitude of nonshivering thermogenesis in animals varies among species, but it appears that in newborn versus adult animals and in cold-adapted versus warm-adapted animals, the contribution of nonshivering thermogenesis to heat generation is significant (Himms-Hagen, 1976).

Shivering Thermogenesis

The precise mechanisms and factors that govern the onset of shivering and the decline of nonshivering thermogenesis are unclear. With increasing age, shivering thermogenesis takes over a more prominent role in thermoregulation. It has been shown that shivering is triggered only after all the other cold defense mechanisms, such as behavioral responses, nonshivering thermogenesis (both ineffective under anesthesia), and maximal thermoregulatory vasoconstriction, have failed to maintain body temperature within the interthreshold range (Hemingway, 1963; Hemingway and Price, 1968). Until recently, newborns and infants were considered to be unable to shiver, presumably because of the general immaturity of the musculoskeletal system on the one hand and the limited muscle mass on the other hand, which would render muscle activity ineffective in defense against cold. However, a few reports exist about shivering in neonates occurring at rectal temperatures of 35.0° to 35.3°C (Brück, 1992; Petrikovsky et al., 1997). It is debatable whether this shivering was indeed thermoregulatory in origin or whether drugs and other factors (all mothers received an intrapartum amnioinfusion) were to blame. For clinical purposes, it is probably reasonable to say that neonates do not shiver, and if they do, it is of no (or only minor) significance for thermoregulation.

For a short time and only in an otherwise healthy and young person, shivering can result in an up to a sixfold increase in metabolic heat production and oxygen consumption, but only a twofold increase is sustainable (Horvath et al., 1956; Benzinger, 1969; Ciofolo et al., 1989; Just et al., 1992; Giesbrecht et al., 1994). Oxygen consumption in elderly patients (usually the age group with the highest risk for adverse cardiac events) increases on average by approximately 130% during shivering (Bay et al., 1968).

Shivering is characterized by involuntary, irregular muscular activity usually beginning in the muscles of the upper body (commonly the masseter). Overt shivering is preceded by a generalized increase in muscle tone, and only once this muscle tone reaches a certain threshold will shivering be detectable (Guyton, 2000). The intensity of shivering is higher in central muscles than it is in peripheral muscles (Bell et al., 1992).

Shivering occurs in two different electromyographic patterns: a basal, continuous shivering with low intensity at a rate of 4 to 8 Hz and superimposed bursts of high intensity at a rate of 0.1 to 0.2 Hz. The former is associated with type 1 and the latter with type 2 muscle fibers, with the bursts creating the typical “waxing and waning” pattern in the electromyogram (Stuart et al., 1966; Haman et al., 2004).

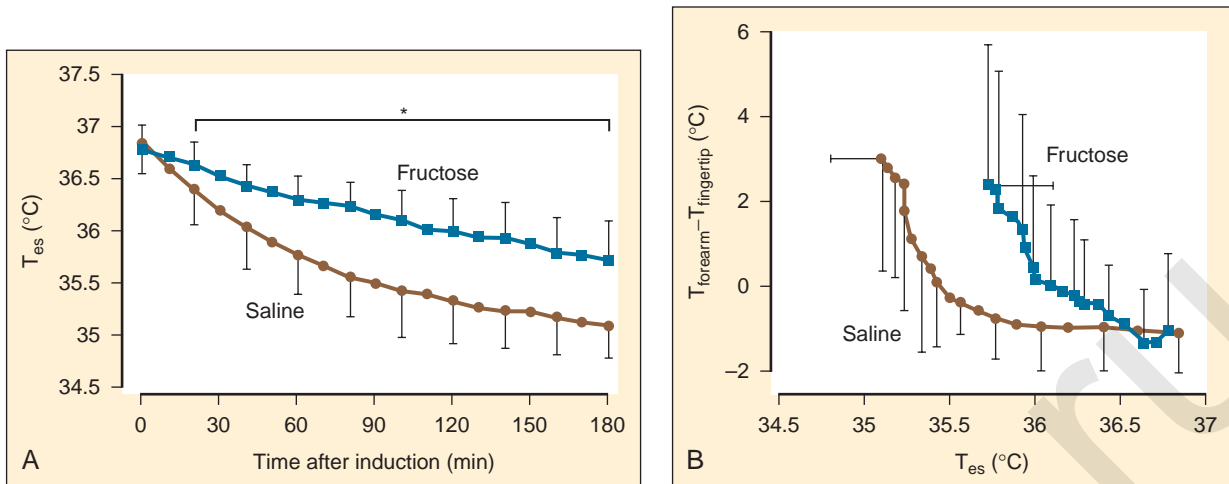

Impulses from cold receptors impinge at the motor center for shivering in the dorsomedial part of the posterior hypothalamus, adjacent to the wall of the third ventricle. In warm conditions, this center is inhibited by impulses from the heat-sensitive area in the preoptic region of the anterior hypothalamus. However, predominantly cold impulses from the skin and the spinal cord activate the shivering center, resulting in stimulation of anterior motor neurons of the spinal cord. Initially, this leads to the described generalized increase in skeletal muscle tone throughout the body, but it does not cause the actual shivering.

In healthy patients, this rise in oxygen consumption is easily met by increased cardiac output without any signs of cardiopulmonary compromise. In patients with already limited hemodynamic, coronary, or pulmonary reserves, this increase in oxygen demand can lead to decreased mixed venous oxygen content and eventually to decreased arterial oxygen content and tissue hypoxia. An inverse correlation has been shown between intraoperative temperature and postoperative oxygen demand, as well as between different anesthetics (see “Thermoregulation and General Anesthesia,” p. 172) (Roe et al., 1966). Shivering is not only an unpleasant experience for the patient in the postoperative period; it has also been implicated in increased intracranial and intraocular pressure, wound dehiscence, and dental damage (Mahajan et al., 1987; Rosa et al., 1995; Alfonsi, 2001).

Although the incidence of postoperative shivering is inversely related to the core temperature, shivering was also found in patients who were kept strictly normothermic during isoflurane or desflurane anesthesia, indicating that a substantial fraction of shivering is nonthermoregulatory, with pain being one potential trigger (Horn et al., 1998, 1999). Inhibition of shivering with meperidine in awake, actively cooled volunteers resulted in a more than threefold higher and more than four-times prolonged core temperature afterdrop with a rewarming rate decreased by 37% when compared with the shivering control group (Giesbrecht et al., 1997).

Dietary Thermogenesis

Stimulation of energy expenditure and thermogenesis by certain nutrients (i.e., proteins and amino acids) is a well-known phenomenon (Lindahl, 2006). Despite muscle paralysis and decreased metabolism during general anesthesia, the infusion of small amounts of amino acids resulted in up to a fivefold increase in heat generation during anesthesia compared with that in adults who were awake (Sellden et al., 1994). Using pre- and intraoperative amino-acid infusions, the same researchers were able to use this advantage clinically to achieve a core temperature of $36.5^\circ \pm 0.1^\circ \text{C}$ at the end of surgery, whereas the temperature dropped to $35.7^\circ \pm 0.1^\circ \text{C}$ in the control group (Sellden and Lindahl, 1999). Similar findings have been reported for preoperative amino-acid infusion in patients undergoing spinal anesthesia (Kasai et al., 2003). Although effective, the exact mechanism behind this form of thermogenesis has not yet been fully elucidated. It seems that stimulation of cellular amino-acid oxidation is crucial. Furthermore, protein synthesis and breakdown in extrasplanchnic tissues that require extra synthesis of ATP, could be a contributing factor as well. Approximately half of the heat generated in association with amino-acid infusions is splanchnic in origin. Blood flow in extrasplanchnic (but not splanchnic) tissues increases

■ **FIGURE 6-5. A**, Core temperature measured at the distal esophagus (T_{es}) during surgery. Patients receiving the fructose infusion had significantly greater core temperatures than those receiving saline (* $P = 0.001$). **B**, Relationship between the forearm-minus-fingertip temperature gradient ($T_{forearm} - T_{fingertip}$) and distal esophageal (core) temperature (T_{es}). Patients assigned to fructose infusion experienced vasoconstriction (increased in the gradient) at a significantly higher core temperature than did those receiving saline infusion ($P < 0.001$). (From Mizobe T, et al.: Fructose administration increases intraoperative core temperature by augmenting both metabolic rate and the vasoconstriction threshold. *Anesthesiology* 104:1124-1130, 2006.)

significantly, reflected by a raise in cardiac output of almost 20% (Brundin and Wahren, 1994). Except for a different time course, the average whole-body thermic effect of intravenous amino-acid administration is not different from the one seen with oral protein ingestion. Fructose administration has also been shown to increase the metabolic rate by 20% in anesthetized adult surgical patients. In a study of 20 patients, Mizobe et al. (2006) noted that intravenous fructose increased the intraoperative core temperature, oxygen consumption, and the vasoconstrictive threshold (Fig. 6-5). Dietary thermogenesis has the potential to cause hyperthermia not only during general anesthesia with attenuated thermoregulation, but also in the patient who is awake (Selden, 2002).

EFFECT OF ANESTHESIA ON THERMOREGULATION

Anesthesia and Hypothermia

There is no generally accepted definition for hypothermia, but the distinction between mild (core temperature 34.0° to 35.9° C), moderate (32.0° to 33.9° C), and severe hypothermia (below 32.0° C) appears useful and reasonable for clinical purposes (Brux et al., 2005). General anesthesia reduces the threshold at which the body initiates a thermoregulatory response to cold stress (Boxes 6-3 and 6-4). Mild intraoperative hypothermia (1° to 3° C below normal) is common and results from a combination of the following events:

1. A reduction of approximately 30% in metabolic heat generation during anesthesia (Brismar et al., 1982).
2. Increased environmental exposure.
3. Anesthetic-induced central inhibition of thermoregulation (Sessler and Ponte, 1982; Sessler, 1991).
4. Redistribution of heat within the body (Hynson et al., 1991a).

Box 6-3 General Effects of Anesthetics on Thermoregulation

1. Lowering of the threshold temperature for cold defense
2. Increasing the threshold temperature for heat defense
3. Tenfold widening of the interthreshold range to approximately 2° to 4° C
4. Generally no effect on the gain of the thermoregulatory response (except for desflurane)

Box 6-4 Specific Effects of Anesthetics on Thermoregulation

1. Opioids reduce threshold temperature for vasoconstriction and shivering as a linear function of dose.
2. Propofol reduces threshold temperature for vasoconstriction and shivering as a linear function of dose.
3. Volatile anesthetics produce a nonlinear inhibition of the thermoregulatory defense mechanisms, with the inhibition being proportionally greater at higher end-tidal concentrations.
4. Volatile anesthetics at comparable minimum alveolar concentrations produce similar degrees of thermoregulatory inhibition.
5. N_2O decreases vasoconstriction threshold less than halogenated volatile agents.

Hypothermia during general anesthesia has a typical profile and usually develops in three phases (Fig. 6-6):

1. Internal redistribution of heat.
2. Thermal imbalance.
3. Thermal steady state (plateau or rewarming).

FIGURE 6-6. This graph illustrates the three phases typical for the course of intraoperative hypothermia during general anesthesia. A represents the internal redistribution of heat; B is the thermal imbalance phase with ongoing net loss of heat to the environment; and C is the thermal steady state, which in children and infants is a rewarming phase. (Modified from Bissonnette B: *Thermoregulation and paediatric anaesthesia*. *Curr Opin Anaesthesia* 6:537, 1993.)

Internal Redistribution

In order to understand the concept of internal redistribution, it is helpful to use the previously described division of the human body into three thermal compartments, the central, peripheral, and skin (or “shell”) compartments. The core temperature represents the central compartment temperature, which contains the vessel-rich group organs receiving approximately 75% of the cardiac output and representing about 10% of the body

weight in adults and up to 22% in neonates. In an awake adult at rest, the entire central compartment accounts for approximately 66% of the body mass and extends to about 71% during general anesthesia (Deakin, 1998).

The peripheral compartment comprises the remaining part of the body mass (mainly muscles) and acts as a dynamic buffer to accommodate any changes in core temperature by thermoregulatory vasodilation or vasoconstriction. Its estimated buffer capacity of over 600 kJ allows the body to maintain core temperature constant with a minimal amount of energy expenditure for thermoregulation despite absorption or dissipation of significant amounts of heat.

The skin compartment is almost virtual and represents the barrier between the previous two compartments and the environment. After induction of anesthesia, peripheral vasodilation causes an increase in the size of the central compartment, forcing it to redistribute its heat within a larger volume. In addition, the anesthesia-induced reduction in metabolic heat generation decreases the amount of energy available to compensate for the enlargement of this compartment. The concept of internal redistribution of heat, therefore, consists primarily not of heat loss to the environment, but of a measurable decrease in core temperature and an increase in the peripheral and skin compartment temperatures because of redistribution of heat.

With induction of anesthesia, the central core temperature starts to decrease rapidly by approximately 0.5° to 1.5° C during the first 30 to 45 minutes of anesthesia (Fig. 6-7). Although this process results in reduced core temperature, the total body-heat content decreases only slightly. Heat—as the name implies—is mainly redistributed and not dissipated. This redistribution of heat accounts for 81% of the core temperature

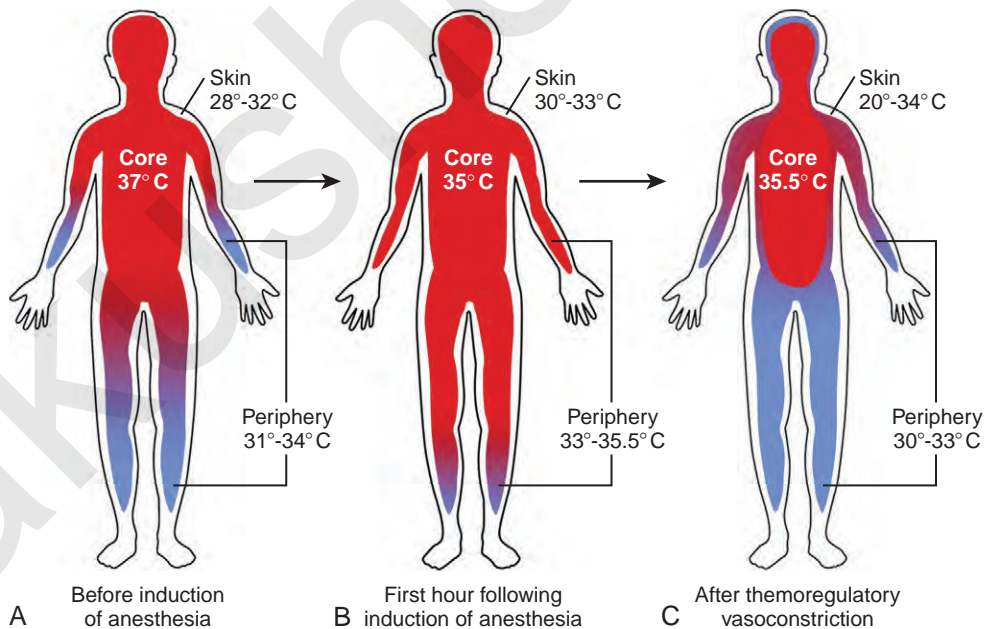

FIGURE 6-7. The dynamic changes within the three temperature compartments of a child before induction of anesthesia, during the first hour of anesthesia, and after thermoregulatory vasoconstriction. In the awake human, temperature and size of the compartments are considered normal (A). After the first hour of anesthesia, the internal redistribution of heat results in a rapid decrease in core temperature and an increase in peripheral temperature, together causing enlargement of the central compartment and shrinkage of the peripheral compartment (B). The drop in central temperature is mainly caused by the distribution of its heat to a larger volume, and actual heat loss is minimal at this stage. C, Once thermoregulatory vasoconstriction has been initiated (after about 3 hours of anesthesia), the central compartment is shrinking in favor of the peripheral compartment. The rise in central temperature is now due to the fact that generated heat is contained in a smaller volume.

decrease in the first hour of anesthesia, whereas the remainder is the result of the anesthesia-induced reduction in metabolism and increased heat loss. For the subsequent 2 hours of anesthesia, the impact of redistribution on total heat loss decreases to approximately 43% (Matsukawa et al., 1995b). Accordingly, administration of a vasoconstrictor, such as phenylephrine, can limit the drop in core temperature caused by redistribution (Ikeda et al., 1999a).

Internal redistribution results in shrinkage of the peripheral compartment and enlargement of the central compartment, which explains not only the decreased core temperature, but also the increased temperature in the peripheral and skin compartments (Fig. 6-7). This is reflected by a more than fourfold increase in the perfusion of the forearms and particularly the legs after induction of anesthesia, and a forearm-fingertip or calf-toe temperature gradient that may exceed 8° C (Matsukawa et al., 1995b).

Thermal Imbalance

The second phase, which is the result of reduced heat production combined with increased heat loss to the environment, lasts about 2 to 3 hours (see Fig. 6-6). This heat loss leads to an approximately linear decrease in mean body temperature (typically 0.5° to 1.0° C/hr). Decreased heat production during anesthesia is caused by limited or absent muscle activity, work of breathing, and the reduced metabolic rate (Stoen and Sessler, 1990; Washington et al., 1992). Heat loss to the environment is a function of the temperature difference between body surface and ambient structures (concept of patient warming up the environment), and therefore decreases passively as the patient becomes more hypothermic. As mentioned earlier, radiation, convection, evaporation, and conduction all contribute to heat loss from the patient to the environment during anesthesia and surgery.

Thermal Steady State (Plateau or Rewarming Phase)

The third stage of the hypothermic response to anesthesia consists of a thermal steady state, in which metabolic heat production equals heat dissipation to the environment, and the core temperature therefore remains constant (see Fig. 6-6). This plateau normally occurs between a core temperature of 34.5° to 35.5° C. This is only possible if the patient increases the heat production, decreases the heat loss, or both to prevent further hypothermia.

A study of adults who were anesthetized with isoflurane showed that the effect of thermoregulatory vasoconstriction reduces heat loss by a maximum of 25%, which is relatively small compared with the fall in metabolic rate and the increase in evaporative heat loss from the surgical incision (Sessler et al., 1992). Heat loss to the environment is determined mainly by the capillary blood flow in large areas of the skin that cover the limbs and the trunk. These capillaries markedly outnumber the arteriovenous shunts, but they cannot constrict as effectively as the shunts. It is possible that vasoconstriction contributes to the thermal plateau by reestablishing the temperature gradient between the central and the peripheral compartments and thereby preventing metabolic heat from being transported to the periphery, from which it would dissipate (see Fig. 6-7). The metabolic heat produced in the body core is once again confined to a smaller central compartment, allowing the core temperature to remain constant.

To reinforce this theory of compartment size, it should be noted that the use of a limb tourniquet during surgical procedures can influence the thermoregulatory response in children and adults (Bloch et al., 1992; Estebe et al., 1996). The tourniquet may induce hyperthermia, which is most likely the result of decreased effective heat loss from distal skin areas, as well as from metabolic heat constraint to the central thermal compartment. Upon release of the tourniquets, the core temperature drops quickly to levels similar to those in patients who were part of a control group without a tourniquet (Estebe et al., 1996; Sanders et al., 1996; Akata et al., 1998). Despite having a constant core temperature, total body-heat content continues to decrease, because heat loss to the environment continues.

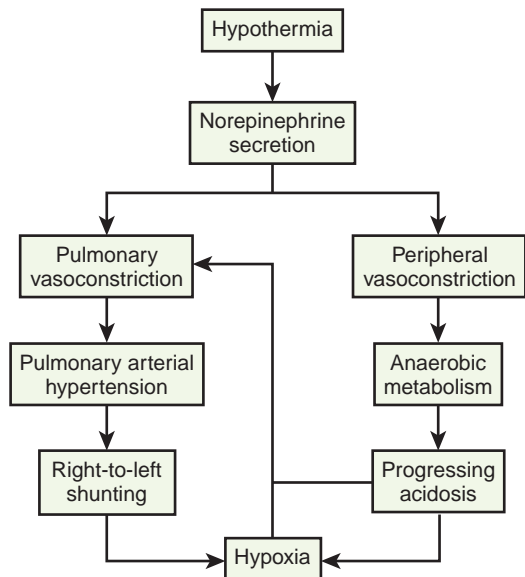

Unlike in adults, this third phase in infants and children is a rewarming rather than a plateau (see Fig. 6-6). As mentioned, general anesthesia decreases heat production by inhibiting muscular activity and nonshivering thermogenesis and by reducing the metabolic rate. Thus, the only possible explanation for this rewarming phase must be the occurrence of marked vasoconstriction within the peripheral and central compartments that results in shrinkage of the central compartment. The amount of metabolic heat produced is then distributed within a smaller central compartment volume and results in a higher core temperature. This is associated with a simultaneous increase in oxygen consumption, carbon dioxide production, and systemic norepinephrine levels, an effect that has been observed in infants who were anesthetized with isoflurane and paralyzed with vecuronium (Bissonnette, personal observation).

In contrast to adult responses, intraoperative thermoregulatory responses in infants are effective enough to significantly increase the core temperature despite a constant ambient temperature. A clinical study in anesthetized children found a twofold increase in oxygen consumption during mild hypothermia (Ryan, 1982). Both active and passive rewarming imposes significant physiologic stress on the infant. Passive surface rewarming (with the use of warm blankets, bundling, or other measures) turns off the skin's cold receptors. If normal core temperature is not reached or maintained with passive surface rewarming, hypothermia may result in hypoventilation or even apnea, relative anesthetic overdose (reduced minimum alveolar concentration [MAC] at lower temperatures), and metabolic acidosis. The increased oxygen demand to maintain normal core temperature in the anesthetized infant may create or exacerbate a preexisting cardiopulmonary insufficiency. The release of norepinephrine to trigger vasoconstriction may contribute to the development of acidosis and hypoxia, thereby facilitating right-to-left pulmonary shunting. Sustained pulmonary artery hypertension and right-to-left pulmonary shunting may begin a vicious cycle of hyperthermia (Fig. 6-8).

In infants, a correlation between intraoperative hypothermia and an early increase in postoperative oxygen consumption has been demonstrated (Roe et al., 1966).

Anesthesia and Hyperthermia

Similar to hypothermia, hyperthermia triggers important physiologic thermoregulatory responses by using thresholds and gains. Similar to hypothermia, the threshold temperature

■ **FIGURE 6-8.** The vicious cycle of hypothermia in neonates and infants. (Modified from Klaus M, Faranoff A: Care of the high-risk neonate, Philadelphia, 1986, WB Saunders.)

represents the central temperature for which a particular regulatory effector becomes active, whereas the gain quantifies the intensity of the response (Fig. 6-9). The effector mechanisms during hyperthermia are well preserved during anesthesia (Lopez et al., 1993). The efferent-response thresholds are shifted to higher temperatures with an expansion of the interthreshold range, which corresponds to the difference between the normal central temperature and the first efferent response triggered by the hypothalamus. An interesting observation with regard to the interthreshold range resides in the difference between the shift observed for hypothermia and the shift seen for hyperthermia.

The poikilothermic range to the hypothermic side in the anesthetized patient may be expanded by up to 3.5° C. In contrast, clinical studies in human volunteers have demonstrated that the threshold for active vasodilation and sweating is only 1.0° to 1.4° C higher in anesthetized patients than in those who

are awake (Lopez et al., 1993). This observation suggests that the human physiology responds more aggressively to the threats from hyperthermia than from hypothermia. Thus, hyperthermia seems to be a far more dangerous threat to the body than a comparable degree of hypothermia (Lopez et al., 1993).

The efferent responses during hyperthermic stress are limited to two mechanisms: active thermoregulatory vasodilation and sweating. Vasodilation triggered in response to warm stress is not simply the absence of vasoconstriction, but rather an active process mediated by sympathetic cholinergic impulses and release of vasoactive substances (e.g., vasoactive intestinal peptide [VIP], histamine) that results in increased dissipation of heat (Detry et al., 1972; Rübsamen and Hales, 1984; Kellogg et al., 1998; Bennett et al., 2003; Wilkins et al., 2004). It has been demonstrated that the effect of hyperthermia on the peripheral vasculature results in a significant increase in blood flow (Tankersley et al., 1991; Matsukawa et al., 1995b). The observation of active cutaneous vasodilation in infants under anesthesia, although difficult to quantify (skin flushing), suggests that this thermoregulatory response to hyperthermia is preserved.

Sweating represents an increase in evaporative cutaneous heat loss during episodes of heat stress. The relatively high heat of vaporization of sweat (2.5×10^6 J/kg) makes sweating an extremely effective process. This allows for up to a fivefold increase in heat loss to the environment, making it proportionally more effective than all the cold-defense mechanisms combined (Fusi et al., 1989).

A study in adult volunteers showed that sweating remains functional during isoflurane anesthesia (Sessler, 1991b).

The benefits provided by induced hyperthermia (vasodilation) may be desirable during peripheral microvascular surgery, where an increase in regional blood flow is important. One of the clinical limitations of induced hyperthermia to increase cutaneous blood flow is the efficiency of the sweating mechanism. Despite active transfer of approximately 50 W of heat across the patient's skin via convection and radiation, it was possible to demonstrate that the central temperature remains relatively constant or even decreases for exactly this reason (Sessler, 1993). Although shivering can easily double the heat production, sweating can result in the dissipation of more than 10 times the amount of normal basal heat production (Guyton, 2000).

■ **FIGURE 6-9.** Thermoregulatory thresholds and gains in awake and anesthetized adults, children, and infants. The vertical height/depth of each line indicating the threshold temperature represents the maximal intensity of each effector response, whereas the slope of the lines represents the gain of the response. The temperature scale corresponds to the core temperature. The sensitivity of the thermoregulatory system is the range between the first cold response (*vasoconstriction*) and the first warm response (*sweating*) and is called *interthreshold range*, which is significantly expanded during anesthesia. NST, Nonshivering thermogenesis.

Thermoregulation and General Anesthesia

Both intravenous and inhalational anesthetics can interfere with thermal regulation at peripheral and central receptor sites. In adults, general anesthesia has been shown to lower the thermoregulatory threshold temperature, triggering an average response to hypothermia by approximately 2.5° C, while the increases in the threshold temperature initiating a response to hyperthermia is less pronounced (approximately 1.3° C) (see Fig. 6-9) (Sessler et al., 1988a; 1988b). This anesthesia-induced expansion of the interthreshold range results in a wider temperature range over which active thermoregulatory responses are absent. Within this range, humans behave poikilothermically, with the body temperature changing passively in proportion to the difference between metabolic heat production and heat loss to the environment. Vasoconstriction and nonshivering thermogenesis are the only thermoregulatory responses available to anesthetized, paralyzed, hypothermic infants and children. Patients with mild hypothermia during surgery (e.g., a central body temperature of about 34.5° C) demonstrate profound peripheral vasoconstriction, which can easily be verified using the skin's surface temperature gradients (e.g., forearm versus fingertip skin temperature), volume plethysmography, a laser Doppler flowmeter, or other techniques (Stuart et al., 1966; Sessler et al., 1988a, 1988b).

Thermoregulation and Inhalational Anesthetics

The maximum intensity of peripheral thermoregulatory vasoconstriction during anesthesia is similar to that in volunteers who are awake, indicating that the gain of the response is preserved, but that it is triggered at a markedly lower threshold temperature. The only exception seems to be desflurane, which lowers not only the threshold temperature for vasoconstriction but also its gain (Kurz et al., 1995b). The temperature at which vasoconstriction and nonshivering thermogenesis are triggered identifies the corresponding lower thermoregulatory threshold for the anesthetic agent at any given concentration or dose.

Halothane administration in a concentration of 1.0% in oxygen to healthy adults undergoing donor nephrectomy reduced the threshold temperature for thermoregulatory vasoconstriction to 34.4° ± 0.2° C (Sessler et al., 1988a). In infants and children who were anesthetized with 0.6% halothane combined with a caudal epidural block with bupivacaine, the threshold temperature for vasoconstriction was 35.7° C (Bissonnette and Sessler, 1992). Of note, in children with a body weight of over 30 kg, the central temperature continued to drop even after the vasoconstriction threshold temperature had been reached, whereas children and infants with a body weight below 30 kg were able to maintain or even slightly increase their central temperature. This shows that thermoregulatory defense in infants and younger children is more effective than in older children and adults.

The administration of subanesthetic concentrations of nitrous oxide (10% to 25% in a normoxic mixture) to healthy adult volunteers resulted in a significant but dose-independent reduction of shivering thermogenesis (Cheung and Mekjavic, 1995).

In a concentration of 0.6 (63%) MAC, administration of nitrous oxide resulted in a calculated reduction of the vasoconstriction threshold to 35.7° ± 0.6° C (Goto et al., 1999). Overall,

nitrous oxide decreased the thermoregulatory vasoconstriction threshold less than equally potent concentrations of sevoflurane and isoflurane.

In a small study of adults anesthetized with isoflurane, the decrease in the threshold temperature for thermoregulatory vasoconstriction was found to be inversely correlated to the isoflurane concentration, with the threshold temperature decreasing by approximately 3° C per 1% increase in end-tidal isoflurane concentration (Stoen and Sessler, 1990). In a more recent study, the same group found that this dependence on dose was not linear, with isoflurane reducing the threshold temperature disproportionately at higher anesthetic concentrations (Xiong et al., 1996). In adults anesthetized with 0.7% isoflurane, the shivering-temperature threshold decreased, as did the maximum intensity of shivering. The gain of shivering increased significantly and was associated with a pattern of clonic muscular activity that was not a component of regular shivering (Ikeda et al., 1998a).

The thermoregulatory vasoconstriction-threshold temperature in infants and children anesthetized with isoflurane differs only slightly from that in adults (Bissonnette and Sessler, 1990). In pediatric patients anesthetized with 1 MAC halothane in 70% nitrous oxide, this same threshold temperature is higher (35.8° ± 0.5° C) than reported for adults (34.4° C) (Bissonnette and Sessler, 1990; Sessler et al., 1988a). In the adult study, the patients were anesthetized without nitrous oxide and the administered halothane concentration (1.3 MAC) was significantly higher than the one used in the pediatric study (1.0 MAC). In a separate study, a similar thermoregulatory threshold (35.8° ± 0.3° C) was found in pediatric patients who were anesthetized with 1 MAC of halothane in oxygen combined with a caudal epidural block with bupivacaine (Nebbia et al., 1996).

Thermoregulatory inhibition during general anesthesia with equally potent concentrations of halothane is therefore likely to affect adults and children similarly. The high surface area-to-mass ratio in infants, which allows for a rapid loss of heat to the environment, is largely offset by the high intrinsic metabolic rate. Heat loss is further reduced by the well-developed thermoregulatory vasoconstriction mechanism (Bissonnette and Sessler, 1990). Although a trend toward increased threshold temperatures was noted in smaller infants and children anesthetized with similar (age-corrected) concentrations of isoflurane, differences between groups were not statistically significant and spanned only about 0.3° C. This indicates that inhibition of thermoregulatory vasoconstriction is similar in anesthetized infants and children and relatively independent of body weight (Bissonnette and Sessler, 1990). This relatively constant degree of thermoregulatory inhibition in infants and children of different ages is in marked contrast to the age-related changes in the MAC of isoflurane. In infants 1 to 6 months of age, the MAC for isoflurane is approximately 1.5 times higher than the MAC for adults.

With regard to decreasing the threshold temperature for thermoregulatory vasoconstriction, sevoflurane was found to be similar to, although slower than, isoflurane, (Ozaki et al., 1997; Saito, 1997).

Desflurane increases the sweating threshold temperature in a concentration-dependent, linear way. The threshold temperatures for vasoconstriction and shivering at 0.8 MAC are comparable with the other volatile anesthetics, however, at 0.5 MAC, the drop in vasoconstriction threshold temperature was less pronounced. Thus, for desflurane there may be a nonlinear

concentration-response relationship for cold-defense mechanisms (Annadata et al., 1995b). Desflurane also reduces the gain of thermoregulatory vasoconstriction (Kurz et al., 1995).

Enflurane is a peculiar inhalational agent with respect to its thermoregulatory effects. In healthy adult volunteers anesthetized with 1.3% enflurane (equivalent to approximately 0.77 MAC), the threshold temperature for thermoregulatory vasoconstriction was $35.1^\circ \pm 0.6^\circ \text{C}$ without any patient stimulation and $35.5^\circ \pm 0.8^\circ \text{C}$ during painful electrical stimulation. This result demonstrated a slight, although clinically insignificant, effect of nociception in offsetting the anesthesia-induced thermoregulatory inhibition (Washington et al., 1992). Combination with caudal or lumbar epidural blockade eliminates this effect during abdominal and peripheral surgical procedures. Thermoregulatory studies with enflurane in the pediatric population are hampered by the lack of enflurane MAC studies for this age group. In pediatric patients aged 1 to 12 years, 1.67% enflurane (equal to 1 MAC in adults, which is estimated to be equivalent to 0.75 to 1.0 MAC for the age group studied) combined with caudal bupivacaine caused a profound drop in the threshold temperature for thermoregulatory vasoconstriction (Nebbia et al., 1996). Most patients in this study failed to achieve thermoregulatory vasoconstriction despite reaching a mean core temperature of $33.9^\circ \pm 0.9^\circ \text{C}$. It was therefore concluded that the risk of hypothermia with enflurane is significantly higher when compared with the risk for isoflurane or halothane.

The effects of different inhalational anesthetics on the threshold temperature for thermoregulatory vasoconstriction are summarized in Figure 6-10. In addition, hypothermia can affect the physical characteristics of inhalational anesthetics,

as well as the pharmacokinetics and pharmacodynamics of intravenous anesthetic drugs. Hypothermia reduces the MAC of inhalational agents (for isoflurane there is a linear MAC decrease of 5.1% per $^\circ \text{C}$ drop in core temperature) and increases their tissue solubility (Vitez et al., 1974; Eger and Johnson, 1987; Antognini, 1993; Antognini et al., 1994; Liu et al., 2001). Thus, for any inspired concentration of an inhalational anesthetic agent in a hypothermic patient, an increased amount of the agent is delivered to the tissues, when in fact the anesthetic requirements are decreased. Hypothermia also affects the pharmacokinetics of barbiturates and narcotics (Kadar et al., 1982; Koren et al., 1987).

Thermoregulation and Intravenous Agents

The effect of opioids on thermoregulation remained unclear until a few years ago. Alfentanil has been shown to significantly reduce the threshold temperature for thermoregulatory vasoconstriction. This reduction appears to be linear and in proportion to the plasma drug concentration (Kurz et al., 1995a). Meperidine and sufentanil linearly reduce the shivering threshold temperature (Alfonsi et al., 1998). Meperidine reduces the threshold temperature for shivering twice as much as it does the temperature for vasoconstriction, a side effect that is clinically used to treat postoperative shivering (Ikeda et al., 1997). Neither meperidine nor alfentanil reduce the gain and the maximum shivering intensity (Ikeda et al., 1998b). Tramadol slightly decreases the threshold temperature for sweating, whereas the threshold temperatures for vasoconstriction and shivering decrease linearly with the tramadol plasma concentration. In adult surgical patients, Mohta et al. (2009) have shown that tramadol is an effective prophylactic drug for reducing the incidence of postanesthetic shivering. Overall, with a doubling only of the interthreshold range, its effects on thermoregulation can be considered mild (De Witte et al., 1998).

A comparison between the temperature effects in children anesthetized with either ketamine or halothane showed that halothane decreases rectal temperature more than ketamine. Regardless of the agent used, children with the highest surface area-to-body weight ratio (i.e., the smallest children) had the greatest decrease in body temperature (Engelman and Lockhart, 1972). Core hypothermia in adults who are induced with ketamine is less pronounced when compared with the effect when they are induced with propofol. This finding was preserved during maintenance of anesthesia with sevoflurane in nitrous oxide/oxygen (Ikeda et al., 2001).

In the case of propofol, a small study of adult volunteers showed a significant and linear decrease in the threshold temperatures for vasoconstriction and shivering, whereas in another study the sweating threshold temperature increased only slightly (Leslie et al., 1994; Matsukawa et al., 1995c). Furthermore, induction of anesthesia with a single bolus dose of propofol (2.5 mg/kg) in adults and maintenance of anesthesia with sevoflurane in 60% nitrous oxide/oxygen resulted in lower core temperatures ($35.5^\circ \pm 0.3^\circ \text{C}$) when compared with patients who only received sevoflurane in nitrous oxide/oxygen for induction and maintenance of anesthesia ($36.2^\circ \pm 0.2^\circ \text{C}$) (Ikeda et al., 1999b). This led to the suggestion that brief propofol-induced vasodilation is sufficient enough to facilitate the core-to-peripheral redistribution of body heat, resulting in nonrecoverable heat loss to the environment.

FIGURE 6-10. Threshold temperature (in $^\circ \text{C}$) for thermoregulatory vasoconstriction in adults for different concentrations of inhalational anesthetics either alone or in combination with nitrous oxide. The x-axis denotes the MAC equivalents of the different inhalational anesthetics. (Data compiled from Sessler and Ponte, 1982; Washington et al., 1992; Annadata et al., 1995; Kurz et al., 1995b; Ozaki et al., 1995; Goto et al., 1999.)

Midazolam slightly reduces the threshold temperature for sweating, whereas the decrease in the threshold temperature for vasoconstriction is more profound, resulting in a threefold expansion of the interthreshold range, which is comparable with the results found for central neuraxial nerve blockade (Kurz et al., 1995c). These results contrast with the findings for inhalational anesthetics, propofol or opioids, which can expand the interthreshold range by a factor of 10 to 15 (Kurz et al., 1995c).

A bolus dose of clonidine followed by an infusion results in a dose-independent increase in the threshold temperature for sweating, but its gain remains unchanged (DeLaunay et al., 1996). The use of clonidine for premedication neither affects redistribution hypothermia nor does it worsen hypothermia during general anesthesia (Bernard et al., 1998).

Dexmedetomidine given to healthy adult volunteers does not affect the threshold temperature for sweating, but reduces the threshold temperatures for vasoconstriction and shivering in a dose-dependent way (Talke et al., 1997). Easley et al. (2007) have reported that dexmedetomidine (0.5 mcg/kg) was effective in the treatment of shivering within 5 minutes.

Atropine blocks sympathetic cholinergic-mediated sweating and increases the threshold temperature for sweating and therefore may lead to hyperthermia (Fraser, 1978).

Thermoregulation and Regional Anesthesia

During regional anesthesia, central thermoregulation remains functional, as does metabolic heat generation, thereby providing some protection against hypothermia (Hynson et al., 1991). Regional anesthesia interferes with regional thermal sensation (afferent and efferent pathways) and inhibition of thermoregulatory vasoconstriction and shivering in the anesthetized area. Increased internal redistribution of body heat followed by increased heat loss to the environment may contribute to intraoperative hypothermia. In many aspects, the factors responsible for intraoperative hypothermia during neuraxial blockade are similar to those for patients under general anesthesia: redistribution of body heat from the core to the peripheral compartment accounts for 89% of the initial drop (i.e., in the first hour) in core temperature. In the following 2 hours, redistribution contributes to 62% of the core temperature decrease (Matsukawa et al., 1995a; 1995b). The extent of this redistribution, and thus the decrease in core temperature, depend on inhibition of peripheral vasoconstriction rather than on centrally mediated effects. Neuraxial anesthesia usually affects a major part of the body mass and the decrease in core temperature can be quite pronounced. However, heat production during regional anesthesia is only minimally decreased (Hynson et al., 1991).

In contrast to patients undergoing general anesthesia, patients under central neuraxial anesthesia may fail to reach a steady state in which heat loss and heat generation are equal, because peripheral vasoconstriction is completely abolished in the area affected by neuraxial blockade. In addition, extensive regional anesthesia may alter or even block the thermal input to the hypothalamus from the anesthetized body part, with the number of dermatomes blocked being directly proportional to the inhibition of central thermoregulation (Ozaki et al., 1994; Leslie and Sessler, 1996; Frank et al., 2000). Heat loss may therefore be an ongoing issue until

sympathetic function and consequently the ability for vasoconstriction have been restored. Under these circumstances, hypothermia during regional anesthesia may become even more profound than during general anesthesia. In an attempt at compensation, peripheral vessels not affected by regional anesthesia are maximally vasoconstricted, although this is often not sufficient to prevent a further drop in core temperature, particularly when the body mass affected by regional anesthesia is approximately the same or even larger than the unblocked mass.

Shivering is initiated once the patient's core temperature reaches the shivering threshold; however, neuraxial blockade reduces the gain of shivering by more than 60%, mainly because the upper body muscles fail to compensate for lower body paralysis (Kim et al., 1998). It seems unlikely that systemic absorption of local anesthetics contributes to the thermoregulatory changes seen under regional anesthesia, because a study generating equal plasma drug concentrations without regional anesthesia failed to reproduce these thermoregulatory disturbances (Glosten et al., 1991).

Compared with general anesthesia, the use of regional anesthesia reduces the risk of hypothermia, especially during surgery with small incisions where the patient can be kept well insulated. In contrast, regional anesthesia for large surgical incisions predisposes a patient to more profound hypothermia than with general anesthesia, and recovery to normal body temperature may be prolonged (Cattaneo et al., 2000).

In adults, the changes in threshold temperatures for sweating, vasoconstriction, and shivering during spinal anesthesia and epidural anesthesia seem to be comparable and result in a twofold expansion of the interthreshold range (Ozaki et al., 1994). In adults, the combination of general anesthesia with thoracic epidural anesthesia further reduced the threshold temperature for thermoregulatory vasoconstriction and thus significantly aggravated hypothermia compared with general anesthesia alone (Joris et al., 1994). Interestingly enough, diabetic patients with autonomic neuropathy showed lower core temperatures and delayed thermoregulatory vasoconstriction during general anesthesia than diabetic patients without autonomic dysfunction (Kitamura et al., 2000).

Unlike the thermoregulatory effects of regional anesthesia in adults, the institution of a caudal block in children anesthetized with halothane does not significantly alter the threshold temperature for thermoregulatory vasoconstriction in children (35.7° C without versus 35.9° C with caudal block) (Bissonnette and Sessler, 1992). Nevertheless, temperatures during regional anesthesia should be monitored in adult and pediatric patients, because significant hypothermia is common and remains otherwise undetected and therefore also untreated. However, a survey revealed that only a third of clinicians monitors body temperature during regional anesthesia in adults (Frank et al., 1999).

ADVERSE EFFECTS OF HYPOTHERMIA

Heat loss in children undergoing surgery can occur for a variety of reasons. Exposure of body cavities to low environmental temperatures and humidity, infusion of cold fluids, and ventilation with cold and dry gases, in combination with the infant's physical characteristics of the large body surface area-to-mass ratio and the minimal insulating tissue layer, the potential for

an infant or a child to become hypothermic during anesthesia is significantly increased. Nevertheless, hypothermia must not be viewed as an inevitable consequence of surgery. Although hypothermia may be protective for a small subgroup of patients with certain ischemic conditions, in the majority of patients the adverse effects outweigh the benefits, and inadvertent core hypothermia must be avoided (Illievich et al., 1994). In a review of temperature monitoring and perioperative thermoregulation, Sessler (2008) noted that hypothermia-related complications include increased morbidity, surgical wound infections, coagulopathies, increased allogenic transfusions, negative nitrogen balance, delayed wound healing, delayed postoperative anesthetic recovery, prolonged hospitalization, shivering, and patient discomfort.

A study of 200 adult patients scheduled for colorectal surgery showed that patients who were allowed to become hypothermic (core temperature $34.7^{\circ} \pm 0.6^{\circ} \text{C}$) during the procedure suffered from a more than threefold higher rate of surgical wound infections than the group who was actively warmed and kept normothermic ($36.6^{\circ} \pm 0.5^{\circ} \text{C}$) (Kurz et al., 1996). Furthermore, the times until suture removal and discharge from hospital in the hypothermia group were prolonged by 1 and 2.6 days, respectively. It has been suggested by these and other researchers that the vasoconstriction triggered by hypothermia may result in a decreased tissue partial pressure of oxygen, which leads to increased wound infection and finally delayed wound healing, even in the absence of an infection (Fig. 6-11) (Jonsson et al., 1991). A shorter

hospital stay (2.7 fewer days) for normothermic versus hypothermic patients has also been reported by others (Selden and Lindahl, 1999). In addition, hypothermia itself has been shown to reduce chemotaxis and phagocytosis of granulocytes, natural killer cell cytotoxicity, migration of macrophages, and synthesis of immunoglobulins, thereby directly affecting the immune response (Leijh et al., 1979; van Oss et al., 1980; Wenisch et al., 1996; Beilin et al., 1998).

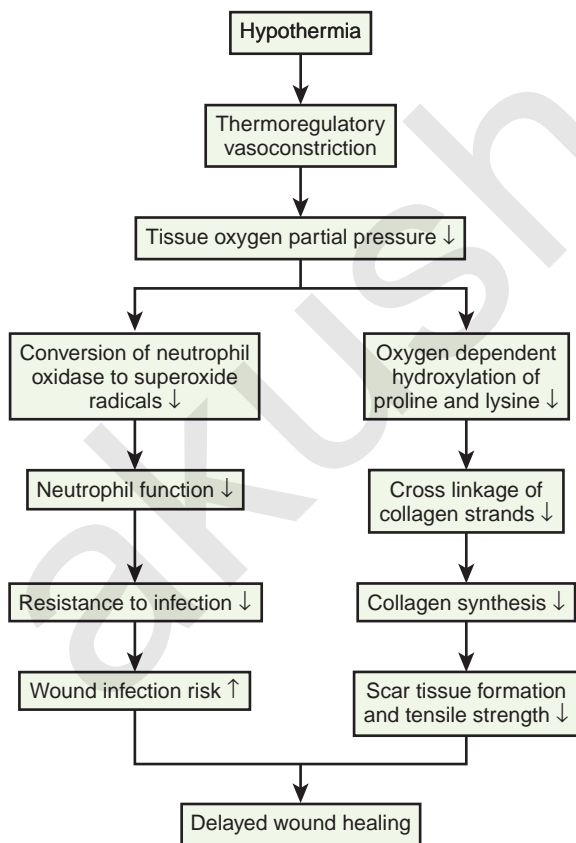

Hypothermia significantly delays the reactions in the coagulation cascade (most likely because of a direct effect on the activity of the coagulation factors) with prolongation of prothrombin time and partial thromboplastin time (Rohrer and Natale, 1992). Inhibition of platelet function with prolonged bleeding time was found during hypothermia, secondary to inhibited up-regulation of platelet surface protein GMP-140 and down-regulation of the glycoprotein GP Ib-IX complex, reduced platelet aggregation, and thromboxane B_2 generation (the stable metabolite of thromboxane A_2) (Michelson et al., 1994). This platelet dysfunction is fully reversible with rewarming. Thromboelastography confirms these findings with a prolongation of the reaction and coagulation times, as well as a reduction in the clot formation rate (Downing et al., 1995). It is therefore not surprising that blood loss in patients undergoing hip arthroplasty was found to be significantly higher in the hypothermia group (core temperature, $35^{\circ} \pm 0.5^{\circ} \text{C}$) than in the normothermia group (core temperature, $36.6^{\circ} \pm 0.4^{\circ} \text{C}$) (Schmied et al., 1996). Similar results have been confirmed by other researchers (Bock et al., 1998; Rajagopalan et al., 2008).

Notably greater incidences of myocardial ischemia and PaO_2 values below 80 mm Hg have been reported in hypothermic patients (defined by sublingual temperature measured on arrival to the recovery room) when compared with normothermic patients in the first 24 hours after lower extremity vascular surgery with either epidural or general anesthesia (Frank et al., 1993). Although these findings are most likely not relevant to most pediatric patients because of the lack of coronary heart disease, they nevertheless demonstrate the widespread and potential impact of hypothermia on the body in surgical patients.

Hypothermia results in diminished metabolism of drugs and prolongs their action. Although intraoperative hypothermia in adults resulted in delayed recovery from anesthesia when compared with normothermic patients, no such differences could be demonstrated in children (Bissonnette and Sessler, 1993; Lenhardt et al., 1997).

Studies on the effects of hypothermia and muscle relaxants have demonstrated that hypothermia decreases the requirements for nondepolarizing muscle relaxants because there is an increased sensitivity of the neuromuscular junction, as well as diminished biliary (indicating a reduced affinity for the drug substrate to microsomal enzymes) and renal elimination of the drug (Ham et al., 1978; Miller et al., 1978). Similar findings have been confirmed for other medications (McAllister and Tan, 1980).

Although similar studies are lacking for the pediatric population, there are no reasons to believe that the results would be significantly different from those in adults. Avoiding hypothermia in the infant and child is therefore as crucial as in adults and requires not only an understanding of thermal physiology, but also meticulous attention to detail in anesthetic care.

■ **FIGURE 6-11.** Hypothermia and its adverse effects on immune function and wound healing (↓ represents a decrease; ↑ indicates an increase in the corresponding response).

PREVENTION OF HYPOTHERMIA

Operating Room Temperature

Keeping the operating room temperature at an optimal level is crucial in the prevention of hypothermia. The major source of heat loss in the anesthetized patient is caused by radiation. As mentioned previously, radiant heat loss is a function of the temperature difference between the patient and the environment. The effectiveness of controlling ambient operating room temperature in controlling the temperature of newborns during surgery has been confirmed (Bennett et al., 1977). In adults, 21° C is reported as the critical ambient temperature for maintaining normal nasopharyngeal or esophageal temperatures (36° to 37.5° C) (Morris and Wilkey, 1970; Morris, 1971a, 1971b). Operating room temperatures of 27° and 29° C are recommended for full-term and premature newborns, respectively. It is essential that every operating room be equipped with an individual thermistor control unit so that the temperature in each operating room can be controlled independently to meet the needs of each patient.

Convective heat loss in the operating room is due to the constant air draft caused by the air conditioning system. Keeping the patient covered provides the best protection against this form of heat loss.

Evaporative heat loss from the respiratory tract accounts for only 5% to 10% of total heat loss during anesthesia. However, more important are the evaporative heat losses from open body cavities during surgery. In order to reduce this form of heat loss, the relative humidity of the operating room should be kept in the range of 40% to 60%.

Radiant Heaters

Radiant heaters are mainly used during induction of anesthesia and insertion of catheters, until the patient is prepared and draped. Prolonged use of radiant heaters may result in increased insensible water losses. The minimal manufacturer-recommended distance of the radiant heater from the skin must be respected at all times in order to avoid skin burns.

Reflecting Blankets

The use of reflective blankets in adults has produced conflicting results, and data on their use in infants and children are sparse. In adults, it has been reported that intraoperative normothermia can be maintained when the reflective blanket covers 60% or more of the patient's body surface area (Bourke et al., 1984). One drawback of reflective blankets is the potential build-up of condensation on the inner side, which can result in wet clothes or skin, putting the patient at high risk for evaporative heat loss. With regard to heat conservation, it seems not that important what material the cover is made of; instead, it is important to cover as much of the body surface as possible (Sessler et al., 1991). The practice of covering the head with a plastic bag provides an easy, inexpensive way to significantly reduce radiant, convective, and evaporative heat losses (Fig. 6-12).

■ **FIGURE 6-12.** The head of an infant constitutes a large fraction of its body size; therefore, covering the infant's head and as much as possible of the remaining body surface with plastic wrap can significantly reduce evaporative and convective heat loss.

Skin-Surface-Warming Devices

The use of skin-surface-warming devices in adults before the induction of anesthesia reduces the magnitude of hypothermia that results from internal redistribution of heat (Glosten et al., 1993). Aggressive skin-surface warming induces peripheral vasodilation and favorably increases the temperature of the peripheral compartment to values approaching those of the central compartment. The net result is an increased mean body temperature, and the skin-surface warming reduces the amount of energy transferred from the central to the peripheral compartment after induction of anesthesia. A variety of passive and active skin-surface warmers are available, including circulating hot-water blankets, infrared radiant heaters, and convective forced-air heaters, which blow warm air through a disposable blanket to raise the effective ambient temperature immediately surrounding the patient (Stephen et al., 1960; Vale and Lunn, 1969; Morris, 1971b; Goldblat and Miller, 1972; Sessler and Moayeri, 1990; Steele et al., 1996). A newer system that simulates water immersion using a special garment and feedback algorithms analyzed by computer to achieve a preset body temperature is available, seems to perform well, and is also safe in children (Nesher et al., 2001a, 2001b; Nesher et al., 2002). Of all these devices, convective forced-air warmers are by far the most effective, not only from a thermoregulatory perspective, but also from a cost and convenience point of view. Not only can they maintain normal body temperature, but they can also rewarm a hypothermic patient (Sessler and Moayeri, 1990; Kurz et al., 1993; Ciuffo et al., 1995; Karayan et al., 1996). In patients with decreased peripheral perfusion (e.g., because of high doses of vasoconstrictors, aortic cross clamping for coarctation or abdominal aortic aneurysm repair, or severe peripheral arterial occlusive disease) the device should be used with great caution only and not for extended lengths of time to avoid skin burns, particularly in infants and neonates (Azzam and Krock, 1995; Truell et al., 2000; Siddik-Sayyid et al., 2008).

Warming Mattresses

The use of warming mattresses reduces conductive heat loss. Warming mattresses set at 40° C and covered with two layers of cotton blankets have been demonstrated to effectively conserve heat (Goudsouzian et al., 1973). This measure is mainly efficient for infants with a body surface area of less than 0.5 m². In older children and adults, only a small proportion of the skin's surface area is in direct contact with the heating mattress, which makes these devices generally less effective to maintain normothermia.

Warming of Intravenous Fluids

Rapid infusion of chilled intravenous fluids (1° to 6° C) can be used effectively to induce hypothermia. The administration of 1 L of an ice-cold infusion in an adult is expected to decrease the core temperature by approximately 1.7° C, but values of up to 3° C are possible (Baumgardner et al., 1999; Rajek et al., 2000). Thus, intravenous fluids and blood products should be warmed before administration. It is particularly important to warm fluids in instances of rapid or massive fluid administration. In addition, attention should be paid to the length and the type of the infusion tubing, because significant heat loss of the infusion during transit from the warming device to the intravenous cannula may occur (Faries et al., 1991; Bissonnette and Paut, 2002). Even when warming the infusion to 37° C, a flow rate of more than 750 mL/hr is required to keep its temperature above 32° C at a distance of 25 cm away from the warmer when the infusion tubing is exposed to ambient air (20° C) (Faries et al., 1991). Because this flow rate is usually beyond the needs of regular pediatric cases, the length of the infusion tubing distal to the warmer should be kept as short as possible. Although a study demonstrated that conservative fluid management (1 mL/kg per hour of crystalloids warmed to 37° C) in patients aged 1 to 3 years resulted in less core hypothermia when compared with the control group who received a more aggressive fluid replacement (10 mL/kg per hour) (Ezri et al., 2003), this should not preclude pediatric patients from receiving appropriate intraoperative fluid resuscitation.

Because both the peritoneal and thoracic cavities are large heat-exchanging areas, solutions for intraoperative irrigation should always be warmed to body temperature. Although desirable from a thermoregulatory point of view, antimicrobial solutions for surgical skin preparation should not be warmed, because heat can cause chemical breakdown of the iodine solution and thereby inactivate its antimicrobial properties.

Humidified and Heated Gases

When breathing spontaneously (without an endotracheal tube or laryngeal mask airway in place), the tracheobronchial epithelium heats and moistens the inspired air, an energy-dependent process (evaporation and convection). Intubation significantly reduces the epithelial surface area that is available for warming and humidification of inspired gases. In order to minimize convective and evaporative heat losses from the respiratory tract and to minimize adverse effects on the tracheobronchial epithelium, inspiratory gases should be

heated and humidified. Airway humidification in intubated patients prevents tracheal damage caused by dry inspired gases, increases tracheal mucus flow, and minimizes respiratory heat losses (Berry et al., 1973; Forbes 1974; Mercke 1975; Chalon et al., 1979b; Tollofsrud et al., 1984). Heat and humidity can be added to inspired gases either actively by evaporative or ultrasonic heated humidifiers or passively by heat and moisture exchanging filters ("artificial noses") (Newton, 1975; Chalon et al., 1979a, 1984; Bissonnette et al., 1989a). Furthermore, there is considerable evidence that a relative humidity level of at least 50% is required to maintain normal ciliary function in the respiratory tract and to help prevent bronchospasm (Forbes, 1974; Mercke, 1975; Chalon et al., 1979a; Chan et al., 1980). More recent research, however, suggests an even higher humidity level of 75% to 100% to effectively maintain mucociliary function (Kilgour et al., 2004). Humidification to 50% (but not to 75% to 100%) is easily obtained with heat and moisture exchanging filters and should be standard for long procedures (Forbes, 1974; Mercke, 1975; Chalon et al., 1979a). In adults, heating and humidification of gases to 37° C and 100% relative humidity not only effectively helps maintain normothermia, but it also helps reverse hypothermia during general surgery (Pflug et al., 1978; Stone et al., 1981).

Because of the higher minute ventilation per kilogram of body weight in pediatric patients, airway humidification for infants is even more important and effective in helping to maintain normothermia than it is for adults (Bissonnette and Sessler, 1989a; Bissonnette et al., 1989). In newborns, heat loss during general anesthesia is significantly reduced when gases are heated and when humidified gases are used instead of dry anesthetic gases (Fonkalsrud et al., 1980). Although high-temperature humidification devices can decrease intraoperative evaporative heat loss, they may cause tracheal burns. Because there may be a large temperature gradient between the humidifier and the endotracheal tube, it is important to measure airway temperature as close to the patient as possible. This has the advantage of preventing heated gases from accidentally burning the trachea while providing the warmest possible inspiratory gas. In addition, intraoperative heat loss can be minimized. If these devices are used, it is recommended to heat inspiratory gases to normal body temperature only. Although heat and moisture exchanging filters are less effective than active humidifiers (especially in the first hour after induction of anesthesia), they seem to provide a reasonable, convenient, and cost-effective alternative (Bissonnette et al., 1989a).

Additional advantages of heat and moisture exchangers in small infants include the lack of risk for airway burns and over-humidification with the consequences of overhydration, and the reduced risk for breathing-circuit disconnection (Smith and Allen, 1986; Shroff and Skerman, 1988). Heat and moisture may falsely increase the esophageal temperature by about 0.35° C when compared with tympanic or mean body temperature (Bissonnette et al., 1989b).

All heat and moisture exchangers increase the dead space of the anesthesia tubing; however, the smallest ones have a dead space of less than 2 mL. At a fresh gas flow of 30 to 60 L/min, the increase in airway resistance is minimal, typically creating a pressure gradient of less than 2 cm H₂O. Most heat and moisture exchangers now commonly have an in-built filter for bacteria, viruses, and latex particles (Barbara et al., 2001). Copious secretions from the tracheobronchial tree may result in partial or complete obstruction of the filter and thereby severely affect ventilation (Prasad and

Chen, 1990; Barnes and Normoyle, 1996; Stacey et al., 1996). The in vitro specifications of the heat and moisture exchangers given by the manufacturers do not always match the actual in vivo performance (Lemmens and Brock-Utne, 2004).

Transportation

Care in the transportation of an infant with regard to temperature management cannot be overemphasized. One short transport (e.g., to the critical care unit) can be enough to render all successful intraoperative efforts to maintain normothermia ineffective. It is therefore essential that the incubator (if available) be fully warmed before transport both to and from the operating room. Older infants and children should at least be covered with a warmed blanket for transport, and if the patient is hypothermic despite all the measures taken in the operating room, it is helpful to bring the forced-air warming blanket with the patient to the critical-care or the post-anesthesia care unit, so that the rewarming process can be continued there.

SUMMARY

Because of the small size with increased body surface area-to-body weight ratio and increased thermal conductance, infants and young children are at significant risk for thermal

instability. This risk is even higher for premature infants and infants who are small for gestational age. Although awake infants are able to maintain normothermia, they can do so only within a narrow range of ambient temperatures and only for a limited amount of time. The exposure to the operating room with its normally low ambient temperature combined with the high airflow from the air-conditioning system during anesthesia and surgery, and the use of cold infusions and dry anesthetic gases can easily overwhelm the thermal homeostatic mechanisms and, in certain instances, result in potentially serious complications. A sound understanding of the physiology and the limitations of the thermoregulatory system during anesthesia has improved the recognition, prevention, and management of these perioperative disturbances. The knowledge of the different effects of each anesthetic agent on the thermoregulatory mechanism undoubtedly proves useful in providing safe anesthesia.

DEVELOPMENTAL PHARMACOLOGY

Developmental changes profoundly affect the clinical response to medicines. Dr. Abraham Jacobi, a founder of American pediatrics, recognized more than a century ago that children are not “miniature men and women, with reduced doses and the same class of disease in smaller bodies,” that pediatrics “has its own independent range and horizon,” and that age-appropriate pharmacotherapy was important (Kearns et al., 2003). More recently, as the immaturity of renal and metabolic systems has been recognized, the pharmacologic uniqueness of babies and infants has been specifically recognized (Anderson and Holford, 2008). Physical growth, development, organ maturation, physiologic changes, and coexisting disease that occur throughout the spectrum of development—from preterm newborn to adolescence and adulthood—profoundly influence drug

pharmacokinetics and pharmacodynamics, and ultimately the panoply of both desirable and undesirable clinical responses. This chapter presents the basic pharmacologic principles relevant to understanding basic pediatric pharmacology in general, and that of pediatric anesthetic pharmacology in particular.

Medications that are commonly used in children are not regularly tested in children, and drug labeling often consists exclusively of adult data. Of the 140 new molecular entities of potential use in pediatrics, only 38% were labeled for use in children when they were initially approved (Tod et al., 2008). Much use of drugs in pediatrics, particularly in newborns and infants, is off-label use. About one third of drugs prescribed in office-based pediatric practice, two thirds of those prescribed in hospitals, and 90% of drugs used in pediatric intensive care units are used for indications other than those for which they have been approved (Tod et al., 2008). When data were submitted to the

U.S. Food and Drug Administration (FDA) to support labeling changes intended to guide pediatric drug use, on average, only 2.2 pediatric studies were represented (Abdel-Rahman et al., 2007). A considerable amount of pediatric drug use is based on “extrapolation” (or worse) from adult dosing and use guidelines. A major address of pediatric pharmacology research in the past decade has focused on the challenge of characterizing developmental changes in pharmacokinetics and pharmacodynamics, as well as determining proper pediatric dosing guidelines, particularly the downward scaling of adult doses to children.

Physiology and Development

Growth and maturation are seminal features of pediatric development, and it is important to understand that they vary independently (Anderson and Holford, 2008; Rhodin et al., 2009; Sumpter and Anderson, 2009). Growth is an increase in size, often characterized by changes in weight. Maturation is a time-dependent phenomenon, often characterized by age. Traditionally, the common metric of maturation was postnatal age (PNA), the time since birth. With the superiority of neonatal intensive care and the survival of neonates as small as 500 g and 24 weeks' gestation, who have clearly immature and widely variant degrees of development at birth, it is now well established that PNA is an inadequate metric of organ maturation, which actually begins before birth. Postconceptual age (PCA), the sum of gestational age (the period between conception and birth) and PNA, is a superior metric. Because of the inexactitude in determining the date of conception, the alternate metric of postmenstrual age (PMA) is often used instead. Particularly for infants and very small children, use of PCA or PMA rather than PNA is important in pediatric pharmacology and therapeutics.

Body composition changes dramatically during growth and development (Anderson and Holford, 2008). Simply stated, compared with adults, infants have big heads, large torsos, and short, stumpy legs. Figure 7-1 depicts developmental changes in pediatric physiology that can affect drug disposition. Table 7-1 describes the changes in organ weight that occur during growth. The most significant changes with age are in total body water, the intracellular vs. extracellular distribution of body water, and muscle and fat mass (Tables 7-2 and 7-3). Total body water content constitutes 75% of body weight in the full-term newborn and 80% to 85% of body weight in the preterm neonate. This decreases to about 60% at 5 months and remains relatively constant until puberty. Extracellular water redistributes intracellularly during the first year of life. Extracellular fluid is 45% to 50% of body weight in premature and newborn infants, decreasing to 26% at 1 year and 18% in adults. In contrast, body fat increases with age, from 3% in premature neonates and 12% in full-term newborns, to 30% at 1 year of age. “Baby fat” is shed when toddlers start walking and drops to adult levels of about 18%, concomitant with an increase in muscle mass. A major consequence of body-composition changes may be differences in drug volume of distribution, with neonates and infants having larger volumes of water-soluble drugs, as described below.

The relative lack of dosing data for many drugs used in pediatrics has necessitated the use of extrapolations from adult dosing. Considerable effort has been expended to provide a scientific basis for such extrapolations, such as of volumes of distribution, clearance, renal function, and dose. Basic models for

predicting physiologic function and drug dose based on size include the linear per-kilogram model, the surface-area model, and the allometric model. It is now increasingly evident and accepted that allometric scaling provides the most accurate information. Throughout nature, many body-size relationships are of the form:

$$Y = a \cdot W^b$$

where Y is the biological characteristic, W is the body mass, and a and b are empirically derived constants. For physiologic functions such as cardiac output, metabolic rate, oxygen consumption, glomerular filtration rate (GFR), and pharmacologic functions such as drug clearance, the power exponent b is 0.75. For physiologic volumes such as blood volume, lung volume, tidal volume, and stroke volume, and pharmacologic volumes such as the volume of distribution, the power exponent is 1. For time-based physiologic functions such as circulation time, heart rate, and respiratory rate, and pharmacologic functions such as drug elimination half-life, the exponent is 0.25 (Johnson and Thomson, 2008). This allometric model may then be used to scale metabolic processes across size:

$$Y_i = Y_{\text{std}} \cdot \left(\frac{W_i}{W_{\text{std}}} \right)^{\text{power}}$$

where W_i is the weight of any individual and W_{std} is the weight of a standardized individual (such as a mythical 70-kg adult). The applicability of scaling will subsequently become apparent.

Pharmacokinetic Parameters

Pharmacokinetics refers to the time course of drug disposition in the body and the processes that affect it. These processes include absorption, distribution, metabolism and transport, and excretion. Conceptually, pharmacokinetics is characterized by the fundamental primary parameters of volume of distribution and clearance and by the secondary parameter of half-life (which is proportional to volume of distribution and inversely proportional to clearance).

Volume of Distribution

Volume of distribution (V_d) is a theoretic concept that relates the amount of drug in the body (dose) to the concentration (C) of drug that is measured (in blood, plasma, and unbound in tissue water). Volume of distribution is the volume of fluid “apparently” required to contain the total-body amount of drug homogeneously at a concentration equal to that in plasma (or blood) (Fig. 7-2):

$$C_0 = \frac{\text{dose}(X)}{V_d} \text{ or } V_d = \frac{\text{dose}(X)}{C_0}$$

The volume of distribution does not necessarily correspond to any specific physiologic volume or space. Drugs such as highly water-soluble compounds, which are confined intravascularly, have a small volume of distribution (approximately equal to intravascular volume), whereas lipophilic drugs that distribute to tissues have a large volume of distribution (that may be so large as to exceed total body water). For example, in adults the volume of distribution of gentamicin is 0.2 to 0.3 L/kg, whereas that of digoxin is 8 to 10 L/kg. Plasma protein binding of drugs decreases the apparent volume of distribution,

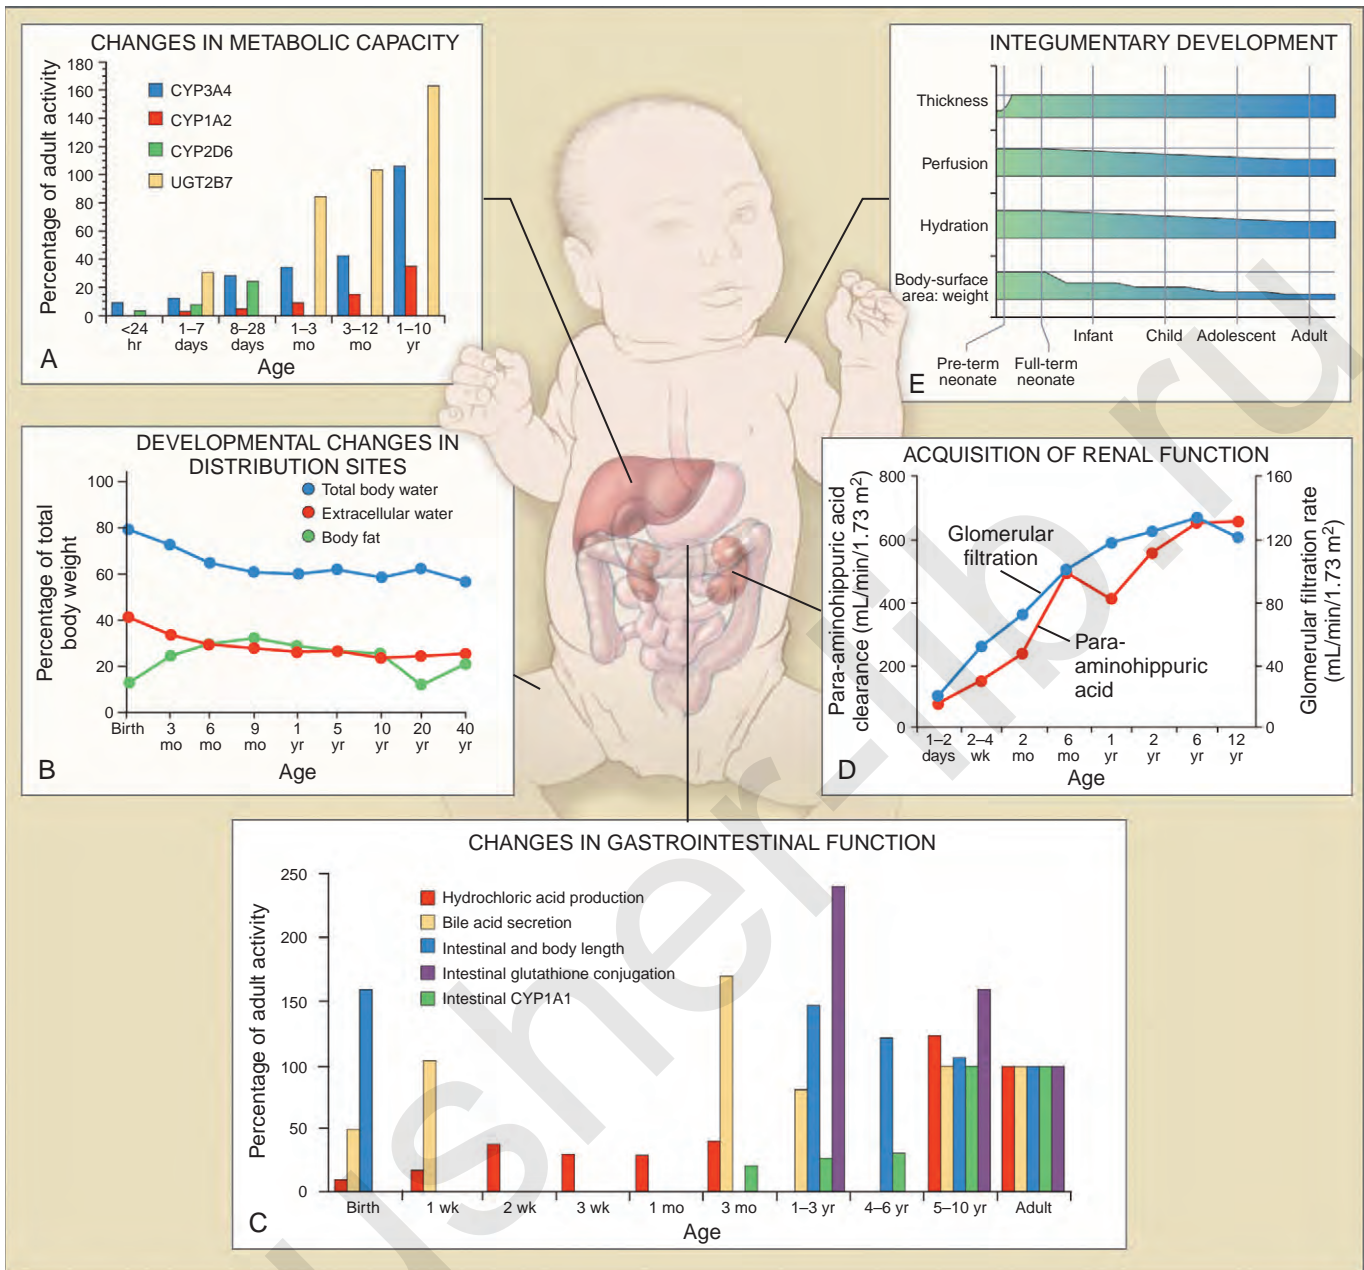

FIGURE 7-1. Developmental changes in physiologic factors that influence drug disposition in infants, children, and adolescents. **A**, Activity of many cytochrome P450 (CYP) isoforms and a specific UGT isoform is markedly diminished during the first two months of life. Increases to adult activity over time are enzyme- and isoform-specific. **B**, Age-dependent changes in body composition, which influence the apparent volume of distribution for drugs. Infants in the first 6 months of life have markedly expanded total body water and extracellular water as compared with older infants and adults. This is expressed as a percentage of total body weight. **C**, Age-dependent changes in both the structure and function of the gastrointestinal tract. As with hepatic drug-metabolizing enzymes (**A**), the activity of cytochrome CYP1A1 in the intestine is low during early life. **D**, Effect of postnatal development on the processes of active tubular secretion—represented by the clearance of para-aminohippuric acid and the GFR, both of which approximate adult activity by 6 to 12 months of age. **E**, Age dependence in the thickness, extent of perfusion, and extent of hydration of the skin and the relative size of the skin surface area (reflected by the ratio of body surface area to body weight). Although skin thickness is similar in infants and adults, the extent of perfusion and hydration diminishes from infancy to adulthood. (From Kearns GL et al: *Developmental pharmacology: drug disposition, action, and therapy in infants and children*, N Engl J Med 349:1157, 2003.)

and tissue binding increases the apparent volume of distribution. The major practical value of volume of distribution lies in the calculation of initial drug dosing (loading):

$$\text{dose}(X) = C_0 \cdot V_d$$

A major consequence of growth and maturational changes in body composition may be differences in volume of distribution. In general, neonates and infants have larger distribution volumes for water-soluble drugs and smaller volumes for lipophilic drugs. For example, the volume of distribution of gentamicin is

TABLE 7-1. Changes in Organ Weights with Age (Percentage of Body Weight)

Organ System	Fetus	Full-Term Newborn	Adult
Skeletal muscle	25.0	25.0	40.0
Skin	13.0	4.0	6.0
Skeleton	22.0	18.0	14.0

0.5 to 1.2 L/kg in neonates and infants compared with 0.2 to 0.3 L/kg in adults (Echeverrisa).

Clearance

Clearance is the fundamental parameter describing the ability to eliminate a drug. Clearance may refer to elimination from the body (systemic or total clearance) or by a specific organ (renal or hepatic clearance). Clearance is not the amount of drug actually eliminated, but rather represents the theoretic amount of biologic fluid (blood or plasma) from which the drug is completely removed per unit time (mL/min, L/hr). Systemic clearance represents the sum of hepatic clearance; renal clearance; and for some drugs, other routes of clearance (e.g., pulmonary elimination of volatile anesthetics, hydrolysis in blood, or dialysis).

$$CL_{\text{total}} = CL_{\text{renal}} + CL_{\text{hepatic}} + CL_{\text{other}}$$

where CL indicates clearance. Clearance is achieved through the processes of metabolism and excretion. A major practical value of understanding clearance is that at steady-state, total clearance is a primary determinant of dose and dosing interval (dose rate) when the desired steady-state plasma concentration (C_{ss}) is known:

$$\text{Dose rate} = C_{ss} \cdot CL_{\text{total}}$$

Renal Clearance

The kidney is the most important organ for elimination of water-soluble drugs and metabolites. This is particularly true for infants and small children, in whom hepatic metabolism is underdeveloped, and in whom age-dependent renal clearance is a major determinant of age-appropriate drug dosing (Kearns et al., 2003). Maturation of renal function, which occurs independently of PNA, is a dynamic process. Nephrogenesis begins between about weeks 5 and 9 of gestation and is complete by week 36, after which there are changes in renal blood flow (Kearns et al., 2003; Rhodin et al., 2009). GFR is approximately 5 mL/min in full-term neonates, but about one fifth that in pre-term neonates. GFR increases with PMA, at a rate described as a maturation function (MF), based on the sigmoidal hyperbolic Hill equation, where PMA_{50}^{γ} is the maturation half-time, and γ is the Hill coefficient:

$$MF = \frac{PMA^{\gamma}}{PMA_{50}^{\gamma} + PMA^{\gamma}}$$

The rate of GFR maturation is nonlinear and maximum at about 48 weeks' PMA. It varies with prematurity, with pre-term neonates (33 to 34 weeks' PMA) having a slower increase (14 mL/min per 1.73 m² per week PMA) in the first few weeks of life than full-term neonates (39 to 41 weeks' PMA; 94 mL/min per 1.73 m² per week PMA). In general, healthy newborns' GFR is about 30% of adult GFR and reaches adult values at about 8 to 12 months of age. Renal tubular function matures more slowly, reaching adult levels at about 12 to 18 months of age. For example, the dosing interval for tobramycin, which is eliminated renally, is 24 hours in full-term newborns but 36 to 48 hours in preterm newborns (Kearns et al., 2003).

Renal drug clearance depends on glomerular filtration, active tubular secretion, and active and passive tubular reabsorption. In addition to both the growth and the maturational

FIGURE 7-2. Apparent volume of distribution. The real volume of the beaker is 5 L ($V_d = 50 \text{ mg}/10 \text{ mcg/mL} = 5 \text{ L}$). However, based on measured concentrations in fluid and calculated according to the equation for V_d on p. 180, the volume of distribution may vary (thus *apparent volume*). It depends on significant tissue or plasma protein binding. Significant tissue binding (i.e., significant digoxin binding to myocardial Na^+ , K^+ -ATPase) increases volume of distribution ($V_d = 10 \text{ L}$; see the text for explanation). Because routinely measured fluid concentration includes both free unbound and plasma protein bound drug, the increased protein binding reduces volume of distribution ($V_d = 2.5 \text{ L}$).

aspects of renal function, disease and concomitant drug administration (either directly or by altering rates of renal maturation) can also affect renal function.

Hepatic Clearance

For many drugs, including several used in anesthesia (e.g., sedative hypnotics, benzodiazepines, opioids, and neuromuscular blockers), hepatic clearance (CL_H in the following formulas) is a major route of elimination (Wilkinson, 1987). Hepatic clearance is the product of liver blood flow (Q_H) and the hepatic extraction ratio (E_H) of a drug.

$$CL_H = Q_H \cdot E_H$$

E_H is defined as the fraction of drug entering the liver that is eliminated in one pass through the liver.

$$E_H = \frac{C_{in} - C_{out}}{C_{in}}$$

E_H depends on liver blood flow and the intrinsic clearance of the drug (CL_{int}), defined as the total capacity of the liver to eliminate drug in the absence of limitations from blood flow.

$$E_H = \left(\frac{CL_{int}}{Q_H + CL_{int}} \right)$$

CL_{int} functionally represents drug biotransformation (the total activity of enzymes and transporters involved in metabolism and biliary secretion). Thus, combining the previous equation with the equation for hepatic clearance:

$$CL_H = Q_H \cdot \left(\frac{CL_{int}}{Q_H + CL_{int}} \right)$$

Since only an unbound drug is considered diffusible into liver cells (although in reality a simplification), E_H also depends on the fraction of unbound drug in the blood (f_u) (Baker and Parton, 2007). Therefore the three theoretic primary determinants of hepatic drug clearance are liver blood flow, intrinsic clearance (biotransformation), and plasma protein binding.

$$CL_H = Q_H \cdot E_H = Q_H \cdot \left(\frac{CL_{int} \cdot f_u}{Q_H + CL_{int} \cdot f_u} \right)$$

In reality, the important determinants of hepatic clearance are liver blood flow and the extraction ratio (Fig. 7-3). For drugs with a high extraction ratio (e.g., lidocaine, fentanyl, sufentanil, and propofol), hepatic clearance depends primarily on hepatic blood flow (because intrinsic clearance is so efficient, drug delivery to the liver becomes rate limiting). For low-extraction drugs (e.g., methadone, diazepam, and alfentanil), hepatic clearance is independent of hepatic blood flow and depends primarily on intrinsic clearance (metabolism).

Absorption

Although the predominant route of drug administration in pediatric anesthesiology is intravenous, the oral route is the

FIGURE 7-3. Effect of increasing liver blood flow on the hepatic clearance of drugs with varying extraction ratios. Each curve represents a drug whose extraction ratio at 1.5 L/min is shown above that flow. For drugs with a low extraction ratio, an increase in liver blood flow within the physiologic range (arrow) produces very little change in hepatic clearance. For a drug with a high extraction ratio, however, increases in liver blood flow produce an almost proportional increase in hepatic clearance. (From Wilkinson GR, Shank DG: *Commentary: a physiological approach to hepatic drug clearance*, Clin Pharmacol Ther 18:377, 1975.)

most commonly used in children. Changes in physiologic processes that accompany normal growth and development can affect drug absorption (Kearns et al., 2003; Abdel-Rahman et al., 2007). In general, neonates and small children absorb drugs more slowly than older children and adults, resulting in delayed and lower peak drug concentrations. Neonatal gastric pH is relatively high (greater than 4) compared with older children and adults, thus acid-labile drugs (such as penicillin G) are more efficiently absorbed and have greater bioavailability. Conversely, weak acids (such as phenobarbital) may require larger doses because of reduced bioavailability. In the first few months of life, gastric emptying, intestinal motility, and intestinal drug transport increase.

Parenteral drug absorption may also be affected by development. Transdermal bioavailability is increased in infants because there is a thinner stratum corneum in preterm neonates, better skin hydration and perfusion in small children, and a larger surface area-to-volume ratio. Intramuscular bioavailability is greater in neonates and infants than in older children because of a higher density of skeletal muscle capillaries. Rectal drug bioavailability in drugs undergoing extensive first-pass metabolism is higher in neonates and infants, because hepatic metabolism is immature. Conversely, rectal formulations may be expelled more quickly in young children because of more frequent high-amplitude pulsatile contractions.

Distribution

The age-dependent changes in body composition described above can result in developmental differences in drug distribution. For hydrophilic drugs with relatively small volumes of distribution, greater total body water and larger extracellular fluid spaces result in larger volume of distribution, and hence lower intravascular drug concentrations. Lipophilic drugs with relatively large volumes of distribution are not similarly affected.

Plasma protein binding can exhibit developmental differences, although the clinical significance of protein binding in pharmacokinetics and pharmacodynamics remains unresolved (Benet and Hoener, 2002; Trainor, 2007). The primary binding proteins are albumin (for acidic drugs) and α_1 -acid glycoprotein (for basic drugs). Decreased plasma albumin and α_1 -acid glycoprotein concentrations in neonates may result in increased unbound (free) drug concentrations and hence pharmacologic effect.

Metabolism

Metabolism of a drug can result in bioactivation of an inactive prodrug, formation of an active or inactive metabolite, or occasionally a toxic metabolite. The liver is the primary site of drug metabolism, although the intestine can metabolize oral drugs before they reach the systemic circulation and extrahepatic metabolism (e.g., renal, blood, and other tissues) may be important for certain drugs (i.e., remifentanyl and propofol). Phase I reactions (oxidation, reduction, and hydrolysis) chemically modify the drug structure to add, form, or uncover a functional group and render the molecule more water soluble. Phase II reactions (glucuronidation, sulfation, and glutathione conjugation) add an endogenous molecule to the drug or metabolite to render it even more water soluble for elimination. Typical pathways of drug metabolism are provided in Table 7-4.

TABLE 7-4. Pathways in Drug Metabolism

Reaction	Examples
Phase I	
Oxidation reactions	Thiopental, methohexital
Aliphatic hydroxylation	Pentazocine, meperidine, glutethimide, doxapram, ketamine, chlorpromazine, fentanyl, propranolol
Aromatic	Lidocaine, bupivacaine, mepivacaine
Expoxidation	Phenytoin
O-Dealkylation	Pancuronium, vecuronium, codeine, phenacetin, methoxyflurane
N-Dealkylation	Morphine, meperidine, fentanyl, diazepam, amide local anesthetics, ketamine, codeine, atropine, methadone
N-Oxidation	Meperidine, normeperidine, morphine, tetracaine
S-Oxidation	Chlorpromazine
Oxidative deamination	Amphetamine, epinephrine
Desulfuration	Thiopental
Dehalogenation	Halogenated anesthetics
Dehydrogenation	Ethanol
Reduction Reactions	
Axo reduction	Fazadinium
Nitroreduction	Nitrazepam, dantrolene
Carbonyl reduction	Prednisolone
Alcohol dehydrogenation	Ethanol, chloral hydrate
Hydrolysis Reactions	
Ester hydrolysis	Ester local anesthetics, succinylcholine, acetylsalicylic acid, propanidid amide local anesthetics
Phase II: Conjugation Reactions	
Glucuronamide	Oxazepam, lorazepam, morphine, nalorphine, codeine, fentanyl, naloxone
Sulfate	Acetaminophen, morphine, isoproterenol, cimetidine
Methylation	Norepinephrine
Acetylation	Procainamide
Amino acid	Salicylic acid
Mercapturic acid	Sulfobromophthalein
Glutathione	Acetaminophen

Modified from Tucker GT: Drug metabolism, *Br J Anaesth* 51:603, 1979.

Comprehensive reviews of human drug metabolism are available, but a generalized overview is instructive for understanding developmental changes in biotransformation (Kramer and Testa, 2008; Pelkonen et al., 2008; Zanger et al., 2008). Cytochrome P450 (CYP) is the main oxidative (phase I) metabolizing enzyme system, and more than 50 human P450s have been identified, although only a small fraction are responsible for the majority of drug metabolism (Fig. 7-4) (Paine et al., 2006; Zanger et al., 2008). Individual CYPs are classified by their sequence evolution and amino-acid similarities (Ingelman-Sundberg et al., 2007; Zanger et al., 2008). Those with greater

FIGURE 7-4. Cytochrome P450 isoform content in human liver and intestine. (Data from Rowland-Yeo K et al.: *Abundance of cytochromes P450 in human liver: a metaanalysis*, *Br J Clin Pharmacol* 57:687, 2004; Paine et al.: *The human intestinal cytochrome P450 “pie,”* *Drug Metab Dispos* 34:880, 2006.)

than 40% sequence homology are grouped in a family (designated by an Arabic number, e.g., *CYP3*); those with more than 55% homology are in a subfamily (designated by a letter, e.g., *CYP3A*), and individual CYPs are identified by a third number (e.g., *CYP3A4*). The majority of drugs in humans are metabolized by CYPs 1, 2, and 3 (particularly CYPs 1A2, 2B6, 2C8, 2C9, 2C19, 2D6 and 3A4, 3A5, and 3A7). CYPs can have numerous genetic variants, and there are several highly polymorphic CYPs. Allelic CYP variants are designated by an asterisk and number (e.g., *CYP3A5*3*, where the “wild-type” is always *1) (Ingelman-Sundberg et al., 2007; Zanger et al., 2008). CYPs can have varying degrees of substrate specificity, and some are very accommodating, like CYP3A, which metabolizes approximately one third to one half of all therapeutically used drugs.

The developmental pattern of biotransformation activity generally follows a hyperbolic curve with age that begins in fetal development, with hepatic drug metabolism and very low clearance before and during the first month. It reaches near adult levels at approximately 1 year, becomes maximum before puberty, and declines slightly into adulthood

(Johnson and Thomson, 2008). There are, however, enzyme and isoform-specific patterns of developmental maturation of drug-metabolizing enzymes (Blake et al., 2005; Hines, 2008). Several pertinent examples are in the following paragraphs.

The CYP3A family is the most important drug-metabolizing enzyme. The important isoforms are CYP3A4 (the major CYP present in the adult liver and the intestine), CYP3A5 (which metabolizes very many of the CYP3A4 substrates with equal or diminished activity and is polymorphically expressed), and CYP3A7 (a fetal form that is usually less active than 3A4 or 3A5). CYP3A undergoes a “developmental switch” with CYP3A7, the predominant CYP3A expressed in fetal liver (Stevens, 2006; Hines, 2008). Indeed it is the most abundant of any CYP and is thought to be important in fetal steroid metabolism and homeostasis (Fig. 7-5, A). CYP3A7 expression decreases during gestation, declines further after birth, and is typically undetectable after the first year. CYP3A4 expression is low during development and then increases after the first 6 months of age. CYP3A metabolizes many drugs of importance in anesthesiology, including all of the fentanyl series opioids (except remifentanyl), most benzodiazepines, and local

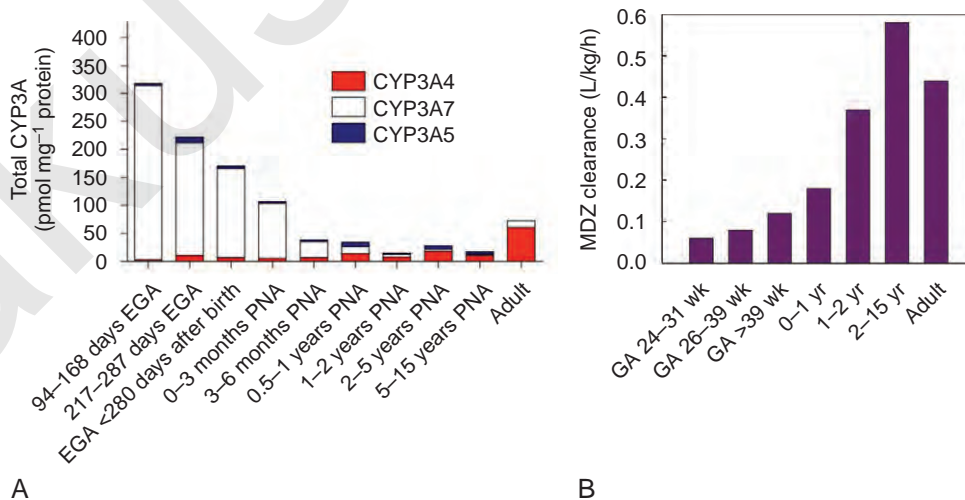

FIGURE 7-5. Developmental aspects of hepatic CYP3A expression and activity. **A**, Content of hepatic CYP3A4, CYP3A5, and CYP3A7 proteins as a function of age. **B**, Clearance of the CYP3A substrate midazolam. EGA, Estimated gestational age; PNA, postnatal age. (A From Stevens JC: *New perspectives on the impact of cytochrome P450 3A expression for pediatric pharmacology*, *Drug Discov Today* 11:440, 2006; B, Redrawn from de Wildt SN et al.: *Cytochrome P450 3A: ontogeny and drug disposition*, *Clin Pharmacokinet* 37:485, 1999.)

anesthetics. Although high in abundance, CYP3A7 has low activity toward many drugs (1% to 3% of the activity of CYP3A4 towards midazolam and alfentanil) (Björkman, 2006). Therefore, CYP3A-catalyzed drug metabolism and clearance increases with age. For example, the hepatic extraction of midazolam is only 0.04 in neonates, compared with 0.38 in adults (Björkman, 2006). Midazolam clearance is similarly very low in neonates, particularly in preterm infants. The age-dependent maturation of midazolam clearance is shown in Figure 7-5, B.

Other hepatic CYP isoforms also demonstrate maturation of expression. CYPs 1A2, 2C9, 2C19, 2D6, and 2E1 are expressed minimally or not at all in the fetus, but substantial increases occur after birth. CYP2D6 metabolizes about one fourth of all drugs, including antidepressants, antipsychotics, β -blockers, and numerous orally administered opioids, most notably catalyzing bioactivation of the inactive prodrugs codeine and tramadol (to the pharmacologically active metabolites morphine and O-desmethyltramadol, respectively) (Ingelman-Sundberg et al., 2007; Madadi and Koren, 2008). Isoform-dependent maturation of CYP enzymes in infants is exemplified by the development of tramadol metabolism and disposition, which shows that CYP2D6-catalyzed O-demethylation matures faster than CYP3A-catalyzed N-demethylation (Fig. 7-6). CYP1A2 metabolizes caffeine and theophylline, two methylxanthines that are commonly used in pediatrics. CYP1A2 is essentially absent in fetal liver and

■ **FIGURE 7-6.** Age-dependent and cytochrome P450 (CYP) isoform-dependent development of tramadol metabolism and disposition. Tramadol is a relatively inactive prodrug. Tramadol undergoes CYP2D6-catalyzed O-demethylation to the active analgesic metabolite O-desmethyltramadol, and CYP3A4-catalyzed N-demethylation to the inactive metabolite N-desmethyltramadol. The O-desmethyltramadol/tramadol concentration ratio represents a bioactivation pathway and reflects CYP2D6 activity. The N-desmethyltramadol/tramadol concentration ratio represents an inactivation pathway, and reflects CYP3A4 activity. The figure shows the influence of age on metabolite/tramadol concentration ratios in 24-hour urine collections in neonates and infants after administration of intravenous tramadol. Maturation of CYP2D6 activity is faster than that of CYP3A4. (Redrawn from Allegaert K et al.: *Determinants of drug metabolism in early neonatal life*, *Curr Clin Pharmacol* 2:23, 2007.)

minimally active in neonates, such that 85% of caffeine is eliminated unchanged renally in neonates (Cazeneuve et al., 1994). CYP1A2 activity matures rapidly thereafter, reaching adult values by age 6 months, and caffeine clearance in these children reflects primarily hepatic demethylation (Kearns et al., 2003).

Compared with hepatic CYP enzymes, the ontogeny of CYPs in the intestine is far less understood. CYPs 3A4, 3A5, and 2C9 are the predominant intestinal isoforms, accounting for approximately 80% (3As) and 15% (2C9) of the total, respectively, with the remainder comprising CYPs 1A1, 1A2, 2C19, 2J2, and 2D6 (Paine et al., 2006). CYP3A expression declines from the proximal to distal intestine, with 75% occurring in the duodenum and jejunum (Paine et al., 1997). In the intestine, like in the liver, CYP3A4 is the predominant CYP3A isoform, and CYP3A5 is polymorphically expressed in 20% to 70% of adults (Paine et al., 1997). In otherwise histologically normal duodenal biopsies from a population of 74 children, CYP3A4 protein expression increased steadily with age (Fig. 7-7) (Johnson and Thomson, 2008). In fetal duodenum it was essentially absent, and in neonates it was expressed at about half the level seen in mature children. Intestinal CYP3A enzyme activity followed the same pattern as enzyme expression (Johnson and Thomson, 2008).

Other phase I enzymes are important in drug metabolism. Ester hydrolysis is a ubiquitous reaction catalyzed by a diverse array of esterases in blood and tissue. Esterase activity is important in the hydrolysis of remifentanyl to an inactive metabolite, resulting in termination of clinical effect. Remifentanyl is hydrolyzed by nonspecific esterases in plasma (and more so tissue, but not by plasma cholinesterase (Manullang and Egan, 1999). In contrast, and unlike most ester drugs, red-cell rather than plasma esterases metabolize esmolol. Whereas CYPs mostly mature in the first months to year of life, esterase activity in neonates is already at levels nearly equivalent to those in adults (Allegaert et al., 2008). For example, remifentanyl clearance in children from the ages of 1 month to 9 years old resembles that in adults (Sumpter and Anderson, 2009).

■ **FIGURE 7-7.** Developmental aspects of duodenal CYP3A4 expression and activity (mean \pm SD). The number of patients in each group is given in brackets. CYP3A protein expression was measured by Western blotting. Statistically significant differences were observed between the fetus group and all of the other groups and between neonates and children older than 5 years ($p < 0.05$). The age-related pattern of duodenal CYP3A activity was similar to that of CYP3A protein expression (not shown). (From Johnson TN et al.: *Enterocytic CYP3A4 in a paediatric population: developmental changes and the effect of coeliac disease and cystic fibrosis*, *Br J Clin Pharmacol* 51:451, 2001.)

Phase II drug-metabolizing enzymes include glucuronosyltransferases (UGTs), sulfotransferases (SULTs), acetyltransferases, and glutathione transferases, all catalyzing conjugation reactions with multiple isoforms of each enzyme, often with isoform-dependent ontogeny (Blake et al., 2005; Hines, 2008). The two main UGT families are UGT1 and UGT2. UGT1A1, the major enzyme responsible for bilirubin conjugation, is not detectable in fetal liver, increases immediately after birth, and reaches adult levels by 3 to 6 months of age. UGT2B7 is of particular interest, because it conjugates morphine. UGT2B7 activity in fetal liver is present at 10% to 20% of adult values and increases in neonates to reach adult values by 2 to 3 months after birth. Morphine clearance is very low in premature infants and increases substantially over the first year of life. SULT ontogeny is isoform-specific, with SULT1E1 activity highest in the fetus and declining thereafter, SULT2A1 activity is barely detectable in neonates and increases in neonates, whereas SULT1A1 activity is constant from fetal age to adulthood.

Elimination

Elimination refers to all processes that remove a drug from the body, including drug metabolism (biotransformation) and excretion. Returning to the concept of drug elimination in general, it is now appreciated that several elements affect the development of drug elimination from fetus to adult, including patient size, organ maturation, organ function, and coexisting disease. Developmental patterns of drug clearance are shown for several drugs in Figure 7-8. For drugs in which renal elimination largely determines systemic clearance, the age-dependence of such clearance approximates that of GFR. In contrast, when hepatic metabolism predominates, the pattern differs.

The complexity of developmental pharmacokinetics can be appreciated using a drug such as propacetamol. Propacetamol is an N, N-diethylglycine ester prodrug of acetaminophen

FIGURE 7-8. Clearance maturation, expressed as a percentage of mature clearance. Maturation profiles for acetaminophen, morphine, and dexmedetomidine, in which glucuronidation and renal excretion play a major role, resemble that for renal function (GFR). For propofol, cytochrome P450 enzymes also contribute to biotransformation and elimination, thus causing faster maturation than that predicted from renal excretion alone. The maturation half-time (TM₅₀) and Hill coefficient are shown for each drug. (From Sumpter A, Anderson BJ: *Pediatric pharmacology in the first year of life*, *Curr Opin Anaesthesiol* 22:469, 2009.)

(paracetamol), which is hydrolyzed by plasma esterases after intravenous administration to the active metabolite acetaminophen. Acetaminophen in turn undergoes both phase I, and more so phase II metabolism, to glucuronic acid, sulfate, cysteine, and glutathione conjugates. Figure 7-9 shows the developmental aspects of propacetamol pharmacokinetics (Anderson et al., 2005). Consistent with the relative age invariance of esterase expression, ester hydrolysis to the active metabolite, acetaminophen, was also age invariant. The central compartment volume of distribution was also age invariant, whereas the peripheral compartment volume was somewhat decreased in neonates. Clearance increased markedly with age in the first year, from 12% of adult values at 27 weeks' PCA to 84% of its mature value by 1 year. Importantly, PCA was more important than PNA, as described above.

Scaling Pediatric Dosing

Ideal clinical practice would be informed by age-specific clinical pharmacokinetic data for every drug used in children. As this remains an unattained ideal, considerable effort has been expended to establish pharmacokinetic models to predict age-dependent dosing based on adult data (Anderson and Holford, 2008; Johnson, 2008; Tod et al., 2008; Sumpter and Anderson, 2009). Several principles are now apparent, some of which have been described previously in this chapter. Loading doses depend on concentration and central volume of distribution. For central volumes, allometric modeling (p. 195) suggests that the volume of distribution scales with a power of 1, such that

$$V_{\text{child}} = V_{\text{std}} \cdot \left(\frac{W_i}{70} \right)$$

where W_i is the weight of any individual and V_{std} is the volume of a standardized 70-kg adult. Because maintenance dosing equals the product of concentration and clearance, the fidelity of clearance models is important. Historically, the linear per-kilogram model, the body-surface area model, and the allometric three-fourths power model have been used. There is a nonlinear relationship between clearance and size. The linear per-kilogram model, although widely used, is the most inaccurate of the three models, because clearance (per kg) is larger in children than in adults. It leads to underprediction by more than 10% at body weights less than 47 kg, and approaches 50% for a 3.5-kg newborn. The body-surface area model, which assumes that adults and children are geometrically similar (although they in fact are not), over-predicts clearance by more than 10% at body weights below 20 kg. The allometric model, which is based on physiologic principles and has been well-validated clinically, is the most accurate.

$$CL_{\text{child}} = CL_{\text{adult}} \cdot \left(\frac{W_{\text{child}}}{70} \right)^{0.75}$$

Figure 7-10 compares the accuracy of the linear per-kilogram, the body-surface area, and the allometric three-fourths power models.

Clearance, however, depends on not just growth (size), but also on maturation of organ clearance processes (i.e., PCA). It is also influenced by concomitant diseases and potentially by drug interactions, which can influence organ function. While allometry alone provides reasonable estimates of clearance in older children using adult data, it alone is insufficient to

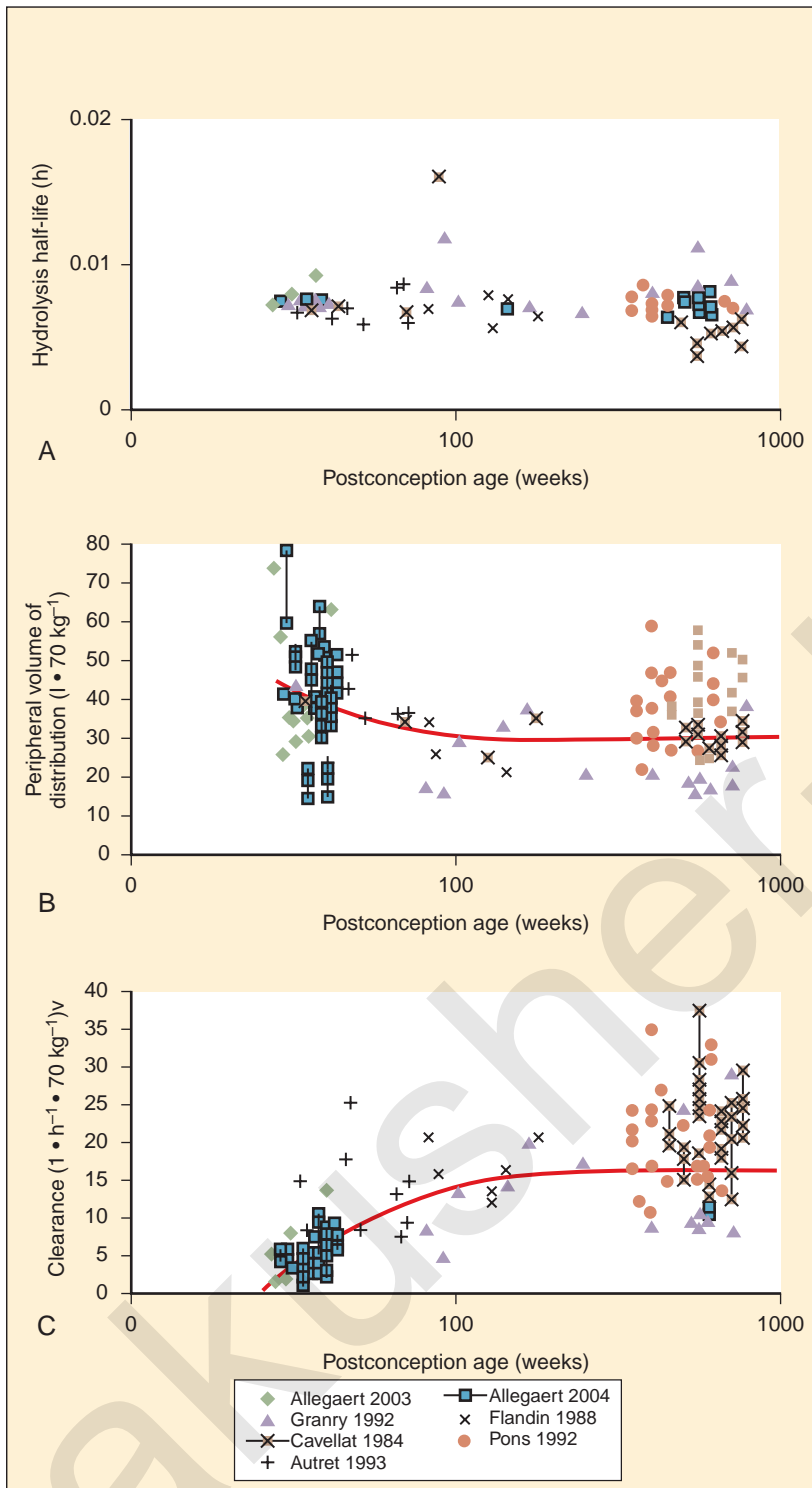

FIGURE 7-9. Developmental aspects of intravenous propacetamol disposition. **A,** Lack of effect of age on the half-life of propacetamol hydrolysis to acetaminophen. **B,** Influence of age on the peripheral compartment volume of distribution (V_3) of acetaminophen, standardized to a 70-kg person. The solid line represents the nonlinear relation between V_3 and age. Peripheral volume of distribution decreased from 27 weeks' postconceptional age to reach 110% of the value in older children by 6 months. The central volume of distribution did not change with age. **C,** Influence of age on acetaminophen's apparent systemic clearance, standardized to a 70-kg person. The solid line represents the nonlinear relation between clearance and age. Clearance increased from 27 weeks' postconceptional age to reach 84% of the value in older children by 1 year. Data are from a meta-analysis, with different symbols representing different individual studies. (From Anderson BJ et al.: *Pediatric intravenous paracetamol (propacetamol) pharmacokinetics: a population analysis*, *Pediatr Anesth* 15:282, 2005.)

predict clearance in infants and young children (Sumpter and Anderson, 2009). Therefore, the most parsimonious model for prediction drug clearance is as follows:

$$CL_{\text{child}} = CL_{\text{adult}} \cdot \left(\frac{W_{\text{child}}}{70} \right)^{0.75} \cdot MF \cdot OF$$

where MF is the maturation function (with a value from 0 to 1), and OF is organ function (also with a value from 0 to 1). The

only major exception to this rule is in neonates, where organ maturation is relatively uninitiated, and the practical relationship is best approximated by the linear per-kilogram model.

For practical purposes, size models have been simplified for clinical use. This is also influenced by regulatory considerations, which sort children into the categories of neonates (younger than 1 month), infants (1 month to 2 years), children (2 to 12 years), and adolescents (12 to 18 years). **Table 7-5** presents age-specific dose adjustments. An even simpler method suggests

■ **FIGURE 7-10.** Relative differences in clearance determined by the dose per surface area and the dose per kilogram of weight models when compared with the allometric $\frac{3}{4}$ -power weight model. (From Anderson BJ, Holford NH: *Mechanism-based concepts of size and maturity in pharmacokinetics*, *Ann Rev Pharmacol Toxicol* 48:303, 2008.)

1 month, 1 year, 7 years, and 12 years, respectively for doses that are one eighth, one fourth, one half, and three fourths of the adult doses (Anderson and Holford, 2008). It is important to remember that these dose adjustments are for drug disposition only, and they do not take into account any age-dependent differences in pharmacodynamic response.

Pharmacodynamics

Pharmacodynamics refers to the biological effect of a drug, specifically the concentration (usually plasma)-effect relationship (or more precisely, the effect site concentration-effect relationship, although the effect-site concentration is rarely actually measured). Far less is known about the developmental aspects

of pharmacodynamics than of pharmacokinetics. The concentration-effect relationship defining drug pharmacodynamics is characterized by potency and efficacy. Potency (drug concentration, or less correctly drug dose, that produces a specific effect) is characterized by the ED_{50} , defined as the concentration producing half-maximal effect in a graded dose-response curve in a single experiment, cell, animal, or individual. Potency can also be characterized by the ED_{50} , or as the concentration producing an all-or-nothing (quantal) response in a quantal dose-response curve in 50% of a population of cells, animals, or individuals. Efficacy is the maximum possible response at the highest possible drug concentration. The developmental aspects of drug pharmacodynamics are therefore best described by age-dependent changes in potency and efficacy. Often, however, the only information available is age dependence of clinical drug response, which may reflect both pharmacokinetic and pharmacodynamic changes.

True age-related pharmacodynamic changes may be qualitative or quantitative, and they may apply to both therapeutic and adverse effects (Stephenson, 2005). One example of quantitative differences in therapeutic response is the effect of warfarin in prepubertal, pubertal, and adult patients. Despite equivalent plasma drug concentrations, warfarin effects on prothrombin fragments 1 and 2 and on the international normalized ratio (INR) were higher in prepubertal patients than in adults. Similarly, augmented response was observed with cyclosporine, in which peripheral blood monocytes from infants had twofold lower proliferation and sevenfold lower interleukin-2 expression compared with older subjects. Examples of age-dependent adverse effects occurring only in children include chloramphenicol toxicity (“gray baby syndrome”), limb deformation from thalidomide during embryogenesis, tetracycline staining of dental enamel, and valproic acid hepatotoxicity, which is increased in young children. Generalized factors leading to age-dependent drug responses include physiology, pathology,

TABLE 7-5. Pediatric Maintenance Doses of Drugs Expressed as a Percentage of Adult Dose Using an Allometric $\frac{3}{4}$ Power Model*

Approximate Age	Weight (kg)	Percentage of Adult Dose	Fraction of Adult Dose
Birth	3.2	5	1/20
2 months	4.5	13	1/8
4 months	6.5	17	
12 months	10	23	1/4
18 months	11	25	
5 years	18	36	
7 years	23	43.5	
10 years	30	53	1/2
11 years	36	61	
12 years	40	66	
14 years	45	72	3/4
16 years	54	82	
Adult	70	100	1

* The neonatal estimate based on size is reduced further by 50% to account for age-related maturational changes of clearance.

host response to disease, and adverse drug reactions, as well as pharmacodynamics (Stephenson, 2005).

For drugs used in anesthesia, the best information on developmental pharmacodynamics has been obtained for inhaled anesthetics, and to a lesser extent, certain intravenous anesthetics. The potency of inhaled anesthetics is significantly affected by developmental age. The principal metric of inhaled anesthetic potency (the median effective concentration, or EC_{50}), has been called the *minimum alveolar concentration (MAC)* and defined as the “minimum alveolar concentration of anesthetic at 1 atmosphere that produces immobility in 50% of those patients or animals exposed to a noxious stimulus,” where the stimulus is usually an incision (Mapleson, 1996). Other endpoints have been analogously defined, such as MAC_{AWAKE} endpoint, which defines loss (or return) of consciousness. The quantal EC_{50} of all inhaled anesthetics is similarly influenced by age, with a common log-linear negative slope (for age older than 1 year) (Mapleson, 1996). For decreasing ages younger than 40 years, EC_{50} (MAC) increases 6% per decade. Thus, the MAC for sevoflurane is conceptually 20% greater at age 10 and 27% greater at age 1 (i.e., 2.16% and 2.29% at ages 10 and 1, respectively, for a MAC of 1.8% at age 40 (Mapleson, 1996). A clinical study found the MAC of sevoflurane to be 2.5% in children between 1 and 12 years old and 3.2% in infants 6 to 12 months old, compared with 2% at age 40 (Lerman et al., 1994; Mapleson, 1996). The MAC_{AWAKE} endpoint for sevoflurane was 0.43%, 0.45%, and 0.66% in children 8 to 12 years old, 5 to younger than 8 years, and 2 to younger than 5 years, respectively (Davidson et al., 2008c). The ratio between the MAC_{AWAKE} endpoint and MAC did not differ with age.

Measures of the age-dependent change in apparent anesthetic potency may be influenced by the clinical drug effect used as the index of response. For example, various electroencephalogram (EEG)-derived parameters (e.g., spectral edge frequency, bispectrum, and bispectral index [BIS]) have been used to measure volatile anesthetic effects in children (Wodey et al., 2005; Tirel et al., 2006; Davidson et al., 2008b). Although there were age-dependent effects of volatile anesthetics on various EEG parameters, the EEG itself was found to be highly age-dependent. Specifically, EEG was fundamentally different in infants between 0 and 6 months old, and caution was suggested in the use of BIS to determine volatile anesthetic pharmacodynamics in children (Wodey et al., 2005; Davidson et al., 2008b). Similar results were obtained when EEG-derived parameters were used to evaluate age and propofol effects, and EEG results in children younger than 1 year old were considered inaccurate (Jeleazcov et al., 2007).

Compared with inhaled anesthetics, much less is known about developmental aspects of intravenous drug pharmacodynamics. In part, this reflects the ease, lack of expense, ubiquity, and real-time availability of measuring end-tidal inhaled anesthetic concentrations, compared with measuring plasma concentrations of intravenous anesthetics. Limited data are available for propofol, which suggests slightly lower sensitivity (diminished potency) in children. Plasma propofol concentration-effect (BIS) curves analyzed in children (mean age of 10 years, range of 6 to 13 years) and adults (mean age of 18 years, range of 14 to 32 years) found graded EC_{50} means values of 4 vs. 3.3 mcg/mL, respectively. When propofol infusions were targeted to maintain a steady-state BIS of 50, measured mean plasma concentrations were 4.3 ± 1.1 and 3.4 ± 1.2 mcg/mL, respectively (Rigouzzo et al., 2008). Somewhat lower propofol

potency was also reported by others (Jeleazcov et al., 2008). In contrast, one study found no difference in propofol EC_{50} in adults and children, however, predicted rather than measured plasma concentrations were used in the analysis, which is a limitation of such studies (Munoz et al., 2006). Increased propofol EC_{50} in children is consistent with diminished EC_{50} in older adults (Schnider et al., 1999). No data are available regarding propofol pharmacodynamics in neonates.

In summary, available data suggest some developmental age-dependence of inhaled and intravenous anesthetic pharmacodynamics, with somewhat lower potency in young children. Nonetheless, developmental changes in drug pharmacodynamics, in general, appear to be much smaller and of less clinical significance than developmental changes in drug pharmacokinetics.

Nonlinear Pharmacokinetics

For some drugs, an increase in dose is not followed by proportional increases in plasma C_{ss} and area-under-the-plasma-concentration curve (AUC). Instead, the C_{ss} and AUC increase more than expected. The explanation for this nonlinear pharmacokinetics is that the enzymes responsible for metabolism and elimination of the drug may be saturated. The nonlinear pharmacokinetics, also called *Michaelis-Menten kinetics*, occur when the maximum rate of metabolism (V_{max}) for the drug is approached. Michaelis-Menten pharmacokinetics describes the rate of production of molecules (drug metabolites) produced by enzymatic chemical reactions. Enzymes can perform up to several million catalytic reactions per second. To determine the maximum rate of an enzymatic reaction, the substrate (plasma drug) concentration should be increased until a constant rate of product (drug metabolite) formation is achieved. This is the maximum velocity (V_{max}) of the enzyme. At this point, the active sites of the enzymes are saturated with drug, and a constant amount of drug begins to be eliminated per unit of time (“zero-order” kinetics). Because the substrate (drug plasma) concentration at V_{max} cannot be measured exactly, the metabolism of drug can be characterized by Michaelis-Menten constant (K_m), or the drug plasma concentration at which the rate of metabolism is half of its maximum ($K_m = V_{max}/2$). For practical purposes, the K_m is the plasma concentration at which, when the dose is increased, the nonproportional increase in C_{ss} and AUC start to occur.

For most of drugs that are metabolized by hepatic enzymes and eliminated by the liver, the K_m is above the required therapeutic range and the drugs follow linear kinetics. However, when the therapeutic range is above the K_m , nonlinear kinetics occurs. For example, the average K_m and therapeutic range for phenytoin are 4 mg/L and 10 to 20 mg/L, respectively, and many patients on phenytoin experience nonlinear pharmacokinetics.

The nonlinear pharmacokinetics may also be seen in low-clearance drugs for which elimination is significantly influenced by the binding of the drug to plasma proteins. In this scenario, after increasing the dose of the drug, a less-than-expected increase in C_{ss} and AUC occurs. This would suggest that the plasma protein-binding sites have been saturated and that the free fraction of low-clearance drug has increased. The latter would result with increased clearance and a less-than-expected increase C_{ss} occurs. However, if measured, the free fraction of the low-clearance drug increases proportionally.

Both valproic acid and disopyramide follow this type of nonlinear pharmacokinetics (Bowdle et al., 1980; Lima et al., 1991).

Compartment Models

For many drugs, after intravenous administration, the process of distribution throughout plasma and tissues occurs rapidly and simultaneously, and the whole body could be thought of as a single compartment. In this single-compartment model, after bolus intravenous administration of the drug, there is a monoexponential decrease in plasma concentration. The latter is the result of the elimination process that allows a constant portion of the drug (not amount) in the body to be eliminated per unit of time. In this case, the drug follows the first-order kinetic. The first order elimination of a drug from the body or plasma (C_p) is defined as follows:

$$A_B \times A_B^0 \times e^{-K_d t}, \text{ or } C_p \times C_p^0 \times e^{-K_d t}$$

A_B^0 is the initial amount in the body and C_p^0 is plasma concentration immediately after the bolus; t is the time since bolus, and K_d is the rate constant of elimination. The $e^{-K_d t}$ represents the fraction of the A_B^0 remaining at time t . The K_d is an index of the body's capacity to remove the drug. The elimination rate constant K_d is the fraction of the total amount of drug in the body that is removed per unit of time. It is a function of clearance and volume of distribution:

$$K_d = CL / V_d$$

The elimination rate constant (K_d) can be also thought of as the fraction of the volume of distribution that is effectively cleared of drug per unit of time. Because the drug plasma concentration diminishes monoexponentially, a graph plot of the logarithm of the plasma concentrations vs. time yields a straight line. The elimination rate constant defines the slope of this curve, and two plasma concentrations measured during the decay or elimination phase can be used to calculate the K_d (Fig. 7-11):

$$K_d = \ln C_{p1} - \ln C_{p2} / (t_2 - t_1)$$

The K_d is often expressed in terms of a time required for one half of the total amount of drug in the body to be eliminated, or the plasma concentrations to decrease by one half, that is, by the half-life of the drug ($t_{1/2}$). If plasma

concentrations decrease by 50% and $C_{p1} = 2C_{p2}$, then in the previous equation, $t_2 - t_1 = t_{1/2}$ and:

$$K_d = \ln 2 / t_{1/2}$$

$$t_{1/2} = 0.693 / K_d$$

The half-life, like K_d , is dependent on volume of distribution and clearance, and this relationship is shown in the next equation:

$$t_{1/2} = (0.693 \times V_d) / CL$$

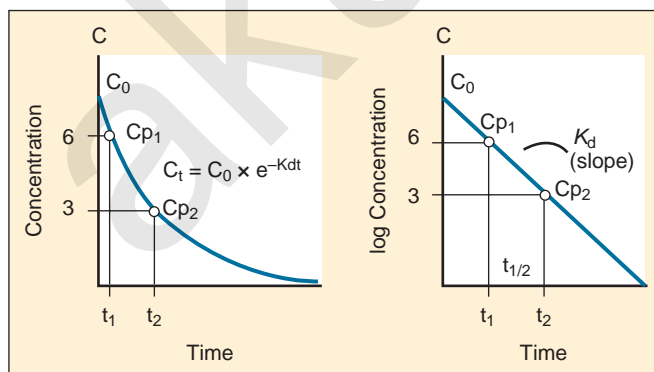

The half-life is a variable that determines the following factors:

1. The time needed ($5 \times t_{1/2}$) to reach plasma C_{ss} of the drug after initiation of an infusion;
2. The time needed to reach new C_{ss} 's after increasing or decreasing the infusion rate;
3. The time needed for the drug to disappear from plasma after the infusion is stopped; and
4. The time it takes for all the drug from the body to be eliminated after cessation of the drug infusion (Fig. 7-12).

The short half-life is an obvious advantage for drugs given by intravenous infusion. It allows for drug effects to be easily and dynamically titrated; it requires a relatively shorter time for C_{ss} 's to be achieved; and if toxicity occurs, it is easier to handle. For drugs administered intermittently (oral or parenteral) a short half-life is a disadvantage because multiple doses are needed, it is difficult to keep the plasma concentration within the therapeutic window, and a missed dose could drop plasma concentrations below the minimal therapeutic level. It should be emphasized that volume of distribution and clearance may change independently of one another and alter the half-life in the same or opposite directions. For the given clearance, drugs with smaller volume of distribution have a shorter half-life and a faster recovery after the infusion of an anesthetic agent. Reduced clearance, with no changes in volume of distribution, increases the half-life and recovery time after intravenous infusion.

Most of the drugs used in anesthesia do not follow the simple, one-compartment pharmacokinetics but rather behave like a two- or even three-compartment model. Distribution of anesthetic drugs into and out of peripheral tissues determines the pharmacokinetic profile and the time course of the anesthetic drug's effect. For the two-compartment model, the central compartment includes the blood and organs or tissues that have high blood flow and can be thought of as a rapidly equilibrating volume. The second compartment has a volume (V_l) that equilibrates at a much slower pace. After bolus administration of a drug that follows the two-compartment model, the two distinct phases of distribution and terminal elimination can be distinguished, and the decay of plasma concentration over time is defined by the biexponential equation (Fig. 7-13). Changes in plasma and the site-of-action concentrations would depend on drug elimination and on the equilibrium between central and peripheral tissue compartments.

For many anesthetic drugs, three phases can be distinguished after intravenous bolus administration. This three-compartment model is composed of the central compartment

■ **FIGURE 7-11.** Single-compartment model. The initial plasma (body) drug concentration (C_p^0) produced by single loading dose diminishes monoexponentially (left). The semilogarithmic graph of concentration vs. time yields a straight line (right).

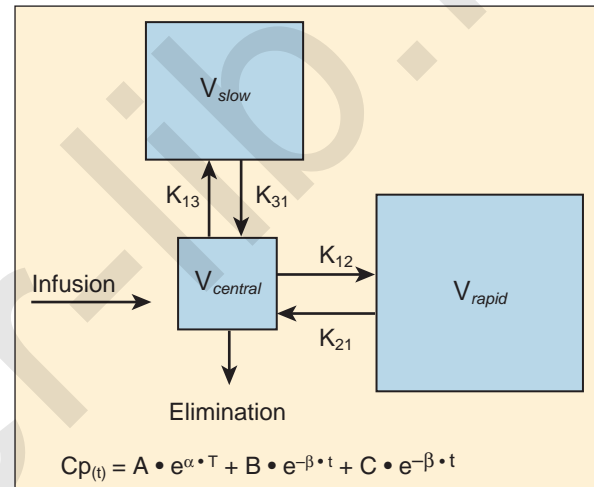

■ **FIGURE 7-12.** Changes in plasma concentration and steady-state level after intravenous infusion are in the function of half-life.

■ **FIGURE 7-13.** Two-compartment model. For many drugs, after an intravenous bolus, there is no “instantaneous” and even distribution of the drug throughout the body (as in the one-compartment model). Drugs distribute with different paces between the initial or central (V_c) compartment (i.e., circulation and well-perfused organs, including the brain) and the tissue or peripheral compartment (V_t). The changes in plasma concentrations follow the biexponential decay.

and two additional compartments that include the respective rapid and slow equilibrating tissues and organs (Fig. 7-14). Likewise, the three-compartment model is characterized by the triexponential plasma concentration equation, three volumes of distribution, and five rate constants of distribution and terminal elimination (K_{12} , K_{21} , K_{13} , K_{31} , and K_{10}).

After an intravenous bolus, the anesthetic or hypnotic drug dilutes almost immediately, within the single circulation time, into the central compartment (i.e., in the bloodstream and in the highly perfused organs such as the brain and spinal cord). The central volume of distribution can be used to calculate the loading dose. Subsequently, there is a redistribution of drug out from the CNS back into the blood and to the peripheral compartments with rapid equilibrium (muscles viscera; V_{drapid}). Finally, the drug diffuses into poorly perfused tissues (fat) that slowly equilibrate with the central compartment. The initial redistribution, rather than metabolic clearance, determines the termination of the

■ **FIGURE 7-14.** Three-compartment model. For many anesthetic drugs, three phases in distribution can be distinguished after intravenous administration. After immediate distribution into the central compartment (i.e., bloodstream and highly perfused organs), there is redistribution of drugs (i.e., from the brain) back into circulation (K_{21}) and to peripheral tissue with rapid equilibrium (K_{12}). The drug also diffuses at a very slow pace into and out from the poorly perfused tissues (K_{13} , K_{31}). The triexponential decay describes the changes in plasma concentrations.

effect of single boluses of parenteral anesthetics. If prolonged anesthesia is required, the maintenance infusion rate should compensate not only for the drug clearance but initially also for the transient loss of anesthetic by redistribution to the peripheral compartments that are governed by “intercompartmental clearance” and elimination rate constants (K_{12} , K_{21} , K_{13} , and K_{31}).

Context-Sensitive Half-Time

Traditionally, clearance, volume of distribution, and half-life are standard pharmacokinetic parameters used to characterize the drug’s offset of action. As discussed previously, they are derived from one- and two-compartment models or, through the use of computer simulation programs, from multicompartment models. These pharmacokinetic parameters can be relatively easy to apply to calculate the infusion rate and predict

the offset of action of water-soluble drugs with small volumes of distribution and relatively simple patterns of disposition (i.e., muscle relaxants).

For the anesthesiologist, pharmacokinetic factors are often used for the routine selection and use of various intravenous anesthetic agents. Drugs with short elimination half-lives are commonly selected for brief procedures, whereas drugs with longer half-lives are selected for lengthier procedures. Drugs with small volumes of distribution tend to decrease the time required for recovery after intravenous infusion, and agents with decreased plasma clearances may increase the time for recovery. In general, formulas for the calculation of continuous infusions incorporate knowledge of these pharmacokinetics. For bolus administration of drug, the volume of distribution and the desired plasma concentration are needed. Table 7-6 lists plasma concentrations in adults for some of the opioids. The bolus dose is calculated as the product of the volume of distribution and the desired plasma concentration (C_p):

$$\text{Bolus dose} = V_d \times C_p$$

The maintenance infusion rate (MIR) is calculated as the product of the desired plasma concentration and the clearance:

$$\text{MIR} = \text{CL} \times C_p$$

Although these formulas work well, Shafer and Varvel (1991) and Hughes et al. (1992) have demonstrated the complex interactions that occur with prolonged infusions, especially in drugs that are lipid soluble.

The offset of drug effect depends on reduction of the plasma concentrations and the withdrawal of drug from the site of action; that is, for anesthetic from the receptor site in the CNS. If steady state is achieved and all compartments are saturated, then the half-life of elimination phase, which is a function of the first-order processes of elimination, correlates with a decrease in the site-of-action drug concentrations and with the offset of drug action. However, after infusion of a highly lipophilic anesthetic agent, when steady state is not achieved and not all compartments are saturated, the decline in concentrations (i.e., the offset of action and recovery from anesthesia) depends on complex interactions between the duration of the infusion and

initial distribution, redistribution, and metabolic and elimination first-order processes. The classic descriptors of a drug's pharmacokinetics and offset of action (terminal half-time) are of little help to anesthesiologists in predicting the offset of action and recovery from anesthesia for the intravenous anesthetic drugs. Fortunately, with the help of pharmacokinetic and pharmacodynamic simulation models, new predictors of offset of drug effects have evolved (Shafer and Varvel, 1991; Hughes et al., 1992; Youngs and Shafer, 1994).

Using pharmacokinetic and pharmacodynamic models and basic pharmacokinetic profiles of commonly used synthetic opioid analogs, Shafer and Varvel (1991) were the first to construct the offset of action (recovery) curves as a function of the duration of infusion for fentanyl, alfentanil, and sufentanil (Fig. 7-15). Hughes et al. (1992) introduced the term *context-sensitive half-time* (context refers to the duration of infusion) as a time required for a drug concentration to decrease to half of its value after drug infusion of a given duration. Of importance is that for any given drug, its context-sensitive half-time varies with the duration of the drug infusion. Because for most intravenous anesthetic drugs the 50% fall in concentration is not sufficient for recovery from anesthesia, other decrement times have been introduced (Youngs and Shafer, 1994), for example, 80% and 90% decrements.

After a short intravenous infusion (0 to 15 minutes), fentanyl and other synthetic opioid analogs have similar context-sensitive half-times (Fig. 7-15). However, after prolonged infusion (longer than 1 hour), there is a marked difference among four synthetic opioid analogs (fentanyl, sufentanil, alfentanil, and remifentanil), and these differences do not correlate with their classic pharmacokinetic parameters (Table 7-7). In contrast to its older congeners, remifentanil has a short and steady context-sensitive half-life of 3 minutes, which does not change with the increasing duration of infusion (Egan et al., 1996). This contrasts with alfentanil, which has a context-sensitive half-time that increases to 1 hour after a 4-hour infusion (Ebling et al., 1990; Scholz et al., 1996). This difference is because of the unique pharmacokinetic profile of remifentanil. It is a highly liposoluble (volume of distribution at steady state [V_{dss}] of 30 L) opioid analog that undergoes widespread metabolism (deesterification), including metabolism in the circulation. Unlike other opioids, the termination of action of remifentanil does

TABLE 7-6. Opioid Concentrations that Ablate Responsiveness to Intraoperative Noxious Stimuli and Permit Adequate Ventilation on Emergence*

	Fentanyl	Alfentanil	Sufentanil
Induction and Intubation			
Thiopental	3 to 5	250 to 400	0.4 to 0.6
O ₂ /N ₂ O only	8 to 10	400 to 750	0.8 to 1.2
Maintenance			
N ₂ O/potent vapor	1.5 to 4	100 to 300	0.25 to 0.5
O ₂ /N ₂ O only	1.5 to 10	100 to 750	0.25 to 1.0
O ₂ only	15 to 60	1000 to 4000	10 to 60
Adequate ventilation	1.5	125	0.25 on emergence

* Opioid concentrations given in ng/mL.

■ **FIGURE 7-15.** Context-sensitive half-time: the time required for drug concentration to decrease by half of its value (Y axis) after cessation of infusion of given duration (X axis) for fentanyl and its congeners, sufentanil, alfentanil, and remifentanil (see the text for explanation). (Modified from Shafer SL, Varvel MD: *Pharmacokinetics, pharmacodynamics, and rational opioid selection*, *Anesthesiology* 74:53, 1991; Egan TD: *Clin Pharmacokinet* 29:80, 1995.)

TABLE 7-7. Pharmacokinetic Parameters of Synthetic Opioids after Single Intravenous Bolus Administration

	Volume of Distribution (V_{dss} ; L/kg)	Elimination Half-Life ($t_{1/2\alpha}$ min)	Distribution Half-Life ($t_{1/2\beta}$ min)	Total Body Clearance (mL/min/kg)	Context-Sensitive Half-Time (3-hr Infusion)
Fentanyl	4	2 to 3	220 to 300	10 to 20	100
Sufentanil	1.7	1.4	160	10 to 15	30
Alfentanil	0.75	0.6 to 12	90 to 120	8	50
Remifentanil	0.3 to 0.4	1 to 1.5	6 to 14	50	3

Data from Egan TD et al.: Remifentanil versus alfentanil: comparative pharmacokinetics and pharmacodynamics in healthy adult male volunteers, *Anesthesiology* 84:821, 1996; Ebling WF et al.: Understanding pharmacokinetics and pharmacodynamics through computer simulation I: the comparative clinical profiles of fentanyl and alfentanil, *Anesthesiology* 72:650, 1990; Scholz J et al.: Clinical pharmacokinetics of alfentanil, fentanyl and sufentanil, an update, *Clin Pharmacokinet* 31:275, 1996.

not depend on redistribution but rather on extremely rapid metabolic clearance. Kapila et al. (1995) demonstrated that the context-sensitive half-times of remifentanil (3 minutes) and alfentanil (50 to 55 minutes) derived from computer modeling are similar to measured context-sensitive half-times (3.2 and 47 minutes for remifentanil and alfentanil, respectively), and both correlate with measured pharmacodynamic offset (recovery of minute ventilation). The latter confirms the value and clinical applicability of this new pharmacokinetic-pharmacodynamic parameter in predicting the offset of anesthetic drugs.

The context-sensitive half-time curves provide a better, clinically more relevant comparison of the pharmacokinetic profiles of anesthetic drugs than the traditional pharmacokinetic parameters (Fig. 7-16). After a single intravenous dose, commonly used anesthetic and hypnotic drugs have a short duration of action. However, after prolonged infusions the context-sensitive half-times and duration of action increase. For some drugs (e.g., propofol and ketamine), this increase is modest, whereas for others (e.g., diazepam and thiopental), it is quite dramatic. In the case of midazolam, the rapid increase in its context-sensitive half-time with prolonged duration of infusion occurs in the presence of a relatively short elimination half-life ($t_{1/2\beta}$), and this is most likely because of the low clearance of midazolam.

The data regarding the context-sensitive half-times and other decrement times of anesthetic agents in the pediatric population are limited, at best. In children aged 3 to 11 years, longer context-sensitive half-times than in adults were reported for propofol. After a 1-hour infusion in children and

■ **FIGURE 7-16.** Context-sensitive half-time for commonly used general anesthetics. (From Reves JG et al.: *Nonbarbiturate intravenous anesthetics*. In Miller RD, editor: *Anesthesia*, ed 5, New York, 2000, Churchill Livingstone.)

adults, the context-sensitive half-times for propofol are 10.4 and 6.6 minutes, respectively, and after a 4-hour infusion, they are 19.6 and 9.5 minutes, respectively (McFarlan et al., 1999). This is probably due to the altered compartment volumes and may lead to slower recovery from a propofol infusion in children than in adults (Short et al., 1994). In contrast,

the shorter context-sensitive half-time of fentanyl was determined in pediatric population (2 to 11 years old) compared with published data in adults (Ginsberg et al., 1996).

Population Pharmacokinetics

Pharmacokinetics and pharmacodynamics of drugs in the pediatric population and in adults are different. Furthermore, neonates, infants, children, and adolescents have distinct differences in physiologic development, and the pediatric population is quite heterogeneous with regard to pharmacokinetics and pharmacodynamics of drugs across different age groups. These differences justify studying pharmacokinetics and pharmacodynamics in children of various ages. However, the testing of medications in children presents a dilemma: while society wants to spare children from the potential risk involved in research, children may be harmed if they are given medications that have been inadequately studied (Steinbrook, 2002).

Classical nontherapeutic pharmacokinetics studies involve administering either single or multiple doses of a drug to a relatively small group of subjects and require multiple sampling to characterize the concentration and time profile of the drug. Conducting standard nontherapeutic pharmacokinetic studies with frequent sampling in children imposes many ethical and practical issues, and an alternative and preferable approach in many pediatric situations is the population pharmacokinetics (PPK) approach. This approach, in addition to dense data and frequent sampling, deal with sparse data and infrequent sampling of blood from a larger population, and it allows many obstacles related to classical nontherapeutic pharmacokinetic studies in children to be overcome.

PPK is an area of clinical pharmacology that studies the sources and the correlates of variability in drug-plasma concentration parameters among individuals in the target population of patients who are receiving clinically effective doses of a drug (Shen and Lu, 2007). PPK is focused on the quantitative assessment of the typical pharmacokinetic parameters, as well as the within- and between-individual and residual variability in drug absorption, distribution, metabolism, and excretion (Steiner, 1992; Ette and Williams, 2004). The population approaches use mathematic and statistic modeling to investigate the dose-concentration-effect relationship and to quantitatively and qualitatively assess factors that may explain interindividual variability (Sheiner et al., 1979). In the early 1980s, Sheiner and Beal introduced the new PPK data analysis approach (i.e., the population approach) and demonstrated that estimates of PPK parameters could be obtained even if only two or three samples are collected per patient (Sheiner and Beal, 1980, 1981, 1982). They also introduced a new software program (the Nonlinear Mixed Effects Model, or NONMEM) that was capable of performing the new type of analysis, and this is now the most commonly used population modeling program (Sheiner and Beal, 1980; Sheiner et al., 1979).

The PPK approach allows not only major contributions to variability of key pharmacokinetic parameters to be established, but it also goes one step further and allows the relative contributions of different factors to be determined. In this regard, size, age, and renal function are major contributors to vancomycin clearance variability in neonates. Using the PPK and NONMEM modeling, Anderson and colleagues (2002a) have shown that size explains 49.8%, age accounts for 18.2%, and renal func-

tion explains 14.1% of clearance variability of vancomycin in neonates. The small unexplained percentage (18%) is residual variability in clearance and suggests that target concentration intervention is unnecessary if size, age, and renal function are used to predict the dose (Anderson et al., 2002a).

Body Size and Maturation Adjustments

Two major features of children that are not seen in adults are growth and development, and these unique characteristics of the pediatric population can be studied by using size and age as covariates. PPK studies in children cover a population with much wider range in body size than similar studies in adults, and body weight can vary in the pediatric population up to 200-fold (i.e., 0.5 to 100 kg). Even when only one particular age group is studied, it is not uncommon that tenfold differences in body weight are reported. Both primary pharmacokinetic parameters, clearance, and volume of distribution are functions of body size. Therefore, to identify the potential effects of other covariates in predicting pharmacokinetic parameters, it is necessary to use size as a primary covariate and standardized clearance and volume of distribution to appropriate body size.

In adults, to account for impact of body size, pharmacokinetic parameters are traditionally adjusted to body weight or body surface area. However, these empirical approaches, although appropriate when adjusting for dose, clearance, or volume of distribution in adults, may be inappropriate for scaling small children to adults (Holford, 1996). The body-weight adjustments may underpredict clearance, whereas the body surface area model may overpredict clearance in children (and the error increases with decreasing weight) (Mitchell et al., 1971; Holford, 1996; Anderson et al., 2006). Measurement of body surface area, which can be calculated from height and weight by DuBois formula:

$$BSA = (W^{0.425} \times H^{0.725}) \times 0.007184$$

where *BSA* represents body surface area, *W* is weight, and *H* is height. It may also be calculated by using several very similar formulas; however, all formulas may be inaccurate, especially in younger pediatric patients (Holford, 1996; Anderson et al., 2006). Infants are not morphologically similar to adults (they have short legs, relatively big heads, and large body trunks), and direct photometric measurement has been suggested to be an inaccurate prediction of body surface area in children younger than 12 years old, or *BSA* greater than 1.3 m² (Mitchell et al., 1971).

A method for body-size adjustment that has begun to be used regularly in PPK studies in children is allometric size adjustment. Allometry is a methodology used to relate morphology and body function to the size of an organism. This methodology had found wide application in drug development to predict pharmacokinetic parameters in humans based on data from different animal species. Gillooly and colleagues (2001) have shown that in almost all species, including humans, when the log of the basal metabolic rate is plotted against the log of body weight, a straight line with a slope of 0.75 is produced (Fig. 7-17).

In the allometric size adjustment model, pharmacokinetic parameters are studied by body weight of an individual by power model:

$$F_{\text{size}} = (W / W_{\text{adult}})^{\text{PWR}}$$

■ **FIGURE 7-17.** A comparison of the temperature-standardized relation for whole-organism metabolic rate (W) as a function of the body mass (kg). Data points represent unicells, plants, ectotherms, and endotherms, all standardized to 20 °C. The three lines indicate that the “allometric 0.75 power model” fits for unicells, poikilotherms and homeotherms. (From Gillooly JF et al.: *Effects of size and temperature on metabolic rate*, *Science* 293:2248, 2001.)

where F_{size} is a factor for size, W is a body weight of an individual, W_{adult} is body weight of an adult of standard 70-kg size, and PWR is allometric power exponent.

The allometric “0.25 power” model can be used to predict the pharmacokinetic estimates in children with PWRs of 0.75, 0.25, and 1 for clearance, half-life, and volume of distribution, respectively (West et al., 1997, 1999; Anderson et al., 2006). Using the fixed power exponent allows investigators to delineate secondary covariate effects from the effects of size. The allometric scaling also allows direct comparison of pediatric and adult pharmacokinetic estimates and can be used to predict the pediatric dose based on the adult dose (Table 7-5).

Age is used as a covariate to describe the maturation process in the pediatric population. Several quantitative models that describe the maturation of clearance have been developed, and they vary depending on age group studied (Allegaert et al., 2006; Anderson et al., 2000). Rhodin and colleagues (2009) have studied the effects of size and maturation on GFR in 923 individuals from eight studies, from 22 weeks’ PMA to 31 years of age. They demonstrated that PMA is a better descriptor of maturation changes than PNA and that a sigmoid hyperbolic model describes the nonlinear relationship between GFR and PMA. Half of the adult values are reached at 48 weeks PMA, and at 1 year PNA the predicted GFR is 90% of the adult GFR (Rhodin et al., 2009).

Data Modeling

There are three main approaches to modeling data collected from a group of subjects: naïve pooled data, the standard two-stage approach, and mixed-effects models. In the naïve pooled-data approach, time-concentration data pooled together from different subjects are treated as if all doses and all observations pertain to a single subject. This approach does not allow information about the magnitude and the causes of between-subject variability to be collected, and it is adequate only if data are extensive for each subject and if there is only minor between-subject variability. In the standard two-stage approach,

individual time-concentration profiles are analyzed, and the individual parameters (i.e., volume of distribution and clearance) are estimated in the first stage by separately fitting each subject’s data. In the second stage, individual estimates are used as variables and combined to obtain summary measures. If data are sparse, misrepresentation may occur easily.

In contrast to the naïve pooled-data and the two-stage approaches that use dense data from a small group of subjects, the mixed-effects models study the variability in drug response in the population of interest, using sparse data (often only two or three samples) from a large number of subjects. The mixed-effects modeling approach, similar to the naïve pooled-data approach, analyzes the data of all individuals at once, but it takes into consideration the interindividual effects. The modeling is “mixed” because it describes the data using a mixture of fixed effects (parameters’ differences predicted by covariates) and random effects (between subject and residual or unexplained variability). In their seminal work in the early 1980s, by using phenytoin data collected from therapeutic monitoring in epileptic patients, Sheiner and Beal showed not only how estimates of PPK could be obtained from few samples per patient, but they also demonstrated that the naïve pooled-data and the two-stage approaches may both result in biased parameter estimates. The advantages of this approach are that in addition to sparse data, it can handle the imbalance in data per individual and it can estimate the between-observation variability. Obviously, the use of sparse data and imbalanced data allows many ethical concerns and practical problems related to frequent sampling to be overcome. The disadvantage is that this approach needs advanced training for the use of specialized software such as NONMEM, and fitting complicated models can be time consuming.

NEUROTOXICITY

One of the most active areas of investigation in the past several years involves the potentially toxic effects of sedative and anesthetic agents on the developing nervous system. Newborn animal model studies have reported apoptosis in multiple areas in the CNS during the period of rapid synaptogenesis, when exposure to agents that work via *N*-methyl-D-aspartate (NMDA) antagonists or γ -aminobutyric acid (GABA) agonist pathways occurs (Ikonomidu, 1999; Jevtovic-Todorovic et al., 2003; Mellon et al., 2007). Although this effect was originally shown in newborn rodent models, recent work has demonstrated the same histologic changes in nonhuman primates (Wang and Slikker, 2008). Ketamine, isoflurane, and sevoflurane have all been shown to produce apoptosis in the brains of developing rodents in a dose-dependent manner (Ikonomidu et al., 1999; Jevtovic-Todorovic et al., 2003; Fredriksson et al., 2007; Loepke et al., 2009; Satomoto et al., 2009; Stratmann et al., 2009). Apoptosis has also been demonstrated in the spinal cord (Sanders et al., 2008). The period of vulnerability is thought to coincide with the period of synaptogenesis, which is at about day 7 in rats and from late pregnancy through early toddlerhood in humans. Concern and interest increased with the demonstration of long-term learning deficits at early maturity in rats when they were exposed to an “anesthetic cocktail” of midazolam, nitrous oxide, and isoflurane for 6 hours on postnatal day 7 (Jevtovic-Todorovic et al., 2003). Combinations of nitrous oxide, midazolam, and isoflurane may cause more apoptosis than single agents (Jevtovic-Todorovic et al., 2003; Fredriksson et al., 2007). In

monkeys, ketamine produced apoptosis when given for 24 hours in late gestation or to 5-day-old monkeys but not to 30-day-old monkeys (Slikker et al., 2007). Also a shorter administration period of ketamine did not produce apoptosis in 5-day-old monkeys. There is mixed evidence for long-term measurable changes in cognitive function or behavior in rodents exposed to anesthesia in the neonatal period (Jevtovic-Todorovic et al., 2003; Fredriksson et al., 2007; Loepke et al., 2009; Stratmann et al., 2009). No data have been presented that examine long-term effects in primates. The application of these findings to human neonates and infants has many unknown elements, including the window of vulnerability, the duration of exposure, and the dose of agent necessary to affect long-term neurodevelopment. The mechanism that triggers apoptosis is not clear, but there is some evidence that apoptosis may be triggered as a result of decreased release of trophic factors from the axon (Head et al., 2009). The possibility that GABA receptors may be involved is complicated by the observation that the morphology of GABA receptors changes during this period, as do their downstream actions, and that the addition of a GABA agonist does not completely reverse the apoptotic effect of GABA antagonists. In addition to apoptosis, there is also increasing evidence that anesthetics can cause a change in dendritic morphology. This may also be to the result of anesthesia causing relative inactivity of neurons and a decrease in relevant trophic factors. A series of articles in *Anesthesia & Analgesia* in June 2008 presented the data and controversies well. Editorials in *Anesthesiology* in November 2008 through January 2009 presented several approaches to investigating the presence and extent of such a neurotoxic effect in human infants and young children who are exposed to anesthetic agents (Cattano et al., 2008; Davidson et al., 2008a; Jevtovic-Todorovic et al., 2008; Loepke et al., 2008; Loepke and Soriano, 2008; McGowen and Davis, 2008; Sanders et al., 2008; Sun et al., 2008, Wang and Slikker, 2008; Hansen and Flick, 2009). Great efforts will be ongoing in the near future to further delineate the mechanisms, to investigate the extent of the problem in humans, and to study possible therapeutic options to minimize such toxicity. An FDA advisory panel held in April 2007 concluded “there was no scientific basis to recommend changes in clinical practice” with the current data (the meeting transcript can be found at www.fda.gov/ohrms/dockets/ac/2007-4285t1.pdf).

INTRAVENOUS AGENTS

Sedative Hypnotics and Barbiturates

A variety of sedative-hypnotic agents can be used for premedication or induction of anesthesia. These agents are administered intravenously, but for premedication oral, sublingual, intranasal, rectal, or less commonly, intramuscular routes are used.

On a milligram-per-kilogram basis, barbiturates are more lethal to newborns than to more mature animals (Carmichael, 1947; Weatherall, 1960; Goldenthal, 1971). The sleeping times of newborn animals are markedly prolonged at sublethal doses given on an equal milligram-per-kilogram basis (Weatherall, 1960). Greater penetration of the blood-brain barrier by barbiturates has been found in neonates compared with older animals (Domek et al., 1960).

Neonates have a decreased ability to metabolize barbiturates (Mirkin, 1975). The longer-acting barbiturates, which are in

part excreted unmetabolized in the urine, would be expected to have prolonged or elevated blood levels (Knauer et al., 1973; Boreus et al., 1975). Glucuronic acid conjugation of barbiturates develops rapidly and increases 30-fold during the first 3 weeks of life (Brown et al., 1958).

Short-acting barbiturates (e.g., methohexital, thiamylal, and thiopental) can be used to induce anesthesia in infants and children. These agents produce rapid induction of hypnosis with minimal relaxation or analgesia. The pharmacokinetics of short-acting barbiturates in infants, children, and adults were studied extensively by Brodie (1952), Dundee and Barron (1962), Mark (1963), Saidman and Eger (1966), and Lindsay and Shepherd (1969). Because of the child's proportionately greater amount of vessel-rich tissue, the uptake of short-acting barbiturates should be more rapid; the effect more quickly achieved; and metabolism, excretion, and recovery more prompt unless retarded by supplementary agents (Eger, 1974). These agents are used less commonly now than in the past in many centers where other short-acting sedatives have supplanted the short-acting barbiturates.

Thiopental

Thiopental is an ultra short-acting barbiturate used as an intravenous induction agent in anesthesia. It has been also used in critical care settings as a continuous infusion for the treatment of intracranial hypertension and status epilepticus. Hiccoughs, sneezing, and other respiratory irregularities are rarely seen on induction, and there is no excitement or extrapyramidal activity associated with its use. It decreases cerebrospinal fluid pressure, making it useful for diagnostic and operative neurologic procedures (Dawson et al., 1971). Intraocular pressure also is decreased. Awakening is quiet, occasionally interrupted by shivering, and associated with a low incidence of nausea (Smith et al., 1955). Porphyria, seldom encountered in the United States, is a specific contraindication to barbiturates (Dundee and Barron, 1962). Thiopental requirements for induction of anesthesia reveal an inverse relation with age. Jonmarker et al. (1987) reported that the ED_{50} of thiopental in infants is significantly greater (7 mg/kg) than that in adults (4 mg/kg) (Fig. 7-18). Westrin et al. (1989) determined the dose of thiopental needed for satisfactory induction of 10 healthy, unpremedicated neonates who were 0 to 14 days old and 20

■ **FIGURE 7-18.** Estimated $ED_{50} \pm SD$ for thiopental in the various age groups. (From Jonmarker C et al.: *Thiopental requirements for induction of anesthesia in children*, *Anesthesiology* 67:104, 1987.)

infants who were between 1 and 6 months old. In this study, the ED_{50} for thiopental induction was 3.4 ± 0.2 mg/kg in neonates and 6.3 ± 0.7 mg/kg in infants aged 1 to 6 months. In an in-vitro study in which the free fraction of thiopental was measured in the serum of neonates and adult volunteers, Kingston et al. (1990) noted that neonates had a free drug fraction that was 1.5 to two times greater than that of adults. The increased free fraction of thiopental may explain the decreased induction dose required by the neonate. Sorbo et al. (1984) studied the pharmacokinetics of thiopental in 24 surgical patients aged 5 months to 13 years. The volume of distribution of the central compartment ranged from 0.3 to 0.4 L/kg. The steady-state volume of distribution was approximately 2 L/kg and did not differ statistically from values previously measured in adults. The elimination half-time and clearance of thiopental in these infants and children were 6.1 ± 3.3 hours and 6.6 ± 2.2 mL/kg per minute, respectively. These values were significantly different from the values of 12 ± 6 hours and 3.1 ± 0.5 mL/kg per minute, respectively, observed in adults. After a single intravenous dose, clinical effect is mainly terminated by redistribution. When repetitive or larger doses are used, redistribution becomes less effective and metabolism plays a more important role, explaining the shorter recovery times in children when compared with adults.

Methohexital

Methohexital, a methylated oxybarbiturate, is more potent than thiopental by a ratio of about 3:1, is more rapidly eliminated, and produces more undesirable side effects (Clarke et al., 1968). Greater speed of recovery provides its principal indication, especially for outpatient care or for situations where very brief effect is wanted, such as for cardioversion or electroconvulsive therapy. The incidence of involuntary muscular movement, hiccoughs, and respiratory irregularity during induction is definitely greater with methohexital than with thiopental. Although methohexital has been used via the intramuscular or rectal route without tissue damage, some studies suggest that the high concentration of rectal methohexital can cause mucosal damage (Miller et al., 1961). Administration of 10% methohexital to rats via the rectal route produces minor, self-limited lesions in the rectal mucosa (Hinkle and Weinlander,

1989). The recommended dose for intravenous use is 1 to 2 mg/kg, and in children younger than 5 years, 25 to 30 mg/kg can be administered rectally.

In a study of 85 children, Khalil et al. (1990) compared 25 mg/kg of rectal methohexital in a 10% and a 1% concentration. In this study, 1% was associated with a better success rate, faster onset time, high plasma concentration, and longer recovery time than the 10% concentration. In addition, they noted that the length of the rectal catheter had no effect on the pharmacodynamics of the drug. A 10% solution of methohexital at a dose of 25 mg/kg usually produced sleep in 6 to 10 minutes, which coincided with peak serum levels (Goresky and Steward, 1979; Letty et al., 1985).

Forbes et al. (1989a) reported on the plasma concentrations of 60 children after doses of 15, 20, 25, or 30 mg/kg of rectal methohexital (Fig. 7-19). The dose of 30 mg/kg resulted in significantly higher plasma concentrations for up to 20 minutes. In addition, in a separate study of 12 patients who were premedicated with 25 mg/kg of 2% rectal methohexital, Forbes et al. (1989b), using pulsed Doppler and two-dimensional echocardiography, noted a significant increase in heart rate but no change in cardiac index, stroke volume, ejection fraction, or blood pressure.

Audenaert et al. (1995) prospectively reviewed the effects of rectal methohexital in 648 patients. They noted that after a 30 mg/kg dose of 10% methohexital, children fell asleep 85% of the time. Sleep usually occurred in 6 minutes. Sleep was less likely to occur in patients with myelomeningocele or in patients receiving phenobarbital or phenytoin therapy. Side effects of defecation after administration occurred in 10% of patients, and hiccoughs occurred in 13% (Audenaert et al., 1995). The intravenous dose for induction using methohexital dissolved in a lipid emulsion was determined by Westrin (1992), who noted that the dose (adjusted by body weight) needed for induction in infants younger than 5 months was almost twice that for older children (Fig. 7-20).

Beskow et al. (1995) compared intravenous induction of methohexital (3 mg/kg) and thiopental (7.3 mg/kg) in 41 infants aged 1 month to 1 year. In this study of short surgical procedures, recovery as measured by spontaneous eye opening after methohexital was significantly shorter than it was for thiopental.

■ **FIGURE 7-19.** Plasma methohexital concentrations after rectal administration of methohexital 15 mg/kg, 20 mg/kg, 25 mg/kg, or 30 mg/kg. Mean \pm SEM. * $P < 0.05$, 15 mg/kg vs. 30 mg/kg; † $P < 0.05$, 20 mg/kg vs. 30 mg/kg. Benzodiazepines and Antagonists

Diazepam

Diazepam produces relatively pleasant sedation or hypnosis with few side effects and prompt recovery. Its action is caused by depression of the amygdala of the limbic system and spinal internuncial neurons. It is a specific treatment of seizure disorders in children (Lombroso, 1966; Carter and Gold, 1977). Intravenous administration of 0.2 to 0.3 mg/kg usually induces hypnosis, but the requirement varies widely. Diazepam appears to cause less cardiac depression than do barbiturates (Muenster et al., 1967; Abel and Reis, 1971).

Diazepam is metabolized by the CYP-linked monooxygenase system. In adults, the metabolite, desmethyldiazepam, is eliminated more slowly ($t_{1/2} = 150$ hours) than the parent compound ($t_{1/2} = 20$ to 30 hours) (Meberg et al., 1978).

The plasma half-life of diazepam and the nature of the diazepam metabolites formed vary with maturity (Morselli et al., 1974). The premature infant and the mature infant at term eliminate diazepam at a slower rate than older infants, children, and adults. In premature infants, a demethylated derivative of diazepam, N-desmethyldiazepam, could not be measured in plasma until 4 hours after injection, in comparison with older infants and children, in whom N-desmethyldiazepam was

measured in the plasma by 1 hour and had peaked by 24 hours. In adults, 71% of diazepam or its metabolites was excreted in the urine, and about 10% was excreted in the feces. As an oral premedicant or intravenous induction agent, the recommended dose of diazepam is 0.1 to 0.2 mg/kg. The local pain on injection intravenously has decreased its current use, along with the availability of other short-acting benzodiazepines (e.g., midazolam).

Midazolam

Midazolam is a water-soluble, short-acting benzodiazepine. Its chemical configuration confers a pH-dependent ring phenomenon. At pH 4, the diazepam ring opens, and a highly stable water-soluble compound results. At physiologic pH values, the ring closes and thereby increases the drug lipophilic activity. Cardiovascular stability, transient mild respiratory depression, minimal venous irritation, amnesia, and short duration of action are reasons why midazolam has replaced diazepam.

Midazolam is metabolized in the liver; less than 1% is excreted unchanged in the urine. Midazolam undergoes extensive metabolism (involving CYP3A4, CYP3A5, and CYP3A7) to a major hydroxylated form, 1-OH-midazolam. The protein binding of midazolam is extensive, with a free fraction of only 3% to 6%. Midazolam has an intermediate rate of absorption (0.5 to 1.5

hours) and a bioavailability of 30% to 50%. The terminal elimination phase ranges from 1 to 4 hours (Smith et al., 1981).

In children, the pharmacokinetics of midazolam have been reported. Payne et al. (1989) noted that in healthy children, midazolam administered at 0.15 mg/kg intravenously, the volume of distribution at steady state, the elimination half-life, and the clearance were 1.29 L/kg, 70 minutes, and 9.1 mL/kg per minute, respectively. Jones et al. (1993) have also reported on the kinetics of intravenous midazolam (0.5 mg/kg) in 12 healthy children and noted that the kinetics were consistent with a three-compartment model with a volume of distribution of 1.9 L/kg, $t_{1/2\beta}$ of 107 minutes, and a clearance of 15.4 mL/kg per minute. However, because the drug exhibits dose-related changes in clearance, comparisons between studies become difficult (Salonen et al., 1987). The kinetics of midazolam have also been determined after intramuscular, rectal, and oral administration. Payne et al. (1989) noted that times for peak serum concentrations after intramuscular, rectal, and oral administration were 15, 30, and 53 minutes, respectively, whereas the drug clearance and bioavailability via these three different routes were 10.4, 50.8, and 33.4 mL/kg per minute and 87%, 18%, and 27%, respectively. The lower bioavailability after oral or rectal administration is consistent with the commonly used oral dose of 0.5 mg/kg, which is almost five times higher than intravenous dosing.

In a study involving pediatric patients aged 6 months to 16 years, Reed et al. (2001) characterized the pharmacokinetic profile of both oral and intravenous midazolam using noncompartmental models. After oral administration, midazolam absorption was rapid, with adolescents absorbing the drug at half the rate seen in children younger than 12 years old. In young children, the volumes of distribution were larger; the largest volume of distribution was observed in children, whereas adolescents had a slower clearance and longer half-life after intravenous administration. There was great variability between patients in oral bioavailability, which averaged 36% (with a range of 9% to 71%) and in metabolism. An oral dose of 0.2 to 0.3 mg/kg was suggested as adequate in most children for sedation. The authors emphasized the importance of titrating intravenous dosing in the individual patient (Reed et al., 2001).

The pharmacokinetics of rectally administered midazolam in children were reported by Saint-Maurice and colleagues (1986). In this study of 16 children who were administered midazolam at 0.3 mg/kg, the terminal half-life and clearance were 106 minutes and 42.5 mL/kg per minute, respectively. Differences in the plasma clearance rates between pharmacokinetic studies involving rectal, oral, and intramuscular forms of administration were probably related to changes in drug bioavailability. Decreases in bioavailability increase the apparent drug clearance.

Commercially prepared solutions for oral midazolam are available. Literature on the pharmacokinetics and pharmacodynamics of oral midazolam has been hindered by the fact that studies have used different vehicles for administering the drug. Different vehicles affect drug absorption and, consequently, onset time and drug bioavailability (Brosius and Bannister, 2003). In addition, concurrent antacid use and grapefruit juice may increase the onset time and drug bioavailability of midazolam (Goho, 2001; Lammers et al., 2002).

Population studies involving the pharmacokinetics of midazolam in neonates have been reported. Using NONMEM and a two-compartment model, 531 midazolam concentrations from 187 infants were analyzed. The clearance and the central

volume were noted to be 70 ± 13 mL/kg per hour (or 1.02 mL/kg per minute) and 591 ± 65 mL/kg, respectively. Of interest was that the clearance was 1.6 times higher in full-term neonates with a gestational age of more than 39 weeks than in neonates of fewer than 39 weeks' gestation (Burtin et al., 1994).

The pharmacokinetics of midazolam in premature infants after both oral and intravenous administration were described by de Wildt and colleagues (2001, 2002). In premature infants with 24 to 34 weeks' gestational age and at 3 to 11 days of life, de Wildt et al. noted the apparent volume of distribution, clearance, and half-life were 1.1 L/kg, 1.8 mL/kg per minute, and 6.3 hours, respectively, after a single 0.1-mg/kg bolus dose. In addition, the metabolite 1-OH midazolam was markedly reduced compared with reports in older children. Also of note was that in those infants exposed to indomethacin, midazolam clearance was increased (Fig. 7-21) (de Wildt et al., 2001).

In a separate study of preterm infants who were administered oral midazolam, de Wildt et al. (2002) noted that midazolam clearance was markedly decreased and that the bioavailability was 0.4. The decrease in clearance was thought to mirror the pattern of CYP3A4 intestinal and hepatic activity (de Wildt et al., 2002). The kinetics of midazolam are affected by the use of extracorporeal membrane oxygenation (ECMO); Mulla et al. (2003) noted that the volume of distribution and half-life of midazolam are significantly increased in neonates requiring ECMO.

The cardiovascular and respiratory effects of midazolam have been reported in adults. Midazolam decreases systolic and diastolic blood pressures by 5% to 10%, decreases systemic vascular resistance by 15% to 30%, and increases heart rate by 20%. Right- and left-sided filling pressures are usually unaffected. Reeves et al. (1979) observed that 0.2 mg/kg midazolam was a safe agent for induction of anesthesia in patients with compromised myocardial function. In healthy patients, no significant difference was found in the hemodynamic effects of induction doses of 0.25 mg/kg midazolam and 4 mg/kg thio-pental (Lebowitz et al., 1982).

■ **FIGURE 7-21.** Effect of postnatal indomethacin exposure on midazolam disposition in preterm infants. Midazolam concentration vs. time curve after a single intravenous dose (0.1 mg/kg) to preterm infants with ($n = 11$, open circles) and without ($n = 13$, solid circles) postnatal indomethacin exposure. Each dot represents mean \pm SD concentration at each time point. (Redrawn from de Wildt SN et al.: Pharmacokinetics and metabolism of intravenous midazolam in preterm infants, *Clin Pharmacol Ther* 70:525-531, 2001.)

Respiratory depression is commonly associated with midazolam administration, and this respiratory depression is poorly related to dose, not reversed by naloxone, and independent of the rate of administration of the drug (Forster et al., 1983; Alexander and Gross, 1988; Alexander et al., 1992).

As an intravenous induction agent in children, midazolam in doses as high as 0.6 mg/kg was not as reliable as thiopental (Salonen et al., 1987). The most common pediatric use for intravenous midazolam other than as an anesthetic adjunct has been its use as a sedative for intensive care patients. Rosen and Rosen (1991) demonstrated the usefulness of continuous midazolam in critically ill pediatric patients. In their retrospective report of patients sedated for 4 to 72 hours who received a slow intravenous bolus (0.25 mg/kg) followed by a continuous infusion at 0.4 to 4 mg/kg per hour, they noted that all of their patients were adequately sedated, their patients' oxygen consumption was significantly reduced, and enteral feedings were successful in all of those in whom it was attempted. However, others have noted reversible neurologic abnormalities associated with prolonged intravenous midazolam infusions (Engstrom and Cohen, 1989; Sury et al., 1989; Bergman et al., 1991).

Even with the extensive experience of intravenous midazolam in adult patients and volunteers, most of the pediatric experience with midazolam is derived from its use as a preanesthetic medication delivered via the intramuscular, oral, rectal, intranasal, and sublingual routes of administration. More than 85% of anesthesiologists responding to a survey of premedication practices indicated that they prescribe midazolam (Kain et al., 1997). In children, midazolam has been shown to produce tranquil and calm sedation, reduce separation anxiety, facilitate induction of anesthesia, and enhance anterograde amnesia (Twersky et al., 1993). Kain et al. (2000) have shown that 0.5 mg/kg of oral midazolam can produce significant anterograde amnesia at 10 and 20 minutes and anxiolysis as early as 15 minutes after administration. Numerous studies have documented the efficacy of orally administered midazolam (Feld et al., 1990; Weldon et al., 1992; Levine et al., 1993b). The appropriate dose appears to range between 0.5 and 1 mg/kg. Its time of onset ranges from 15 to 30 minutes. Oral midazolam can also be safely administered to children with cyanotic heart disease without affecting oxygen saturation (Levine et al., 1993a). Serious side effects of midazolam are uncommon. However, several postoperative behavioral problems (fearfulness, nightmares, food rejection) were observed in children premedicated with oral midazolam (0.5 mg/kg) (McGraw, 1993). Postoperative dysphoria and crying can be very difficult for families when it occurs; a duration of 15 to 20 minutes sounds short but may seem very long for those caring for such a child. In addition, McMillan et al. (1992) have noted loss of balance, dysphoria, and blurred vision in some patients receiving 0.75 and 1 mg/kg orally. Hiccups have been associated with midazolam administration via the rectal, nasal, and oral routes (Marhofer et al., 1999). One major disadvantage of oral midazolam is its bitter taste. It should be administered in a flavored syrup or drink; however, a commercially available liquid preparation is now available. Almenrader et al. (2007) reported that 14% of children refused oral midazolam in a study comparing oral clonidine with oral midazolam premedication. They also reported a trend toward an increased incidence of emergence agitation in the midazolam group, with parental satisfaction favoring clonidine. Alternatively, Ko et al. (2001) in a study of 88 children having outpatient surgery, reported a lower incidence of

emergence agitation after a sevoflurane/N₂O/O₂ anesthetic when oral midazolam 0.2 mg/kg was given.

Oral midazolam has been associated with prolonged recovery times in some studies, but others, using BIS and measured end-tidal gases, did not find this problem (Viitanen et al., 1999; Brosius and Bannister 2001, 2002).

In a multicenter study involving 455 children, Coté et al. (2002) reported on the effectiveness of commercially prepared midazolam syrup. In this study, oral midazolam was effective for sedation and anxiolysis at a dose as low as 0.25 mg/kg. Doses as high as 1 mg/kg had minimal effects on respiration and oxygen saturation (Fig. 7-22).

Rectal administration of midazolam has also been successfully used to sedate patients. Saint-Maurice et al. (1986) have shown that after a dose of 0.3 mg/kg, a maximum plasma concentration of 100 ng/mL was achieved with levels of sedation as judged by mask acceptance, with patient cooperation being satisfactory in all 16 patients. Coventry et al. (1991), in a double-blind study of pediatric patients requiring sedation for computed tomography evaluations, noted that 0.3 and 0.6 mg/kg of rectal midazolam was ineffective in providing satisfactory sedation. Spear et al. (1991) noted that the optimum dose of rectal midazolam was 1 mg/kg and that doses of 0.3 mg/kg resulted in patient struggling during anesthesia induction.

Nasal and sublingual transmucosal routes of administration have also been used for midazolam preanesthesia medications. Wilton et al. (1988) and Davis et al. (1995) demonstrated the usefulness of preanesthetic sedation of preschool children with 0.2 to 0.3 mg/kg of intranasal midazolam. Walbergh et al. (1991) determined plasma concentrations after administration of 0.1 mg/kg of intranasal midazolam. In these patients, peak plasma concentrations of midazolam occurred within 10 minutes after its administration, with peak plasma concentrations ranging from 43 to 106 ng/mL. In this study, plasma midazolam concentrations exceeded threshold sedation values for adults (40 ng/mL) as early as 3 minutes after its nasal administration

FIGURE 7-22. Percentage of patients exhibiting anxiety from baseline to time elapsed after administration of oral midazolam. There was a positive association between dose and onset of anxiolysis ($P = 0.01$); a larger proportion of children achieved satisfactory anxiolysis within 10 minutes at the higher doses. (From Coté CJ et al.: A comparison of three doses of a commercially prepared oral midazolam syrup in children, *Anesth Analg* 94:37, 2002.)

and exceeded this level for as long as 30 minutes. Because intranasal midazolam can irritate the nasal mucosa, its use is limited by the volume of drug to be administered. The sublingual mucosa has a rich vascular supply and drugs are absorbed systemically, thereby eliminating hepatic first-pass metabolism. Karl et al. (1993), in a comparative study of intranasal and sublingual midazolam administration, demonstrated the two routes to be equally effective but that the sublingual route of administration had better patient acceptance.

Pandit et al. (2001) demonstrated that when aliquots of midazolam dissolved in strawberry syrup were placed on the antero-superior aspect of the child's tongue, 0.2 mg of midazolam was effective in 95% of patients for parental separation. When midazolam was administered sublingually, Khalil et al. (1998) noted that in children aged 12 to 129 months who received either placebo or 1 of 3 doses of midazolam (with none of these children receiving placebo), 28% of those receiving 0.25 mg/kg, 52% of those receiving 0.5 mg/kg, and 64% of those receiving 0.75 mg/kg of midazolam showed satisfactory sedation (drowsy) 15 minutes after drug administration. Children receiving the two higher doses of midazolam (0.5 and 0.75 mg/kg) accepted mask induction willingly, whereas the group receiving 0.25 mg/kg resembled the placebo group.

Flumazenil

Flumazenil blocks the effects of benzodiazepines on the GABAergic inhibition pathway in the CNS. Flumazenil does not have significant agonist activity of its own and does not appear to reverse the effects of opioids. Flumazenil has a short duration of action. Its plasma half-life is between 0.7 and 1.3 hours. It is metabolized and cleared by the liver and excreted in the urine (Rocari et al., 1986). Adverse effects of flumazenil include nausea, vomiting, blurred vision, sweating, anxiety, and emotional lability. Serious adverse effects include seizures and cardiac dysrhythmias; these events have been associated with patients physically dependent on benzodiazepines, patients with epilepsy, and patients having taken multiple drug ingestions or overdoses. Clinical trials in adults suggest a use of flumazenil in reversing the effects of conscious sedation, general anesthesia in benzodiazepine overdose, and hepatic encephalopathy.

Use of flumazenil in pediatric patients has been related to clinical situations requiring benzodiazepine reversal in anesthesia and for the treatment of benzodiazepine overdose (Roald and Dohl, 1989; Jones et al., 1991). Doses of flumazenil varied between 0.005 and 0.1 mg/kg, with 0.01 mg/kg being the most commonly used dose. In a study of 107 children undergoing procedural sedation, Shannon et al. (1997) noted that a mean dose of 0.017 mg/kg of flumazenil was used to reverse a mean midazolam dose of 0.18 mg/kg. Because of its short half-life relative to the half-life of most benzodiazepines, re-sedation is a common finding after flumazenil use. Consequently, repeat administrations and careful patient observations are necessary (Jones et al., 1993).

Other Sedative Agents

Etomidate

Etomidate is a potent, short-acting, nonbarbiturate sedative-hypnotic agent without analgesic properties. After a single intravenous bolus injection, it has a rapid onset (5 to 15 seconds) with

a peak effect at 60 seconds and a short duration of action (3 to 5 minutes) that is terminated by redistribution. It produces a central depressant effect through GABA mimetic action. Administered intravenously, it has been used for induction and maintenance of anesthesia; use for prolonged sedation in critically ill patients has become very uncommon because of steroid-synthesis effects. Little information is available about the use of etomidate in infants and small children.

Etomidate is metabolized in the liver. Only 2% of the drug appears unchanged in the urine. Etomidate causes little change in cardiovascular function in either healthy or compromised patients (Guldner et al., 2003). In a study of children with atrial septal defects (ASDs) undergoing cardiac catheterization, Sarkar et al. (2005) noted that induction doses of intravenous etomidate had no significant effect on the hemodynamics or on the shunt fraction. Myoclonic movements that are not associated with epileptiform electroencephalographic activity occur in 30% to 75% of patients after induction with etomidate (Ghonheim and Yamanda, 1977). Pain at the injection site is a common side effect. A new formulation of etomidate dissolved in a fat emulsion of medium and long-chain triglycerides is available. A study in children using this formulation reported a low incidence (5%) of pain at injection; however, a higher incidence of myoclonic movements (85%) is reported as well (Nyman et al., 2006).

Etomidate has both anticonvulsant and proconvulsant qualities. In patients with known seizure disorders, etomidate can produce epileptiform activity (Ebrahim et al., 1986; Modica et al., 1990). A major side effect limiting etomidate use is its suppression of adrenal steroid synthesis and reports of increased mortality after its use (Ledingham and Watt, 1983). Etomidate blocks adrenal steroid synthesis through inhibition of two mitochondrial enzymes dependent on CYP: cholesterol side-chain cleavage enzyme and 11 β -hydroxylase (Wagner et al., 1984). The inhibition of steroid synthesis occurs with both prolonged continuous infusions and with single induction doses (Longnecker, 1984; Wagner and White, 1984). Dönmez et al. (1998) noted in a randomized prospective study of 30 children undergoing cardiopulmonary bypass that when etomidate (0.3 mg/kg) was used as an induction agent, it significantly suppressed the increased cortisol levels associated with the stress responses of surgery and cardiopulmonary bypass. In critically ill children a single bolus dose has shown impaired adrenal function associated with increased mortality (den Brinker et al., 2008). In adult trauma patients, single-dose etomidate administration for rapid-sequence intubation was associated with chemical evidence of adrenal suppression, increased length of stay in the intensive care unit (ICU), and an increased number of days using a ventilator (Hildreth et al., 2008). However, other studies of adults suggest that for ICU patients receiving etomidate for induction, their clinical outcome and therapy were no different from patients induced with other sedative hypnotic agents (Ray and McKeown, 2007). For induction of anesthesia, the recommended intravenous dose is 0.3 to 0.4 mg/kg. Recent studies by Cotton et al. (2009) with an etomidate analog suggests that the analog undergoes ultra rapid metabolism, maintains the drug's sedative properties, and has no adrenal suppression. It is probably best to avoid etomidate use in patients with adrenally suppressed states.

Propofol

Propofol is an alkylphenol that is formulated in 10% soybean oil, 2.25% glycerol, and 12% purified egg phosphatide. This form of reconstitution is used because of anaphylactic reactions that

occurred when propofol was reconstituted with polyethoxylated castor oil (Cremophor-EL). The rapid redistribution and metabolism of propofol result in a short duration of action and allow for the drug to be administered via repeated injections or continuous infusions with minimal accumulation. Kinetic studies in both adults and children reveal a drug with a large steady-state volume of distribution, a slow elimination half-life, and a rapid clearance. Glucuronidation of propofol is a major route of elimination. Uridine 5-diphosphate-glucuronosyltransferases (UGTs) are the drug metabolizing enzymes for phase II. Extrahepatic metabolism of propofol occurs, and at these extrahepatic sites, conjugation is governed by different exons than in the liver (Takahashi, 2008). Mutations in these locations can markedly affect glucuronidation. In radiolabeled isotope studies, 88% of the radioactivity is excreted in the urine, 2% is excreted in the feces, and the remainder is excreted as 1- and 4-glucuronides and 4-sulfate conjugates. In patients with hepatic and renal impairments, no statistically significant alterations occur in the pharmacokinetics. Because the clearance of the drug exceeds the capacity of the liver blood supply, extrahepatic sites of metabolism appear to be involved with the clearance of propofol. These extrahepatic sites of metabolism were suggested in studies of patients undergoing liver transplantation where metabolic products of propofol metabolism were produced when propofol was administered only during the anhepatic phase of the operation. The effect of fentanyl on propofol clearance is not clear. In studies by Cockshott et al. (1987), fentanyl decreased propofol clearance, whereas in other studies, no effect was noted (Saint-Maurice et al., 1989; Gill et al., 1990).

Another important aspect of propofol pharmacokinetics is that the drug can limit its own clearance. Propofol is eliminated by hepatic conjugation to inactive metabolites, which are excreted by the kidneys. A 2-mg/kg bolus dose of propofol for the induction of anesthesia can reduce blood flow to the liver by 14%. Bolus doses of propofol may cause a small but persistent change in blood flow to the liver, resulting in decreased clearance and higher-than-predicted plasma concentrations.

The pharmacokinetics of propofol in children have been described by numerous investigators (Saint-Maurice et al., 1989; Jones et al., 1990; Marsh et al., 1991; Kataria et al., 1994; Knibbe et al., 2002; Zuppa et al., 2003). In computer-controlled infusions of propofol in children younger than 10 years, Marsh et al. (1991) noted the volume of the central compartment to be 0.34 L/kg and the clearance of the drug to be 34.3 mL/kg per minute. Kataria et al. (1994) using three different pharmacokinetic modeling approaches, analyzed the kinetics of single-bolus and continuous infusions of propofol in children. In all three models, the pharmacokinetics were well described by a three-compartment model with a central compartment of 0.52 L/kg and a clearance of 34 mL/kg per minute.

The pharmacokinetics of propofol were studied in a small number of children after cardiac surgery. When propofol was used to provide sedation for 6 hours, Knibbe et al. (2002), using population kinetics, reported propofol to fit a two-compartment model with a clearance of 35 mL/kg per minute and a central compartment of 0.78 L/kg. In addition, the authors suggested that children may have a lower pharmacodynamic sensitivity to propofol in that higher plasma concentrations were needed to maintain sedation than those reported in adults.

The pharmacodynamics of propofol have been well described and reviewed (Shafer, 1993). Because of the pharmacokinetic properties of propofol, infusions allow for more rapid decreases

FIGURE 7-23. Curves showing time required for 50% decreases in propofol and thiopental concentrations after discontinuation of a continuous infusion. (From Shafer SL: *Advances in propofol pharmacokinetics and pharmacodynamics*, J Clin Anesth 5:145, 1993.)

in plasma concentrations and faster patient recoveries from anesthesia (Fig. 7-23) (Mirakhor, 1988; Borgeat et al., 1990; Watcha et al., 1991; Larsson et al., 1992; Lebovic et al., 1992; Nightingale and Lewis, 1992; Reimer et al., 1993; Shafer, 1993). One of the newer pharmacokinetic terms is *context-sensitive half-life*, used to describe the time to decrease drug concentration by 50% after variable infusion durations. Such values can show how long a drug's effects may persist after discontinuing infusions, based on how long it has been infused. McFarlan et al. (1999) reported a propofol infusion simulation to keep blood concentration of propofol at 3 mcg/mL in children aged 3 to 11 years. After a bolus of 2.5 mg/kg, infusion rates were 250 mcg/kg per minute for 15 minutes, then 216 mcg/kg per minute for 15 minutes, 183 mcg/kg per minute for 30 minutes, 166 mcg/kg per minute for 1 hour, and 150 mcg/kg per minute for the second and fourth hours. The predicted context-sensitive half-life in children was 10.4 minutes (for a 1-hour infusion) to 19.6 minutes (4-hour infusion), compared with values of 6.7 to 9.5 minutes in adults. Engelhardt et al. (2008) prospectively used this changing infusion schema to reach predicted propofol concentrations in 17 healthy children between 1 and 6 years of age. They found concentrations were higher than predicted in the first 30 minutes (7.1 mcg/mL vs. 6.6 mcg/mL) but the differences at 30, 50, and 70 minutes were not significant and no child needed rescue doses of propofol.

In general, with induction doses of propofol, blood pressure decreases, as does systemic vascular resistance. Changes in heart rate are variable, and cardiac output decreases slightly. In studies evaluating propofol requirements for induction of anesthesia in children, Manschot et al. (1992) noted that in children aged 3 to 15 years receiving 5 mcg/kg of alfentanil to reduce the pain of propofol injection, age-related differences in propofol requirements were demonstrated. In children aged 10 to 15 years, 1.5 mg/kg of propofol was sufficient to induce sleep, whereas in children aged 3 to 9 years, a dose of 2.5 mg/kg was needed. In a study by Hannallah et al. (1991) in which alfentanil was not administered, the ED₅₀ and ED₉₅ for loss of eyelash reflex were 1.3 and 2 mg/kg, whereas the ED₅₀ and ED₉₅ for induction of anesthesia

were 1.5 and 2.3 mg/kg, respectively. Westrin (1991), in a study of infants aged 1 to 6 months and children aged 10 to 16 years, noted that the ED₅₀ of propofol was 3 mg/kg for infants and 2.4 mg/kg for the older children. In all three of these studies, propofol was administered over 10 to 30 seconds. However, as with most hypnotic agents, propofol also demonstrates a rate-dependent induction. Stokes and Hutton (1991) demonstrated that with the use of slower infusion rates, induction time for anesthesia increases but smaller doses could be used.

Peeters et al., (2006) studied propofol pharmacokinetics and pharmacodynamics in unventilated infants after craniofacial surgery. Twenty-two infants, aged 1 month to 2 years, received propofol at 33 to 66 mcg/kg per minute in the ICU, based on Comfort-B scores and bispectral index (BIS) monitoring. Population kinetic analysis using NONMEM showed propofol kinetics was best described by a two-compartment model. Body weight was a significant covariate (i.e., use of body weight made the model fit the measured concentrations more closely). Clearance was 0.169 L/min (or 77 mL/min per kilogram), steady-state volume of distribution 144 L (or 16.1 L/kg) and central volume 20.3 L (or 2.3 L/kg). These values are much higher than those reported in children receiving ventilation. The importance of dose titration was emphasized by the great interpatient variability in propofol effect on Comfort-B scores or BIS readings.

In patients with congenital heart disease, Gozal et al. (2001) demonstrated that despite lower systemic and pulmonary pressures, propofol did not modify the characteristics of the patient's underlying intracardiac shunts.

In normal children aged 1 to 6 years, Karsli et al. (2002), using transcranial Doppler, noted that propofol decreases cerebral blood flow velocity and that there is a relationship between cerebral blood flow velocity and propofol dosing. In addition, Wilson-Smith et al. (2003) noted that in healthy children who were given propofol for their elective surgery, the effects of nitrous oxide on cerebral blood flow velocity were preserved.

In addition to its anesthetic action, propofol appears to have antiemetic properties. In adult patients, Borgeat et al. (1992) demonstrated that 10 mg of propofol administered in the recovery room was effective in reducing the incidence of nausea and vomiting. Watcha et al. (1991) noted that in pediatric patients undergoing strabismus surgery, propofol alone effectively decreased the incidence of postoperative emesis (23%) compared with a similar group of patients anesthetized with halothane and nitrous oxide and supplemented with prophylactic droperidol (50%). However, in patients who received propofol and nitrous oxide, Watcha et al. (1991) noted that the incidence of emesis increased significantly (60%). Weil et al. (1993) also noted the antiemetic effect in pediatric patients with strabismus who were anesthetized with propofol and nitrous oxide compared with patients anesthetized with halothane and nitrous oxide. This antiemetic effect of propofol was even more pronounced in patients who received no opioids. Reimer et al. (1993) noted no difference in the incidence of emesis between pediatric patients undergoing strabismus repair who were anesthetized with halothane and nitrous oxide and those receiving propofol in oxygen or propofol with nitrous oxide. Differences between studies with regard to the antiemetic effect of propofol may be a function of the basic design of each study. Variations in premedications, opioid administration, and postoperative fluid intake may be factors that make comparisons of the studies difficult.

The antiemetic effects of propofol have also been demonstrated in pediatric patients undergoing short ear, nose, and throat surgical procedures and ambulatory surgical procedures (Borgeat et al., 1990; Martin et al., 1993).

In patients undergoing radiofrequency ablation, a procedure that is associated with an incidence of emesis as high as 60%, Erb et al. (2002) noted that propofol-based anesthesia was associated with a markedly decreased incidence of nausea (21%) and emesis (6%) compared with rates of nausea and vomiting of 63% and 55%, respectively, in children anesthetized with isoflurane.

Side effects from propofol include tolerance to the drug, pain on injection, spontaneous excitatory movements, and anaphylactic reactions. Tolerance has been reported in a pediatric patient undergoing numerous exposures for radiation therapy (Deer and Rich, 1992). Pain from injection is a common problem with propofol administration and may be related to the size of the vein in which it is administered. Westrin (1991) noted that pain during the injection occurred more often in the infants (50%) than in the older children (18%). The addition of 5 to 15 mcg/kg of alfentanil, 1% lidocaine (1 mg), or 0.1 mg/kg lidocaine can markedly attenuate the pain on injection (Valtonen et al., 1989; Manschot et al., 1992; Kwak et al., 2009). The addition of thiopental and the use of inhaled nitrous oxide also have been shown to attenuate the pain on injection (Beh et al., 2002; Cox, 2002).

Involuntary motor movements have been associated with propofol, and these spontaneous movement disorders appear to occur in the absence of epileptic form activity on electroencephalography (Borgeat et al., 1993; Reynolds and Koh, 1993). Anaphylactic reactions have also been reported. Initial studies with propofol using 10% polyethoxylated castor oil as a solubilizing agent had reported instances of anaphylactic reactions (Briggs et al., 1982). Laxenaire et al. (1992) have reported on 14 patients with life-threatening reactions within minutes after receiving propofol in its current preparation. In some patients, these anaphylactic reactions occurred during the patient's first exposure to propofol.

Because of its lipid base, propofol has been associated with bacterial growth and patient infection if strict aseptic techniques during handling are not observed. Because of patient safety concerns, 0.005% ethylenediaminetetraacetate (EDTA) or metabisulfite was added to the formulation by different manufacturers. In a study comparing propofol with and without EDTA, Cohen et al. (2001) noted no differences in clinical profiles between the two drugs and noted that both formulations lower ionized calcium without any apparent clinical effect.

A major concern with propofol administration is the development of the propofol infusion syndrome (PRIS). PRIS has been defined as arrhythmias during the infusion plus one or more of the following: lipemic plasma, hepatomegaly, metabolic acidosis with or without an increase in serum lactate, or rhabdomyolysis with myoglobinuria. The occurrence of deaths in infants, children, and adults has raised concerns regarding the safety of propofol infusions for ICU-patient sedations. The pathogenesis of PRIS is unclear. Proposed mechanisms include enzyme block steps in mitochondrial fatty acid oxidation and inhibition of β -adrenergic receptors and calcium channel function. The rare occurrence of PRIS suggests a genetic susceptibility. PRIS is associated with concomitant catecholamine and steroid administration and high-dose infusion. Although monitoring of biochemical markers has been proposed to detect the development of PRIS, it may result in a false sense of security (Veldhoen et al., 2009).

Ketamine

Ketamine is a racemic, nonbarbiturate cyclohexamine derivative that produces dissociation of the cerebral cortex from the limbic system. Ketamine appears to block afferent impulses in the diencephalon and associated pathways of the cortex, sparing the reticular formation of the brain stem. This may be the mechanism of its action. It may also act on the brain stem (Domino et al., 1965). There is often electroencephalographic seizure activity, particularly in the limbic system and cortex, without clinical manifestations (Schwartz et al., 1974). Clinically, a ketamine anesthetic produces effective sedation and analgesia, but patients may keep their eyes open. Many reflexes are preserved. Preservation of gag reflex, laryngeal irritability, and continued muscle tension occur. Intravenous doses of 2 mg/kg produce a highly predictable response in children. On a milligram-per-kilogram basis, the amount of ketamine required to prevent gross movements is four times greater in infants younger than 6 months than in 6-year-old children (Lockhart and Nelson, 1974).

White et al. (1980) compared both the l- and d-isomers of ketamine in adult surgical patients with respect to the efficacy and side effects of these isomers. In this study, they noted that the d-isomer produced the most satisfactory anesthetic state and the lowest incidence of negative emergence reactions, whereas the l-isomer produced the least satisfactory anesthesia and the highest incidence of emergence reactions.

The pharmacokinetics of ketamine in patients of different ages were determined (Table 7-8). In infants younger than 3 months old, the volume of distribution was similar to that in older infants but the elimination half-life was prolonged. Clearance was reduced in the younger infants; reduced metabolism and renal excretion in the young infant are the likely causes. Ketamine is metabolized in the liver, and its major metabolite is norketamine. Norketamine has about 30% of the clinical activity of ketamine.

In the anesthetic state associated with ketamine, respiration and blood pressure are usually well maintained. The use of ketamine in infants, particularly at the high doses required for lack of movement, has been associated with respiratory depression and apnea (Eng et al., 1975). Generalized extensor spasm with opisthotonos also has been seen in infants (Radney and Badola, 1973). In addition, acute increases in pulmonary artery pressure have occasionally occurred in infants with congenital heart disease during ketamine anesthesia for cardiac catheterization. Studies suggest that pulmonary vascular resistance is not changed by ketamine in infants with either normal or

elevated pulmonary vascular resistance, as long as the airway and ventilation are maintained (Hickey et al., 1984; Marray et al., 1984). In a study of 60 children with congenital heart disease randomized to receive propofol infusion or propofol with ketamine 0.5 mg/kg during cardiac catheterization, Akin et al. (2005) reported that hypotension and bradycardia were higher in the group that received propofol alone. Williams et al. (2007) studied ketamine 2 mg/kg bolus over 5 minutes followed by infusion at 10 mcg/kg per minute in 15 children with pulmonary hypertension having cardiac catheterization with sevoflurane (1 MAC decreased to 0.5 MAC after ketamine) and spontaneous ventilation. No changes in pulmonary artery pressure or resistance index were found.

The mechanism of cardiorespiratory stimulation has not been entirely clarified. Dowdy and Kaya (1968), Traber et al. (1970), and other groups have shown that there is a direct negative inotropic action on the denervated heart. In the presence of intact sympathetic and autonomic nervous systems, however, a pressor effect causes increased blood pressure, heart rate, and cardiac output, a response present in all ages. This serves as a most valuable adjunct in the management of poor-risk patients but is a contraindication in the presence of hypertension or tachycardia. In their investigation of ketamine, Dowdy and Kaya (1968) also found evidence of antiarrhythmic activity.

Ketamine increases cerebrospinal fluid pressure significantly for 5 to 15 minutes, but as shown by Dawson et al. (1971), the increase may be held within acceptable limits by pretreatment with thiopental (Gardner et al., 1971; Lockhart and Jenkins, 1972). Elevation of intraocular pressure also occurs after ketamine administration. In a group of 15 children, Yoshikawa and Murai (1971) noted an average increase of 30% that was maximum within 15 minutes after administration of ketamine and evident for approximately 30 minutes. In addition to the elevation of intraocular pressure, nystagmus limits its usefulness in eye surgery.

Ketamine had the advantage of a clean record with no known toxic effects on the liver, kidneys, or other organ systems. However, it has been the most thoroughly studied anesthetic/sedative agent implicated in causing neuronal apoptosis after exposure in newborn animal model studies.

A major drawback to ketamine administration in older children is the high incidence of hallucinations and bad dreams. In adults, this occurs in 30% to 50% of patients, and in prepubescent children, the incidence is noted at 5% to 10%. Hallucinations were uncommon in children, but the awakening phase may entail considerable excitement (Wilson et al., 1970).

Ketamine can be administered orally, and part of its effect is secondary to its metabolite norketamine. Gutstein and colleagues (1992) compared oral premedication with ketamine at either 3 or 6 mg/kg. With 3 mg/kg, 73% of the children were sedated within 30 minutes. At the 6 mg/kg dose, 100% of the patients were sedated, and 67% tolerated intravenous cannulation. Onset times for the 3- and 6-mg/kg dose groups were 19.6 and 11.2 minutes, respectively (Gutstein et al., 1992).

Use of low-dose ketamine as an analgesic adjunct has emerged in select populations in recent work. Aouad et al. (2008) conducted a prospective randomized double-blind comparison of propofol alone (1 mg/kg) to propofol and ketamine (0.5 mg/kg of each) in 63 children undergoing anesthesia for oncologic procedures. The combination group had fewer patients needing rescue propofol (83% vs. 100%) or fentanyl (43% vs. 75%) and showed more stable hemodynamics. However, 40% of the

TABLE 7-8. Pharmacokinetics of Ketamine: Effect of Age

Age	$t_{1/2\beta}$ (min)	V_d ss (L/kg)	CL (mL/min per kg)
<3 Months	184.7	3.46	12.9
4-12 Months	65.1	3.03	35.0
4 Years	31.6	1.18	25.1

$t_{1/2\beta}$ Elimination half-life; V_d ss, volume of distribution at steady state; CL, clearance.

combination group had agitation during recovery (vs. 6% with propofol alone). Slavik and Zed (2007) reviewed studies of ketamine and propofol for procedural sedation and anesthesia using MEDLINE, EMBASE, and the Cochrane databases and found eight clinical trials to include. They found that the ideal ratio of ketamine to propofol was unclear; better clinical efficacy of the combination over propofol alone was not shown; better hemodynamic and respiratory status was demonstrated in some studies; and at higher ketamine doses, greater adverse effects were apparent (Slavik and Zed, 2007).

Several investigators have studied low dose-ketamine given intravenously or into the tonsillar bed in children undergoing tonsillectomy with conflicting results (O'Flaherty et al., 2003; Conceicao et al., 2006; Batra et al., 2007; Dal et al., 2007; Erk et al., 2007; Abu-Shahwan, 2008; Honarmand et al., 2008). Most studies involved 60 to 100 children and compared the perioperative course looking at pain scores, rescue analgesics, and side effects compared with patients in a control group (receiving saline). Ketamine at doses less than 0.25 mg/kg were ineffective, and at 0.5 mg/kg results were positive in some studies and negative in others. The addition of low-dose ketamine infusions in 11 children with advanced cancer and pain that was inadequately treated with high doses of opiates (0.1 to 0.2 mg/kg per hour titrated up to 0.5 mg/kg per hour in 3 of 11 patients) improved pain control and allowed decreases in opiate pain medications in 8 (Finkel et al., 2007).

Clonidine

Clonidine is an α_2 -adrenergic agonist that has been used as a premedication, anesthetic adjunct, extender for postoperative analgesic duration, and to prolong the analgesia associated with regional anesthetic blocks. In one prospective, randomized, blinded study, 60 children (aged 5 to 11 years) received placebo, 2 mcg/kg or 4 mcg/kg oral clonidine 100 minutes before inhalation induction of anesthesia with halothane/N₂O/O₂ (Nishina et al., 1996). Sedation, separation from family, and tolerance to mask application were better in the 4 mcg/kg clonidine group. Halothane was titrated to maintain blood pressure and heart rate within 20% of baseline, and the 4-mcg/kg group used 45% less halothane. No delay in transfer to ward postoperatively was found (15 to 17 minutes). Heart rates were slower in the group receiving 4 mcg/kg, but bradycardia did not occur, although all children received atropine 30 mcg/kg with the premedication.

Bergendahl et al., (2006) reviewed clonidine use in pediatric anesthesia both as premedication and for intraoperative use. Rectal absorption is rapid, and clonidine shows high bioavailability. Some studies included in this review found improved postoperative analgesia with oral clonidine, decreased vomiting, and shivering. Postoperative confusion and agitation in young children receiving clonidine compared with children receiving placebo or midazolam was reported by some. Persistence of postoperative sedation (or calmness) is a desirable feature to some assessors.

Addition of clonidine to local anesthetics for caudal blocks has been successful in extending duration of analgesia in most studies, although some increases in side effects have occurred in some studies. Two case reports of caudal blocks with clonidine in formerly premature infants with the appearance of postoperative apnea have limited its use in this population.

Atropine use is often recommended to minimize heart rate decreases, and this extra step may be a partial explanation for the lack of more extensive use of this agent.

Potts et al. (2007) recently reported a population analysis of clonidine in children using NONMEM and reporting their results using allometric scaling (to a standard of 70 kg). Published data from four studies (two intravenous, one rectal, and one epidural clonidine) were combined with an open-label group of children who received clonidine 1 to 2 mcg/kg after cardiac surgery (380 observations). The mean age was 4 years, and the mean weight was 17.8 kg. Clearance was 14.6 L/hr per 70 kg, central volume was 62.5 L/70 kg, and peripheral volume was 119 L/70 kg with the distribution half-life of 12 minutes and elimination half-life of 9 hours. At birth, clearance was low at 3.8 L/hr per 70 kg, reaching 82% of adult values by age 1 year. Absorption was slower from epidural sites than the rectum (Fig. 7-24; Table 7-9). Simulations showed context-sensitive half-lives increased with infusion duration (1, 3, 6, and 10 hours) and decreased with increasing age (Table 7-10). The relatively long elimination half-life and importance of intact renal function for clearance may be features explaining the current preference for the newer α_2 -agonist dexmedetomidine.

Dexmedetomidine

One of the newer additions to the list of intravenous sedative and anesthetic drugs is dexmedetomidine. It is a selective α_2 -agonist with sedative and analgesic properties. Dexmedetomidine is more selective for the α_2 -adrenoreceptor with a reported ratio of α_2 to α_1 of 1600:1, which is seven to eight times higher than that reported for clonidine. Its sedative effect is attributed to hyperpolarization of noradrenergic neurons in the locus coeruleus (Carollo et al., 2008). This suppression of locus coeruleus neurons is similar to normal sleep. It provides respiratory stability, with no ventilatory depression accompanying its sedative, anxiolytic, and analgesic effects in adults. Mahmoud et al. (2009) have shown dexmedetomidine to be a useful anesthetic agent for magnetic resonance imaging (MRI) evaluations of airways in children with obstructive sleep apnea (OSA). Although hemodynamic effects of hypotension or bradycardia are less commonly seen than with clonidine, they have been reported. Dexmedetomidine has also been suggested as a novel treatment for atrial and junctional tachyarrhythmias (Chrysostomou et al., 2008). Tobias and Berkenbosch (2004) reported early experience with dexmedetomidine infusions in 30 ventilated infants and children, comparing it with midazolam. Decreases in morphine use were found in the high-dose dexmedetomidine group (0.5 mcg/kg per hour) compared with those receiving midazolam (0.1 mg/kg per hour). Heart rates were slower in the dexmedetomidine group, but hypotension was not seen. In pediatric cardiac surgical patients, Chrysostomou et al. (2009) suggest that higher doses may be needed in the younger patients.

In neurosurgeries requiring an intraoperative “awake” period to assess patient responses during deep brain stimulation for Parkinson’s disease, or in surgeries near speech areas, or in surgery for epilepsy, dexmedetomidine has proved very useful to allow anesthesia without intubation (Mack et al., 2004).

Koroguli et al. (2005) noted that in children aged 1 to 7 years undergoing MRI that dexmedetomidine was superior to midazolam. However, in a separate study, Koroguli et al. (2006), also noted that dexmedetomidine has slower recovery and discharge compared with propofol. The slower recovery times with dexmedetomidine compared with propofol have also been observed by Heard and others (2008).

Hammer and colleagues (2008) reported dexmedetomidine effects on cardiac electrophysiology in 12 children (aged 5 to 17 years). One mcg/kg administered over 10 minutes and then 0.7 mcg/kg per hour for 10 minutes led to decreased heart rates, increased blood pressure, and depressed sinus and atrioventricular (AV) node function. Respiratory rate and end-tidal CO₂ during spontaneous ventilation were unchanged (Hammer et al., 2008). Caution in dexmedetomidine use for patients who are poorly tolerant of bradycardia or at risk for AV nodal block was emphasized. Jooste and others (2010) demonstrated in post-cardiac transplant patients that a rapid IV bolus dose had a transient increase in systemic and pulmonary pressures, as well as a decrease in heart rate. These transient changes were more pronounced in the systemic system as opposed to the pulmonary circulation.

Because dexmedetomidine has pharmacolytic properties that simulate normal sleep, Mahmoud et al. (2009) have demonstrated its usefulness in patients with sleep apnea.

Pharmacokinetics for dexmedetomidine in adults demonstrate desirable characteristics for use as titrated intravenous infusions for sedation and anxiolysis. Its elimination half-life is 2 hours (8 hour for clonidine), and its distribution half-life is 6 minutes (Carollo et al., 2008). Several groups have reported pharmacokinetics in children of dexmedetomidine. Petroz et al. (2006) studied 36 children, 18 from Canada and 18 from South Africa, in an open-label study. Blood was sampled for 24 hours after 10-minute infusions of 2, 4, or 6 mcg/kg per hour and analyzed by NONMEM. Concentrations were below detection after 6 hours; a two-compartment model central volume of distribution of 0.8 L/kg was constructed with a systemic clearance of 0.013 L/kg per minute and an elimination half-life of 110 minutes. Table 7-11 lists the pharmacokinetic values from this and other studies; a puzzling finding was dexmedetomidine concentrations that were consistently 30% higher in Canadian

Data from Petroz GC, Sikich N, James M et al.: A phase 1, two-center study of the pharmacokinetics and pharmacodynamics of dexmedetomidine in children, *Anesthesiol* 105:1098, 2006; Vilo S, Rautiainen P, Kaisti K et al.: Pharmacokinetics of intravenous dexmedetomidine in children under 11 years of age, *Br J Anaesth* 100:697, 2008; Potts AL, Warman GR, Anderson BJ: Dexmedetomidine disposition in children: a population analysis, *Pediatr Anesth* 18:722, 2008; Diaz SM, Rodarte A, Foley J: Pharmacokinetics of dexmedetomidine in postsurgical pediatric intensive care patients: preliminary study, *Ped Crit Care Med* 8:419-24, 2007.

children, which was thought to have occurred because of a handling problem with specimens. Context-sensitive decrement times did not increase after 90- to 120-minute infusions with the context-sensitive half-life, plateauing at about 70 minutes and the 80% decrement time at about 220 minutes. Heart rate and blood pressure decreased over the hour after the infusion and decreased with higher infusion doses, whereas respiration and oximetry were stable. Sedation lasted less than 1 hour. Vilo et al. (2008) studied eight children (aged 2 to 11 years) and eight infants (aged 1 to 23 months) after receiving dexmedetomidine at 1 mcg/kg. Analysis of blood samples used noncompartmental methods. Data are summarized in Table 7-11. Clearance was similar in the two age groups, but volume of distribution (steady state) was larger in the younger group, making the half-life longer. Interindividual variation was large, especially in the infants. All were sedated by the dexmedetomidine but easily aroused, and five of the eight children needed extra sedation during MRIs. Based on the volume at steady state, younger children would be predicted to need larger initial dexmedetomidine doses with similar maintenance rates to older children or adults.

Potts et al. (2008) looked at population pharmacokinetics in 45 children after cardiac surgery aged 4 days to 14 years (mean age of 3.4 years). Population parameter estimates for a two-compartment model using NONMEM were reported using allometric scaling to 70 kg. In Table 7-11 the results are corrected for comparison with others' work. Clearance increased from 15.5 L/hour per 70 kg at birth to reach 72% adult values at 6 months and 87% by 1 year (Table 7-12). Clearance in children at 39.2 L/hour per 70 kg is slightly less than adult values of 44.8 to 52.5 L/hour per 70 kg. Volumes of distribution were 103.5 to 126 L/70 kg, and half-lives were 12 minutes (α , distribution) and 2.3 hours (β , elimination), similar to adult reports. Context-sensitive half-lives after infusions of 1, 3, and 10 hours were longer in neonates (1.24 for 1 hour to 2.07 for 10 hours) than at age 1 year (0.49 to 1.09 hours) or in adults (0.49 to 1.45 hours). Large intersubject variability was attributed to age and size differences (Fig. 7-25).

In addition to intravenous administration, dexmedetomidine can also be administered intramuscularly and intranasally. Dyck et al. (1993) demonstrated a 73% bioavailability after intramuscular

TABLE 7-12. Age-Related Dexmedetomidine Clearances Described Using Both the Allometric “ $3/4$ Power” Model (per 70 kg) and the Linear per Kilogram Model (per kg)

Age (years)	Weight (kg)	CL _{std} (L/h ⁻¹ /70 kg ⁻¹)	CL (L/h ⁻¹ /kg ⁻¹)
0	3.5	15.56	0.47
1 Months	4.5	18.10	0.51
3 Months	6	22.62	0.60
6 Months	7.5	28.45	0.71
1 Year	10	34.09	0.79
2 Years	12	37.58	0.83
3 Years	14	38.49	0.82
4 Years	16	38.83	0.80
8 Years	25	39.13	0.72
12 Years	38	39.18	0.65

From Potts AL et al.: Dexmedetomidine disposition in children: a population analysis, *Pediatr Anesth* 18:722, 2008.

FIGURE 7-25. Simulated dexmedetomidine concentration-time profile after a dosage regimen of 1 mcg/kg⁻¹ for 10 minutes and a maintenance infusion of 0.7 mcg/kg⁻¹ per hour⁻¹ for 50 minutes in a 5-year-old child (20 kg), with 95% prediction interval simulated using 1000 children with an age range of 2.4 to 14.5 years. Pharmacokinetic parameters for the simulation are those determined from this study. A concentration of 0.304 mcg/L⁻¹ is associated with recovery from sedation (return to baseline alertness) and is represented by the dashed line. (From Potts AL et al.: *Dexmedetomidine disposition in children: a population analysis*, *Pediatr Anesth* 18:722, 2008.)

administration in adult volunteers and that intramuscular injection did not result in the biphasic hemodynamic response observed with intravenous administration. Intranasal doses of 1 to 2 mcg/kg have been shown to induce sedation in children (Yuen et al., 2007, 2008; Talon et al., 2009). Transmucosal dexmedetomidine has a bioavailability of 80% (Anttila et al., 2003).

In addition to its use as a sedative agent, dexmedetomidine has been demonstrated to decrease the incidence of postoperative emergence agitation and effectively treat postemergence shivering. Ibacache et al. (2004) noted that a single dose of dexmedetomidine (0.3 mcg/kg) markedly attenuated the incidence of sevoflurane-associated emergence agitation, while Easley et al. (2007) reported that 0.5 mcg/kg of dexmedetomidine effectively stopped postoperative shivering in children within 5 minutes.

OPIOIDS

To avoid the major adverse hemodynamic effects caused by potent inhalation anesthetic agents, the use of narcotic anesthesia has reemerged. Relative potencies of the various narcotics are listed in Table 7-13. Initially, meperidine (0.5 to 1 mg/kg)

TABLE 7-13. Comparative Opioid Potencies

Drug	Potency
Morphine	1
Metadone	1
Meperidine	0.1
Alfentanil	40
Fentanyl	150
Sufentanil	1500

and morphine (0.05 to 0.1 mg/kg) were used to reinforce nitrous oxide anesthesia in the neonate. However, concerns regarding the toxicity and increased sensitivity of neonates to narcotics were raised. Way et al. (1965) demonstrated that morphine depresses newborn respiration more than meperidine and that these decreases in ventilatory response to increased CO₂ concentrations occur at a dose one third (on a milligram-per-kilogram basis) of that administered to adults (Fig. 7-26). In laboratory animals, narcotics are more toxic to newborn animals than to older animals (Goldenthal, 1971). For morphine and dihydromorphine, the blood-brain barrier is more permeable in newborn animals than in older animals. The brain concentration of morphine several hours after injection was two to four times greater in brains of younger rats despite equal blood concentration (Fig. 7-27). This finding may be related to greater perfusion, to greater permeability, or to both in the

newborn. Whereas increased permeability of the blood-brain barrier (BBB) to morphine occurs in neonatal nonhuman primates (1 to 3 days after birth), the adult BBB permeability is achieved by two months of age (Lynn et al., 1991). Such developmentally increased permeability is not seen with meperidine; this is not surprising because the lipid solubility of meperidine is quite high (Kupferberg and Way, 1963).

Studies involving opiate receptor-binding sites in rats have suggested that changes in receptor ontogeny also may be responsible for the respiratory depressant and analgesic effects observed in newborns. Zhang and Pasternak (1981) have shown that both low-affinity and high-affinity opiate receptors are present in rats. Low-affinity receptors are associated with respiratory depression, whereas high-affinity receptors are associated with analgesia. In the rat model, low-affinity receptors are present in large numbers at birth, and the number remains constant through 18 days of life. By contrast, high-affinity receptors are scarce at birth and do not reach significant proportions (50% of the adult value) until 15 days of life. Respiratory depression in infants may be a function not only of the lipophilicity of opioids but also of the maturational changes in the opiate receptor pool. In addition to age-related changes in opioid receptor pools, genetic factors may affect the μ -opioid receptor (OPRM1). Single nucleotide polymorphisms (SNPs) resulting in a single amino-acid change can have effects on opioid side effects and analgesia. Individuals homozygous for the G allele of the 118 A > G polymorphism seem to require higher doses of intravenous and oral morphine to achieve adequate levels of analgesia (Matthes et al., 1996; Klepstad et al., 2004; Romberg et al., 2004, 2005; Chou et al., 2006).

Clinical studies on opioid sensitivity have been conflicting. Early reports by Kupferberg and Way (1963) suggested neonates had more respiratory depression after opioid administration than did adults. However, Lynn et al. (1993) evaluated the respiratory depressant effects of intravenous morphine infusions in 30 postoperative patients aged 2 to 570 days and noted no evidence of a relationship of any given morphine concentration

■ **FIGURE 7-27.** Brain and blood levels of morphine in young and older rats. Note that in young rats, brain concentrations of lower dose (50 mg/kg) were equivalent to brain concentrations of a higher dose of 150 mg/kg in older animals, even though the plasma concentrations were lower in the younger animals. (From Kupferberg HI, Way EL: *Pharmacologic basis for the increased sensitivity of the newborn rat to morphine*, J Pharmacol Exp Ther 109:141, 1963.)

with respiratory depression and age. Infants who had a morphine C_{ss} over 20 ng/mL, 67% of subjects, had elevated levels of arterial P_{CO_2} during spontaneous ventilation (six of nine infants), perhaps showing evidence of a threshold concentration.

Nichols et al. (1993) studied the extent and duration of respiratory depression after intrathecal administration of 0.02 mg/kg of morphine to 10 patients aged 4 months to 15 years. Although intrathecal morphine depresses ventilation for at least 18 hours, there was no relationship of age and ventilatory depression.

Age-related sensitivities have also been studied after intravenous fentanyl administration. Hertzka et al. (1989) determined that fentanyl-induced ventilatory depression as assessed by skin surface P_{CO_2} and ventilatory patterns was not greater in infants (older than 3 months) than in children or adults. In addition to age sensitivities, Zhou et al. (1993) demonstrated ethnic differences in the disposition and effects of morphine. In a study in Chinese and Caucasian adult volunteers, they found that Chinese subjects had an increased morphine clearance with decreased respiratory and hemodynamic depressant effects. Interestingly, the decreased respiratory and hemodynamic susceptibility did not correlate with the gastrointestinal effects, with Chinese subjects experiencing more nausea and vomiting than Caucasians. The complexities of opioid actions, both related to analgesia and to side-effect profiles, are still incompletely studied for "old" agents like morphine, as well as newer ones like the fentanyl derivatives.

Morphine

The pharmacology of morphine has been studied in both adults and children. In adults, morphine is 30% to 35% protein bound, whereas in neonates, it is 18% to 22% bound (Bhat et al., 1990, McRorie et al., 1992). Morphine is a drug with a high hepatic extraction coefficient; consequently, morphine clearance is determined by hepatic blood flow. Increases in hepatic blood flow can further increase morphine clearance, whereas decreases in hepatic blood flow can lower drug clearance. Morphine is inactivated by N-demethylation and glucuronidation. The two major metabolic products are morphine 6-glucuronide and morphine 3-glucuronide, which are mainly excreted by the kidneys. In adults, sulfate metabolism accounts for 5% to 10% of the drug's metabolism. In neonates the enzymes for glucuronide metabolism are immature, and the role of sulfation in morphine metabolism may be more pronounced. McRorie et al. (1992) demonstrated that in the neonate, sulfation contribution to morphine metabolism is

proportionately higher, because glucuronidation is deficient. This effect diminishes by 4 to 6 months of age as glucuronidation reaches adult values.

As with other drugs, morphine appears to undergo age-related changes in its pharmacokinetic profile (Table 7-14). The presence of age-related changes in the neonatal period appears somewhat controversial. Bhat et al. (1990) studied the pharmacokinetics in 20 newborn infants younger than 5 days of age after a single bolus administration of intravenous morphine. In this study, they concluded that with increasing gestational age, drug clearance increases by 0.9 mL/kg per minute per week of gestation and that with increasing gestational age, both distribution and elimination half-life also decreased. Compared with term infants, Bhat et al. noted that in infants with fewer than 30 weeks' gestation, morphine had a longer elimination half-life (10 ± 3.7 h) and slower clearances (3.4 vs. 15 mL/kg per minute). However, Chay et al. (1992) reported no difference in the pharmacokinetics of continuous morphine infusions in preterm and term infants. There was no reported correlation of gestational age or conceptual age with drug clearance or elimination half-life. In addition, these investigators noted that a plasma concentration of 125 ng/mL was necessary to provide adequate sedation in 50% of the neonates. These values are quite high compared with the analgesic values of 12 ng/mL needed after cardiac surgery (Lynn et al., 1984). How much of this difference is related to the desired effect (sedation during mechanical ventilation vs. postoperative analgesia) is not clear.

Most studies of morphine pharmacokinetics in infants and children have reported large interindividual variability, as shown in Fig. 7-28. This makes predicting effect and duration of action in an individual problematic. The same variability has been seen with meperidine and even with fentanyl (Pokela et al., 1992).

Bouwmeester et al. (2004) using an allometric model standardized to a 70-kg person, described a total-body clearance for morphine of 80% of that of adults at 6 months of age and 96% of that predicted in adults by 1 year of age; these findings correlate with the ones previously described by McRorie et al. (1992) (Table 7-15). It was also estimated that the formation of M3G in 1-year old infants accounts for 86% of morphine elimination, compared with 55% in adults, and that the morphine volume of distribution increased exponentially from 83 L per 70 kg at birth to 136 L per 70 kg at 6 months of age. Interestingly, Anand et al. (2008), using the same allometric model, found higher volumes of distribution (190 L per 70 kg) in preterm neonates (23 to 32 weeks' gestation) than the ones described by Bouwmeester et al. (2004).

*Weights are estimates only.

In addition to age, morphine pharmacokinetics can be influenced by disease. Patients with renal failure were reported to be sensitive to narcotic intoxication after morphine administration. Chauvin et al. (1987b) studied the pharmacokinetics of morphine in adult patients with renal insufficiency. For morphine, they found that morphine in patients with chronic renal failure has similar rates of clearance and half-lives but significantly smaller steady-state volumes of distribution compared with morphine in age- and weight-matched control patients. Although chronic renal failure did not alter the elimination of unchanged morphine, metabolites of morphine accumulated at higher plasma levels for longer periods of time in the patients with chronic renal failure. In studies of patients with renal failure, Osbourne et al. (1993) noted that morphine metabolism is impaired and that the metabolites of morphine (morphine 3-glucuronide and morphine 6-glucuronide) accumulate in the plasma (Fig. 7-29). Hanna et al. (1993) have also demonstrated abnormal kinetics of morphine metabolites in patients with renal failure. Patients with renal failure had a prolonged elimination half-life and decreased clearance in the pharmacokinetic profile of morphine 6-glucuronide. In patients with renal impairment, the increased opioid sensitivity may be a function

of decreased morphine metabolism coupled with impaired clearance of the metabolites, which have analgesic and respiratory activity.

In patients with liver disease, the effects of disease can be unpredictable. Patwardhan et al. (1981) described the effects of liver disease on morphine kinetics in adult patients with cirrhosis and in healthy adult volunteers. Compared with healthy subjects, patients with moderate-to-severe cirrhosis had a normal elimination and disposition of morphine but a prolonged elimination half-life and decreased clearance of indocyanine. (Indocyanine is taken up and excreted solely by the hepatocytes, making it a reliable indicator of liver disease). Because morphine is a highly extracted drug and its clearance depends on hepatic blood flow, the investigators postulated that morphine has extrahepatic sites of metabolism in the gastrointestinal tract and kidneys.

In a limited study of 21 children aged 6 months to 10 years who underwent cardiopulmonary bypass for repair of their underlying heart defects, Dagan et al. (1993) noted that in the postbypass period, for patients requiring inotropic support, morphine clearance was 50% less than that reported for other children. Similarly Lynn et al. (1998) reported increased

■ **FIGURE 7-29.** **A**, Morphine and metabolite levels in normal volunteers (mean \pm SEM; data correction to 10 mg/70 kg). **B**, Pharmacokinetics of morphine and morphine glucuronides in patients with kidney failure. (From Osborne R et al.: *The pharmacokinetics of morphine and morphine glucuronides in kidney failure*, Clin Pharmacol Ther 54:158, 1993.)

morphine clearance in infants after noncardiac surgery than in age-matched infants receiving morphine after cardiac procedures.

Geiduschek et al. (1997) described a morphine clearance of 11.7 ± 9.3 mL/kg/min in neonates supported by ECMO. Peters et al. (2005), using an allometric model, described an initial reduced morphine clearance at the start of ECMO (2.2 L/hr per 70 kg) that rapidly normalizes after 2 weeks of therapy.

In addition to intravenous infusions, intraspinal axis administration of opioids has been studied. Nordberg et al. (1984) noted that in adults, after 0.5 mg of intrathecally administered morphine (L2-4), the cerebrospinal fluid kinetics revealed a terminal half-life of 175 minutes, a volume of cerebrospinal fluid distribution of 0.88 mL/kg, and a clearance of 2.8 mL/kg per minute. In pediatric patients undergoing craniofacial surgical repairs, Nichols et al. (1993) noted that the cerebrospinal

fluid concentrations at 6, 12, and 18 hours after 0.02 mg/kg of intrathecal administration were 2860, 640, and 220 ng/mL, respectively. These children had good analgesia, but all were mechanically ventilated, so respiratory effects were not assessed.

In children, Attia et al. (1986) demonstrated that the pharmacokinetics of epidural morphine were similar to values reported in adults. After a 50-mcg/kg epidural bolus, the volume of distribution was 7.9 L/kg, the elimination half-life was 74 minutes, and the clearance was 28 mL/kg per minute. In addition to morphine pharmacokinetics, Attia et al. (1986) noted that the onset and duration of analgesia were 30 minutes and 19 hours, respectively, and that respiratory depression as evidenced by changes in the slope of the ventilatory response to CO₂ was impaired for 22 hours after epidural administration.

Intranasal use of morphine has been reported in adults. Fitzgibbon et al. (2003) after an intranasal dose of 40 mg of morphine in adults receiving opioids (i.e., not naïve to opioid effects) found an absolute bioavailability of 22% and a relative (to oral) bioavailability of 226%, with a C_{max} of 62 ± 22.8 ng/mL and a $t_{1/2}$ of 2 ± 0.7 hours. In a clinical trial, Stoker et al. (2007) found that reduced intranasal morphine doses (7.5 mg and 15 mg) are effective for moderate to severe pain as well. There are no reported studies in children.

Meperidine

Meperidine, like morphine, is an agonist at the μ -opioid receptor that shows great interindividual variability. In infants and neonates, the pharmacokinetics varied greatly between subjects, with a $t_{1/2}$ of 10.7 hours (range of 3.3 to 59.4 hours), median clearance of 8 mL/kg per minute (range of 1.8 to 34.9 mL/kg per minute), and a median steady-state volume of distribution of 7.2 L/kg (range of 3.3 to 11) (Pokela et al., 1992). Normeperidine, its active metabolite, has a half-life that is dependent on renal function and can accumulate with high doses or in patients with decreased renal function; normeperidine may precipitate tremors or seizures (Saneto et al., 1996; Kussman and Sethna, 1998). Meperidine also has local anesthetic activity because of its interactions with sodium ion channels. It has been used as a local anesthetic after tonsillectomy and adenoidectomy procedures in children with mixed results (Elhakim et al., 1997; Nikandish et al., 2008). Its routine use in many pediatric centers has become very uncommon because of the undesirable effects of accumulating normeperidine and because there are a host of other agents available. However, meperidine in small doses can be used to treat postoperative shivering.

Fentanyl

Fentanyl is a synthetic opiate with a clinical potency 50 to 100 times that of morphine. It is metabolized by dealkylation, hydroxylation, and amide hydrolysis to inactive metabolites. It has a high hepatic extraction coefficient and a high pulmonary uptake (Roerig et al., 1987). Heberer noted that cirrhosis in adults had no effect on fentanyl kinetics. Fentanyl has relatively minimal hemodynamic effects and is used both as an adjunct to nitrous oxide anesthesia and as a sole anesthetic agent. Bradycardia and chest-wall rigidity are potential problematic features of high-dose fentanyl anesthesia. The cardiovascular effects of fentanyl at doses of 30 to 75 mcg/kg fentanyl (with pancuronium) are minimal (Hickey et al., 1984). Modest decreases in mean arterial pressure and systemic vascular resistance index were noted by Hickey and colleagues (1985).

In neonates, Murat et al. (1988) have shown that although baroreceptor control of heart rate is present, fentanyl anesthesia (10 mcg/kg) can significantly depress the baroreceptor response to both hypotension and hypertension. In comparative studies of opioid-induced respiratory depression with sufentanil and fentanyl administration in adults, Bailey et al. (1990) noted that ventilatory depression (both magnitude and duration) was less after sufentanil administration. In addition, although the two drugs have similar half-lives, analgesia lasted longer after sufentanil administration. The dose of fentanyl needed to ensure satisfactory anesthesia for infants varies with the surgical stress

and disease comorbidity. Hickey and Retzack (1993) have shown that in a pediatric patient with reactive pulmonary vasculature, 25 mcg/kg of fentanyl was needed to prevent an acute episode of right ventricular failure secondary to pulmonary hypertension in the patient who was undergoing upper airway instrumentation and manipulation. Ellis and Steward (1990) have shown that in children undergoing hypothermic cardiopulmonary bypass or profound hypothermia with circulatory arrest who were anesthetized with fentanyl, a dose of at least 50 mcg/kg of fentanyl was needed to blunt the hyperglycemic response to hypothermia and circulatory arrest. Yaster (1987) noted that in neonates anesthetized with fentanyl, metocurine, and oxygen who were undergoing a wide variety of surgical procedures, fentanyl (10 to 12.5 mcg/kg) provided reliable hemodynamic stability for 75 minutes.

In a study of children aged 6 months to 6 years undergoing cardiac surgery with cardiopulmonary bypass, Pirat et al. (2002) compared three groups of patients. One group received intravenous fentanyl, the second group received intrathecal fentanyl, and the third group received both intravenous and intrathecal fentanyl. In this study, intrathecal fentanyl offered no advantage over intravenous fentanyl with regard to hemodynamic stability or suppression of the biochemical stress response. However, the combination of intrathecal and intravenous fentanyl was associated with better hemodynamic stability in the prebypass period compared with either group alone.

Duncan et al. (2000) reported a dose-ranging study of 40 pediatric patients undergoing cardiac surgery using one of five intravenous fentanyl doses: 2, 25, 50, 100, and 150 mcg/kg. In this study, patients in the 2 mcg/kg group had significant rises in prebypass glucose, prebypass and postbypass cortisol, and prebypass and postbypass norepinephrine. No significant rises occurred in glucose, cortisol, and catecholamines in any of the higher dosage groups. Patients in the group receiving 2 mcg/kg had significantly higher mean systolic blood pressures and heart rates. Higher doses of fentanyl (100 and 150 mcg/kg) offered little advantage over 50 mcg/kg in controlling these neuroendocrine stress responses.

Age-related differences in the kinetics and sensitivity to fentanyl and changes in kinetics associated with pathophysiologic conditions and types of surgery create variability and make generalizations difficult (Johnson et al., 1984; Koren et al., 1984; Collins et al., 1985; Koehntop et al., 1986; Singleton et al., 1987). In the neonate, fentanyl clearance seems comparable with that of the older child or adult, whereas in the premature infant, fentanyl clearance is markedly reduced. In premature infants, fentanyl half-life was reported as 6 to 32 hours (Collins et al., 1985). In infants and children, fentanyl plasma concentrations were less than those in adults after similarly administered intravenous doses (milligrams per kilogram) (Fig. 7-30) (Singleton et al., 1987). These marked variations in kinetics reflect age differences and perhaps differences in anesthetics, surgeries, or duration of sampling.

Fentanyl pharmacokinetics after continuous infusions for fewer than 24 hours in critically ill children have demonstrated increased steady-state volume of distribution (15.2 L/kg), prolonged terminal elimination half-life (24 hours), and normal clearances (Katz and Kelly, 1993). The pharmacokinetics after 48 hours of continuous fentanyl infusion in newborns were reported for 12 neonates. In these infants (mean gestational age, 32 weeks; mean weight, 1.88 kg; mean PNA, 6 ± 9 days), the volume of distribution was noted as 17 ± 9 L/kg, total body

FIGURE 7-30. Fentanyl concentration-vs-time curves for adults (top curve), children (middle curve), and infants (bottom curve). (From Singleton MA et al.: *Plasma concentrations of fentanyl in infants, children, and adults*, *Can Anaesth Soc J* 34:152, 1987.)

clearance was 1154 mL/kg per hour, and the half-life was 9.5 ± 2.6 hours (Santeiro et al., 1997). In addition, the relatively high total body clearance was noted to correlate with PNA, suggesting that hepatic blood flow increases with age. Gauntlett et al. (1988) found that fentanyl clearance increased with PNA, with most of the increase occurring by 2 weeks of age.

In a study of neonates who were not undergoing surgery, Saarenmaa et al. (2000) studied the fentanyl clearance in the first few days of life of 38 infants who were at 26 to 42 weeks' gestation and had birth weights of 835 to 3550 g. This study reported a correlation of fentanyl clearances with gestational age and birth weight (Fig. 7-31).

Prolonged fentanyl infusions, however, were associated with tolerance. In this context, tolerance is defined as the need to increase drug doses to maintain a stable drug effect (e.g., an increased dose of fentanyl to achieve pain relief on day 7 vs. day 1 of use). In neonates sedated with fentanyl via continuous infusion while undergoing ECMO, Arnold et al. (1991) noted that the daily infusion rates and plasma concentrations required to keep the infant sedated increased over time. Although prolonged continuous infusions of fentanyl may increase the volume of distribution, prolong the elimination half-life of the drug, and consequently prolong recovery on discontinuation, the development of tolerance may minimize this pharmacologic consequence.

In addition to intravenous administration, fentanyl has been administered transmucosally as a means of providing sedation to children. The pharmacokinetics and bioavailability of oral transmucosal fentanyl citrate (OTFC) were studied by Streisand et al. (1991) using adult volunteers studied on three separate occasions (Fig. 7-32). Plasma levels of fentanyl were determined after intravenous, transmucosal, or gastrointestinal (oral) administration. Regardless of the mode of administration, the terminal elimination half-life was similar in all three groups (425 to 469 minutes). Compared with the oral group, peak plasma concentrations of fentanyl occurred earlier (22 vs. 101 minutes) and were higher (30 vs. 1.6 ng/mL) in the OTFC groups. The bioavailability of OTFC was 50%, compared with 30% in the oral group. This difference in the bioavailability probably relates to the first-pass (hepatic

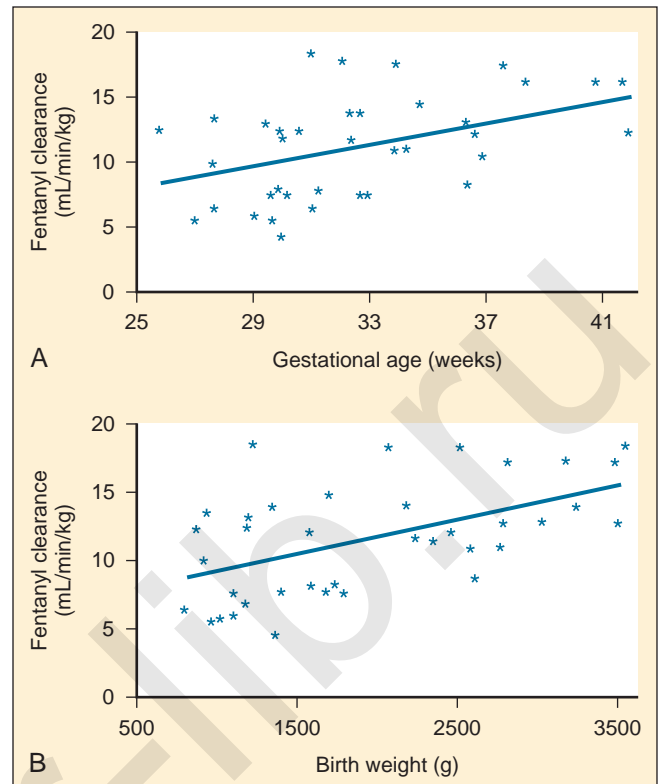

FIGURE 7-31. Plasma clearance of fentanyl correlates with gestational age and birth weight. (From Saarenmaa E et al.: *Gestational age and birth weight effects on plasma clearance of fentanyl in newborn infants*, *J Pediatr* 136:767, 2000.)

FIGURE 7-32. Plasma concentrations of fentanyl after oral transmucosal, intravenous, and oral administration. (From Streisand JB et al.: *Absorption and bioavailability of oral transmucosal fentanyl citrate*, *Anesthesiology* 75:226, 1991.)

extraction) effect observed with orally administered drugs (Streisand et al., 1991). In children, Dsida et al. (1998) and Wheeler et al. (2002) found less bioavailability of OTFC, with levels similar to the ones achieved by adults after oral administration (33% and $36 \pm 1\%$). In a subsequent study comparing pharmacokinetic parameters of oral administration of

the intravenous formulation of fentanyl and OTFC, Wheeler et al. (2004) found similar pharmacokinetic parameters. However, there was a high interpatient variability, especially in the early hours after oral administration of intravenous fentanyl; the pharmacokinetic variables for the orally administered intravenous formulation were peak plasma concentrations (C_{\max} : 1.83 ng/mL, standard deviation [SD] 1.19 ng/mL), time to C_{\max} (1.74 hours, SD 1.54 hours), apparent volume of distribution at steady state (17.5 L/kg, SD 7.20 L/kg), and apparent oral fentanyl clearance (3.33 L/kg, SD 2.25 L/kg⁻¹ per hour⁻¹). Therefore, as stated by the authors, this method of administration should be used with caution until further data are available.

Intranasal administration of fentanyl has also been used to provide postoperative analgesia for pediatric patients (Galinkin et al., 2000; Manjushree et al., 2002). After 2 mcg/kg of intranasal fentanyl, Galinkin et al. (2000) noted the mean fentanyl concentrations at 10 and 34 minutes were 0.8 and 0.6 ng/mL, respectively. In a study comparing intranasal fentanyl with intravenous fentanyl, Manjushree et al. (2002) noted that onset time to analgesia after 1 mcg/kg of fentanyl was slower (13 minutes) for the intranasal route than for the intravenous route of administration (8 minutes).

Darwish and collaborators (2007), using a fentanyl buccal tablet of 400 mcg in healthy adult volunteers, have found predictable pharmacokinetics after single- and multiple-dose administration. In 2008, the FDA posted a safety alert for this formulation. This formulation is intended only for management of breakthrough pain in adult patients with cancer who are tolerant to opioid therapy. In pediatrics, the applicability for this formulation is unlikely given its high dose.

Sufentanil

With the hypothesis that increase in potency is associated with increased opiate effects and decreased nonspecific cardiovascular effects, other fentanyl congeners have been developed. Sufentanil, a potent synthetic opioid, is an N-4 substituted derivative of fentanyl. It is a highly lipophilic compound that is distributed rapidly and extensively to all tissues. Sufentanil is approximately five to 10 times more potent than fentanyl and has an extremely high margin of safety. The major pathways for sufentanil metabolism involve O-demethylation and N-dealkylation; minimal amounts are excreted unchanged in urine. Desmethyl sufentanil, the major metabolite of sufentanil, possesses about 10% the activity of the parent compound.

Pharmacokinetic and pharmacodynamic studies of sufentanil were conducted in infants, children, and adults. In adults, compared with fentanyl, the smaller volume of distribution (2.48 L/kg) and high clearance rate (11.3 mL/kg per minute) of sufentanil contribute to its short terminal elimination half-life (149 minutes). Meuldermans et al. (1982) demonstrated that sufentanil is more protein bound (92%) than fentanyl (84%), and that pH affects protein binding. Decreasing pH from 7.4 to 7 increased protein binding by 28%; conversely, increasing pH from 7.4 to 7.8 decreased protein binding by 28%.

Clinical studies assessing the hemodynamic and endocrine stress response of sufentanil have been done in adults undergoing cardiopulmonary bypass (deLange et al., 1982; Sebel and Bovill, 1982). Sufentanil appears to block some of the stress responses to cardiac surgery. Stress-induced increases

in antidiuretic hormone and growth hormone appear to be blocked before, during, and after cardiopulmonary bypass, whereas the catecholamines (norepinephrine, epinephrine, and dopamine) show a large surge during the bypass and post-bypass periods (deLange et al., 1982; Bovill et al., 1983). In a double-blind study, Rosow et al. (1984) found the drugs fentanyl and sufentanil to be comparable with regard to hemodynamic stability.

The pharmacokinetic and pharmacodynamic effects of sufentanil in children have been studied. Hickey et al. (1984) compared the hemodynamic response of 5 and 10 mcg/kg of sufentanil to 50 to 75 mcg/kg of fentanyl in patients with complex congenital heart disease. Although heart rate and blood pressure changed slightly, they noted marked improvement in the patient's oxygenation with both fentanyl and sufentanil. They concluded that both sufentanil and fentanyl were safe anesthetics in high doses, and that both agents favorably decreased pulmonary vascular resistance and thereby increased pulmonary blood flow and systemic oxygenation in patients with cyanotic heart disease. Davis et al. (1987) examined both the pharmacodynamics and pharmacokinetics of high-dose sufentanil (15 mcg/kg) and oxygen in infants and children undergoing cardiac surgery. Sufentanil provided marked hemodynamic stability after an infusion and during the stress periods of incision and sternotomy (Table 7-16). The hemodynamic responses to sufentanil were similar to those noted by Hickey et al. (1984) but differed from the increases in blood pressure and heart rate occurring after intubation, sternotomy, and incision observed in older children undergoing repair of their congenital heart defect (Moore et al., 1985).

Greeley et al. (1987) investigated age-related changes in the pharmacokinetics of sufentanil in pediatric patients undergoing cardiothoracic surgery. They noted that sufentanil best fit a three-compartment model and that neonates had significantly smaller clearance rates, larger volumes of distribution at steady state, and longer elimination half-lives than infants, children, and adolescents (Table 7-17). The developmental pharmacokinetic changes of improved clearance and elimination for sufentanil were further substantiated in another report in which infants were studied within the first 8 days of life and then again at 3 to 4 weeks of age (Greeley and de Bruin, 1988).

TABLE 7-16. Hemodynamics during Sufentanil Anesthesia in Infants and Children Undergoing Open-Heart Surgery

$t_{1/2\alpha}$, Distribution phase half-life; $t_{1/2\beta}$, elimination phase half-life; CL, clearance; V_d ss, volume of distribution at steady state.

Guay et al. (1992) studied the pharmacokinetics of sufentanil in 20 healthy pediatric patients aged 2 to 8 years. After intravenous administration of 1 to 3 mcg/kg of sufentanil, the elimination half-life was 97 ± 42 minutes, the volume of distribution at steady state was 2.9 ± 0.6 L/kg, and the plasma clearance was 30.5 ± 8.8 mL/kg⁻¹ per minute⁻¹. It is unclear whether the doubling of the plasma clearance value in healthy children was a function of the study design or the patient's underlying disease. A similar effect was noted for morphine in infants with and without cardiac disease (Lynn et al., 1998).

In addition to its use as an anesthetic agent, sufentanil has been used as a preanesthetic medication in children. Pharmacokinetic studies in adults after intravenous and intranasal administration show that the area under the curve from 0 to 120 minutes after intranasal dosing was 78% of that after intravenous injection (Helmers et al., 1989). By 30 minutes after drug administration, plasma sufentanil concentrations were identical for the two routes of administration.

The role of the kidneys in sufentanil elimination and metabolism has not been well defined. The effects of renal failure in sufentanil kinetics were assessed in adolescent patients with chronic renal failure (Davis et al., 1988). There was no statistical difference in apparent volume of distribution, elimination, and clearance between patients with renal failure and patients in a control group. However, there was a large amount of variability in both groups of patients. In patients with renal failure, sufentanil must be administered carefully on the basis of responses elicited in individual patients.

The pharmacodynamics of sufentanil were also evaluated in neurosurgical patients. The effects of opioids on intracranial pressure (ICP) and cerebral perfusion pressure have been controversial. In intubated patients with severe head injuries (less than 8 on the Glasgow Coma Scale), sufentanil administration was associated with an increase in ICP, a decrease in mean arterial blood pressure, and a decrease in cerebral perfusion pressure (Albanese et al., 1993). The effects of sufentanil in the EEGs of premature infants were reported by Nguyen and colleagues (2003). Bolus injection and continuous infusion increased EEG discontinuity, decreased burst suppression, and increased interburst intervals.

In adult patients undergoing nonintracranial neurosurgical procedures, Trindle et al. (1993) noted that cerebral blood flow velocity (as assessed by transcranial Doppler) increased after sufentanil infusion. This increase in velocity was similar for equipotent doses of fentanyl (Trindle et al., 1993).

In a study of adult patients with head trauma, Scholz et al. (1994) noted that sufentanil bolus (2 mcg/kg), combined with a sufentanil continuous infusion (150 mcg/hr) and midazolam continuous infusion (9 mg/hr), resulted in decreases in both ICP and mean arterial pressure. Perfusion pressure was noted to be stable.

Alfentanil

Alfentanil, a potent, short-acting analog of fentanyl, is rapidly distributed to the brain and central organs and then rapidly redistributed to more remote sites. It is about one fourth as potent as fentanyl and has one third the duration of action. After a single bolus injection, the drug's decreased volume of distribution results in a significantly shorter elimination half-life. Its low lipid solubility allows less penetration of the blood-brain barrier. The concentration in brain tissue is markedly less than that in plasma. The duration of narcotic effect appears to be governed by redistribution and elimination. The redistribution principle is most important after a small single-dose infusion, whereas elimination determines the effect of a large single bolus, multiple small-bolus infusions, or a continuous infusion. Alfentanil is metabolized in the liver by oxidative N-dealkylation and O-demethylation in the CYP3A4 system (Yun et al., 1992). The pharmacologically inactive metabolites are excreted in the urine, with the major metabolite being noralfentanil (Camu et al., 1982). Alfentanil metabolism is catalyzed by CYP3A3/4 and CYP3A5 (Klees et al., 2005). Interindividual differences in the expression of this cytochrome and its susceptibility to inducers and inhibitors may account for the clinical variability in alfentanil kinetics and dynamics (Kharasch and Thummel, 1993). Although gender differences in CYP activity can affect drug metabolism, Kharasch et al. (1997a), in a study of young women, could find no differences in alfentanil clearance on different days of the menstrual cycle. Differences in CYP activity can markedly influence the pharmacokinetics of alfentanil, specifically its context-sensitive half-time. Using normal, low, and high CYP3A4 activity, Kharasch et al. (1997b) have postulated through computer simulations that alfentanil can behave similarly to remifentanyl (high CYP3A4 activity) or fentanyl (low CYP3A4 activity) (Fig. 7-33).

Protein binding has a significant influence on the pharmacokinetics of alfentanil. Alfentanil is 88% to 95% protein bound in the plasma and is independent of concentration and blood pH. The plasma protein most responsible for binding of alfentanil is α_1 -acid glycoprotein. In adults, changes in the binding and in the pharmacokinetics of alfentanil occur during and after cardiopulmonary bypass (Hug, 1984). Disease states, including end-stage kidney or liver failure, can alter protein binding of opioids in children. Davis et al. (1989b) studied the effects of liver disease and kidney disease on the binding characteristics of alfentanil. Compared with healthy children, patients with kidney disease had a significant decrease in protein binding ($89.2\% \pm 5.4\%$ vs. $93.1\% \pm 3.2\%$), an increase in α_1 -acid glycoprotein concentration (108.8 ± 44.3 vs. 71.8 ± 30.7 mg/dL), and no change in albumin concentration (3910 ± 754 vs. 4555 ± 524 mg/dL), whereas

■ **FIGURE 7-33.** Effect of P450 3A4 activity on the time required for a 50% decrease in alfentanil venous plasma concentration after targeted infusions of variable durations. Half-times for fentanyl and remifentanyl in normal participants were calculated using reported kinetic parameters. (From Kharasch E et al.: *The role of cytochrome P450 3A4 in alfentanil clearance: implications for interindividual variability in disposition and perioperative drug interactions*, *Anesthesiology* 87:36, 1997.)

patients with liver disease had a significant decrease in protein binding ($85.9\% \pm 6.2\%$ vs. $93.1\% \pm 3.2\%$), no change in 1-acid glycoprotein concentration (65.8 ± 31.8 vs. 71.8 ± 30.7 mg/dL), and a decrease in albumin concentration (3045 ± 1255 vs. 4555 ± 524 mg/dL). Alfentanil binding has been studied in adult burn patients and noted to be increased from 90% to 94% protein bound (Macfie et al., 1992). Because alfentanil is highly protein bound, even small changes in the drug's free fraction could have marked pharmacodynamic effects in patients with kidney or liver failure.

The pharmacokinetics of alfentanil have been studied in both adults and children, but limited information is available for children of different ages. The limited, age-related, developmental pharmacokinetic data for alfentanil are presented in Table 7-18. In a study by Meistelman et al. (1987), children aged $5 (\pm 1.1)$ years had significantly smaller volumes of distri-

bution and shorter elimination half-lives but similar clearance values compared with those young adult patients aged $31 (\pm 4)$ years). Goresky et al. (1987) noted no differences in volume of distribution, elimination half-life, or clearance in infants aged 3 to 12 months compared with children aged 1 to 14 years. On the other hand, Roure et al. (1987) noted that children aged $33 (\pm 18)$ months had faster clearance rates and elimination half-lives but similar volumes of distribution compared with those of adults. As Maitre et al. (1987) noted in population studies of alfentanil pharmacokinetics in adults, differences in the pharmacokinetic profiles among the pediatric studies may be related to the large interpatient variability of alfentanil. Davis et al. (1989a) have studied the pharmacokinetics of a single bolus of alfentanil in newborn premature infants and older children. In their study, newborn premature infants had considerably longer elimination half-lives (525 ± 305 vs. 60 ± 11 minutes), slower clearance rates (2.2 ± 2.4 vs. 5.6 ± 2.4 mL/kg per minute), and larger volumes of distribution (1 ± 0.39 vs. 0.48 ± 0.19 L/kg) than those observed in the older children (Fig. 7-34).

In a report on the influence of gestational age on the pharmacokinetics of alfentanil in neonates, Killian et al. (1990) noted no changes in alfentanil kinetics between preterm and term infants. Wiest et al. (1991) studied the kinetics of alfentanil in neonates after a loading dose and variable continuous infusion route. Noncompartmental analysis revealed a clearance rate of 3.24 mL/kg per minute, a volume of distribution of 0.54 L/kg, and an elimination half-life of 4.1 hours. However, they noted an effect of alfentanil plasma concentration on plasma clearance, suggesting dose-dependent pharmacokinetics in these ill neonates.

The effects of renal failure and cirrhosis on alfentanil kinetics were studied in adult and in pediatric patients. Chauvin et al. (1987a) have studied the pharmacokinetics of alfentanil in adult patients with chronic renal failure. The clearance and half-life values for alfentanil were similar in patients with renal failure and in control patients, but the steady-state volumes of distribution of alfentanil were significantly greater in patients with renal disease than in control patients. However, when the kinetic values for alfentanil were corrected

TABLE 7-18. Alfentanil Age-Related Pharmacokinetics

Reference	Age	No. of Patients	V_d (L/kg)	CL (mL/min per kg)	$T_{1/2\beta}$ (min)
Meistelman et al. (1987)	4 to 8 yr	8	0.163	4.7	40
Meistelman et al. (1987)	25 to 40 yr	5	0.457	4.2	97
Goresky et al. (1987)	4 to 12 mo	5	0.500	8.3	76
Goresky et al. (1987)	1 to 14 yr	8	0.416	7.7	84
Davis et al. (1989a)	1 to 3 days (premature, 26 to 35 wk)	5	0.840	1.35	455
Killian et al. (1990)	1 to 3 days (term)	5	0.820	1.7	328

V_d , Volume of distribution; CL, clearance; $t_{1/2\beta}$, elimination half-life.

■ **FIGURE 7-34.** Alfentanil concentration-vs.-time curves in newborn premature infants and older children. Both groups received 25 mcg/kg of alfentanil. (From Davis PJ et al.: *Pharmacokinetics of alfentanil in newly born premature infants and older children*, *Dev Pharmacol Ther* 13:21, 1989.)

for protein binding, the steady-state volumes of distribution and rates of clearance of unbound drug were similar in both groups of patients.

The effects of cirrhosis on alfentanil pharmacokinetics in adults were demonstrated by Ferrier et al. in 1985. Patients with cirrhosis have lower total plasma clearance (1.60 vs. 3.06 mL/kg per minute) and prolonged terminal elimination half-life (219 vs. 97 minutes) but a similar volume of distribution (0.390 vs. 0.355 L/kg) as those values of patients in a control group.

In contrast to the studies in adults, the pharmacokinetics of alfentanil in children with cholestatic hepatitis or end-stage kidney disease who are about to undergo either liver or kidney transplantation appear to be unaffected by the disease process (Davis et al., 1989b). Whether this difference is related to age or to the underlying pathophysiology of the disease states remains unanswered.

As do other opiates, alfentanil produces a shift to the right in the ventilatory response curve. Although this shift is dose dependent, the ventilatory depressant effects dissipate by 30 to 50 minutes after the dose is given (Kay and Pleuvry, 1980; Kay and Stephenson, 1980).

Goldberg et al. (1992) noted that in healthy adult patients, prolonged alfentanil administration sometimes resulted in arterial oxygen desaturation and depression of the hypercapnic respiratory drive even though the patients were easily arousable. Muscle rigidity can occur with rapid-acting opiates such as fentanyl, sufentanil, and alfentanil. Pokela et al. (1992) have reported that rigidity, which requires changes in ventilator settings, occurs in neonates after alfentanil administration.

The cardiovascular effects of alfentanil were assessed during both low- and high-dose infusions (Kay and Pleuvry, 1980; Kay and Stephenson, 1980). At doses of 150 mcg/kg, heart rate, mean arterial pressure, and systemic vascular resistance were noted to decrease. Pulmonary capillary wedge pressure, pulmonary vascular resistance, right atrial pressure, and pulmonary artery pressure increased slightly (Kramer et al., 1983).

The neuroendocrine stress response with alfentanil has been studied in adults. Alfentanil incompletely suppresses the stress response. High-dose alfentanil can blunt the growth hormone, antidiuretic hormone, and cortisol responses to bypass.

Epinephrine and norepinephrine concentrations are increased with the onset of bypass (deLange et al., 1982; Stanley et al., 1983).

Meretoja and Rautiainen (1990) noted that in children aged 1 month to 2 years, oral flunitrazepam premedication and alfentanil bolus of 20 mcg/kg followed by a continuous infusion of 0.5 mcg/kg per minute provided adequate sedation for patients spontaneously breathing room air who were undergoing cardiac catheterization. In these patients, hemodynamic variables changed less than 11%.

In adults, Ausems et al. (1986) have defined the Cp50 values of alfentanil for various surgical and anesthetic stimulations (Fig. 7-35). Using these adult Cp50 plasma values, initial bolus and infusion rates can be estimated for children.

Remifentanil

Remifentanil is the hydrochloride salt of 3-[4-methoxycarbonyl]-4-[(1-oxopropyl)phenylamino]-1-piperidine] propanoic acid methyl ester. Because of its ester linkage, remifentanil is susceptible to metabolism by blood and tissue esterases. Its primary metabolic pathway is through de-esterification to form a carboxylic acid metabolite, which is only one 300th to one 1000th the potency of the parent compound. In adult studies, the pharmacokinetic profile of remifentanil is best described by a biexponential decay curve, with a small volume of distribution (0.39 L/kg), a rapid distribution phase (0.94 minute), and an extremely short elimination half-life (10 minutes) (Egan et al., 1993; Glass et al., 1993; Westmoreland et al., 1993).

In addition, computer simulations show that the duration of remifentanil infusion has no effect on the time to decrease the plasma or effect site concentration by 50%. The half-time for achieving an equilibration constant between plasma and the effect compartment ($t_{1/2 K_{e0}}$) is 1.3 minutes. Thus, the context-sensitive half-time is a flat line.

For opioids, which undergo organ elimination, the neonatal profile of opioids demonstrates prolonged clearances, large volumes of distribution, and markedly prolonged half-lives. However, in neonates remifentanil has a rapid clearance, a large volume of distribution, and a half-life that does not change with age. In an

■ **FIGURE 7-35.** Relationship between the alfentanil plasma concentrations (with 66% nitrous oxide) and their effects for three specific events of short duration (intubation, skin incision, and skin closure). (From Ausems ME et al.: *Plasma concentrations of alfentanil required to supplement nitrous oxide anesthesia for general surgery*, *Anesthesiology* 65:362, 1986.)

age-related study of remifentanyl pharmacokinetics, Ross et al. (2001) noted that the volume of distribution was largest in the infants younger than 2 months (mean value of 452 mL/kg) and decreased to mean values of 223 to 308 mL/kg in the older patients. There was a more rapid clearance in the infants younger than 2 months (90 mL/kg per minute) and infants aged 2 months to 2 years (92 mL/kg per minute) than in the other groups (mean of 46 to 76 mL/kg per minute). The half-life was similar in all age groups, with mean values of 3.4 to 5.7 minutes. Because the redistribution phase and elimination half-life are so rapid, a bolus injection before a continuous infusion of remifentanyl is usually unnecessary.

Another unique feature of remifentanyl kinetics in children is that its pharmacokinetic profile is unchanged by cardiopulmonary bypass. For opioids, which undergo organ elimination, cardiopulmonary bypass prolongs drug clearance, increases volume of distribution, and increases half-life. The pharmacokinetic profile of remifentanyl appears to be unaffected by cardiopulmonary bypass (Fig. 7-36) (Davis et al., 1999).

The pharmacodynamics of remifentanyl were studied in children and infants. Multiple case reports of remifentanyl use in neonates and infants suggest its usefulness (Wee and Stokes, 1999; Chiaretti et al., 2000; German et al., 2000; Dönmez et al., 2001; Foubert et al., 2002). In a multicenter trial of infants younger than 2 months who were undergoing pyloromyotomy, Galinkin et al. (2001) and Davis et al. (2001) noted that remifentanyl provides stable hemodynamic conditions and that new onset of postoperative apnea, as detected by pneumograms, did not occur with remifentanyl.

Pharmacodynamic studies suggest that the short duration of remifentanyl in older children can be used to promote faster emergence times (Davis et al., 1997, 2000). As with other opioids, the issue of tolerance is a concern with remifentanyl. In a systematic review of randomized controlled trials comparing remifentanyl with other opioids in adult patients, Komatsu et al. (2007) found a 40% additional need for postoperative analgesics (RR 1.36, 95% CI 1.21-1.53); confirming earlier studies

by Guignard et al. (2000) and Vinik and Kissin (1998). In pediatrics Crawford et al. (2006) demonstrated increased cumulative morphine consumption during the first 24 hours after spine instrumentation, in patients who had remifentanyl infusion when compared with patients who received morphine intraoperatively. In a study done on cultured rat dorsal horn neurons exposed to different levels of remifentanyl comparable with the ones used in clinical practice, Zhao and Joo (2008) found an increase in NMDA responses that is consistent with remifentanyl-induced hyperalgesia and tolerance.

The incidence of postoperative nausea and vomiting appears to be similar to the incidence seen with other opioids (Eltzschig et al., 2002; Komatsu et al., 2007). A higher incidence of postoperative shivering is described in patients receiving remifentanyl (RR 2.15, 95% CI 1.73-2.69) when compared with alfentanil, fentanyl, and sufentanil (Komatsu et al., 2007).

The short context-sensitive half-life of remifentanyl and the issue of rapid appearance of tolerance make it mandatory to have a plan for ongoing analgesia if postoperative pain is anticipated before stopping remifentanyl infusions.

Methadone

Methadone is a synthetic opioid analgesic. It is a racemic mixture with the l-isomer that is 10 to 50 times more potent than the d-isomer. Methadone has an oral bioavailability of 80% with a range of 41% to 99%. It is 60% to 90% protein bound, and α_1 -acid glycoprotein is the main determinant of the free fraction of methadone. After an intravenous dose in adults, the pharmacokinetic profile fits a two-compartment model with a distribution half-life of 6 minutes and an elimination half-life of 35 hours (Gourlay et al., 1982). Findings of the pharmacokinetics of methadone in children suggest that it has a large volume of distribution (7.1 L/kg), a high plasma clearance (5.4 mL/kg per minute), and a long half-life (19.2 hours) (Berde et al., 1991).

Methadone metabolism clearance and disposition have been thought to be governed by hepatic CYP3A4 activity. However, Kharasch et al. (2009), in a set of studies with adult volunteers, have shown that methadone disposition and clearance are unchanged despite profound inhibition of the CYP3A4 and that oral absorption and bioavailability are not affected by glycoprotein transporter activity. Little information is available with respect to methadone's pharmacokinetic profile in end-stage liver or kidney failure. Urinary pH is another important determinant of the elimination half-life of methadone. Acidifying the urine markedly decreases the half-life of methadone and increases its renal clearance (Bellward et al., 1977).

Although methadone has become a cornerstone therapy for opiate dependence and the management of chronic neuropathic and cancer pain, clinical use in children is somewhat limited. In a randomized, double-blind study of morphine and methadone, Berde et al. (1991) noted that the children receiving methadone perioperatively had significantly less opioid requirements in the immediate postoperative period and better pain scores in the entire postoperative period than did children receiving equipotent doses of morphine. However, no differences in opioid requirements were found after the immediate postoperative period. Also, no differences in sedation scores were described; however, the maximum time of methadone administration was 48 hours. Recommended doses of perioperative methadone include a loading dose of 0.1 to 0.2 mg/kg with 0.05 mg/kg

■ **FIGURE 7-36.** Prebypass (brown) and postbypass (blue) pharmacokinetic decay curves of remifentanyl were constructed from the average concentrations of the 12 patients.

(From Davis PJ et al.: *The effects of cardiopulmonary bypass on remifentanyl kinetics in children undergoing atrial septal defect repair*, *Anesth Analg* 89:904, 1999.)

supplemental dose every 4 to 12 hours for a maximum of 2 to 3 days to avoid the possibility of excessive sedation secondary to drug accumulation as a result of the prolonged elimination half-life of methadone.

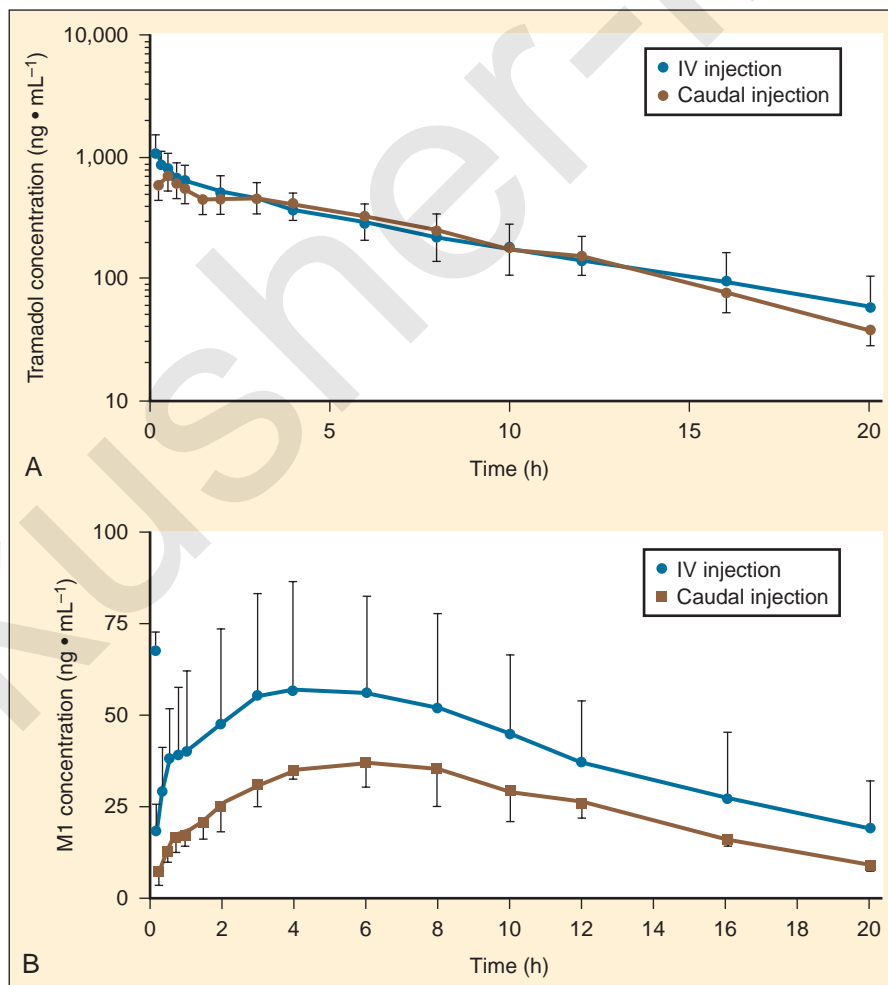

Among opioid analgesics, methadone is unique as a potent blocker of the delayed rectifier potassium ion channel. This results in QT prolongation and can produce torsade de pointes ventricular tachycardia in susceptible individuals and may explain the sudden death associated with its use (Andrews et al., 2009). The effects of methadone on the QT interval may be enhanced by hypokalemia, drugs that increase the QT interval such as erythromycin and ondansetron, or by CYP 3A4 inhibitors such as fluoxetine, fluconazole, valproate, and clarithromycin (Ehret et al., 2006).

Tramadol

Tramadol is a centrally acting agent with two distinct mechanisms of action: opioid and nonopioid. Tramadol acts as an opioid agonist. Tramadol also acts on monoamine systems to inhibit the reuptake of norepinephrine and serotonin. Tramadol is structurally related to codeine. It is metabolized by liver

CYP2D6; about 0.8% of the white population is deficient in this enzyme. Its metabolite, O-demethyl metabolic intermediate, has some analgesic effect. Tramadol is a stereoisomer. The pharmacokinetic profile of the stereoisomer was reported by Bressolle et al. in 2009. The (+)-stereoisomer form provides similar analgesia as the racemic form. The bioavailability of tramadol in adults is 68%, and it is 20% protein bound. Tramadol is metabolized by the 2D6, 2B6, and 3A4 P450 cytochromes. It has an active metabolite with more affinity for the μ receptor than the parent compound. In 14 children aged 1 to 12 years, the intravenous tramadol pharmacokinetic profile demonstrated a volume of distribution, clearance, and half-life of 3.1 L/kg, 6.1 mL/kg per minute, and 6.4 hours, respectively. In the same study, the kinetics of tramadol after caudal administration revealed a volume of distribution, clearance, and half-life of 2.06 L/kg, 6.6 mL/kg per minute, and 3.7 hours, respectively. Of note was that the ratio of caudal and intravenous AUC was 0.83, suggesting there is extensive systemic absorption of caudal tramadol (Murthy et al., 2000) (Fig. 7-37).

The clinical efficacy of tramadol has been reviewed in adults and children by Scott and Perry (2000); in summary, the overall efficacy of tramadol is comparable with equianalgesic doses of parenteral opioids. In children, tramadol has been administered

■ **FIGURE 7-37.** **A,** Mean (SD) serum concentrations of total tramadol after intravenous or caudal injection of tramadol 2 mg/kg. **B,** Mean (SD) serum concentrations of O-dimethyl tramadol (M1) after intravenous or caudal injection of tramadol 2 mg/kg. Box 7-1 Tramadol: Recommended Dosages for Children

ROUTE: FORM

DOSAGE (REPEATED DOSES × 4-6 PER DAY)

Oral, drops	2-3 mg/kg ⁻¹
Oral, tablets	1-2 mg/kg ⁻¹
Rectal, suppositories	1.5 to 3 mg/kg ⁻¹
IV, bolus	2 to 2.5 mg/kg ⁻¹
IV, continuous infusion	0.1 to 0.25 mg/kg ¹ /hr ⁻¹

From Bozkurt P: Use of tramadol in children, *Paediatr Anaesth* 15:1041, 2005.
IV, Intravenous.

orally, intravenously, intramuscularly, and caudally. Its major advantage is its lack of respiratory depression after its administration (Scott and Perry, 2000; Ozcengiz et al., 2001; Viitanen and Annala, 2001; Finkel et al., 2002; Engelhardt et al., 2003; Rose et al., 2003). Doses are presented in [Box 7-1](#).

Hydrocodone

Hydrocodone is a synthetic opiate, available in oral preparations, usually in combination with acetaminophen. It is most commonly used in transitioning from intravenous to oral opiate pain medications or as an oral treatment for acute pain. Oral bioavailability is reported to be 60%, with onset of effect 10 to 20 minutes after dosing and a duration of 3 to 6 hours. Pediatric dosing is suggested as 0.05 to 0.1 mg/kg. Since hydrocodone is combined with acetaminophen, in an elixir form with 2.5 mg hydrocodone and 167 mg acetaminophen in 5 mL, dosing must account for all sources of acetaminophen in order to avoid toxicity related to doses of the acetaminophen that are higher than desired.

In a report comparing oxycodone with hydrocodone in 67 patients older than 12 years of age, with a mean age of 35 years, who were treated in an emergency department after acute fractures, oxycodone 5 mg and hydrocodone 5 mg both combined with acetaminophen gave equivalent pain relief at 30 and 60 minutes after medication. Side effects were similar, except the hydrocodone group showed a higher incidence of constipation (Marco et al., 2005). Litkowski (2005) compared analgesia from oxycodone with ibuprofen, oxycodone with acetaminophen, and hydrocodone with acetaminophen with placebo after third molar extraction in a multicenter trial. There were 249 patients with a mean age of 19 years, and pain relief was equivalent in the acetaminophen groups but less than in the group that received oxycodone with ibuprofen. Onset of pain relief was also faster in the group that received oxycodone with ibuprofen.

The only study of hydrocodone use in children found in several online searches compared 60 children (of a planned 94) receiving either rofecoxib or hydrocodone with acetaminophen (dosed for 0.2 mg/kg hydrocodone every 6 hours) after elective tonsillectomy. Pain was assessed at 6-hour intervals initially by recovery staff and then by parents. Pain at rest was similar between the two groups (3 to 5 on a 10-point scale), but with swallowing, the group that received rofecoxib had scores that

were lower (2 to 4 vs. 4 to 6 in hydrocodone group). Side effects were not compared, because the number of patients was insufficient when the study was stopped early because of a recall of rofecoxib (Bean-Lijewski et al., 2007).

Hydrocodone has been used in the past in cough-suppressant medications because of its strong antitussive effects, but now it is rarely used, partially because reports about adverse effects, including death, have been published (Morrow and Faris, 1987).

Oxycodone

Oxycodone is a semisynthetic opioid analgesic (6-deoxy-7, 8-dihydro-14-hydroxy-3-O-methyl-6-oxomorphine) that was introduced into clinical practice in 1917. It is well absorbed after oral administration, and its bioavailability ranges between 60% to 80%, three times higher than morphine (with an oral bioavailability of 20%). N-demethylation to noroxycodone is the major metabolic pathway. A smaller fraction is metabolized by O-demethylation to oxymorphone. A fraction of both noroxycodone and oxymorphone are further metabolized to noroxymorphone (Kalso, 2005).

Metabolites show variable pharmacologic activity. Oxymorphone is an active metabolite with higher μ -opioid affinity than the parent compound. However, its low plasma concentration suggests a minor role in the analgesic response to oxycodone. Both noroxycodone and noroxymorphone are inactive metabolites. Excretion is mainly by renal elimination. Ten percent is eliminated as unchanged oxycodone; 50% is eliminated as noroxycodone and oxymorphone; and 18% is eliminated as noroxymorphone (Olkkola and Hagelberg, 2009).

In adults, after intravenous administration, the maximum concentration is reached after 25 minutes with a $t_{1/2}$ of 2 to 3 hours and clearance values between 15 and 18 mL/min⁻¹ per kg⁻¹ (Pöhyiä et al., 1991). In children aged 2 to 10 years, mean clearance is similar to adult values at 15.2 (with a range of 8.5 to 21.2) mL/min⁻¹ per kg⁻¹ (Olkkola et al., 1994). For infants younger than 1 week of age, clearance values are lower, with a median value of 9.9 (and a range of 2.3 to 17.2) mL/min⁻¹ per kg⁻¹. Clearance increases with age, reaching adult values by age 2 to 6 months (Pokela et al., 2005). However, high interindividual variability in clearance is described.

Other forms of administration have been used in children. Kokki et al. (2004) studied the pharmacokinetic parameters of 0.1 mg kg⁻¹ oxycodone administered intramuscularly, orally, and transmucosally and compared them with the intravenous form of administration. The mean (SD) $t_{1/2}$ were similar between groups: 163 (26) min for IV administration, 150 (39) min for IM, 150 (44) min for mucosal and 147 (61) for oral administration. Oral and mucosal administration showed greater interindividual variability (Kokki et al., 2004). In a subsequent study, Kokki et al. (2006) used a higher dose of 0.2 mg/kg that was given transmucosally and reported better bioavailability than previously described. However, the median noroxycodone-to-oxycodone AUC ratio reported was 0.78, showing significant hepatic metabolism and suggesting that children probably swallowed some of the oxycodone at the time of administration (Kokki et al., 2006). The recommended dose for intravenous, oral, and intramuscular administration in children is 0.1 mg kg⁻¹ (Kokki et al., 2004). For transmucosal administration a dose of 0.2 mg kg⁻¹ is suggested, but it is still not clear if part of the increase in availability is because of oral absorption.

Controlled-release (CR) oxycodone is recommended for chronic pain treatment in adults. There are no pharmacokinetic studies on CR oxycodone in children. From adult studies it is known that CR oxycodone is absorbed in a biexponential way with a rapid phase that has a mean half-life of 37 minutes and a slow phase with a mean half-life of 6.2 hours (Mandema et al., 1996). The most significant difference from the normal-release form is the time for maximum concentration, which is reported as 3.2 (SD 2.2) hours for the CR form and 1.4 (SD 0.7) hours for the normal-release form (Reeder et al., 1996; Benzinger et al., 1997). Czarnecki and colleagues (2004) studied the use of CR oxycodone for postoperative pain treatment after spinal fusion in children 10 to 19 years of age. In this study, the mean initial dose used was 1.24 mg/kg⁻¹ per day⁻¹ and the average use 13.3 days. Even though the authors did not report any adverse events and suggested that CR oxycodone is a plausible analgesic choice, there are no studies in children and it is not recommended (per manufacturer) for use in pediatrics. Additionally, there is increasing concern about the abuse of CR oxycodone, especially in adolescents (Cicero et al., 2005; Rogers and Copley, 2009).

Oxycodone is a μ -opioid receptor agonist with equianalgesic potency to intravenous morphine, despite the fact that its affinity to the μ -opioid receptor is over 20 times less than morphine. It has been suggested that oxycodone's potency is explained by higher CNS concentration caused by active transport across the BBB (Boström et al., 2006). In adult studies oxycodone showed a similar analgesic profile and incidence of side effects when compared with morphine, except for smaller changes in blood pressure and less sedation (Kalso et al., 1991; Silvasti et al., 1998). Also, in adults it has been shown that side effects are caused by the parent compound and not to metabolites (Lalovic et al., 2006). There is only one study in children that looks at the ventilatory effects of intravenous oxycodone. In this study Olkkola et al. (1994) suggested that oxycodone produced greater ventilatory depression than morphine. Other authors believe it has the same ventilatory effects as morphine in this population (Kalso, 1995).

In patients with renal and hepatic dysfunction, some extra considerations should be taken. Patients with severe hepatic dysfunction show impaired oxycodone elimination with 75% decreased plasma clearance, 50% increased volume of distribution, and an increased elimination half-life of from 3 to 14 hours (Tallgren, 1997). Patients with renal dysfunction show an increased volume of distribution and a prolonged elimination half-life as a result of reduced clearance (Kirvelä et al., 1996).

Codeine

Codeine (7,8-didehydro-4,5-epoxy-3-methoxy-17-methyl-morphinan-6 α -ol phosphate) is considered a weak opioid according to the World Health Organization's three-step analgesic ladder and is recommended for the treatment of mild to moderate pain. In children, codeine has been administered by oral, rectal, and intramuscular routes. It is not used in the intravenous form because of reported cases of severe hypotension (Parke et al., 1992). The recommended dose is 1 mg/kg to a maximum dose of 3 mg/kg per day. It is often used in combination with other analgesics such as acetaminophen, aspirin, and nonsteroidal anti-inflammatory drugs.

Despite the widespread use of codeine in children, there are very few studies related to codeine pharmacokinetics in this age population. In adults, after oral administration codeine peak plasma concentration is reached after 60 minutes, compared with only 30 minutes after intramuscular administration. Terminal half-life is 3 to 3.5 hours, the volume of distribution is 3.6 l kg⁻¹, and the clearance rate 0.85 L/min⁻¹ (Williams et al., 2001). In healthy adult volunteers, rectal and oral administration show good systemic bioavailability with reported values of 90% (Moolenaar et al., 1983). However, when administered in the postoperative period, values after rectal administration are less predictable, with systemic availability reported between 12% and 84% (Persson et al., 1992).

McEwan (2000) studied children between 3 months and 12 years of age and reported peak plasma values at 30 minutes after intramuscular and oral administration of codeine. Additionally, higher peak levels are described after intramuscular administration, which seem to correlate with better analgesia at 30 minutes. However, this effect is not persistent, and both routes showed similar performances after 1 hour. Codeine is metabolized in the liver by three different pathways: glucuronidation to codeine 6-glucuronide (the principal route), N-demethylation to norcodeine (10% to 20%) and O-demethylation to morphine (5% to 15%). Five to 15% of codeine is excreted unchanged in urine (Williams et al., 2001).

In a study of infants (0 to 10 months of age) and young children (3 to 4 years of age), Quiding et al. (1992) found that after administration of rectal codeine, the terminal half-life of codeine and morphine is 2.5 hours in infants; in children, the half-lives are 2.5 hours for codeine and 1.6 hours for morphine. Additionally, they found that AUC of morphine as a percentage of AUC of codeine ranged from 0% to 0.3%, similar to those previously described in adults; the authors concluded that infants at 6 months of age already have O-demethylation activity similar to that of adults (Quiding et al., 1986).

It is generally accepted that codeine's analgesic efficacy is explained by its conversion to morphine (Desmeules et al., 1991; Poulsen et al., 1996). O-demethylation to morphine is dependent on the enzyme cytochrome P450 (CYP2D6). The CYP2D6 gene is highly polymorphic, explaining wide levels of enzyme activity between individuals. There are four described phenotype levels of activity: poor metabolizers (PMs), intermediate metabolizers (IMs), extensive metabolizers (EMs), and ultrarapid metabolizers (UMs). The clinical implication of this variability is the unpredictability of analgesia and side effects of this medication. PMs show no analgesic effect, whereas UMs can show profound levels of analgesia with marked and potentially dangerous side effects (Poulsen et al., 1996; Cizzkowski et al., 2009). An example of this is found in a report by Voronov and colleagues (2007) on apnea and subsequent brain injury after administration of oral codeine in a child (of African origin) who was subsequently found to be an UM. The estimated incidence of UMs varies among racial and ethnic groups. It can be as low as 1% in the European, Caucasian, and Chinese populations, or up to 29% in Ethiopians (DeLeon, 2008, Stamer and Stuber, 2008).

Additionally, reports of randomized clinical trials in children evidenced lower analgesic efficacy of codeine when compared with oxycodone and higher failure rates when combined with acetaminophen and compared with ibuprofen (Charney et al., 2008; Drendel et al., 2009). There are two systematic reviews in adults that show only a small benefit of adding codeine to

acetaminophen (de Craen et al., 1996; Moore et al., 1997). These reports, plus the potential development of severe side effects in UMs, question the use of codeine when more predictable medications are available.

Opioid Agonist-Antagonists

Under this category are opioids that have a high affinity but poor efficacy at the μ -opioid receptor. Because of poor efficacy they act as μ -opioid receptor antagonists. Pentazocine, nalbuphine, and butorphanol belong to this class.

Nalbuphine

Nalbuphine is a phenanthrene opioid derivative, structurally similar to oxymorphone and naloxone. It has an analgesic potency equivalent to morphine with a respiratory depressant and analgesic ceiling effect between 150 and 300 mcg/kg (Beaver and Feise, 1978; Romagnoli and Keats., 1980; Gal and DiFazio, 1982; Julien, 1982). After intravenous administration in adults, it has an elimination half-life of 135.5 ± 55.4 minutes with a clearance of 217.6 mL/min (Sears et al., 1987). After intramuscular and subcutaneous administration, bioavailability is high, with mean values of 83% and 79%, respectively. Absorption is rapid with a C_{max} of 59.96 ± 9.52 ng/mL and 56.14 ± 14.48 ng/mL after intramuscular and subcutaneous injection of 20 mg in adults (Lo et al., 1987). After oral administration the bioavailability is low at 11.8% because of the high clearance rate (Aitkenhead et al., 1988). In children the distribution is similar to adults, but the elimination half-life is shorter (57 ± 14 minutes) (Jaillon et al., 1989). In a study in children receiving 0.3 mg/kg of nalbuphine rectally, the maximum plasma concentration achieved was 24 ± 15 ng/mL in a mean time of 25 ± 11 minutes with an elimination half-life of 162 ± 42 minutes (Bessard et al., 1997).

Nalbuphine has been used for treatment of opioid-induced pruritus. In adults, studies show similar effects to naloxone (Penning et al., 1988; Kendrick et al., 1996). However, one study in pediatrics did not have a similar finding, suggesting that nalbuphine may not be as effective in treating opioid-induced pruritus in children (Nakatsuka et al., 2006). Nalbuphine has also been used to decrease the incidence of emergence delirium after general anesthesia with sevoflurane as the sole agent for nonpainful procedures in children. Dalens et al. (2006) report that administration of a single dose of 0.1 mg/kg of nalbuphine before extubation decreases by 30% the development of emergence delirium without prolonging the postanesthesia recovery time when compared with placebo. The use of nalbuphine as a sole agent for postoperative pain treatment is scarce. There are two studies describing its use with positive reports after tonsillectomy and adenoidectomy procedures (Habre and McLeod, 1997; Van den Berg et al., 1999). However, the ceiling analgesic effect makes its use difficult for moderate to severe pain treatment.

Opioid Antagonists

Naloxone and naltrexone are competitive opioid antagonists at the μ -, κ -, and δ -receptors. At the μ -receptor, both have high affinity but total lack of efficacy, making them act as competitive inhibitors of exogenous and endogenous opiates. Both have

central and peripheral actions but different pharmacokinetic profiles. Naltrexone is orally effective and has a long duration of action, making it excellent for detoxification in opiate-addicted patients. However, when it is used in patients receiving opiates for ongoing pain, acute withdrawal symptoms may be precipitated.

Naloxone has poor bioavailability after oral administration but a very fast onset of action after intravenous administration, making it the most common opioid antagonist used in anesthesia. It is structurally related to morphine and oxymorphone. After intravenous administration in adults, it has a peak effect at 1 to 2 minutes and a half-life of 64 ± 12 minutes (Ngai, 1976). Pharmacokinetic studies in newborns have been conflicting. Early reports in full-term newborns found an increased half-life (233 ± 140 minutes) after intraumbilical administration of 35 mcg of naloxone (Moreland et al., 1980). However, Stile et al. (1987) reported a shorter half-life of 70 ± 35.6 minutes in premature newborns (26 to 34 weeks' gestation). The discrepancies between the two neonatal studies may be explained by differences in the route of administration. Intramuscular naloxone has a bioavailability of 35% in adults with detectable blood levels up to 4 hours after administration (Dowling et al., 2008). In neonates blood levels after intramuscular administration are similar to the ones achieved after intravenous administration, with duration of action up to 24 hours (Moreland et al., 1980). For opioid reversal after anesthesia, doses of 0.01 mg/kg repeated every 2 to 3 minutes are recommended. Lower doses are used to treat opioid side effects, either in bolus or continuous infusion (Gan et al., 1997; Cepeda et al., 2004). Maxwell et al. (2005) described a significant reduction in the incidence of pruritus (50%) and nausea (40%) after morphine as patient-controlled analgesia with the use of a continuous low-dose naloxone infusion (0.25 mcg/kg⁻¹ per hour⁻¹) in children, confirming previous studies in adults. A new peripherally acting μ -opioid receptor antagonist, methylnaltrexone, has been recently approved by the FDA for treatment of opioid-induced constipation in adults (Thomas et al., 2008). There are no studies of this agent in children.

INHALED ANESTHETIC AGENTS

Inhalation anesthesia remains the most common anesthetic technique in children. For people of all ages, the ideal agent would include properties such as rapid change in effect with change in delivery, low toxicity, minimal effects on cardiovascular and respiratory systems, and low cost. An inhalational agent that has a nonpungent odor and low airway irritability would be highly favored, particularly for children in whom inhalational induction is common. For these reasons, and also because of its relatively more favorable cardiovascular profile, sevoflurane is probably the most widely used agent for induction of anesthesia in children. Sevoflurane, isoflurane, and desflurane are all routinely used for maintenance of anesthesia. The use of halothane is now largely limited to countries where the cost of other agents is prohibitive. Although xenon has many potentially favorable properties, experience in children is limited and its high cost may be prohibitive. Nitrous oxide is still widely used as an adjunct to other agents during induction and maintenance of anesthesia. Nitrous oxide is also used by itself for procedural sedation.

Physical Properties

At atmospheric pressure and room temperatures, nitrous oxide and xenon are gases, whereas the other agents are all liquids. Desflurane's boiling point is close to room temperature, so a heated pressurized vaporizer is used to provide a reliable delivery of the agent independent of ambient temperature. Halothane is a polyhalogenated alkane, and sevoflurane, isoflurane, and desflurane are polyhalogenated ethers. Xenon is a naturally occurring element that exists as 0.05 ppm in the atmosphere. It is produced as a byproduct in the fractional distillation of air. Properties of the anesthetic agents are summarized in Table 7-19.

Nitrous Oxide

The physical properties of nitrous oxide may produce some particular clinical considerations. Nitrous oxide reduces the anesthetic requirements for the more potent inhalational agents, speeds the uptake of the more potent agents, and serves to dilute the inspired oxygen content. Inhaling high concentrations of nitrous oxide causes air-filled body cavities to expand. This is because nitrous oxide is considerably more soluble in blood than is nitrogen (partition coefficients of 0.47 for nitrous oxide and 0.014 for nitrogen), and therefore the volume of nitrous oxide diffusing into the cavity exceeds the volume of nitrogen that can diffuse out (Eger, 1974). Assuming a trivial quantity of nitrogen diffuses out of the space while ventilating the lungs with nitrous oxide, then the maximum multiple expansion of the original space that can occur is as follows (Eger, 1974):

$$\text{Multiple} = 100 / (100 - \% \text{ nitrous oxide})$$

Using this equation, if 75% nitrous oxide is inspired, then the space volume may expand up to threefold. The rate at which the space expands varies with the site; a pneumothorax may double in size in 12 minutes, whereas a small bowel obstruction may double in 120 minutes (Eger, 1974). This 10-fold difference

in the rate of expansion is determined in part by the reduction in (mural) blood flow to the bowel as the gas volume within the lumen expands. The same limitation of blood flow does not occur with a pneumothorax. Other cavities that may expand in the presence of nitrous oxide include the middle ear, gas within the ocular globe, and CNS air from a pneumoencephalogram. In situations where oxygenation (either inspired oxygen concentration or tissue oxygenation) must be maximized, the use of nitrous oxide, particularly in concentrations in excess of 50%, must be judiciously reviewed. The potency of nitrous oxide is affected by barometric pressure, being less effective at high altitude than at sea level or below.

Once believed to be entirely nontoxic, nitrous oxide has aroused increasing suspicion of cellular and atmospheric toxicity on several counts. Lymphocyte depression, miscarriage (first trimester), cancer, defects in spermatogenesis, and apoptosis have raised concerns about health risks after prolonged exposure (Brodsky et al., 1984; Rowland et al., 1995; Jevtovic-Todorovic et al., 2003). The half-life of nitrous oxide, an oxygen-free radical scavenger, in the troposphere is approximately 150 years, compared with the half-lives of the polyhalogenated inhalational anesthetics, which have tropospheric half-lives of 5 to 10 years. Although less than 5% of the nitrous oxide released into the atmosphere originates from medical sources, limiting the waste of nitrous oxide through the use of low fresh gas flows and smoke stack scrubbers curbs the depletion of the ozone layer. In infants the expansion of bowel can make abdominal surgery technically difficult. Many surgeons prefer nitrous oxide to be avoided in laparoscopic and laparotomy procedures. Nitrous oxide should be discontinued if bowel expansion becomes problematic or is likely to be problematic (Orhan-Sungur et al., 2005).

Nitrous oxide and xenon are odorless, whereas the halogenated agents all have distinct odors. Desflurane and isoflurane are significantly more pungent than halothane or sevoflurane. Therefore, inhalational induction in a child is considerably more acceptable with sevoflurane or halothane.

TABLE 7-19. The Pharmacology and Solubility of Inhalational Anesthetics

	Halothane	Isoflurane	Sevoflurane	Desflurane	Nitrous Oxide	Xenon

MAC in a 2 year old (%)	0.97	1.60	2.6	8.73	Not known	Not known

Pharmacokinetics

Many principles of pharmacokinetics are common between the inhalation and intravenous anesthetics, but there are some subtle differences. With inhalation agents, differences in partial pressure drive the agent across tissues rather than concentration gradients. For intravenous agents, central compartment (blood) concentrations can change directly as more drug is delivered. Changing inspired partial pressure with inhalation anesthetics has a more indirect effect on the central compartment because of the differences between inspired and alveolar partial pressures. Similarly, the elimination of inhalational agent through the lung also adds a layer of complexity. In spite of these differences, multicompartmental modeling and the concept of effect-site concentration can be applied to both inhalational and intravenous agents.

Wash-in is the uptake and wash-out is the elimination of inhalation anesthetics through the lung. Wash-in is often summarized as the increase over time in the alveolar fraction (F_A) over inspired fraction (F_I) of the agent (F_A/F_I). The F_A is important, because it approximates partial pressure in the blood and because it is measured clinically as the end-tidal concentration.

Wash-In

The F_A is determined largely by the inspired concentration, the circuit characteristics such as the degree of mixing between fresh and exhaled gas, the total fresh gas flow, and the dead space in the circuit. The rate of rise of F_A/F_I is determined by the ratio of alveolar ventilation compared with functional residual capacity, the solubility of the agent in blood, the cardiac output (total perfusion of the lungs), and the gradient of partial pressure of inhalation agent between the alveolus and the pulmonary arterial blood. More soluble agents have a slower wash-in, and lower ventilation itself also results in a slower wash-in (Fig. 7-38). Wash-in of the more soluble agents is also affected to a greater degree by ventilation than is wash-in of less soluble anesthetics (Figs. 7-39 and 7-40). For example, changing ventilation has little effect on wash-in of highly blood-insoluble agents such as nitrous oxide but a substantial effect on wash-in of more blood-soluble agents such as halothane (Eger, 1974). As cardiac output increases, wash-in decreases as the agent is removed more rapidly from the alveolus. Once again the effect changes with solubility, with a greater effect seen in more soluble agents (Eger, 1974). Lastly, wash-in is faster with a lower gradient of partial pressure between alveolus and mixed venous blood (pulmonary arterial blood). In other words, if mixed venous partial pressures are very low and alveolar pressures are high, then wash-in is slower.

The pulmonary arterial partial pressure of the inhalation agent is determined by the redistribution of the agent into the body tissues. This redistribution can be modeled like any other pharmacokinetic system, with the blood being the central compartment and any number of additional peripheral compartments that correlate to organ groups that are rich, moderate, and poor with vessels. In the classic model of compartments grouped by vascular richness, the rate of redistribution to peripheral compartments is determined by the blood flow, tissue and blood solubility, and volume of the compartments. The effect-site partial pressure can also be modeled along with the K_{eo} .

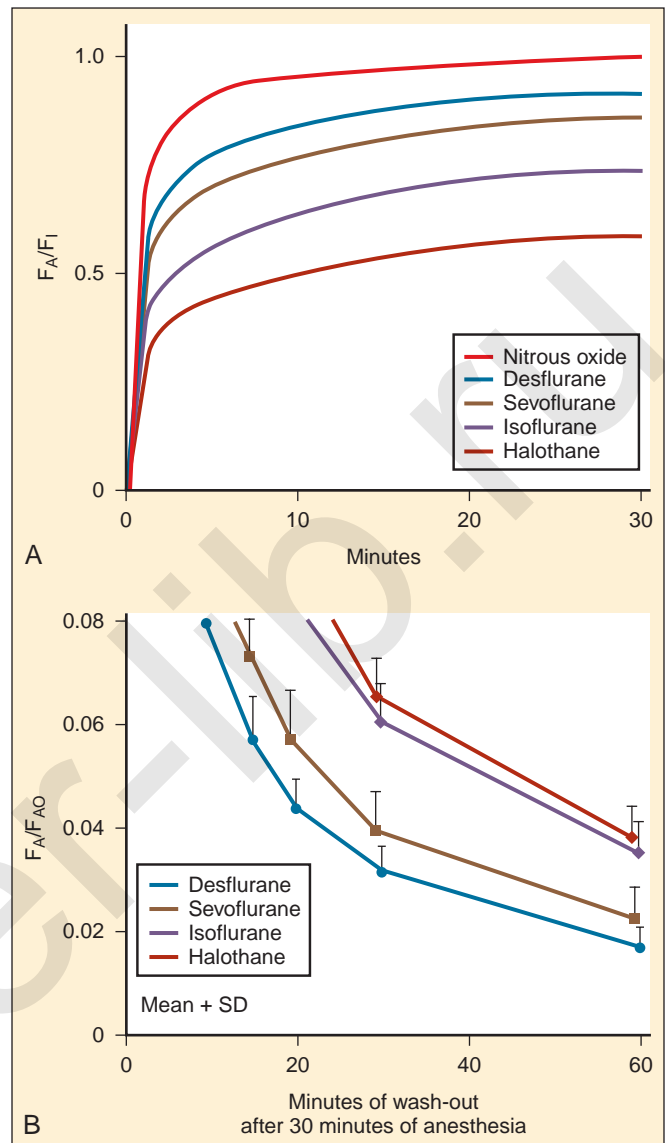

FIGURE 7-38. A, In unstimulated human volunteers, the increase in the alveolar concentration (F_A) toward the inspired concentration (F_I) is more rapid with the least soluble potent inhaled anesthetic (desflurane) and slowest with the most soluble potent inhaled anesthetic (halothane). Only nitrous oxide has a more rapid increase in F_A/F_I than desflurane. Nitrous oxide has a still more rapid increase because of its low solubility in blood and tissues and because of the employment of a greater inspired concentration (i.e., its rise is influenced by the concentration effect). **B**, Elimination, as defined by the decrease in alveolar concentration relative to the last alveolar concentration found during anesthesia (F_{AO}), is most rapid with desflurane, less rapid with sevoflurane, and slowest with isoflurane and halothane. Despite its greater solubility, the decrease with halothane is as rapid as the decrease with isoflurane, because halothane is metabolized and thus is cleared from the body by both the lungs and liver, whereas isoflurane is cleared only by the lungs.

Right to-left shunting of blood influences the relationship between wash-in and the systemic arterial partial pressure of the inhalational anesthetic. Again, the influence of shunt varies with blood-gas solubility. Right-to-left shunting has a greater influence with a less soluble agent than with a more soluble

■ **FIGURE 7-39.** The alveolar concentration of anesthetic/ concentration of inspired anesthetic (F_A/F_I ratio) rises more rapidly if ventilation is increased. Solubility modifies this impact of ventilation; the effect on the anesthetizing partial pressure is greatest with the most soluble anesthetic (ether) and least with the least soluble anesthetic (nitrous oxide). (Modified from *Eger Et II: Ventilation, circulation, and uptake*. In *Eger Et II*, editor: Anesthetic uptake and action, Baltimore, 1974, Williams & Wilkins.)

■ **FIGURE 7-40.** If unopposed by a concomitant increase in ventilation, an increase in cardiac output decreases alveolar anesthetic concentration by augmenting uptake. The resulting alveolar anesthetic change is greatest with the most soluble anesthetic. F_A/F_I is the ratio of alveolar concentration of anesthetic to the concentration of inspired anesthetic. (Modified from *Eger Et II: Ventilation, circulation, and uptake*. In *Eger Et II*, editor: Anesthetic uptake and action, Baltimore, 1974, Williams & Wilkins.)

agent (Fig. 7-41). Thus, in principle for sevoflurane, presence of congenital cyanotic heart disease would slow the onset of anesthesia, whereas if halothane were used the effect of the shunt would be less. Although in theory such shunts may indeed slow wash-in, this is of questionable clinical relevance because the children with shunts may have many factors that can influence induction technique and choice of anesthetic.

Wash-in changes with age. Wash-in is faster in infants than in adults and older children (Fig. 7-42) (Salanitre and Rackow, 1969; Steward and Creighton, 1978; Brandom et al., 1983a; Gallagher and Black, 1985). All reasons for these changes are not completely understood, but the following explanations are included:

- Infants have greater ventilation relative to functional residual capacity (5:1 in neonates and 1.5:1 in adults).
- Agents in neonatal blood have less solubility than in adult blood (Lerman et al., 1984).
- There are different cardiac output and different redistribution of agents from the central compartment in neonates (movement of agent blood into peripheral tissues). Even though neonates have relatively large cardiac output, relatively more is initially distributed to tissues with

less agent solubility and consequently less initial uptake of agent peripherally, leading to greater pulmonary arterial partial pressures and thereby increasing wash-in.

- Total tissue solubility is generally less in infants (Lerman et al., 1986). This leads to a faster rise in pulmonary arterial pressures, as previously described. This change with age may be the result of greater water content in neonates and less protein and lipid. This difference in solubility is the most apparent for halothane.

The effect of age on wash-in varies between inhalational anesthetics. The influence of age is least for less soluble agents such as sevoflurane and desflurane.

Although there are good data describing the faster wash-in in infants, there are fewer data describing in detail how fast concentrations rise in the brain compared with the blood. For halothane, modeling has predicated faster rises in brain and myocardium for infants compared with adults (Fig. 7-43) (Brandom et al., 1983a). This modeling uses the classic model of pharmacokinetics. The time constant (τ) for equilibrium between blood and brain can be roughly estimated from the brain volume, brain-blood solubility, and blood flow. If blood flow to the brain is 50 mL/min per 100 g, and the brain-blood

FIGURE 7-41. When no ventilation-perfusion abnormalities exist, the alveolar (P_A or P_{ET}) and arterial partial pressures rise together (brown lines) toward the inspired partial pressure (P_i). When 50% of the cardiac output is shunted through the lungs, the rate of rise of the end-tidal partial pressure (blue lines) is accelerated, whereas the rate of rise of the arterial partial pressure (purple lines) is retarded. The greatest retardation is found with the least soluble anesthetic, cyclopropane. (From Eger *Et al*, editor: Anesthetic uptake and action, Baltimore, 1974, Williams & Wilkins.)

FIGURE 7-42. The observed ratio of expired to inspired halothane (F_E/F_I) in infants demonstrates their more rapid uptake of halothane compared with adults. Blue circles, Infant observed (mean \pm SD); blue line, infant predicted; brown circles, adult observed (mean \pm SD); brown line, adult predicted. Predicted curves generated from a computerized model. (Data from Sechzer PH et al.: *Anesthesiology* 24:779, 1963; Eger *Et al* et al.: *Anesthesiology* 35:365, 1971a; International Anesthesia Research Society; Brandom BW et al.: Uptake and distribution of halothane in infants: in vivo measurements and computer simulations, *Anesth Analg* 62[4]:404, 1983.)

solubility is 2, then τ equals 4 minutes. Given that three time constants achieve 95% equilibrium, the total time to achieve equilibrium equals 12 minutes. If in neonates the solubility is only 1, then $\tau = 2$ minutes and 95% equilibrium occurs in 6 minutes. It may be important to note that in such classic models there is an assumption that there is no delay between brain concentration and anesthetic effect. This assumption may not always be valid, because an anesthetic effect such as loss of consciousness involves complex neural networks that may themselves have some time constants.

There are few data describing the $t_{1/2}K_{eo}$ constants for inhalational anesthetics. In one study, Fuentes et al. (2008) describe a decreased $t_{1/2}K_{eo}$ for sevoflurane in children compared with that in adults. This fits with the predicted results in the modeling mentioned previously. There are no data yet for the $t_{1/2}K_{eo}$ in children who are younger than 3 years of age. This lack of information is important, because anesthesiologists monitor F_A with end-tidal gas analysis but have no direct way of monitoring effect-site concentration, so any age-dependent difference in $t_{1/2}K_{eo}$ would influence the lag between observed end-tidal concentration and targeted clinical effect.

In summary, small children have a faster induction because of both faster wash-in and shorter $t_{1/2}K_{eo}$. Clinically, a rapid inhalational induction is also facilitated by using a high F_I (overpressure). The maximum concentration that can be delivered varies between agents depending on the maximum incorporated into the design of the vaporizer. Halothane can be administered at up

■ **FIGURE 7-43.** **A**, Predicted concentration of halothane in the brain. Values were derived from a computerized model of anesthetic uptake and distribution. **B**, Predicted concentration of halothane in the heart. (From Brandom BW et al.: *Uptake and distribution of halothane in infants: in vivo measurements and computer simulations*, *Anesth Analg* 62[4]:404, 1983.)

to 5%, whereas sevoflurane can be given at up to 8% (although some vaporizers restrict the maximum sevoflurane concentration to 5% to 7%). Halothane, however, is more than three times as potent as sevoflurane; therefore, halothane vaporizers can deliver more multiples of MAC. Even though sevoflurane may have a faster wash-in than halothane, if 5% halothane is delivered, it will have faster clinical effect than 8% sevoflurane. Because halothane has significant toxic cardiac effects, 5% halothane may quickly lead to cardiovascular collapse.

Wash-Out

When the inhalation anesthetic is discontinued, wash-out represents the decrease over time in F_A/F_I . Factors influencing wash-out are similar to those affecting wash-in (e.g., blood solubility, tissue solubility, and ventilation). In general, wash-out increases as blood solubility decreases. Wash-out may also be influenced by duration of anesthetic, reflecting redistribution from peripheral compartments. This influence is less for less-soluble agents. Comparing context sensitive half-times, there is little difference between sevoflurane, isoflurane, and desflurane after short anesthesia, whereas substantial changes occur after prolonged anesthesia. After 6 hours, decrement time is least for desflurane, followed by sevoflurane and then isoflurane (Bailey, 1997). The wash-out and decrement characteristics of halothane are more complex in that a substantial quantity of halothane is metabolized. Although the context-sensitive half-time for halothane may be higher than for other less soluble agents after short anesthesia, because a substantial amount of halothane is metabolized, its context-sensitive half-time does not rise substantially with time, so that after anesthesia of some hours' duration it is less than sevoflurane.

As many of the factors influencing wash-out are similar to those determining wash-in, it would be expected that age-related effects would be similar, with wash-out being faster in infants. However, no clinical studies have been performed to confirm this expectation. The effect of age on time to recovery from anesthesia may also be influenced by maturational changes in the neurophysiology of arousal and awakening.

Metabolism and Toxicity

Xenon, an inert element, is not metabolized. Nitrous oxide is also not metabolized to any appreciable degree by human tissue; however, in the presence of vitamin B₁₂, intestinal bacteria may reduce nitrous oxide to nitrogen. Amongst the halogenated inhalational anesthetics, desflurane is the least metabolized (0.02%), followed by isoflurane (0.2%), sevoflurane (5%), and halothane (25%) (Kharasch, 1995). The metabolism of isoflurane and desflurane is of no clinical significance (Box 7-2).

Sevoflurane is oxidized *in vivo* to inorganic fluoride ion and hexafluoroisopropanol. This is mainly through the CYP2E1 enzyme system (Kharasch, 1995). The activity of CYP2E1 is low at birth and then gradually increases during childhood (Vieira et al., 1996). Hexafluoroisopropanol is in turn conjugated to form glucuronide and excreted. No renal toxicity has been reported after sevoflurane anesthesia in spite of measured plasma fluoride levels greater than 50 mcm/L, the level associated with methoxyflurane and nephrotoxicity (Ebert et al., 1998a, 1998b).

Box 7-2 In Vivo Metabolism of Inhalational Anesthetics

INHALATIONAL AGENT; PERCENT METABOLIZED

Methoxyflurane; 50
Halothane; 20
Sevoflurane; 5
Enflurane; 2.4
Isoflurane; 0.2
Desflurane; 0.02

The lack of toxicity compared with methoxyflurane may be to the result of differences in where the metabolism occurs. With methoxyflurane, intrarenal metabolism is substantial, leading to high local concentrations of fluoride, whereas most metabolism of sevoflurane occurs in the liver rather than the kidneys, so intrarenal levels of fluorides are not as great.

Sevoflurane is absorbed by and degraded by alkaline hydrolysis in the presence of soda lime or baralyme into five compounds (A through E) (Hanaki et al., 1987; Morio et al., 1992). Only compound A is produced in significant concentrations, with levels of 20 to 40 ppm after several hours of 2.5% sevoflurane and a low fresh gas flow (Liu et al., 1991; Bitto and Ikeda, 1994; Frink et al., 1996). Alkaline hydrolysis is enhanced by increased temperatures, low water content, high concentration of sevoflurane, the use of baralyme rather than soda lime, or the use of new soda lime. Although 100 ppm of compound A has been found to cause renal damage in rats, no evidence for injury has been seen in humans. The production of compound A is less with newer CO₂ absorbents (Kharasch et al., 2002). In spite of the lack of human evidence, some authorities suggest that if sevoflurane is used in a closed circuit system with baralyme or soda lime, then the fresh gas flow should not be less than 2 liters/min.

Carbon monoxide (CO) can also be produced by sevoflurane, isoflurane, or desflurane in the presence of desiccated soda lime or baralyme, although only in minute and clinically inconsequential concentrations. The magnitude of CO production is desflurane > isoflurane > halothane and sevoflurane. Newer CO₂ absorbents that do not have the strong bases such as KOH or NaOH produce effectively no CO (Kharasch et al., 2002).

Potency

The potency of inhaled agents is defined in terms of MAC. The MAC at which 50% of patients do not move on skin incision is termed *1 MAC*. MAC varies between inhalation anesthetics and is generally inversely related to lipid solubility. Another general rule is that MAC is additive; i.e., 0.5 MAC of sevoflurane delivered with 0.5 MAC of isoflurane is equivalent to 1 MAC of isoflurane. In children there are exceptions to the rule; notably, MAC for nitrous oxide and halothane are additive, but MAC is less than additive for both nitrous oxide with sevoflurane and nitrous oxide with desflurane (Fisher and Zwass, 1992; Lerman et al., 1994).

MAC has also been determined in terms of the concentration at which 50% of subjects respond to other forms of stimuli, such as endotracheal intubation (MAC_{INT}), laryngeal mask airway insertion (MAC_{LMA}), and endotracheal extubation (MAC_{EXT}) and in terms of concentration at which 50% of subjects have other types of responses for defined stimuli, such as hemodynamic response to pain (MAC_{BAR}) or awakening (MAC_{AWAKE}). MAC_{INT} is usually 50% higher than MAC, whereas MAC_{LMA} is similar to MAC (Inomata et al., 1994; Kihara et al., 2003). MAC_{BAR} is approximately 30% greater than MAC. MAC_{EXT} is approximately 25% less than MAC, whereas MAC_{AWAKE} for most inhalational anesthetics is about 30% of MAC (Cranfield and Bromley, 1997; Inomata et al., 1998; Kihara et al., 2000). These relationships are often agent dependent; e.g., MAC_{AWAKE} for halothane and nitrous oxide is relatively high at 0.5 MAC (Stoelting et al., 1970; Gaumann et al., 1992). MAC and MAC_{BAR} may be significantly reduced by the addition of antinociceptive agents such as opioids (Katoh et al., 1999). In contrast, MAC_{AWAKE} is less affected by these agents (Katoh et al., 1993a, 1993b).

In clinical practice, anesthesia is given to guarantee that nearly all patients do not respond, so indeed we are far more interested in MAC at which 95% or 99% of subjects do not respond. In spite of this most MAC studies define MAC at 50% response. MAC is also determined for a short skin incision. A typical surgery involves a wide variety of stimuli; some are greater than that used to determine MAC, and many are smaller. Finally, when considering MAC studies it is important to consider the certainty (standard error or 95% confidence interval) around the estimates of MAC. The degree of uncertainty in MAC at 50% and the uncertainty in how to relate MAC at 50% to MAC at 95% make clinical interpretation of MAC data very difficult. This is particularly relevant to children, for whom studies are relatively few.

MAC changes with age (Fig. 7-44 and Table 7-20) (Lerman et al., 1983; Cameron et al., 1984; LeDez and Lerman, 1987; Murray et al., 1991; Taylor and Lerman, 1991; Katoh and Ikeda, 1992; Mapleson, 1996; Nickalls and Mapleson, 2003). In general, MAC rises during the neonatal period to peak in infancy and then declines throughout life, reaching the lowest values in old age. The MAC for sevoflurane is somewhat different. With sevoflurane the MAC the peak occurs in neonates and is therefore not less than it is infants (Lerman et al., 1994). It is not known exactly why MAC changes with age. The MAC for xenon and nitrous oxide has not been determined in children.

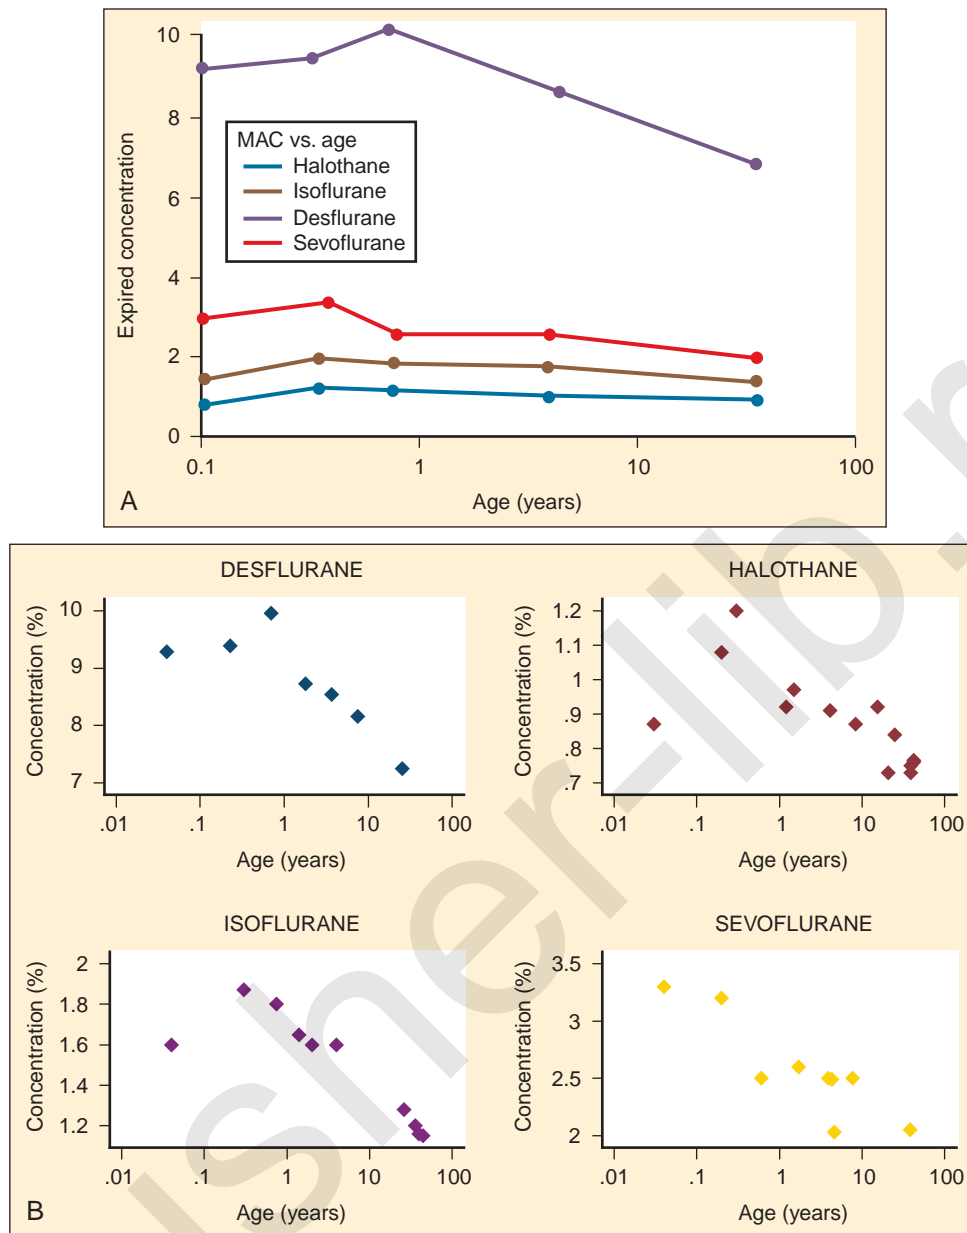

Although studies are few, MAC_{INT}, MAC_{LMA}, MAC_{EXT}, MAC_{BAR}, and MAC_{AWAKE} have a similar relationship to MAC in children (Katoh et al., 1993a, 1993b; Inomata et al., 1994, 1998; Cranfield and Bromley, 1997; Kihara et al., 2003). There is some evidence that MAC_{AWAKE} in children is relatively less in small children (Davidson et al., 2008a). Although this is consistent with animal data, these studies need to be interpreted with caution given the difficulty of measuring wakefulness in small children.

Effects on Systems and Side Effects

Cardiovascular System

Inhalational anesthetics affect the cardiovascular system through many different and often linked mechanisms. They may have direct effects on myocardial contractility, cardiac conduction, or vascular smooth muscle, or there may be indirect activity via autonomic, neurohumoral, or cardiovascular reflex systems. The responses in children may differ from those in adults because of differences in maturation and differences in patterns of coexisting pathology. The contractility of neonatal myocardium is more sensitive to inhalational anesthetics in comparison with adult myocardium, resulting in a greater decrease in contractility (Rao et al., 1986; Krane and Su, 1987; Murat et al., 1990). This effect may be related to a reduced amount of contractile elements in the neonatal myocardium or to differences in the functional maturity of the sarcoplasmic reticulum and calcium channel function.

In children, halothane, isoflurane, desflurane, and sevoflurane all decrease systemic blood pressure in a dose-dependent way. The percentage of decrease in blood pressure compared with blood pressure in the nonanesthetized state is greater in infants than it is in older children. One MAC of sevoflurane results in about a 20% to 30% reduction in systolic blood pressure in neonates and infants, compared with a reduction of about a 10%

■ **FIGURE 7-44.** The MACs of four commonly used inhaled anesthetics are plotted vs. age. Note that MAC is highest in infants 3 to 6 months of age. The reasons for this are not clear. (From Coté CJ: *Pediatric anesthesia*. In: Miller RD, Eriksson LI, Fleisher LA, et al: *Miller's anesthesia*, ed 7, Philadelphia, 2010, Churchill Livingstone.)

reduction in older children. Similarly, 1 MAC of desflurane results in about a 30% reduction in blood pressure in neonates and infants but only about a 20% reduction in older children (Taylor and Lerman, 1991; Lerman et al., 1994). Halothane has a substantially greater effect on myocardial contractility, whereas the other agents decrease blood pressure mainly by decreasing systemic vascular resistance (Wolf et al., 1986). Halothane also results in a dose-dependent decrease in heart rate, but the other agents cause a dose-dependent increase in heart rate. The effect of halothane on atrioventricular conduction is greater in infants than it is in adults and older children (Palmisano et al., 1994). Halothane also sensitizes the myocardium to catecholamines, increasing the risk of arrhythmias particularly during hypercarbia (Karl et al., 1983). Sevoflurane has no effect on atrioventricular conduction and does not change the sensitivity

of myocardium to catecholamines (Navarro et al., 1994). The cardiovascular effects of nitrous oxide have been incompletely studied in children. Xenon has minimal cardiovascular effects in adults but has not been studied specifically for its cardiovascular effects in children.

Respiratory System

Halothane, isoflurane, sevoflurane, and desflurane all depress ventilatory drive and response to CO_2 , resulting in a dose-dependent decrease in alveolar ventilation occurring mainly through reduced tidal volume (Murat et al., 1985, 1987; Brown et al., 1998). Respiratory rate tends to increase up to 1 MAC and then decreases at concentrations greater than 1 MAC. There is some evidence that halothane causes less depression of

TABLE 7-20. Minimum Alveolar Concentrations (MAC) of Volatile Anesthetics in Children

Parameter	MAC Anesthetic Concentration
Halothane	
Neonates	0.87
1-6 mo	1.20
15 ± 7 mo	0.94
Isoflurane	
Preterm <32 weeks' gestation	1.28
Preterm 32-37 weeks' gestation	1.41
7-30 mo	1.69
4-10 yr	1.69
Sevoflurane	
Neonates	3.3
1-6 mo	3.2
6-12 mo	2.5
1-3 yr	2.6
2-12 yr	2.3-2.5

3-5 yr	8.62
5-12 yr	7.98

From Mazoit JX: Pharmacokinetic/pharmacodynamic modeling of anesthetics in children: therapeutic implications, *Paediatr Drugs* 8(3):139, 2006.

respiratory drive than sevoflurane (Brown et al., 1998). Similarly all agents depress the tone of airway musculature, causing an increased risk of airway obstruction and there is some suggestion that halothane may once again cause less depression.

Halothane, isoflurane, and sevoflurane are all bronchodilators (Rooke and Su, 1993). Whereas sevoflurane improves airway and respiratory mechanics in children with airway sensitivity, desflurane causes worsening mechanics (von Ungern-Sternberg et al., 2008). Sevoflurane and halothane are minimally irritating to the airways, but isoflurane, and particularly desflurane, are more irritating and pungent. Induction with desflurane is associated with a substantial risk of airway complications; however, extubation after desflurane anesthesia is not associated with a high rate of complications (Taylor and Lerman, 1991, 1992; Fisher and Zwass, 1992; Zwass et al., 1992; Cranfield and Bromley, 1997). Even though sevoflurane is a minimal irritant, in some measures of airway irritability it is still more irritating than propofol anesthesia (Oberer et al., 2005).

Xenon is odorless and nonirritating to the airways, but it has a density of 5.9 g/L compared with 1.5 g/L for nitrous oxide and 1 g/L for air. The greater density can result in increased work of breathing. This may be clinically significant in neonates.

Central Nervous System

In children, the influence of inhalational anesthetics on the cerebral vasculature is complex and incompletely studied (Szabo et al., 2009). All inhalational agents depress the CNS and reduce cerebral metabolic rate as measured by the cerebral metabolic rate for oxygen (CMRO₂). Agents may also have direct effects on the cerebral vascular tone both directly and indirectly through alterations to autoregulation and responsiveness to CO₂. During inhalation, cerebral blood flow (CBF) during anesthesia and hence cerebral blood volume and intracranial pressure, are thus determined by the direct effect on cerebral vascular tone, the CMRO₂, the capacity for autoregulation, and the cerebral perfusion pressure. All of these can be influenced by inhalational anesthetics to differing degrees, and hence the action of inhalational anesthetics on CBF is varied and difficult to predict. In general, an ideal agent would reduce CMRO₂ with a matched decrease in CBF and minimal effect on autoregulation or responsiveness to CO₂.

All volatile agents are direct cerebral vasodilators, with halothane and desflurane being the most potent and sevoflurane the least potent (Matta et al., 1999; Bedforth et al., 2000; Fairgrieve et al., 2003; Luginbuehl et al., 2003; Sponheim et al., 2003; Barlow et al., 2004). Children may have an increased sensitivity to the vasodilation of inhalational anesthetics (Luginbuehl et al., 2003). Most inhalational anesthetics agents decrease CMRO₂. The decrease in CMRO₂ is greatest with isoflurane and sevoflurane, and least with halothane (Oshima et al., 2003). Considering the effect of the agent on CMRO₂ and direct effects on the vasculature, the total CBF is greatest with halothane, followed by desflurane, isoflurane, and then sevoflurane. The effect is dose-dependent. With isoflurane and sevoflurane there is minimal change in CBF at less than 1 MAC, and any small rise that occurs can be overcome with very mild hyperventilation (Leon and Bissonnette, 1991). Similarly, at less than 1 MAC, isoflurane and sevoflurane have minimal effects on autoregulation and responsiveness to CO₂ (Fairgrieve et al., 2003; Vavilala et al., 2003; McCulloch et al., 2005; Wong et al., 2006).

Nitrous oxide increases CBF and CMRO₂ and impairs autoregulation. It is therefore generally avoided in children at risk of impaired cerebral perfusion (Bedforth et al., 1999; Girling et al., 1999; Rowney et al., 2004). The effect of xenon on cerebral vasculature has been incompletely studied in adults, and there are no studies in children. There is some evidence to suggest xenon has a similar effect as other inhalational anesthetics (Laitio et al., 2009).

Inhalational anesthetics produce reproducible and dose-dependent changes in the EEG. Low concentrations result in an increase in power, especially in the higher frequencies. Increasing concentrations result in a gradual shift of power to the lower frequencies and a decrease in total power. High doses result in burst suppression and an isoelectric EEG. The shifts in frequencies and power differ between agents, with halothane and nitrous oxide rarely exhibiting burst suppression. In older children the EEG patterns are similar to those of adults, but in infants there are significant differences. Infants have substantially lower total power, less obvious shifts in frequency with dose, and greater variability in the time domain (Davidson et al., 2008a).

There are several commercially available processed EEG devices that use the EEG to measure anesthesia depth. Several studies have shown that in older children the indices derived

by these devices correlate with the doses of sevoflurane and isoflurane, and they have some capacity to differentiate conscious states (Davidson, 2006). The indices derived from these devices do not correlate well to concentration of nitrous oxide and xenon, and at 1 MAC they show different values for halothane than for isoflurane or sevoflurane (Davidson and Czarnecki, 2004). In infants the performance of these EEG-derived depth monitors is significantly worse, and they are not recommended for use in infants (Davidson et al., 2005). Although EEG-derived anesthesia depth monitor indices correlate with the dose of anesthesia, there are only a few studies investigating their usefulness in clinical practice in children. These studies have generally found that BIS-guided anesthesia results in slightly lower agent consumption, shorter awakening times, and slightly faster recovery (Bannister et al., 2001; Messieha et al., 2004, 2005). Similar modest differences have been demonstrated for propofol anesthesia (Weber et al., 2005a, 2005b). They have not been shown to reduce awareness in children.

There is great controversy surrounding epileptiform activity and sevoflurane in children. Spiking has been reported by several authors during induction with sevoflurane (Yli-Hankala et al., 1999; Vakkuri et al., 2001; Sonkajärvi et al., 2009). The phenomenon is poorly understood and may be associated with clinical signs of seizures such as myoclonic activity (Voss et al., 2008). There is no evidence to suggest a link between these EEG findings and any adverse postanesthesia outcome, so the clinical significance of unusual or spiking activity during sevoflurane anesthesia is unknown. To limit epileptiform activity, some recommend limiting the inspired concentration of sevoflurane to less than 6%. Note that limiting inspired sevoflurane concentration in this way may only have an indirect effect on limiting cortical concentration caused by wash-in and the time taken to achieve equilibrium with effect site. Similarly, any limitation in inspired sevoflurane concentration and overpressure should be accompanied by increased care that time is taken to achieve equilibrium to avoid the complications of inadequate anesthesia. Although sevoflurane does increase spiking in patients with epilepsy, there is no evidence that sevoflurane increases the risk of adverse outcome in children with epilepsy, and opinion is divided as to whether or not sevoflurane should be avoided in children with epilepsy (Kurita et al., 2005).

Other Side Effects

Malignant Hyperthermia

Halothane, isoflurane, sevoflurane, and desflurane may all trigger malignant hyperthermia in susceptible individuals, including children. Xenon and nitrous oxide are thought not to trigger malignant hypothermia (see Chapter 37, Malignant Hyperthermia).

Nitrous Oxide Toxicity

Nitrous oxide can oxidize vitamin B₁₂ and hence inhibit its coenzyme function. This may reduce the activity of methionine synthase, which produces methionine from homocysteine, which in turn may impair DNA synthesis. The clinical relevance of this toxicity is unlikely to be relevant after only brief exposure.

Hepatotoxicity

Halothane, isoflurane, sevoflurane, and desflurane have all been associated with transient hepatic dysfunction and raised transaminase enzymes in adults, although the evidence for a causal link is particularly poor for sevoflurane and desflurane. The mechanism of hepatic failure or “halothane hepatitis” is unclear, but it may be the result of an immunologic response to a metabolite. This metabolite is not a product of the other inhalation anesthetics. Although controversial, there is evidence to suggest “halothane hepatitis” can occur in children (Kenna et al., 1987).

Properties of Specific Inhaled Agents

Sevoflurane

Sevoflurane is a polyfluorinated methyl isopropyl ether anesthetic that is the first ether anesthetic to be widely used for the induction of anesthesia in children. Its low blood solubility, half that of isoflurane, speeds the equilibration of alveolar and inspired anesthetic partial pressures (Fig. 7-38). However, the tissue and blood solubilities of sevoflurane and isoflurane in the vessel-rich group (brain, heart, liver, kidneys, and endocrine glands), muscle, and fat groups are indistinguishable. Because the wash-in of inhalational anesthetics is increased by use of the overpressure technique, these physicochemical differences affect the wash-in of the anesthetics to a lesser extent than they do the rate of wash-out and the rate of emergence from anesthesia. In terms of the pharmacokinetics of inhaled anesthetics, changes in alveolar ventilation and cardiac output affect the wash-in of more soluble anesthetics (halothane and methoxyflurane) more than that of the less soluble anesthetic agents (sevoflurane and desflurane) (Eger, 1974). In contrast, increases in the right-to-left shunt (as in an intrapulmonary or intracardiac shunt) affect the wash-in of the less soluble anesthetics (sevoflurane) compared with the more soluble anesthetics (halothane and methoxyflurane) (Lerman, 2002). Because of the low blood and tissue solubilities of sevoflurane, its elimination in infants and children is rapid.

Sevoflurane is a far less potent anesthetic than isoflurane and halothane, as reflected by the MAC of sevoflurane. The MAC of sevoflurane is twice that of isoflurane and three times that of halothane (Lerman et al., 1994). The relationship between age (in the pediatric range) and the MAC of sevoflurane differs from the relationships for isoflurane and halothane in two respects. First, the MAC of sevoflurane does not increase steadily as age decreases, and second, the contribution of nitrous oxide to the MAC of sevoflurane in children is less than it is for halothane. MAC of sevoflurane in neonates and infants younger than 6 months (3.2%) and in infants older than 6 months and children up to 12 years (2.5%) is constant. Why the MAC of sevoflurane does not increase as age decreases as it does with the other inhalational anesthetics is unclear. Although nitrous oxide reduces the MAC of inhalational anesthetics in proportion to its concentration, the same does not hold true for sevoflurane in children. In the case of sevoflurane in children aged 1 to 3 years, nitrous oxide (inspired concentration, 60%) decreases the MAC of sevoflurane by only 25%. The explanation for the blunted effect of nitrous oxide on the MAC of sevoflurane in children also remains unclear.

Sevoflurane is unique among the currently used ether anesthetics in that in unpremedicated children, it is well tolerated when administered for induction of anesthesia, even without nitrous oxide. The incidences of breath holding, coughing, laryngospasm, and desaturation during induction of anesthesia with sevoflurane and halothane are few and similar with the two anesthetics (Black, 1996; Lerman et al., 1996). However, induction of anesthesia with sevoflurane is not always uneventful. Although exceedingly rare, EEG and epileptiform activities were reported during inhalational inductions with sevoflurane in children (Komatsu et al., 1994; Vakkuri et al., 2001; Jaaskelainen et al., 2003). Investigations failed to identify a cause for these episodes (Constant et al., 1999). Rare instances of twitching of the face or limb usually dissipate rapidly as the depth of anesthesia is increased. If the inspired concentration of sevoflurane is increased slowly (i.e., in 0.5% to 1% increments every few breaths), a protracted excitement phase may ensue during the induction. This can be obviated by increasing the inspired concentration of sevoflurane very quickly, without inducing airway reflex responses. Administering 60% to 70% nitrous oxide for approximately 1 minute and then adding 8% (inspired concentration) sevoflurane to the nitrous oxide makes the induction rapid and smooth. Recall of the odor of sevoflurane is rare, and excitement during the induction of anesthesia is minimal. Other techniques for rapid induction of anesthesia in children with sevoflurane have included a single-breath (vital capacity) induction with 8% sevoflurane, which is 40% more rapid than a single-breath induction with 5% halothane (Agnor et al., 1998). Whichever technique is used to induce anesthesia, clinicians continue to be surprised by anesthetized children who withdrew on attempted cannulation of a vein. This results not from a flaw in the anesthetic, sevoflurane, but rather in the combination of its pharmacology and delivery. Compared with halothane, the modestly increased maximum vaporizer concentration of sevoflurane is overshadowed by the 250% greater MAC. This limits the alveolar concentration that can be achieved in the first few minutes of anesthesia. This may reduce the probability of circulatory depression during induction of anesthesia with sevoflurane, but it also prevents clinicians from inducing a deep level of anesthesia quickly and thereby preventing a response to stimulation.

Like halothane, sevoflurane is a potent respiratory depressant. At concentrations greater than 1.5 MAC, sevoflurane is a more potent respiratory depressant than halothane. Indeed, apnea may occur in the unstimulated child breathing 8% inspired sevoflurane. Premedication with midazolam or other medications may potentiate the respiratory depression with sevoflurane. After an inhalational induction with sevoflurane, spontaneous ventilation usually resumes after a brief period of apnea or manual ventilation of the lungs and a reduction in the inspired concentration of sevoflurane. Sevoflurane maintains cardiovascular homeostasis in infants and children. At 1 MAC for sevoflurane, heart rate is usually maintained in infants and children even when they are not pretreated with atropine, although rare instances of a slowing of the heart rate have been reported, particularly at concentrations exceeding 1 MAC (Lerman et al., 1994). Systolic pressure is usually reduced 20% to 25% from awake values. These responses to 1 MAC sevoflurane are similar to those after other inhalational anesthetics. Arrhythmias during sevoflurane anesthesia are uncommon; the incidence of arrhythmias during sevoflurane anesthesia after exogenous epinephrine is similar to that during isoflurane

anesthesia. In infants and children with congenital heart disease undergoing cardiac surgery, hypotension and desaturation in cyanotic children after sevoflurane anesthesia occurred less often than they did after halothane anesthesia (Russell et al., 2001). In parallel with the rapid elimination of sevoflurane, the recovery profile for sevoflurane is rapid compared with that for halothane. Transient agitation and involuntary movements during emergence from anesthesia have been reported. Emergence agitation occurs primarily in preschool-aged children, lasts 10 to 20 minutes, and is often self-limited. Although agitation has been attributed to pain, pain as the sole explanation was dispelled when agitation was noted in children after lower abdominal surgery with a working caudal block in situ and after sevoflurane for MRI procedures, where no pain occurs (Aono et al., 1997; Cravero et al., 2000). One of the most difficult problems has been defining emergence agitation, which could not previously be assessed with any scale or measurement (Sikich and Lerman, 2004). It is important to note that emergence agitation is not unique to sevoflurane; it also occurs after other anesthetic agents, including isoflurane and desflurane.

Sevoflurane is degraded both *in vivo* (to inorganic fluoride and hexafluoroisopropanol) and *in vitro* (via alkaline hydrolysis in the presence of soda lime or baralyme to five compounds (A through E) (Hanaki et al., 1987; Morio et al., 1992). *In vivo*, sevoflurane is metabolized by microsomal CYP IIE1 isozyme in both the liver and kidneys (Kharasch et al., 1995a, 1995b). The peak plasma concentration of inorganic fluoride is proportional to the duration of exposure to sevoflurane in children. However, there have been no instances of sevoflurane-induced nephrotoxicity after several million anesthetic procedures. Two plausible explanations for the absence of nephrotoxicity are the rapid elimination of sevoflurane and the small extent of intrarenal metabolism of sevoflurane, the putative source of inorganic fluoride-induced nephrotoxicity (Kharasch et al., 1995a). *In vitro*, sevoflurane is both absorbed and degraded in the presence of soda lime and baralyme, yielding only compound A in significant concentrations; up to 20 to 40 ppm in closed circuits in humans (Liu et al., 1991). Alkaline hydrolysis of sevoflurane is enhanced by high temperatures, decreased water content in the absorbent, increased inspired concentration of sevoflurane, and new absorbent. In infants and children, compound A concentrations during sevoflurane anesthesia in a closed circuit increase in parallel with increasing in age (Frink et al., 1996). In concentrations up to 100 ppm for 3 hours, compound A causes histopathologic changes in the kidneys of rats, although no evidence of histopathologic or pathophysiologic renal changes have been reported in humans (Gonsowski et al., 1994a, 1994b). In the presence of desiccated soda lime and baralyme, sevoflurane is degraded to only an extremely small extent to CO (Fang et al., 1995; Wissing et al., 2001). When both potassium hydroxide and sodium hydroxide are eliminated from the absorbent, sevoflurane produces only minute concentrations of CO (Murray et al., 1999; Versichelen et al., 2001). The combination of high-dose sevoflurane with desiccated baralyme has resulted in instances of extreme heat and fire within the absorbent canister (Previte et al., 2004; Wu et al., 2004; Dunning et al., 2007).

Desflurane

Desflurane is a potent polyfluorinated methyl ethyl ether anesthetic available for use in infants and children. The single substitution of a fluorine atom for a chlorine atom on the carbon

atom of isoflurane dramatically changes the physicochemical properties of this anesthetic (Table 7-19). Blood-gas and tissue-blood solubilities are only fractions of those of halothane and isoflurane (Yasuda et al., 1989). As a result, the wash-in of desflurane is the fastest of all of the available potent inhalational anesthetics (Fig. 7-38). As in the case of sevoflurane, changes in alveolar ventilation and cardiac output exert small effects on the pharmacokinetics of this anesthetic, whereas changes in right-to-left shunting exert a large effect (Eger, 1974; Lerman, 2002). Just as the wash-in of desflurane is extremely fast, the wash-out of desflurane is extremely rapid. Of the potent inhalational anesthetics, the elimination of desflurane is most rapid (Fig. 7-38) (Yasuda et al., 1991).

The MAC of desflurane in infants and children is least in neonates, increasing throughout infancy and reaching a zenith of 9.9% in infants aged 6 to 12 months. MAC decreases thereafter with increasing age through adolescence (Taylor and Lerman, 1991). Nitrous oxide (60%) decreases the MAC of desflurane by only 26% in children, an effect similar to that of sevoflurane (Fisher and Zwass, 1992).

Inhalational inductions with desflurane are not recommended because upper airway reflexes are often triggered (50% incidence of breath holding, 40% incidence of laryngospasm) (Taylor and Lerman, 1992; Zwass et al., 1992). If anesthesia is induced by either the intravenous or inhalational route, desflurane may be used to maintain anesthesia (Taylor and Lerman, 1992; Zwass et al., 1992). Like sevoflurane, desflurane maintains cardiovascular homeostasis at 1 MAC (Taylor and Lerman, 1991). At this concentration, heart rate and systolic blood pressure are depressed 20% to 25% compared with awake values (Taylor and Lerman, 1991). Arrhythmias and bradycardia are uncommon with this anesthetic.

The rate of recovery after desflurane anesthesia parallels the extremely rapid wash-out of this anesthetic (Taylor and Lerman, 1992; Davis et al., 1994). Early experience with the rapid recovery after discontinuation of desflurane resulted in the precipitous onset of excruciating surgical pain. A strategy to prevent pain on emergence must be considered and the intervention instituted before discontinuation of this anesthetic.

Desflurane resists metabolism both *in vivo* (0.02%) and *in vitro* (in the presence of soda lime and baralyme) (Smiley et al., 1991). *In vivo*, insignificant blood concentrations of inorganic fluoride are produced after desflurane anesthesia. However, *in vitro* degradation of desflurane may be problematic. If the CO₂ absorbent becomes desiccated and is incubated with desflurane, then desflurane may react with the constituents to release CO₂ into the inspired limb of the breathing circuit (Fang et al., 1995; Wissing et al., 2001). Other ether anesthetics, including isoflurane and enflurane, and all difluoromethyl ethyl ether anesthetics (including desflurane), undergo a similar path of degradation to CO in the presence of desiccated absorbent, albeit to a lesser extent than desflurane (Baxter et al., 1998). Absorbent becomes desiccated by circulating fresh gas through an absorbent canister for a prolonged period of time without a reservoir bag in place. In some anesthetic machines, this continuous fresh gas flow desiccates the absorbent by flowing retrograde through the canister, exiting where the reservoir bag usually is attached. Without the ability to detect CO in the breathing circuit, contamination of the breathing circuit with CO might present a serious risk to patients, particularly those anesthetized after the anesthetic machine has not been used for a prolonged period (i.e., Monday mornings). To preclude

this complication, the fresh gas flow should be discontinued when the anesthetic machine is not in use, the reservoir bag should never be removed from the canister, and most importantly, the anesthetic machine should be turned off when it is not in use. If there is a suspicion that the absorbent has been desiccated, the absorbent must be replaced before any anesthetic is administered. There are no guidelines for rehumidifying desiccated absorbents. Not all absorbents produce CO when they are exposed to the desflurane. Those absorbents that lack both potassium hydroxide and sodium hydroxide do not produce CO.

With a boiling point close to room temperature, a heated, pressurized vaporizer was developed to deliver a predictable concentration of desflurane. This vaporizer requires electrical current to maintain a predictable temperature and pressure that are independent of ambient conditions.

Isoflurane

The pharmacology of isoflurane is very similar to that of desflurane with a few exceptions. As mentioned, the chemical structure of isoflurane is identical to that of desflurane except that isoflurane has a chlorine atom instead of a fluoride atom on the carbon atom (Table 7-19). Because isoflurane is more soluble in blood and tissues than desflurane, the wash-in and wash-out of isoflurane are slower than those of desflurane (Fig. 7-38) (Yasuda et al., 1991). The MAC of isoflurane is between those of halothane and sevoflurane (Table 7-19) (Cameron et al., 1984).

Like desflurane, isoflurane triggers airway reflex responses during inhalational inductions and is not suited for this purpose. Although numerous attempts were made to ameliorate the airway responses to an inhalational induction, clinicians abandoned the notion of using it for this purpose. Isoflurane is used similarly to desflurane for the maintenance phase of anesthesia.

Once anesthesia is induced, whether the airway is instrumented or not, children and adults breathe isoflurane without difficulty. Similarly, they emerge from isoflurane anesthesia without difficulty.

Isoflurane, like desflurane, does not depress the circulation in children. In fact heart rate often increases during isoflurane anesthesia, and blood pressure is well maintained. Unlike in the adult, rapid increases in the inspired concentration of isoflurane do not trigger a central sympathetic (tachycardia and hypertension) response that requires intervention with an opioid or other agent.

The *in vivo* metabolism of isoflurane, 0.2%, yields small concentrations of inorganic fluoride in the blood without significant intrarenal production. Nephrotoxicity after isoflurane anesthesia is not a substantive risk. However, in the presence of desiccated soda lime and baralyme, isoflurane can produce CO.

Halothane

Halothane was the standard of practice with which all other inhalational anesthetics were compared until the introduction of sevoflurane. Halothane is the only nonether anesthetic that is used today, being an alkane in structure. The wash-in of halothane is the slowest of the currently used anesthetic agents because it is the most soluble (see Table 7-19). This means that the time to equilibration of inspired and alveolar (or brain) partial pressures of halothane is the greatest of the anesthetics.

Although this may be viewed as a safety factor, the potency of halothane is the strongest of the anesthetic agents. These two factors, together with the ability to deliver a maximum inspired concentration of 5% halothane with all vaporizers, resulted in numerous episodes of cardiorespiratory instability that included hypotension and bradycardia or arrhythmias. In particular, concern was expressed in the 1980s about the ability of neonates to tolerate halothane anesthesia because of the hemodynamic consequences. Based on the current understanding of the pharmacology of halothane, several conclusions may be made about the past experience with this anesthetic in pediatric anesthesia:

- The MAC for halothane in neonates is less than that in older infants.
- Halothane depresses both the circulation and respiration in infants and children.
- With the design of the vaporizer and given the potency of halothane, it is easier to overdose children with halothane than with other anesthetic agents.

Halothane is metabolized approximately 15% to 20% in humans. Immunologic responses, including hepatitis, have been documented after repeated halothane anesthesia, even in children (Kenna et al., 1987). With the declining use of this agent in clinical practice, it is unlikely to pose a serious threat to children.

LOCAL ANESTHETIC AGENTS

All local anesthetic agents in clinical use consist essentially of three parts tertiary amine and an aromatic ring linked by an intermediate chain. The tertiary amine is a weak base and is positively charged at physiologic pH. The intermediate chain contains either an ester or an amide. The substituted aromatic ring is lipophilic, whereas the positively charged tertiary-amine end is relatively hydrophilic (Fig. 7-45).

Local anesthetics are thus classified as either amino-esters (e.g., cocaine, tetracaine, chlorprocaine, and procaine) or amino-amides (e.g., lidocaine, bupivacaine, ropivacaine, and

levobupivacaine). Amino-amides are more commonly used in pediatric practice, and the pharmacology of these agents in pediatrics has been reviewed by Mazoit and Dalens (2004).

Physiochemical Properties

The potency and duration of action of local anesthetic agents are dependent on the lipophilicity of the local anesthetic molecule, the degree of ionization (pK_a), the pH of the preparation and of the tissue, the degree of protein binding, the intrinsic vasoconstrictor properties of the drug, and temperature (Heavner, 2007). Lipophilicity determines the affinity of the molecule for lipid membranes and increases the potency and the duration of action. Lipophilicity is increased by increasing the size of the alkyl substitution on the aromatic ring or on or near the tertiary amine (Heavner, 2007).

The pK_a of a drug is the hydrogen ion concentration (pH) at which 50% of the drug exists in its ionized hydrophilic form (i.e., in equilibrium with its un-ionized lipophilic form). All local anesthetic agents are weak bases. At physiologic pH, the lower the pK_a the greater the lipophilicity. The pH of the site where the local anesthetic is placed determines the degree of ionization and thus the activity of the drug. Sodium bicarbonate has been used clinically to increase the speed of onset by raising the pH of a local anesthetic solution by increasing the un-ionized fraction (lipophilicity).

Bupivacaine, mepivacaine, and ropivacaine—but not lidocaine—have an asymmetric carbon atom that allows these drugs to exist as different isomers or S- and R+ enantiomers. A racemic mixture contains equal amounts of the S- and R+ enantiomers. Bupivacaine is a racemic mixture of equimolar amounts of R+ bupivacaine and S- bupivacaine (Leone et al., 2008).

The pharmacokinetic properties of enantiomers are essentially the same, but their stereospecificity influences the protein binding and pharmacodynamics (Burm, 1994, 1997; Kremer et al., 1988). Ropivacaine and levobupivacaine are pure S- enantiomers that have less cardiac toxicity and a greater sensory motor differential (Bardsley et al., 1998; Mazoit et al., 2000; Leone et al., 2008). This differential effect is poorly understood but may be related to the length of spread along the nerve, to selective inhibition of the Na^+ and K^+ channels that are present in different proportions in different nerve types, or to preferential blockade of the tetrodotoxin-resistant sodium channels (Oda et al., 2000; Berde, 2004).

The intrinsic vasoconstrictor properties of a local anesthetic drug influence the initial rate of uptake from the site of injection into the central circulation (T_{max}) and the duration of action. It may also influence the peak plasma concentration (C_{max}). Some local anesthetic agents have a biphasic effect on the blood vessels, for example, ropivacaine at low concentrations vasoconstricts, but at higher concentration it has vasodilator effects.

Finally, the duration of action of local anesthetic agents is shorter in neonates and infants despite the use of larger weight-scaled doses for both central and peripheral nerve blockade (Berde, 2004). This may be because of age-related differences in the pharmacodynamic responses, the degree of myelination of the nerves that increases with age, spacing of the nodes of Ranvier, the length of nerve exposed, tissue barriers, and other factors including pharmacogenetic variation.

■ **FIGURE 7-45.** Structures of two local anesthetics, the aminoamide lidocaine and the aminoester procaine. In both drugs a hydrophobic aromatic group is joined to a more hydrophilic base, the tertiary amine, by an intermediate amide or ester bond. (From Coté CJ: *Pediatric anesthesia*. In: Miller RD, Eriksson LI, Fleisher LA, et al: *Miller's anesthesia*, ed 7, Philadelphia, 2010, Churchill Livingstone.)

Mechanisms of Action

Local anesthetics are potent reversible sodium channel blockers with marked stereospecificity that influences their action. They interfere with nerve cell membrane excitation and subsequent conduction of action potentials in excitable tissue. They bind to the inner vestibule of the voltage-gated sodium channel after passing through the cell membrane. Various subtypes of sodium channel exist that are tetrodotoxin sensitive or resistant in different nerve fibers (Baker and Wood, 2001; Heavner, 2007). Nerve fibers vary in their sensitivity to local anesthetic agents. Small myelinated axons, A γ motor and A δ sensory axons, are the most sensitive, followed by the large myelinated A α and A β fibers. The least susceptible are the slow conducting fibers, the small unmyelinated C fibers.

The local anesthetic agents enter the sodium channels in the “active” or “open” state and render them “inactive” or “closed.” The membrane is thus stabilized, and propagation of a depolarizing wave is prevented. The affinity of the local anesthetic drug to the sodium channel varies with the gating state of the channel. Their affinity is high when the sodium channel is open and activated (during sensory transmission, motor activity, or tachydysrhythmias of the myocardium), and the affinity is low at slow excitation rates or when the sodium channel is inactivated or closed (Heavner, 2007). Neonates have a higher heart rate than adults and may thus be more prone to myocardial toxicity. Hypoxia, acidosis, hypothermia, and electrolyte disorders increase the risk of toxicity (Freysz et al, 1989, 1993; Timour et al., 1990).

Local anesthetic agents also inhibit the K^{2P} channel, blocking repolarization and delaying recovery after depolarization. This effectively prolongs the action potential and adds to risk of toxicity (i.e., convulsions or dysrhythmias) (Kindler and Yost, 2005). The distribution of Na⁺ and K⁺ ions in the channel varies from one nerve type to another and may explain the differential blockade of sensory and motor nerves by individual local anesthetic agents (Kindler and Yost, 2005).

Local anesthetic agents may also have beneficial systemic actions on inflammatory cells and in chronic pain by interaction with G-protein receptors (Hollman et al., 2004).

Systemic Absorption

When local anesthetics are used to perform a nerve block they are injected into a specific space (e.g., spinal, caudal, or epidural) or location (e.g., peripheral nerve block, skin infiltration, topical). The speed of absorption is a function of the site of injection, the speed of injection, the amount and concentration of the local anesthetic injected, the intrinsic vasoconstrictor properties of the drug, the blood supply to the site, lipid solubility, absorption into the surrounding tissue, and the pH of the tissue.

Local diffusion into the nerve at the site of injection produces regional anesthesia. Diffusion into the bloodstream produces blood concentrations that can be measured. After a single shot injection, the rate of absorption and the volume of distribution determine the rate at which peak plasma levels are reached. Clearance has little impact, but on the other hand clearance is the major factor that impacts steady-state plasma concentrations during continuous infusions.

Highly vascular areas are more prone to rapid local anesthetic uptake and consequently, toxicity. The rate of absorption

is greatest from the intercostal space and trachea; intermediate from the caudal and epidural spaces and lowest following skin infiltration. The order of site absorption from highest to lowest is intercostal, intratracheal, caudal, epidural, brachial plexus, and subcutaneous.

Absorption from the epidural space is considered biphasic (McCann et al., 2001). The buffering properties of the epidural space are important, and the epidural fat acts as a store where the injected drug can accumulate. The slow release is responsible for a longer terminal half-life. Epidural fat in neonates and infants is less abundant, and the peak plasma concentration occurs earlier in this age group (Eyles et al., 1978).

The systemic effects of local anesthetics are a function of dose, rapidity of injection, site of injection, and ultimately the rate of rise and the plasma concentration reached. Toxic effects involving either the CNS or the heart are directly related to the free (unbound) drug concentration. In general, CNS toxicity occurs at lower plasma concentrations than cardiac toxicity in infants and young children.

Cardiac output also has an influence. A higher cardiac output increases the uptake, producing higher initial plasma concentrations and decreasing the duration of action. Ropivacaine is considered a better agent than bupivacaine for epidural infusions because the vasoconstrictor properties of ropivacaine slow the absorption of the drug into the blood, decreasing the peak plasma levels. Karmakar et al. (2002) have shown that after 2 mg/kg of either caudal ropivacaine or bupivacaine, ropivacaine undergoes slower systemic absorption from the caudal space, but the peak venous plasma concentrations are comparable.

Vasoconstrictors may also be used to reduce the absorption of local anesthetic into the systemic circulation. The efficacy of epinephrine varies with the patient’s age but is also dependent on the vascularity at the site of injection. Epinephrine prolongs the duration of bupivacaine and ropivacaine by approximately 50% in neonates, 25% in infants younger than 4 years old, and 10% in older children (Warner et al., 1987; Hansen et al., 2001). Epinephrine is usually diluted to various concentrations. [Box 7-3](#) is a quick reference guide for converting concentrations to mcg/mL.

Distribution

The volume of distribution is difficult to evaluate and is largely unknown in children. Pharmacokinetic analysis after extravascular injection is difficult. In conventional pharmacokinetic modeling it is assumed that elimination is longer than absorption and that the terminal phase occurs when absorption is almost totally completed (Mazoit and Dalens, 2004). If absorption is longer than elimination, such as when local anesthetic agents are injected extravascularly, the terminal half-life represents the complex

Box 7-3 Epinephrine Dilution and Conversion to mcg/mL

Epinephrine Dilution	mcg/mL
1:100,000	10
1:200,000	5
1:400,000	2.5
1:800,000	1.25

absorption process as well as elimination. It is thus impossible to accurately calculate the volume of distribution, but the total body clearance can be calculated accurately if sampling is long enough. A further confounding factor is that clearance also varies with time (Mazoit and Dalens, 2004).

Tissue binding is another important factor, because the local anesthetic agents are widely distributed outside the blood. Furthermore, the extracellular fluid volume in newborns and young infants is almost twice that of an adult. Theoretically, volume of distribution should be much larger in neonates and infants.

Protein binding and volume of distribution influence the C_{max} of a drug. The peak plasma C_{max} of ropivacaine is delayed in infants and children when compared with adults. The time to C_{max} decreases from 90 to 120 minutes in infants younger than 6 months of age to 30 minutes in adults and children older than 8 years of age.

In infants and children, the pharmacokinetics of ropivacaine has been reported after caudal, epidural, and ilioinguinal blocks (Hansen et al., 2000a, 2000b, 2001a; Lonnqvist et al., 2000; Wulf et al., 2000). Hansen et al. (2001a) showed that infants between the ages of 0 and 3 months have higher free ropivacaine concentrations than infants who are 3 to 12 months of age, and for both these groups of infants the free drug concentrations were within the concentrations reported for adults. However, Wulf et al. (2000) noted that infants had higher peak plasma concentrations than toddlers aged 1 to 5 years, with the peak concentration occurring at 60 minutes in both groups. In a dosing study of children 4 to 12 years of age, Bosenberg et al. (2001) noted that single-shot caudals in doses of 1 to 3 mg/kg resulted in peak plasma levels of free ropivacaine that increased proportionately with increasing doses.

The lungs may also influence the plasma levels. The lungs slow the rate of rise and influence the peak plasma concentration. The lung extraction ratio for amide local anesthetic agents is high (approximately 0.8), resulting in a difference between mixed venous and arterial concentrations. Infants with right-to-left cardiac shunts may therefore be at greater risk of toxicity. Bokesch et al. (1987) demonstrated higher plasma lidocaine levels in the systemic circulation in animals with right-to-left shunts.

Protein Binding

Amide local anesthetics are weak bases and are bound to serum proteins albumen and α_1 -acid glycoprotein (AAG). Protein binding ranges from 65% (lidocaine) to more than 95% (bupivacaine and ropivacaine). The binding properties of these proteins are very different. Albumen has a low affinity but greater capacity for local anesthetics than AAG, which has a high affinity but low capacity. Protein binding is pH dependent; metabolic or respiratory acidosis increases the free fraction, thereby increasing the risk of toxicity. Bilirubin also competes with amide drugs for albumen binding sites (Meunier et al., 2001).

Neonates and infants have lower AAG levels (approximately 0.2 to 0.3g/L) compared with children older than 1 year and adults (about 0.7 to 1 g/L). The free fraction of local anesthetics is therefore increased in neonates. In the first 24 to 48 hours after surgery or other inflammatory processes, however, the plasma level of AAG, an acute phase protein, rapidly increases (Kremer et al., 1988; Bosenberg et al., 2005). This effectively

lowers the free fraction, theoretically providing some protective effect. This effect may abate at approximately 48 hours.

Amide local anesthetics are also linearly bound to red cells (blood-plasma concentration ratio of about 0.60 to 0.85) (Tucker et al., 1970; Meunier et al., 2001). Although this only accounts for less than 20% to 30% of the total amount in blood, it may be relevant in term neonates, especially those with intrauterine growth retardation where the hematocrit may exceed 45% to 60% (Lonnqvist and Herngren, 1995).

Metabolism

The rate and route of metabolism vary with age. Amide local anesthetics are metabolized in the liver by the cytochrome P450 (CYP) enzyme system. The main CYP isoforms involved are CYP3A4 for lidocaine and bupivacaine and CYP1A2 for ropivacaine. These systems are immature at birth. CYP3A4 is partly replaced by CYP3A7 at birth and matures by 9 months. The intrinsic clearance of bupivacaine is only one third that of adults at 1 month of age, and two thirds at 6 months. The major metabolites are 2,6-pipecoloxylidide (PPX) for both bupivacaine and ropivacaine, with the addition of 3-hydroxy-ropivacaine for ropivacaine.

Ropivacaine metabolism also varies with age. Even though CYP1A2 is only fully mature at 3 years, the majority of ropivacaine (70%) is excreted as PPX, whereas 24% of ropivacaine is excreted unchanged by the kidneys at birth (Larsson et al., 1997). In early infancy, only 4% is excreted as 3-hydroxy-ropivacaine, the major metabolite in adults (Bosenberg et al., 2005).

With regard to the ester compounds, those derived from para-aminobenzoic acid (PABA; e.g., procaine, chlorprocaine, and tetracaine) undergo hydrolysis by esterases in the blood (plasma cholinesterase) or tissues. PABA undergoes hepatic biotransformation and clearance. PABA metabolites are thought to be responsible for the allergic reactions seen with this group of drugs. Because of its extremely short duration of action, chlorprocaine has been used primarily for continuous epidural techniques in infants and neonates. The use of tetracaine has generally been limited to spinal and topical anesthesia.

Clearance

Lidocaine has a high hepatic extraction ratio, and its clearance is dependent on hepatic blood flow (Tucker, 1986). In addition, the product of lidocaine metabolism monoethylglycine xylidine (MEGX) may inhibit the intrinsic enzyme involved with its degradation (Bax et al., 1985). MEGX is an active metabolite slightly less potent than lidocaine (Bax et al., 1985). Lidocaine has a longer elimination half-life and larger volume of distribution in children than in adults after either intratracheal or caudal anesthesia (Eyres et al., 1978; Ecoffey et al., 1984). Bupivacaine and ropivacaine have a relatively low hepatic extraction ratio. Protein binding and CYP enzyme activity affect drug clearance, which is low at birth, increasing throughout the first year of life (Mazoit, 1988; Lonnqvist et al., 2000; Hansen et al., 2001a, 2001b; Meunier et al., 2001).

Pharmacokinetic studies have demonstrated age-related differences in clearance between infants and children (Eyres et al., 1983; Ecoffey et al., 1985; Desparmet et al., 1987; Mazoit, 1988; Mazoit and Dalens, 2004). Clearance of bound and unbound

ropivacaine is lower in neonates (33 to 60 mL/min⁻¹ per kg⁻¹, compared with that of infants (160 to 220 mL/min⁻¹ per kg⁻¹ (Hansen, 2000a, 2000b; Lonnqvist et al., 2000; Rapp et al., 2004b; Bosenberg et al., 2005).

All studies of prolonged administration in children have assumed that clearance is unchanged during the whole period of the continuous infusion. In theory, after several hours the clearance of bupivacaine and ropivacaine decreases; this decrease is probably related to the decrease in free fraction, which is related to the increase in AAG plasma levels. The plasma concentration of total bupivacaine tends to increase after 48 hours, especially in infants younger than 4 months old, when the AAG is said to fall. Based on this premise, some authors recommend terminating continuous infusions of bupivacaine after 48 hours in infants under 6 months.

However, there was no decrease observed in AAG levels after 72 hours in the only study to date that has measured AAG levels beyond 48 hours (Bosenberg et al., 2005). In this study, both total and unbound ropivacaine levels were similar at 48 and 72 hours.

Extrapolation of pharmacokinetic data after single-bolus bupivacaine administration for infants and children suggests that for continuous caudal and epidural infusions, rates of 0.2 to 0.4 mg/kg per hour for infants and 0.2 to 0.75 mg/kg per hour for children would provide efficacious and safe plasma concentrations (McCloskey et al., 1992).

Lidocaine

The amide local anesthetics are bound to serum proteins. AAG is the major binding protein. The free drug fraction for lidocaine ranges from 30% to 40%, and for both ropivacaine and bupivacaine it ranges from 4% to 7%. Metabolism of amides is by the liver's cytochrome P450 system. CYP3A4 metabolizes bupivacaine, and CYP1A2 is mostly involved with ropivacaine's metabolism. Lidocaine has a high hepatic-extraction ratio, and its clearance is dependent on hepatic blood flow. In addition, the metabolic product of lidocaine metabolism (MEGX) may inhibit the intrinsic enzyme involved with its degradation. Lidocaine has a longer elimination half-life and a larger volume of distribution in children than in adults after either intratracheal or caudal anesthesia (Eyres et al., 1978; Ecoffey et al., 1984). Bokesch and others (1987) demonstrated higher plasma lidocaine levels in the systemic circulation in animals with right-to-left shunts.

Bupivacaine

Bupivacaine and ropivacaine have a low hepatic-extraction ratio. Thus, protein binding and CYP enzyme activity effect drug clearance (Lonnqvist et al., 2000). Bupivacaine is a racemic mixture of equiosmolar amounts of R⁺ bupivacaine and S⁻ bupivacaine. Drug clearance is low at birth and increases throughout the first year of life. Pharmacokinetic studies have demonstrated age-related differences between infants and children (Eyres et al., 1983; Ecoffey et al., 1985; Desparmet et al., 1987; Mazoit et al., 1988; Mazoit and Dalens, 2004). Extrapolation of pharmacokinetic data after single-bolus bupivacaine administration for infants and children suggests that for continuous caudal and epidural infusions, rates of 0.2 to 0.4 mg/kg per hour for infants and 0.2 to 0.75 mg/kg per hour for children would provide efficacious and safe plasma concentrations (McCloskey et al., 1992).

Ropivacaine

Ropivacaine is a long-acting amide, local anesthetic agent with fewer cardiac and CNS toxicities. It is thought to provide a greater separation of sensory and motor effects. Karmakar and others (2002) have shown that after 2 mg/kg of either caudal ropivacaine or bupivacaine, ropivacaine undergoes slower systemic absorption from the caudal space but with comparable peak venous plasma concentrations. In comparative studies of caudal blocks with ropivacaine and bupivacaine, Khalil and others (1999) and Ivani and others (1998) noted that for children the quality and duration of postoperative pain relief, motor and sensory effects, and time to first micturition were similar.

In infants and children, the pharmacokinetics of ropivacaine have been reported after caudal, epidural, and ilioinguinal blocks (Hansen, 2000a, 2000b, 2001a; Lonnqvist et al., 2000; Wulf et al., 2000; Dalens et al., 2001). Hansen and others (2001) have shown that infants who are 0 to 3 months of age have higher to medium maximum free ropivacaine concentrations than infants who are 3 to 12 months of age, and for both these groups of infants the free drug concentrations are within the concentrations reported for adults. However, Wulf and others (2000) noted that in infants less than one year of age and toddlers 1 to 5 years of age, infants had higher peak plasma concentrations than toddlers, with the peak concentration occurring at 60 minutes in both groups. In a dosing study of children 4 to 12 years of age, Bosenberg and others (2001) noted that single shot caudals in doses of 1 to 3 mg/kg resulted in peak plasma levels of free ropivacaine that increased proportionately to the increase in dose.

McCann and others (2001) reported on the pharmacokinetics of epidural ropivacaine (1.7 mg/kg) in infants and young children. In this study, researchers noted that ropivacaine has a biphasic absorption. As with bupivacaine, ropivacaine shows age-related clearance changes with infants having slower clearance than children, but in both groups the peak plasma concentrations were well below the maximum tolerated venous concentration (2100 mcg/mL for adults). In children receiving 24- to 72-hour epidural infusions of ropivacaine, Berde et al. (2008) noted stable concentrations of unbound ropivacaine with no age dependency or sign of systemic toxicity.

The pharmacodynamics of ropivacaine after caudal blocks have been shown to be similar to bupivacaine with regard to onset time, efficacy, duration of analgesia, and incidence of motor block. In children receiving caudal blocks with 1 MAC of sevoflurane, Ingelmo et al. (2009) noted that the potencies (ED₅₀ and ED₉₅) for ropivacaine and levobupivacaine were similar. Local anesthetic supplements can also affect their duration of action. Ropivacaine's duration of action can be prolonged with neostigmine, clonidine, or ketamine supplementation (Da Conceicao and Coelho, 1998; Ivani et al., 1998, 1999, 2000; Khalil et al., 1999; Morton, 2000; Turan et al., 2003).

Levobupivacaine

Levobupivacaine is one of the enantiomers of bupivacaine. There is less information regarding its use in children than for the other local anesthetics (Gunter et al., 1999; Ivani et al., 2003, 2005; Chalkiadis et al., 2004; DeNegri et al., 2004; Kokki et al., 2004a; Locatelli et al., 2005).

In studies of children 1 to 7 years of age, Ivani and others (2002) noted that caudal bupivacaine, levobupivacaine, and ropivacaine were thought to be clinically comparable. Locatelli and others (2005) reported that caudal bupivacaine was associated with more motor block and longer analgesic block. However, in a study of over 300 children aged 1 month to 10 years, Frawley et al. (2006) noted that onset time, motor block, and analgesia of levobupivacaine was comparable with bupivacaine. In addition, 0.21% levobupivacaine appears to have equivalent potency to racemic bupivacaine. In pediatric patients with continuous infusions of epidurals, DeNegri and others (2004) noted that ropivacaine and levobupivacaine were associated with less motor block than bupivacaine. Cortinez et al. (2008) reported on the pharmacokinetics of levobupivacaine (2.5 mg/kg) after caudal administration in 10 patients 1 to 36 months of age and found that the median range of levobupivacaine's C_{max} and T_{max} were $1.48^{(0.62 \text{ to } 2.40)}$ mcg/mL and $37^{(10 \text{ to } 60)}$ minutes, respectively. No patient had a toxic level.

In a dose-response study by Ivani et al. (2003) of children undergoing caudal block for subumbilical surgical procedures, three concentrations (0.125%, 0.20%, and 0.25%) of levobupivacaine were compared. A dose-response relationship was observed, and they noted the optimal concentration to be 0.2% (Ivani et al., 2003). More information on local anesthetics is given in Chapter 14, Regional Anesthesia.

NEUROMUSCULAR BLOCKING AGENTS

Neuromuscular blocking agents (NMBAs) are used to facilitate intubation, provide surgical relaxation, and control ventilation in the operating room and ICU. NMBAs have no sedative, hypnotic, or analgesic side effects, but they may indirectly decrease metabolic demand, prevent shivering, decrease nonsynchronous ventilation and compliance of the respiratory system, and decrease ICP. The purposes of this section are to review the growth and development of the neuromuscular junction and muscle, the age-related pharmacologic characteristics of NMBA and their antagonists, and the monitoring equipment available for evaluating neuromuscular function.

Neuromuscular Junction and Neuromuscular Transmission

The general anatomy, age-related physiology, and pharmacology of the neuromuscular junction have been well defined (Bowman, 1980; Meakin et al., 1992; Wareham et al., 1994; Calakos and Scheller, 1996; Prince and Since, 1998; Sanes and Lichtman, 1999; Naguib et al., 2002). The neuromuscular system is incompletely developed at birth. The conduction velocity of motor nerves increases throughout gestation as nerve fibers are myelinated. The myotubules connect to mature muscle fibers in the latter part of intrauterine life and in the first several weeks after birth (Table 7-21). Some slow-contracting muscle (e.g., intrinsic muscles of the hand) is progressively converted to fast-contracting muscle, with a concomitant change in the force-velocity relationship. However, both the diaphragm and the intercostal muscles increase their percentage of slow muscle fibers in the first months of life. Synaptic transmission is slow at birth, and the rate at which acetylcholine (ACh) is released during repeated nerve stimulation is limited in the infant.

TABLE 7-21. Development of Skeletal Muscle Fibers

Age	Development
4 wk	Mesenchymal cells become syncytial; myoblasts become myotube
5 wk	Syncytial myotube grows in length; primitive muscle fibers with myofilaments appear
9 wk	More myofilaments appear, grow in length; nuclei centralized
5 mo	Muscle fibers become thicker, longer; myofilaments multiply; myofilaments differentiate into actin and myosin; nuclei move more peripherally
Birth	Myofilaments aggregate into bundles, form myofibrils; muscle fibers grow still thicker, longer; nuclei have shifted peripherally
Adult	Muscle fibers thick and mature; alternating actin and myosin myofilaments aggregate into longitudinal bundles

Box 7-4 Characteristics of the Neonatal Neuromuscular Junction

Acetylcholine receptors change in function and distribution. Slow twitch fibers (type I increase several-fold in first 6 months). Infants younger than 2 months have lower TOF ratio. Infants younger than 2 months have increased fade. Differences are more pronounced in premature infants than in term infants.

Age-related changes in the ACh receptor may also contribute to the reduced margin of safety of neurotransmission in infants compared with adults (Box 7-4).

Acetylcholine Receptors

Prejunctional, postjunctional, and extrajunctional ACh receptors are involved with neuromuscular transmission. The postjunctional, adult ACh receptor consists of five units, that form a rosette with a central pit at the mouth of the ion channel (Fig. 7-46). Each rosette is made up of two α_1 units and β_1 , ϵ , and δ units. These subunits are arranged in a specific order (counterclockwise $\alpha^*-\epsilon-\alpha-\delta-\beta$). The α^* subunit has a binding site with higher affinity for d-tubocurarine. The two binding sites for ACh are at α and δ (Blount and Merlie, 1989; Gu et al., 1990; Pederson and Cohen, 1990). Both sites must interact with the ACh in order for the channel to open and allow the flow of ions (Na^+ , K^+ , Ca^{2+}). If a competitive nondepolarizing NMBA prevents the interaction of ACh with one or two of the subunits α and α^* , the channel cannot open. The immature or fetal ACh receptor subtypes differ in the structure of one subunit from the adult subtype (i.e., a γ subunit which is present in the fetal ACh receptor instead of the ϵ subunit, which is present in the adult ACh receptor). Neonates have a mix of both adult and fetal receptors, but at term the adult subtypes are more common (Table 7-22; Fig. 7-47). A limited number of extrajunctional ACh receptors are also incorporated in the muscle membrane of older infants, children, and adults. Nerve activity inhibits the biosynthesis of ACh receptors at extrajunctional sites.

■ **FIGURE 7-46.** Structure of the fetal nicotinic ACh receptor and a description of the requirements to activate and competitively antagonize receptor function. The five subunits (two α s, β , ϵ , and δ with apparent molecular masses of 40, 50, 60, and 65 kDa, respectively), which are partly homologous in sequence, are arranged to form the perimeter of an internal cavity, which is believed to be the ion channel. Each of the subunits has an extracellular and a cytoplasmic exposure, with the bulk of the peptide chain existing on the extracellular side. The α subunits each carry a recognition site for agonists and competitive antagonists (From Taylor P: *Are neuromuscular blocking agents more efficacious in pairs?* *Anesthesiology* 63:1, 1985.)

Neuromuscular Transmission in the Neonate

The issues of ACh transfer, release, or reformation in the nerve terminal have been well reviewed (Lee, 1987; Naguib et al., 2002). Mobilization of ACh during tetanic stimulation may be limited in the neonate and particularly in the premature infant. Unanesthetized newborns appear to have less neuromuscular reserve during tetanic stimulation than do adults. In neonates, there is no fade of twitch height with repeated stimulation at rates of 1 to 2 Hz; however, there is significant fade at 20 Hz. Premature infants may show post-tetanic exhaustion that lasts for 15 to 20 minutes. Goudsouzian (1980) noted slower contraction times of the thumb after slow and rapid rates of stimulation in full-term infants (aged 1 to 10 days, anesthetized with halothane) than in older children. The percentage of fade at 20, 50, or 100 Hz did not differ between the infants and the older children, but the tetanic stimulus was applied for only 5 seconds. The train-of-four (TOF) ratio, the degree of post-

TABLE 7-22. Distinguishing Features of Mature and Fetal Receptors

Mature Receptors	Fetal Receptors*
ϵ Subunit	γ Subunit
Localized to end-plate region	Junctional and extrajunctional sites
Metabolically stable (half-life = 2 wk)	Metabolically unstable (half-life = 24 hr)
Larger single-channel conductance	Smaller single-channel conductance
Shorter mean open time	Twofold to 10-fold longer mean open time
Agonists depolarize less easily	Agonists depolarize more easily
Competitive agents block more easily	Competitive agents block less easily†

Data from Martyn JA et al.: Up-and-down regulation of skeletal muscle acetylcholine receptors, *Anesthesiology* 76:822, 1992.

*Immature junctional receptors have the same characteristics as upregulated extrajunctional receptors.

†Recent data conflict with this statement: Paul M et al.: The potency of new muscle relaxants on recombinant muscle-type acetylcholine receptors, *Anesth Analg* 94:597, 2002.

Fetal receptors are more sensitive to pancuronium, vecuronium, mivacurium, and rocuronium but not to d-tubocurarine or gallamine.

tetanic facilitation, and the tetanus/twitch ratio increase with age. Crumrine and Yodlowski (1981) noted a decrease in the amplitude of the frequency sweep electromyogram (FS-EMG) at frequencies of 50 to 100 Hz in infants younger than 12 weeks who had been given methohexital (Fig. 7-48). The FS-EMG is a recording of the action potential from an electrical stimulus rate that increases exponentially from one pulse per second to 100 Hz during a stimulation period of 10 seconds. The exponential increase in frequency allows assessment of neuromuscular transmission at tetanic rates without inducing fatigue. Older infants and children responded like adults. The addition of 70% nitrous oxide depressed the FS-EMG 11% to 38% in the group of infants younger than 12 weeks old, and this correlated with failure to sustain tetanus.

■ **FIGURE 7-47.** ACh receptor channels with the subunits (α , β , ϵ , and δ or α , β , γ , and δ) arranged around the central cation channel. Binding of acetylcholine to the two α subunits induces the conformational change that converts the channel from closed to open, although the mean channel open times differ between the two types of ACh receptors depicted here (From Martyn JA et al.: *Up-and-down regulation of skeletal muscle acetylcholine receptors*, *Anesthesiology* 76:822, 1992.)

■ **FIGURE 7-48.** Tracings of the FS-EMG responses from the tibialis anterior muscles of a 1-day-old infant (**A**) and a 4-month-old infant (**B**) premedicated with methohexital. (From Crumrine RS, Yodowski EH: *Assessment of neuromuscular function in infants*, *Anesthesiology* 54:29, 1981.)

Mechanism of Action of Depolarizing and Nondepolarizing Neuromuscular Blocking Agents

Succinylcholine, the only depolarizing relaxant used clinically, produces two different types of blockade: phase I and phase II (Fig. 7-49). During phase I, succinylcholine binds to ACh receptors, causing ion channels to open or depolarize in the same fashion as does ACh. The molecules remain bound to the receptor for an extended period and cause the membrane to remain depolarized and unable to trigger any further muscle action potentials. This initial depolarization and movement of the individual muscle bundles may be seen clinically as fasciculations.

With an infusion or an increased amount of accumulated drug (dose of 4 to 6 mg/kg), a succinylcholine-induced block begins to assume the characteristics of a nondepolarizing block, which is referred to as *phase II block*, *desensitization*, or *dual blockade* (Lee and Katz, 1980; Sutherland et al., 1980; Donati and Bevan, 1983; Goudsouzian and Liu, 1984; Lee, 1986). Post-tetanic facilitation occurs, as well as fade with tetanus and TOF ratio of less than 0.4. These clinical characteristics of a phase II block are identical to those that occur with a nondepolarizing agent. Because a phase II block is functionally a nondepolarizing blockade, anticholinesterase drugs (reversal drugs) are effective, but only when four twitches are present and the plasma concentration of succinylcholine is low. On the other hand, nondepolarizing agents competitively bind one or two α units of the ACh receptor; this prevents both units from binding with ACh to open the ion channel. The drug may also physically block the ion channel in the motor end-plate, this is described as channel blockade. The NMBAs are classified either according to chemical structure or duration of action and are listed in on p. 250 (Table 7-34).

Basic Definitions

ED₉₅ and Intubating Dose

ED₉₅ is the dose of neuromuscular blocking agent that is expected to produce 95% block at the adductor pollicis. Several multiples of the ED₉₅ (e.g., two to three times ED₉₅) are usually administered to ensure adequate neuromuscular blockade for intubation and to minimize the time to maximum block, which is also called the *onset time* (Kopman et al., 2001). The ED₉₅'s (relative potencies), onset, and duration of effect of various neuromuscular blocking agents in infants and children are illustrated in Tables 7-23, 7-24, and 7-25. ED₉₅ values tend to be higher in children than in infants or adults for most nondepolarizing neuromuscular blocking agents, with the exception of atracurium.

■ **FIGURE 7-49.** During continuous infusion of succinylcholine, a phase I block characterized by reduced neuromuscular response, little fade of TOF, and increased blockade with edrophonium is seen initially. During phase II, there is a fade of TOF, and increasing reversibility of the block by edrophonium, and accumulation of the slowly recovering residual block.

TABLE 7-23. Potency (ED₉₅) of Nondepolarizing NMBAs in Infants, Children, and Adults (mcg/kg)*

Drug	Anesthetic	Infant	Child	Adult
Mivacurium	Halothane	85	89	67
Cisatracurium	Narcotic	43	47	40
Vecuronium	Halothane	25	47-60	33
	Narcotic	47-60	81-100	43
Rocuronium	Halothane		300	
	Narcotic	255	402	350
Pancuronium	Halothane	45-50	61-70	67
	Narcotic	66	93	70

*Values are means.

Dose-Response Curves

Dose-response studies in children and then infants are undertaken after adult clinical trials for safety and efficacy have been performed. Three or four doses expected to produce a measurable or less than maximum effect are administered during a standardized anesthetic with standard monitoring conditions (e.g., these TOF every 10 seconds). The ED₅₀ and ED₉₅ are determined from data (Fig. 7-50). ED₅₀ is determined from the middle of the dose-response curve where there is less variability, resulting in a more robust measure. The intubating dose as a multiple of the ED₅₀ may be used to compare onset and duration of NMBAs; however, multiples of the ED₉₅ are routinely used for this comparison. Onset times and lengths of action of different NMBAs may be compared only if equivalent doses or equal multiples of the ED₉₅ are administered.

Onset and Duration of Block, Maintenance Doses, Recovery Index

By current convention, onset is the time to maximum effect, and duration is the time for return of neuromuscular transmission to 25% of baseline, or T₂₅ (Bedford, 1995). In general, the dose of a specific nondepolarizing agent required to produce a particular degree of relaxation is similar in neonates (younger than 1 month), infants (aged 1 to 12 months), and adolescents (older than 13 years). However, in children (aged 3 to 10 years) the dose (ED₉₅) tends to be greater and the onset of block tends to be more rapid than in adults. In addition, the maximal effect (onset) is reached more quickly in neonates and infants than in the older children and adolescents (see Tables 7-23, 7-24, and 7-25).

Differences in onset and duration are influenced by age-related changes in volume of distribution, the time for drug

FIGURE 7-50. Dose-response curve (n = 61) for rocuronium in children during nitrous oxide-halothane anesthesia. Filled circles, Group mean values ± SEM; dashed lines, the 95% confidence limits. (From Woelfel SK et al.: *Effects of bolus administration of ORG-9426 in children during nitrous oxide-halothane anesthesia*, *Anesthesiology* 76:940, 1992.)

to reach the effected site (muscle tissue and the neuromuscular junction), as well as clearance. The effect of a bolus of a specific NMBA depends on tissue sensitivity ($C_{p_{ss}}$), the pharmacokinetics (plasma concentration of drug, volume of distribution, clearance, and elimination half-life), and the pharmacodynamic parameter K_{e0} for the resultant effect or block. Unfortunately, it is difficult to measure the concentration at the neuromuscular junction, because there is a lag time between concentration in the plasma and the neuromuscular junction. Therefore the pharmacodynamic parameters, $C_{p_{ss}}$ and K_{e0} , are measured using a model to determine concentration at the neuromuscular junction.

Duration of block in infants. A prolonged duration of action occurs for both vecuronium and rocuronium in neonates and infants (younger than 6 mo) compared with children and adults. Age does not have this effect on the duration of atracurium

FIGURE 7-51. Recovery of T_1 after 600 mcg/kg rocuronium in infants and children during halothane. (Data from Woelfel SK et al.: *Effects of bolus administration of ORG-9426 in children during nitrous oxide-halothane anesthesia*, *Anesthesiology* 76:940, 1992.)

TABLE 7-26. Duration of Action of Rocuronium in Infants Under 1 Year of Age*

Dose of Rocuronium (mg/kg)	Age (mo)	T_{75} (min)	TOF > 0.7 (min)
0.45	0-1	56.4 ± 16 [†]	62.3 ± 18
	2-4	62.7 ± 32	64.1 ± 27
	5-12	45.8 ± 18	43.7 ± 12
0.6	0-1	100.8 ± 35 [†]	94.8 ± 31
	2-4	70.6 ± 19	63.8 ± 14
	5-12	63.4 ± 21	67.5 ± 18

*Data are from 61 infants and children under isoflurane anesthesia. Values are means.

[†]Age group “0-1 mo” is significantly different from age group “5-12 mo” for both doses of rocuronium at $p \leq 0.05$.

or cisatracurium (Table 7-26 and Fig. 7-51) (Meretoja, 1990; Driessen et al., 2000; Rapp, 2004a).

When neuromuscular transmission has recovered to T_{25} , four twitches using TOF stimuli are usually present. The clinical importance of T_{25} is that maintenance doses of the neuromuscular blocking drug should be administered at this point if muscle relaxation is required for the surgical procedure. Maintenance doses are 0.25 to 0.3 times the intubation dose (Table 7-27). In addition, T_{25} recovery is the earliest time that the pharmacologic reversal agents should be administered for a rapid and full recovery to 100% of baseline neuromuscular transmission.

A recovery index (i.e., RI_{25-75}) is the difference in time to recovery from 25% to 75% of the final baseline (T_{25} to T_{75}). Published indices of recovery provide an expected duration of effect, but monitoring of neuromuscular transmission is preferable. Common recovery indices are from 5% to 25%, 25% to 75%, or 5% to 95% recovery and are another means of comparing NMBAs.

TABLE 7-27. Intubation and Maintenance Doses (mg/kg) of NMBAs in Infants and Children

	Intubation Dose*	Maintenance
Succinylcholine	1-2	—
Cisatracurium	0.1-0.2	0.02-0.05
Vecuronium	0.05-0.1	0.02
Rocuronium	0.3-1.0†	0.1
Pancuronium	0.08-0.1	0.02

Adapted from Rapp HJ, Altenmueller CA, Waschke C: Neuromuscular recovery following rocuronium bromide single dose in infants, *Paediatr Anaesth* 14:329, 2004a.

*The recommended dose range for intubation in infants and children is two to three times ED₉₅. Increasing the dose speeds the onset of neuromuscular block. †0.6-1.0 mg/kg of rocuronium in the infant may have a prolonged duration of action with up to 100 min for recovery to T₇₅. Maintenance dose is one fourth to one third of the intubation dose.

Pharmacologic Differences in Infants and Children: Sensitivity, Volume of Distribution, Clearance

The drug concentration in plasma that produces 50% to 90% twitch suppression at steady-state conditions (C_p or C_p), such as with an infusion, provides a means of comparing drug potencies. Neonates and infants are more sensitive to all NMBAs than children and adults. D-tubocurarine has been well studied in all age groups, and the concentration at the effect site (C_{ss}) for neonates is one half to one third of that for children and adults. However, initial dosing of d-tubocurarine for the neonate should not be decreased, because the volume of distribution is larger, clearance is slower, and the elimination half-life is longer in this patient population.

Different patterns emerge between atracurium and cisatracurium vs. vecuronium and rocuronium in infants. For cisatracurium, the ED₉₅ values are similar for infants, children, and adults at 43, 47, and 40 mcg/kg, respectively (see Table 7-23). The volume of distribution of cisatracurium is increased, and the clearance is more rapid in infants than in children and adults. Thus, the same multiple of ED₉₅ dose has a similar and predictable duration in infants, children, and adults. Mean infusion rates to maintain block at 95% are also similar in infants, children, and adults during the same anesthetic exposure (Table 7-28).

On the other hand, ED₉₅ values for vecuronium in infants and children are 47 and 81 mcg/kg, respectively, with narcotic anesthesia and 25 and 45 mcg/kg with halothane anesthesia. Onset is more rapid in the infant (0.6 to 0.8 times that of the child), and duration is increased with the RI at 1.7 to 2.9 times that of a child. Infants have both increased volume of distribution and mean residence time, but clearance is basically unchanged or slightly less in the infant (5.6 mL/kg per minute) compared with children (5.9 mL/kg minute) (Table 7-29). The C_{p_{ss50}} is lower in the infant. After a single dose of relaxant, recovery depends on both distribution and elimination. The combination of a longer mean residence time and a lower sensitivity for vecuronium explains the prolongation of neuromuscular block in infants. Vecuronium should be considered a long-acting NMBA in neonates and infants.

TABLE 7-28. Continuous Infusion Dose Range (mcg/kg/min) Required to Maintain T₁ < 5%-10%*

Drug	Type	Infant	Child	Adult
Cisatracurium	ICU	2.8 (0.6-4.9)	3.9±1.3	1.0-2.6

t_{1/2β}, Elimination half-life; CL, clearance; Vd_{ss}, volume of distribution at steady state; Cp_{ss50}, steady-state plasma concentration associated with 50% neuromuscular blockade.

Similarly, rocuronium acts as a long-acting NMBA in infants. It has the most rapid onset of action in all age groups because of its low potency (ED₉₅ of 255 to 400 mcg/kg) compared with the other commonly used NMBAs (which have higher potency, with ED₉₅ values between 40 to 90 mcg/kg for mivacurium, cisatracurium, vecuronium, and pancuronium). The most rapid onset occurs in infants when rocuronium is compared with all the other age groups. Here, both the volume of distribution and mean residence time are greater in infants (aged 3 to 12 months) than children (aged 4 to 8 years), but for rocuronium, the clearance is slower for the infant but more rapid in the child than the adult. The effect site concentration that produces 50% block is also less in the infant (Table 7-30) (Wierda et al., 1997; Saldein et al., 2003). These factors contribute to the prolonged length of action of rocuronium in infants.

TABLE 7-30. Pharmacodynamic Data for Rocuronium in Infants, Children, and Adults*

	Infants	Children	Adults
EC ₅₀ ng/kg	652 ± 215	1200 ± 295	954 ± 276
EC ₉₀ ng/kg	1705	2230	2035

*Effect site concentration of rocuronium to produce 50% and 90% neuromuscular block in infants, children, and adults. Note that these concentrations are decreased for the infant, whereas those of children and adults are similar.

Monitoring Neuromuscular Block

Types of Monitoring: Peripheral Nerve Stimulation and Acceleromyography

Restoration of complete skeletal muscle strength is essential to ensure that patients are able to sustain adequate ventilation, cough, and maintain a patent airway after administration of relaxants. Peripheral nerve stimulation (PNS) is routinely used, resulting in a visual or tactile subjective observation of response to an electrical stimulation, single twitch stimulus or TOF. However, expert researchers in the field of neuromuscular study cannot reliably detect fade when the TOF ratio is greater than 0.4 but less than 0.9, either visually or tactily (Viby-Mogensen et al., 1985, 2007; Kopman, 2009). The TOF-Watch objectively measures acceleration of the thumb using a piezoelectric transducer placed on the tip of the thumb. Acceleromyography (AMG) is based on Newton's Second Law: Force = Mass × Acceleration. When TOF stimulation is used, the percentage of TOF ratio is displayed on a digital screen, so fade is quantified without a subjective interpretation (Fig. 7-52).

Neuromuscular Block Effects at Different Muscles

The adductor pollicis is commonly monitored; however, the diaphragm, larynx, flexor hallucis brevis, and orbicularis oculi are also observed clinically. The onset, depth, and duration of action of NMBAs differ at different muscle sites. In adults, block develops faster, is less profound, and recovers more quickly in the centrally located muscles such as the larynx, the masseter (jaw), and the diaphragm than in more peripherally located muscles (such as the adductor pollicis) (Fig. 7-53). In children (aged 18 months to 9 years), complete block occurs earlier in the orbicularis oculi than at the adductor pollicis (0.7 minutes on average), but observation of complete block at either muscle leads to excellent intubation conditions (Plaud et al., 1997). Also, in children (aged 2 to 18 years), onset and recovery are both slower at the flexor hallucis brevis than at the adductor pollicis during inhalational anesthesia. In addition, the ED₉₀ for the diaphragm is 1.6 times the ED₉₀ of the adductor pollicis in infants and children. Doses of pancuronium for 90% relaxation of the adductor pollicis and diaphragm are 42 vs. 70 mcg/kg (0 to 1 year), 47 vs. 81 mcg/kg (1 to 3 years), and 62 vs. 101 mcg/kg (3 to

■ **FIGURE 7-52.** TOF-Watch (Organon Ltd., Dublin, Ireland). This neuromuscular transmission monitor is based on measurement of acceleration using a piezoelectric transducer. Note the transducer fastened to the thumb and the stimulating electrodes. On the display of the TOF-Watch, the TOF ratio is given in percentage. (From Viby-Mogensen J: Neuromuscular monitoring. In Miller ED, Eriksson LI, Fleisher LA, et al: Miller's anesthesia, ed 7, Philadelphia, 2010, Churchill Livingstone.)

■ **FIGURE 7-53.** First twitch height (T₁) against time for vocal cords and adductor pollicis, after vecuronium 0.07 mg/kg. Bars indicate SEM. (From Donati F, Meistelman C, Plaud B: Vecuronium neuromuscular blockaded at the adductor muscles of the larynx and adductor pollicis, *Anesthesiology* 74:833-837, 1991.)

10 years), respectively. Therefore, when there is a 90% block of the adductor pollicis, there is much less block of the diaphragm in infants and children (Laycock et al., 1988). Intubation and supplemental doses of NMBAs are listed in Table 7-27.

Types of Stimuli

Peripheral nerve stimulation can be delivered at different frequencies to assess the depth of neuromuscular block (e.g., TOF, post-tetanic count [PTC], and double burst stimulation [DBS])

and is often used instead of tests of ventilation and grip strength in pediatric patients. TOF stimulation is the most common pattern of stimulation for clinical monitoring of neuromuscular blockade in the operating room, because the response can be elicited without an established baseline, and the peripheral nerve stimulator may be placed at any time during the surgical procedure. This stimulation mode allows for convenient visual and tactile evaluation of moderate degrees of nondepolarizing blockade without the undue discomfort that accompanies tetanic bursts (i.e., 50 to 100 Hz for 5 seconds) (Brull et al., 1990).

In adults, at a TOF ratio of greater than 0.9, vital capacity returns to normal (more than 15 to 20 mL/kg), pharyngeal muscle strengthens to allow recovery of swallowing, diplopia disappears, and maximum inspiratory and expiratory forces are only slightly depressed (-50 cm H₂O) (Kopman and Yee, 1997). No similar data are available for infants and children, but recovery to TOF ratio of greater than 0.9 is recommended (Table 7-31).

Post-tetanic stimulation. PTC is 20 single-twitch stimuli after a tetanic stimulation. This monitoring mode is usually used intraoperatively when there is no response to TOF stimuli. The time to return of TOF can be predicted when PTC is 5 to 10 counts, and this recovery time is more rapid in children than in adults. For example, in children (aged 2 to 5 yrs) who have been given rocuronium (1 mg/kg), when PTC of 1 occurs, the TOF returns in 7 minutes, whereas in adults (aged 18 to 60 years) TOF returns in 16 minutes, and in those aged 65 to 80 years, 22.3 minutes are required (Bakayra et al., 2002, 2003).

Children receiving an atracurium infusion who have a PTC of less than 10 show only one response to TOF stimuli, although a PTC of 15 correlates with 3 to 4 responses to TOF, which is a stage where pharmacologic reversal may be administered (Ridley and Hatch, 1988).

In contrast, children with vecuronium infusions who have a PTC of 5 to 15 have adequate surgical relaxation, and pharmacologic reversal of block can be administered in 6 to 18 minutes (Ridley and Braude, 1988).

In addition to predicting the amount of time for a TOF ratio of three to four twitches to return and therefore when block can be reversed, PTC is useful in the timing of NMBA administration

TABLE 7-31. Clinical Signs and Symptoms in Awake Adult Volunteers When the TOF Ratio is Between 0.7 and 0.9

TOF Ratio	Signs and Symptoms*
0.7-0.75	Double vision Decreased hand grip strength Inability to oppose incisors Unable to clench tongue depressor with teeth Facial weakness Overall weakness Lethargy
0.85-0.90	Double vision Generalized fatigue Able to clench tongue depressor with teeth

From Kopman AF et al.: Relationship of the train-of-four fade ratio to clinical signs and symptoms of residual paralysis in awake volunteers, *Anesthesiology* 86:765, 1997.

*Awake volunteers recovering from mivacurium infusion had these clinical signs before full neuromuscular recovery.

so that the diaphragm is relaxed in children. When the PTC is zero at the AP, it is likely that the diaphragm is also relaxed. In children, the diaphragm recovers from relaxants more rapidly than the adductor pollicis (Laycock et al., 1988).

Double burst stimulation. Because it is difficult to estimate the TOF ratio with sufficient certainty to exclude residual paralysis, DBS was developed (Viby-Mogensen et al., 1985; Ueda et al., 1988; Drenck et al., 1989; Engbaek et al., 1989). DBS consists of two short tetanic bursts of 50 Hz separated by 750 milliseconds, and the ratio of the second to the first response is evaluated. DBS is more sensitive than TOF in children (aged 3 to 10 years) as well as adults when manually detecting residual neuromuscular block. Fade could not be detected manually with TOF greater than 0.44 and with DBS greater than 0.67 (Saddler et al., 1990). Therefore, absence of fade in response to DBS excludes severe residual neuromuscular block but does not indicate adequate clinical recovery of TOF ratio to greater than 0.9 (Fig. 7-54) (Fruergaard et al., 1998; Gätke et al., 2002).

Monitoring Recovery

Complete recovery from neuromuscular block requires a TOF of greater than 0.9 (Kopman et al., 1997, 2009). A large body of evidence in adults exists that depressed pharyngeal and upper esophageal function, decreased chemoreceptor sensitivity to hypoxia, impaired ability to maintain the airway, and increased risk for the development of postoperative pulmonary complications are all consequences of postoperative residual neuromuscular block (Berg et al., 1997; Eriksson et al., 1997).

Residual paralysis (TOF of less than 0.7 to 0.9) in the recovery room occurs in 19% to 54% of patients when long-acting, intermediate-acting, or a single intubating dose of NMBA are used in adults (Debaene et al., 2003). In one study evaluating this effect,

FIGURE 7-54. Fade detected by touch in the response to TOF and DBS in relation to the true TOF ratio, as measured mechanically. The axis indicates the percentage of instances in which fade can be felt at a given TOF ratio. It is not possible to exclude residual neuromuscular block by TOF or DBS with certainty, whether a TOF ratio of 0.7 or 0.9 is taken to reflect adequate recovery of neuromuscular function. (From Viby-Mogensen J: *Neuromuscular monitoring*. In Miller ED, editor: *Miller's anesthesia*, ed 6, Philadelphia, Elsevier Churchill Livingstone.)

no similar residual block was found in children (older than 2 years); however, children always recover faster than adults from NMBA. The block was monitored carefully intraoperatively, and all children received pharmacologic reversal drugs when three or four twitches were present (Baxter et al., 1991). It is appropriate to ensure full recovery in all pediatric patients and especially in infants, because they have a narrow margin of safety.

Timing of Antagonists

Neurotransmission returns promptly if few receptors are blocked at the time of reversal (e.g., T_{25} or when three or four twitches of TOF are present). At this stage, 70% to 75% of receptors may still be occupied (Waud, 1971). Neostigmine (50 mcg/kg) is the recommended dose in infants (Fisher et al., 1983). There is no clinical advantage in attempting to antagonize intense neuromuscular block (fewer than three or four twitches) in children or in administering increased doses of neostigmine or edrophonium (Gwinnutt et al., 1991; Kopman and Eikerman, 2009). Data for this phenomena in children are shown in Figure 7-55 (Meistelman et al., 1988; Donati et al., 1989; Gwinnutt et al., 1991; Bevan et al., 1999). The plasma level of the NMBA should be low enough that the competitive effect of the anticholinesterases allow enough muscle strength to ensure TOF of 0.9 to 1 (Kopman et al., 1997). In addition, certain antibiotics, hypothermia, acidosis, hypocalcemia, and especially inhalational agents can prolong or potentiate neuromuscular block from nondepolarizing relaxants.

The present use of primarily short- and intermediate-acting relaxants may change the rule to “always reverse blockade” with AChs to “always document return of full neuromuscular function (TOF of greater than 0.9)” at the end of the case with either spontaneous or pharmacologically induced (anticholinesterases

or sugammadex) recovery. Clearly, the margin of safety of relaxants is increased by using objective rather than subjective criteria to judge the adequacy of neuromuscular transmission. Experts in neuromuscular studies have documented the difficulty with subjective (visual and tactile) assessment of TOF and DBS in determining complete recovery (Drenck, 1989; Fruergaard, 1998). For these reasons, an objective monitor (see Fig. 7-52), such as the accelerometer (AMG) is highly recommended. In addition, when objective monitoring is used, anticholinesterases can be administered at T_{25} (when 3 to 4 twitches are present) so that the drugs can have a complete response.

Potency or Dose of Neuromuscular Blocking Agent

Intubation doses (two to three times the ED_{95}) for depolarizing and nondepolarizing neuromuscular relaxants for infants and children are shown in Table 7-27. The length of action of recovery to T_{25} is also available (see Tables 7-24 and 7-25). Both age and inhalational anesthetic have an effect on potency. The speed of onset is inversely proportional to the potency of the nondepolarizing agents. With the exception of atracurium, molar potency is highly predictive of a drug's rate of onset of effect. Rocuronium has a more rapid onset than cisatracurium or vecuronium (Kopman, 2009).

Types of Neuromuscular Blocking Agents

Depolarizing Neuromuscular Relaxant: Succinylcholine

Succinylcholine, a rapid-acting and usually short-duration depolarizing muscle relaxant, is useful for rapid-sequence induction and endotracheal intubation. The onset time for 2 mg/kg is 30 ± 7 seconds in children (aged 2 to 10 years) with a T_{25} of 5.2 ± 1.9 min (Woolf et al., 1997). Succinylcholine is metabolized by butyrylcholinesterase, which effects both the onset and duration of action. Prolonged neuromuscular blockade can result from abnormally low or atypical enzyme concentrations. The former ranges from 9 to 23 minutes, whereas the latter genetic variations may last from 4 to 8 hours (Viby-Mogensen and Hanel, 1978; Viby-Mogensen, 1980). This enzyme activity is reduced in neonates, but there is little change in butyrylcholinesterase activity between 3 months and 12 years of age. Clinically, this reduction in neonates has no effect.

Dose, Onset, and Duration in Infants and Children

Neonates and infants require about twice as much succinylcholine (mcg/kg) as older children or adults (Table 7-32). Neonates and infants (younger than 2 years old) have an ED_{95} of 625 and 729 mcg/kg, respectively, for succinylcholine; they also have a faster clearance, larger volume of distribution and have a shorter onset time than children older than 2 years of age, with an ED_{95} of 523 mcg/kg, and adults, with ED_{95} of 290 mcg/kg.

In infants, 1 to 2 mg/kg of succinylcholine produces a block equal to that produced by 0.5 to 1 mg/kg in children aged 6 to 8 years (Cook and Fischer, 1975; Meakin et al., 1990). At equipotent doses, there is no statistically significant difference between the times to recover to 50% and 90% neuromuscular transmission in the two groups. Complete neuromuscular block develops in children given 1 mg/kg of succinylcholine. Because of marked variability in block produced by small

FIGURE 7-55. Recovery characteristics of vecuronium TOF after administration of neostigmine (30 mcg/kg) and atropine (10 mcg/kg) at three predetermined twitch height values during nitrous oxide halothane anesthesia in children: TH 1 vs. TH 10, * $P < 0.01$; TH 1 vs. TH 25, $\square P < 0.01$; TH 10 vs. TH 25, $\circ P < 0.01$. TABLE 7-32. Calculated ED₅₀ and ED₉₅ for Succinylcholine as a Function of Age

Age	ED ₅₀ (mcg/kg)	ED ₉₅ (mcg/kg)	ED ₅₀ (mcg/m ²)	ED ₉₅ Group (mcg/m ²)
Neonates	250	625	3952	9881
Infants	317	729	6277	14,436
Children	184	423	4416	10,154
Adults	—	290	—	11,940

Data from Meakin G et al.: Dose-response curves for suxamethonium in neonates, infants, and children, *Br J Anaesth* 62:655, 1989.

doses of succinylcholine, it is recommended to select doses at the upper end of the range for children undergoing rapid-sequence induction. Succinylcholine (1 mg/kg) in adults reaches complete block in 60 seconds and lasts 6 to 8 minutes; for infants, 3 to 4 mg/kg is necessary, and for children 2 mg/kg is required to achieve the same duration (Meakin et al., 1989). It should be noted that treatment of laryngospasm does not require the full intubating dose of succinylcholine, and a minimal dose such as 0.2 mg/kg allows positive pressure ventilation in children.

Side Effects

Side effects of succinylcholine are well described and include dysrhythmias, increased intraocular pressure, prolonged apnea, injured muscle membranes with associated hyperkalemia, association with masseter spasm and malignant hyperthermia, and death.

Cardiac Arrest

Intractable, unexpected cardiac arrest (ventricular fibrillation or asystole) associated with a 40% to 50% mortality, was reported after the use of succinylcholine in children with undiagnosed Duchenne's muscular dystrophy (Larach et al., 1997). This series of case reports resulted in the FDA issuing a "black box" warning against the elective use of succinylcholine in children. Succinylcholine can also cause rhabdomyolysis and massive hyperkalemia (Tang et al., 1992; Hopkins, 1995; Gronert, 2001, 2002; Holak et al., 2007; Piotrowski and Fendler, 2007; Al-Takroui et al., 2004). A survey (in 221 patients undergoing 444 anesthetics) in families identified with Duchenne's muscular dystrophy and Becker's muscular dystrophy revealed only six cardiac arrests, all in children who were not suspected of having the myopathy; in addition, they were all successfully resuscitated. Patients in whom myopathies were suspected had no cardiac arrests because succinylcholine was avoided (Breucking et al., 2000).

Life-threatening anaphylactic or anaphylactoid reactions have been reported, and drug-specific immunoglobulin-E antibodies to succinylcholine have been demonstrated (Naguib and Magboul, 1998).

Dysrhythmias. In the infant and small child, profound sustained sinus bradycardia (rates of 50 to 60 beats/min) is often observed; asystole occurs rarely. Nodal rhythm and ventricular ectopic beats are seen in about 80% of children given a single intravenous injection of succinylcholine; however, such dysrhythmias are rarely seen after an intramuscular injection of succinylcho-

line. The incidence of bradycardia and other dysrhythmias is increased after a second dose of succinylcholine. Atropine appears to offer adequate protection against these bradyarrhythmias in all age groups. In infants, vagolytic doses of 0.02 to 0.03 mg/kg are required for protection; in older children, adequate protection is provided by doses of 0.005 mg/kg of atropine.

Intragastric pressure. Succinylcholine may increase intragastric pressure caused by the intensity of muscle fasciculations that have been recorded as high as 40 cm H₂O in adults, making them at risk for regurgitation and aspiration. Because of limited muscle mass, the infant or small child seldom has strong fasciculations; only a 4 cm H₂O increase or a decrease in intragastric pressure in infants was observed (Salem et al., 1972).

Intraocular pressure. Intravenous or intramuscular administration of succinylcholine increases intraocular pressure in infants and adults. Dilation of choroidal vessels and contraction of extraocular muscles may be the mechanism. A patient undergoing an enucleation with all extraocular muscles released showed an increase of intraocular pressure with succinylcholine. Typically, the intraocular pressure increases in 60 seconds, peaks at 2 to 3 minutes, and then returns to control levels 5 to 7 minutes after injection. The increase in intraocular pressure can be controlled by pretreatment with a nondepolarizing NMBA. This transient increase in intraocular pressure may be misinterpreted and lead to unnecessary surgery in a patient with glaucoma if tonometry is performed within 5 to 7 minutes of the injection of succinylcholine (see Chapter 27 Anesthesia for Ophthalmic Surgery).

Increased intracranial pressure. Increases in ICP after the administration of succinylcholine are produced by cerebral metabolic stimulation and increases in cerebral blood flow (Lanier et al., 1986, 1989; Minton et al., 1986). These effects are attenuated by prior administration of a nondepolarizing agent, by treatment with thiopental or lidocaine, and by hyperventilation.

Hyperkalemia, myoglobinemia, and increase in creatine phosphokinase. In normal adult patients, succinylcholine increases plasma levels of potassium by 0.3 to 0.5 mEq/L. Alarming levels of potassium, as high as 11 mEq/L, along with cardiovascular collapse, were often reported with succinylcholine in a variety of conditions, including burns, massive trauma, stroke, spinal cord injury, and muscle diseases (Delphin et al., 1987; Rosenberg and Gronert, 1992; Schow et al., 2002). The common denominator is existence of extrajunctional ACh receptors that occurs with massive tissue destruction or CNS injury with muscle wasting. Strong fasciculations are not necessary to produce hyperkalemia in susceptible patients. There are no data to suggest that the infant is any less vulnerable than the adult to massive potassium flux from the listed conditions (Henning and Bush, 1982; Dierdorf et al., 1984).

A high incidence of myoglobinemia occurs after succinylcholine use (1 mg/kg) in prepubertal patients, especially those anesthetized with halothane. Increased muscle fasciculations and myoglobin levels are seen in children younger than 4 years old compared with children between the ages of 4 and 9 years who received succinylcholine (Blanc et al., 1986). Others, however, report no change in fasciculations or myoglobin with age (infant to midteens) (Sekino et al., 1990). Pretreatment with "self-taming" succinylcholine (0.1 mg/kg) did not reduce the fasciculations or the change in myoglobin. Pretreatment with pancuronium and d-tubocurarine decreases the fasciculations but does not obliterate the release of myoglobin.

Plasma levels of creatine phosphokinase, an indicator of muscle injury, increase significantly after succinylcholine administration in children. Children (aged 3 to 15 years) undergoing emergency surgical procedures and who have been pretreated with mivacurium, gallamine, or normal saline before the administration of succinylcholine showed no differences in fasciculations or reported myalgias. However, pretreatment with mivacurium showed decreases in the rise of myoglobin, potassium, and creatine phosphokinase (CPK) levels. A significant association was observed between fasciculations and the release of both myoglobin and CPK (Theroux et al., 2001). The tendency of muscle in children to release myoglobin after depolarization with succinylcholine is not readily explained. Such changes seem to be rare in infants.

Masseter spasm and malignant hyperthermia. Masseter spasm is a marked increase in tension of the masseter muscle that prevents opening of the mouth after succinylcholine has produced neuromuscular block. Resting tension or stiffness in the masseter muscle increases in a dose-related manner as succinylcholine blocks neuromuscular function (DeCook and Goudsouzian, 1980; Van Der Spek et al., 1988, 1989; Plumley et al., 1990; Sadler et al., 1990). Masseter spasm is probably the extreme end of the normal dose-related increase in resting tension seen with succinylcholine. Of 500 children who had halothane and nitrous-oxide anesthetic with 2 mg/kg of succinylcholine, 4.4% had incomplete relaxation and one patient had masseter spasm (Hannallah and Kaplan, 1994). Masseter rigidity alone is not diagnostic of malignant hyperthermia, and this is not currently an indication to change to a nontriggering anesthetic (see Chapter 37, Malignant Hyperthermia).

Present Status of Succinylcholine Use in Infants and Children

Routine use of succinylcholine in infants and children should be avoided because of risk for cardiac arrest, hyperkalemia, and rhabdomyolysis in patients with unsuspected Duchenne's muscular dystrophy. Succinylcholine is only recommended for emergency control of the airways in infants and children.

The introduction of the new ultra-short-, short-, and intermediate-acting relaxants and other strategies to increase the speed of onset of NMBAs has reduced the need for succinylcholine in children. A large intubating dose (four to five times ED_{95}) can be used to accelerate the onset of block with the necessary result of effectively converting the intermediate-acting drugs, cisatracurium, rocuronium, and vecuronium to long-acting relaxants, especially in infants. Rocuronium (1.2 mg/kg, four times ED_{95}) produces good intubating conditions (90% depression of twitch height) in 33 ± 5 seconds in children (aged 2 to 10 years) with the resulting T_{25} of 41 ± 13 minutes (Woolf et al., 1997). Priming is rarely used in children because onset time is already more rapid in children than that in adults. In addition, intubation is routinely performed in pediatric patients without neuromuscular blocking drugs for nonemergent (not rapid-sequence or full-stomach precautions) intubations with a combination of inhalational agents, opioids, propofol, and sedatives. In fact, for rapid sequence in infants and children, remifentanyl 3 mcg/kg and propofol 3 mg/kg produce good to excellent intubating conditions compared with propofol and succinylcholine (2 mg/kg) (Crawford et al., 2005; Simon et al., 2002).

Contraindications to Succinylcholine: Absolute and Relative

The absolute contraindications to succinylcholine include patient or immediate family history of malignant hyperthermia, suspected myopathy, and hyperkalemia.

Relative contraindications include patients with plasma cholinesterase deficiency, hypercarbia, moderate hyperkalemia, increased extrajunctional ACh receptors because of trauma, stroke, immobility, burns, sepsis, or when the other side effects are undesirable.

Nondepolarizing Neuromuscular Relaxants

Selection of Nondepolarizing Relaxant: Dose, Onset, Duration, Side Effects, and Metabolism

At appropriate doses, all nondepolarizing relaxants produce neuromuscular blockade; at equipotent doses, each relaxant produces the same degree of relaxation as any other. Increasing the dose speeds the onset of block. Onset time is more rapid with relaxants that have high ED_{95} values (and therefore low potency; e.g., rocuronium). Potent inhaled anesthetic agents speed the onset of block, but they also lengthen the duration of block in a concentration-dependent manner (Jalkanen and Meretoja, 1997). Factors in selecting one relaxant over another include the onset time, duration of effect, side effects, and routes of elimination (renal or hepatic). In addition, age (neonate, infant, child, adolescent, or adult) and the disease state of the patient are important.

The side effects of the nondepolarizing relaxants are primarily cardiovascular and relate to the amount of histamine release, ganglionic blockade, and vagolysis and are age-related. In infants and children, minimal cardiovascular effects are seen after administration of atracurium or vecuronium at several multiples of the ED_{95} (Brandom et al., 1983b, 1984; Fisher and Miller, 1983; Goudsouzian et al., 1983a, 1983b). At two times ED_{95} , increases in heart rate are seen with pancuronium and rocuronium in children; in contrast, both have minimal effects on heart rate in infants. Because the infant responds with bradycardia to a variety of stimuli (e.g., hypoxia and tracheal intubation), the "potential" vagolytic effects of pancuronium or rocuronium may be a desirable effect.

In adults, atracurium (three times ED_{95}) causes histamine release, whereas vecuronium (at any multiple of ED_{95}) is not associated with histamine release (Tulloch et al., 1990). Infants and children appear to be less susceptible than adults to histamine release after administration of relaxants. In a small series of infants, five times ED_{95} of atracurium did not elicit flushing or alter heart rate or blood pressure (Brandom et al., 1984; Goudsouzian et al., 1985). However, local signs of histamine release after direct intravenous injection of atracurium in infants and children have been described; rarely, flushing with or without mild hypotension is seen at high multiples of the ED_{95} (Nightingale and Bush, 1983). At high doses, d-tubocurarine may cause hypotension and histamine release in children. The different pattern of tryptase release by the various types of relaxants suggests different mechanisms of mast-cell activation (Koppert et al., 2001). Bronchospasm may be related to histamine release or release of leukotrienes. Some relaxants may block prejunctional muscarinic receptors in the airway.

Another area of importance with neuromuscular blocking agents is the risk of anaphylaxis. A 12-year survey at a French

pediatric center showed 60.8% of the IgE-mediated anaphylaxis reported with neuromuscular blocking agents, and vecuronium caused the largest number of reactions (Karila et al., 2005). The second most common agent to produce this reaction is latex. As in adults, NMBAs are responsible for most anaphylactic reactions occurring during anesthesia. Succinylcholine and rocuronium can also have this reaction.

Routes of Elimination of Nondepolarizing Agents

Nondepolarizing NMBAs are eliminated by renal excretion, hepatic uptake and excretion, and biotransformation, including Hofmann elimination (Table 7-33). These drugs filter freely through the glomerulus, and the renal clearance does not exceed the GFR (1 to 2 mL/kg per minute). The degree of metabolism of NMBA varies widely. Hofmann elimination and ester hydrolysis are largely responsible for the breakdown of atracurium and cisatracurium; butyrylcholinesterase is primarily associated with the metabolism of mivacurium. Gantacurium appears to be degraded by two chemical mechanisms, neither which is enzymatic: rapid formation of an inactive cysteine product, and a slower hydrolysis of the ester bond to inactive products.

Hepatic biodegradation has been demonstrated for steroidal relaxants (Savage et al., 1980; Bencini et al., 1983). Rocuronium is primarily eliminated by the liver with no metabolites, and with only a small fraction (10%) eliminated in urine. Only a small fraction (20% to 30%) of pancuronium undergoes metabolism. In contrast, the hepatic metabolism of vecuronium is significant (Savage et al., 1980; Marshall et al., 1983). Spontaneous deacetylation occurs in the liver, and the by-products are 3-hydroxy and 17-hydroxy derivatives. In addition, the 3-hydroxy metabolite is a potent (approximately 80% of vecuronium) neuromuscular blocking agent, and because it has a slower plasma clearance this contributes to the prolonged duration of action, especially in pediatric ICU patients on infusions of vecuronium (Caldwell et al., 1994). The 17-hydroxy and 3, 17-hydroxy metabolites however are far less active (Marshall et al., 1983).

Classification of Nondepolarizing Blocking Drugs

All but one nondepolarizing NMBA fall into the two groups of either aminosteroids (e.g., pancuronium, vecuronium, rocuronium, and rapacuronium) or benzyloisoquinolinium

TABLE 7-34. Classification of NMBAs by Chemical Structure and Duration of Action*

	Benzyloisoquinolinium Compound	Aminosteroidal Compound
Short-acting (10-20 min)	Mivacurium	Rapacuronium
Intermediate-acting (20-50 min)	Atracurium, cisatracurium	Vecuronium, rocuronium
Long-acting (>50 min)	D-tubocurarine	Pancuronium

Modified from Bedford RF: The FDA protects the public by regulating the manufacture of anesthetic agents and the production devices used in anesthetic practice, *Anesthesiology* 82:33A, 1995.

*The ultra-short acting (<10 min) agent, gantacurium, an asymmetric mixed-onium chlorofumarate, is in development.

(e.g., d-tubocurarine, atracurium, cisatracurium, and mivacurium) compounds. Gantacurium is an asymmetric mixed-onium chlorofumarate compound.

Nondepolarizing NMBA can also be categorized by the time to maximum blockade (i.e., onset time) and by the clinical duration of effect (i.e., T_{25}) (Table 7-34). Long-acting (duration of greater than 50 minutes) agents include pancuronium, and intermediate-acting (duration of 20 to 50 minutes) agents are vecuronium, rocuronium, and cisatracurium, but the only short-acting (duration of 10 to 20 minutes) agent of mivacurium is no longer available in the United States. It is still used in Europe. An ultra-short-acting agent (duration of fewer than 10 minutes), gantacurium, is in development. Sugammadex, a drug that irreversibly encapsulates rocuronium molecules and restores neuromuscular function, if approved by the FDA, may transform some intermediate-acting NMBAs (e.g., rocuronium and vecuronium) into agents with an effective short or ultra-short duration.

Long-acting relaxants (e.g., pancuronium) are generally reserved for surgical procedures such as cardiac operations, which last longer than 3 or 4 hours and where an increase in heart rate is desirable in infants and children and postoperative ventilation is planned. Intermediate-acting agents are also commonly chosen for surgical procedures for which postoperative ventilation is anticipated, and NMBAs are titrated

TABLE 7-33. Metabolism and Elimination of NMBAs

Drug	Metabolism (%)	Elimination		Metabolites
		Kidney	Liver	
Succinylcholine	Butyrylcholinesterase (98%-99%)	<2%	None	Monoester
Mivacurium	Butyrylcholinesterase (95%-98%)	<5%	None	Inactive monoester and quaternary alcohol
Cisatracurium	Hoffman elimination (77%)	16%		Laudanosine and acrylates; no clinical effect
Vecuronium	Liver (30%-40%)	40%-50%	50%-60%	3-OH metabolite accumulates in renal failure and is active (80% potency of vecuronium)
Rocuronium	None	10%-25%	>70%	None
Pancuronium	Liver (10%-20%)	85%	15%	3-OH metabolite (66% potency of pancuronium)

Modified from Naguib M, Lien CA: Pharmacology of muscle relaxants and their antagonists. In Miller RD, Eriksson LI, Fleisher LA, et al., editors: *Miller's anesthesia*, ed 7, Philadelphia, 2010, Churchill Livingstone.

with infusions. Intravenous infusions or intermittent bolus of vecuronium, rocuronium, or cisatracurium are the most common neuromuscular drugs that are presently used in the operating room for pediatric patients in the United States (Table 7-27).

Interactions with Inhaled Anesthetics

Inhaled anesthetics both decrease the dose of NMBA needed for intubation and prolong the duration of action and recovery. The duration of anesthesia, concentration of agent and specific inhaled agent all have an effect. The order of potentiation from greatest to least is desflurane, sevoflurane, isoflurane, halothane, and nitrous-oxide-opioid or propofol anesthesia. The proposed pharmacodynamic mechanism is a central effect on motor neurons, inhibition of the ACh receptor, and an increased affinity for the NMBA at the receptor site (Fig. 7-56) (Stanski et al., 1979; Dickinson et al., 1995; Péréon et al., 1999; Paul et al., 2002a).

Ultra-Short-Acting Agents

Gantacurium

Gantacurium, an ultra-short-acting nondepolarizing NMBA in development, may be an alternative to succinylcholine. The chemical structure is a bis-tetrahydroisoquinolinium chlorofumarate, with a wide margin of safety. A study of adult volunteers determined the ED₉₅ to be 0.19 mg/kg; with time to onset of 90% block from 1.3 to 2.1 minutes (dose-dependent). Duration is 4.7 to 10.1 minutes and increases with increasing dose. Recovery rates from T₅ to T₉₅ and from T₂₅ to T₇₅ are 7 and 3 min, respectively, and they are independent of the dose administered. Transient cardiovascular side effects observed (with doses beginning at three times ED₉₅) are suggestive of histamine release. Significant histamine release at four times ED₉₅ was exhibited. No pediatric studies are available (Belmont et al., 2004; Lien et al., 2005).

■ **FIGURE 7-56.** Cumulative dose-response curves for rocuronium-induced neuromuscular blockade during 1.5 MAC anesthesia with desflurane, sevoflurane, isoflurane, and total intravenous anesthesia. (From Wulf H et al.: Neuromuscular blocking effect of rocuronium during desflurane, isoflurane, and sevoflurane anaesthesia, *Can J Anaesth* 45:526, 1998.)

Short-Acting Agents

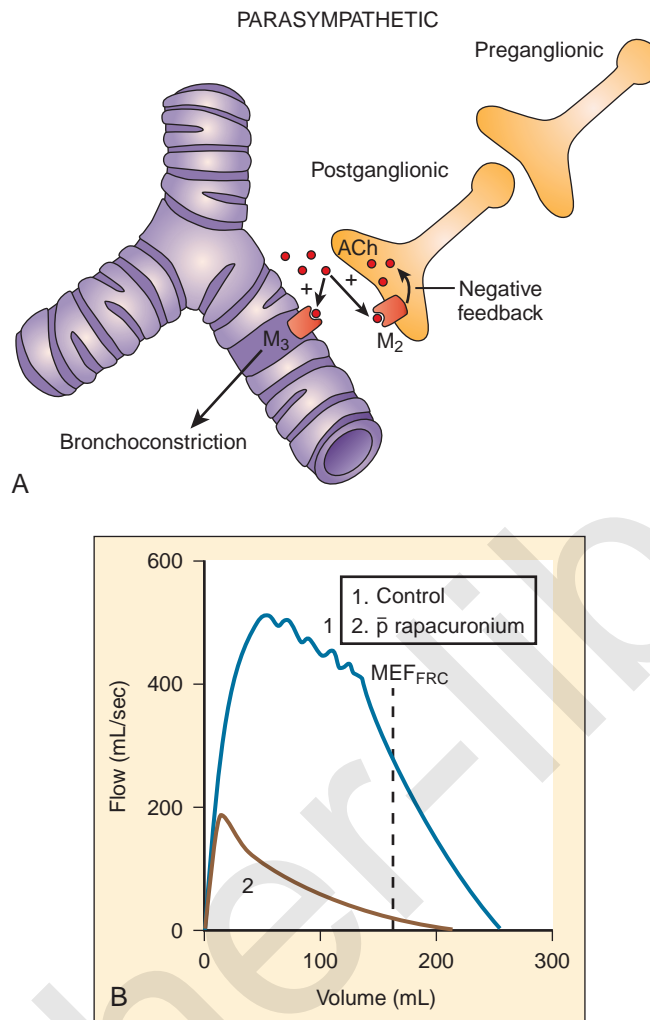

Mivacurium

Mivacurium was discontinued in the United States market in June 2006; however, it is still available in Europe. Mivacurium is metabolized by butyrylcholinesterase more slowly than succinylcholine, and this influences the duration of action (Beaufort et al., 1998; Ostergaard et al., 2000; Gatke et al., 2001). The chemical structure is a bis-benzylisoquinolinium compound, a mixture of three optical isomers. The two active isomers of mivacurium (trans-trans and cis-trans) have a short half-life and rapid clearance because of rapid enzymatic hydrolysis. The cis-cis isomer has minimal neuromuscular blocking effects but is slowly hydrolyzed (Cook et al., 1992a, 1992b; Head-Rapson et al., 1994; Lien et al., 1994). The ED₉₅ of mivacurium during halothane anesthesia in infants and children is 85 and 89 mcg/kg, respectively, compared with an ED₉₅ of 45 to 81 mcg/kg in adults (Woelfel et al., 1993; Meretoja et al., 1994). In infants, mivacurium produces complete neuromuscular blockade as quickly as succinylcholine, but the intubating conditions are less desirable after mivacurium (i.e., a higher incidence of coughing and diaphragmatic movement) (Cook et al., 1995). In children, mivacurium produces complete neuromuscular blockade more slowly than does succinylcholine. During halothane anesthesia, increasing the dose of mivacurium from 0.2 to 0.3 mg/kg (two to three times ED₉₅) does not shorten the time to complete paralysis (1.5 minutes) or produce hypotension or cutaneous flushing (Gronert and Brandom, 1994). Mivacurium can induce histamine release when large bolus doses (e.g., 0.4 mg/kg) are administered rapidly. The most common manifestation of histamine release is transient cutaneous flushing and mild decreases in blood pressure. Recovery to T₂₅ was faster in infants (6.3 minutes) compared with children (10 minutes). Increasing the dose of mivacurium given to children from 0.2 to 0.3 mg/kg did not significantly prolong the time to spontaneous recovery of neuromuscular function to 25% of baseline (Cook et al., 1995). Mivacurium (0.3 mg/kg) has little or no effect on lung mechanics as measured with flow-volume loops (Fine et al., 2002).

The infusion rate of mivacurium to maintain constant neuromuscular block at approximately 95% twitch depression is about twice as great in infants and children as in adults (Markakis et al., 1998). An advantage of mivacurium is that it can be given via infusion for hours without accumulation or prolongation of recovery once the infusion is stopped (Brandom et al., 1990; Goudsouzian et al., 1994).

Rapacurium

Rapacurium is a short-acting aminosteroid with low potency and rapid onset of action. In spite of appropriate studies in infants and children prior to FDA release in 1999, it was withdrawn from the market in 2001 due to the high incidence of respiratory complications, especially bronchospasm (Meakin, 2001; Fine et al., 2002). The affinity of rapacurium to block M₂ receptors is 15 times higher than its affinity to block M₃ receptors, which would explain the high incidence of severe bronchospasm (Fig. 7-57) (Jooste et al., 2003). The doses that produce good to excellent intubating conditions at 60 seconds in infants and children with nitrous oxide-oxygen and alfentanil (12.5 to 50 mcg/kg) are 1.5 and 2 mg/kg, respectively (Meakin et al., 2000). Rapacurium

■ **FIGURE 7-57. A**, Muscarinic (M_3) receptors are located postsynaptically on airway smooth muscle. ACh stimulates M_3 receptors to cause contraction. M_2 muscarinic receptors are located presynaptically at the postganglionic parasympathetic nerve endings, and they function in a negative feedback mechanism to limit the release of acetylcholine. **B**, A typical example of the effect of rapacuronium on partial expiratory flow-volume curves, as obtained by the forced deflation technique, from a 3-year-old child under total intravenous anesthesia (propofol/remifentanyl). 1, The baseline flow-volume curve; 2, a flow-volume curve, executed under the same volume and pressure settings as 1, but obtained after a single-dose infusion of rapacuronium. There is a severe decrease in peak expiratory flow, a flattening of the forced expiratory flow-volume curve, and a decreased forced expiratory volume. The severe decrease in maximal expiratory flow at functional residual capacity (MEF_{FRC}) from the baseline value together with the concavity of the curve toward the volume axis indicate the involvement of relatively small airways. (**A**, From Naguib M, Lien CA: *Pharmacology of muscle relaxants and their antagonists*. In Miller RD, Eriksson LI, Fleisher LA, et al.: *Miller's anesthesia*, ed 7, Philadelphia, 2010, Churchill Livingstone. **B**, From Fine GF, Motoyama EK, Brandom BW et al.: *The effect on lung mechanics in anesthetized children with rapacuronium: a comparative study with mivacurium*, *Anesth Analg* 95(1):56-61, 2002.)

produces block earlier than mivacurium, and recovery is dose related and slower than that from mivacurium during halothane anesthesia (Brandom et al., 2000).

Intermediate-Acting Agents

Atracurium

Atracurium has been replaced in the United States by its metabolite, cisatracurium, because of the histamine-releasing side effect, which is more common in adults than in children (Goudsouzian et al., 1986; Shorten et al., 1993). Atracurium is primarily metabolized by nonspecific esters (ester hydrolysis) and is spontaneously decomposed by Hofmann degradation. Both processes are sensitive to pH and temperature. Deficient

or abnormal butyryl cholinesterases have no effect on atracurium degradation.

The effect of potent inhaled anesthetics on the dose-response relationships of atracurium in infants, children, and adolescents have been studied extensively (Brandom et al., 1985a; Goudsouzian et al., 1983a, 1985; Stiller et al., 1985a, 1985b; Meretoja et al., 1994).

The ED_{95} for atracurium is similar in infants aged 1 to 6 months (150 mcg/kg) and in adolescents, whereas it is greater (280 mcg/kg) in children with both halothane and isoflurane anesthesia. For anesthesia with nitrous oxide and fentanyl, neonates and infants (younger than 1 year old) have an ED_{95} of 226 mcg/kg and children (older than 1 year) have an ED_{95} of 316 mcg/kg (Meretoja and Wirtavuori, 1988). In addition, infusion requirements for children ages 2 to 10 years are decreased

with both halothane and isoflurane (6.3 mcg/kg per minute) compared with balanced anesthesia with fentanyl (9.3 mcg/kg per minute). Neonates, up to 1 month old, have an infusion requirement of atracurium of 0.40 ± 0.02 mg/kg per hour that is 25% less than that of infants and children (0.52 ± 0.02 mg/kg per hour) (Kalli and Meretoja, 1988).

At equipotent doses (ED_{95}), the duration of effect (time from injection to 95% recovery) is 23 minutes in infants and 29 minutes in both children and adolescents, compared with 44 minutes in adults. The T_{25} recovery (minimum time when pharmacologic reversal can be administered) is 10 minutes in infants, 15 minutes in children and adolescents, and 16 minutes in adults. At higher multiples of the ED_{95} , the duration of effect is longer, but the times from T_5 to T_{25} recovery (recovery index) are the same. The shorter duration of effect in the infant results from a difference in pharmacokinetics compared with those of both children and adults. In infants (1 to 8 months), the volume of distribution is larger, clearance is more rapid, and the elimination half-life is shorter than in children (aged 2 to 10 years) or adults. The ED_{95} of atracurium is comparable for neonates and infants (226 mcg/kg).

Cisatracurium

Cisatracurium is a metabolite of atracurium, a mixture of 10 optical and geometric isomers (Welch et al., 1995). The R-R¹ optical isomer in the cis-cis configuration, cisatracurium, is about 1.5 times more potent than atracurium and does not liberate histamine even at very high doses (five times the ED_{95}) (Soukup et al., 1997). Cisatracurium is primarily degraded by Hofmann degradation to laudanosine and a monoquaternary acrylate, which is hydrolyzed by plasma esterases. The by-products of metabolism have no neuromuscular blocking effect, and they are excreted by the liver and the kidneys (Neill et al., 1983).

Cisatracurium is equipotent in infants, children, and adults (Table 7-23). During nitrous oxide-narcotic thiopentone administration, the ED_{50} and ED_{95} values for infants (29 ± 3 mcg/kg and 43 ± 9 mcg/kg, respectively) were similar for children (29 ± 2 mcg/kg and 47 ± 7 mcg/kg) (DeRuiter and Crawford, 2001).

With halothane anesthesia in children, the rate of recovery after a dose of one to two times the ED_{95} was rapid, with a recovery index from T_{25} to T_{75} of 9 to 11 minutes and a recovery index from T_5 to T_{95} 25 to 30 minutes (Meretoja et al., 1996). In a separate study of infants and children anesthetized with nitrous oxide and opioids, 0.15 mg/kg (three times the ED_{95}) of cisatracurium had a mean onset time of maximum blockade in infants of 2 ± 0.8 minutes, whereas that in children was less rapid at 3 ± 1.2 minutes. The clinical duration of action of cisatracurium to T_{25} was significantly longer in infants (43.3 ± 6.2 minutes) than in children (36 ± 5.4 minutes); however, once neuromuscular function started to recover, the rate of recovery was similar in both age groups (Taivainen et al., 2000). Another study with 0.1 mg/kg (two times ED_{95}) of cisatracurium in 15 infants and 15 children with remifentanyl and sevoflurane anesthesia (2% end-tidal) also reported a significantly faster onset (74 vs. 198 seconds), longer clinical duration to T_{25} (55 vs. 41 minutes), and longer recovery to TOF greater than 0.9, 73 (range 56 to 86) minutes vs. 59 (range 43 to 72) minutes in the infants than in children. Here, the inhalational agent accelerated the onset and prolonged the recovery to T_{25} in spite of a smaller dose of cisatracurium. Again, the recovery index was comparable in

both infants and children at 21 vs. 16 minutes (Soltész et al., 2002). One of the benefits of cisatracurium is that once recovery begins, full recovery is rapid and predictable in both infants and children. Also of note is that there were negligible changes in heart rate or blood pressure for both age groups at the larger dose (Brandom, 1998; Taivainen et al., 2000; Meakin et al., 2007).

Cisatracurium infusions have a place in the ICU for postoperative care, especially in patients with organ failure. Postoperative cardiac patients (younger than age 2 years) receiving cisatracurium infusions had a high clearance, low duration of residual block, and a mean return to TOF of greater than 0.9 of 30 minutes (Reich et al., 2004). Another ICU study in children (aged 3 months to 16 years) had an average cisatracurium infusion rate of 3.9 ± 1.3 mcg/kg per minute with a median time to recovery significantly shorter with cisatracurium (52 minutes, with a range of 35 to 73 minutes) compared with vecuronium (123 minutes, with a range of 80 to 480 minutes) (Burmester and Mok, 2005). Steady-state volume of distribution (207 ± 31 mL/kg) and total body clearance (6.8 ± 0.7 mL/min per kg) for cisatracurium are significantly larger in children than those published for adults. Both renal failure and liver disease have minimal effects on the pharmacodynamics of cisatracurium (Table 7-35) (Prielipp et al., 1995; DeWolf et al., 1996).

Vecuronium

Vecuronium has an intermediate duration of action in children and adults; however, the neuromuscular block lasts longer in infants. The ED_{95} of vecuronium in infants and adults is 43 to 47 mcg/kg, whereas in children it is 81 mcg/kg (D'Hollander et al., 1982a; Fisher and Miller, 1983; Meretoja et al., 1988). Onset in the infant (68 seconds) is 0.6 to 0.8 times more rapid than that in the child after 0.1 mg/kg of vecuronium; however, the multiple of the ED_{95} is greater for the infant (two times vs. 1.2 times) (Kalli and Meretoja, 1989). Onset to maximum block from 0.07 mg/kg in the infant with halothane anesthesia occurs in 1.5 ± 0.6 minutes.

ED_{95} , onset and duration in children. The ED_{95} for vecuronium for children with halothane is 45 mcg/kg and with a narcotic is 81 mcg/kg, which is greater than that of adults at 33 mcg/kg

TABLE 7-35. Pharmacokinetic Data for Cisatracurium in Children and Adults*

Variable	Children	Adults
$t_{1/2\alpha}$ (min)	3.5 ± 0.9	
$t_{1/2\beta}$ (min)	22.9 ± 4.5	23 ± 2.7
V_d (mL/kg)	207 ± 31	144 ± 34
CL (mL/kg/min)	6.8 ± 0.7	5.3 ± 1.2

for halothane and 43 mcg/kg for narcotic anesthesia. The time to onset of maximum block after 0.07 mg/kg of vecuronium is 2.4 ± 1.4 minutes in the child under halothane anesthesia with time to recovery of T_{90} of 35 ± 6 minutes, whereas that for adults is 2.9 ± 0.2 minutes for onset and T_{90} of 53 ± 21 minutes (Table 7-25).

Duration of block in the infant and child. At equal doses (0.07 mg/kg) of vecuronium with halothane anesthesia, the duration to T_{90} is longest in infants (73 ± 27 minutes) compared with that in children (35 ± 6 minutes) and adults (53 ± 21 minutes). Vecuronium is a long-acting NMBA in infants.

Recovery to 10% of initial twitch height from 0.1 mg/kg of vecuronium (two times ED_{95}) is also prolonged, at 42 minutes, in the infant (younger than 1 year of age) with nitrous-oxide-fentanyl anesthesia. Time to T_{10} and the recovery index (time from 25% to 75% recovery) were 1.7 to 2.9 times longer in the infant, than in the child (aged 1 to 14 years). Time to full recovery to 100% of T_1 from the start of recovery occurred in 55 minutes for the infant but took only 20 to 24 minutes for the child. Interestingly, TOF was observed to recover more rapidly in younger children. The clinical implication of this observation is not known (Kalli and Meretoja, 1989). In addition, a 100 and 150 mcg/kg initial bolus of vecuronium (two to three times ED_{95}) produced a block of greater than 90% from 59 to 110 minutes respectively, in the neonate and infant group, but only from 18 to 37 minutes for children and from 37 to 68 minutes in adolescents (Meretoja, 1989a). Vecuronium should be regarded as a long-acting NMBA in infants (younger than 1 year old).

Volume of distribution and clearance. Fisher et al. (1983) determined the pharmacodynamics and pharmacokinetics of vecuronium in infants and children. The volume of distribution and the mean residence time are greater in infants than in children. Clearance is similar in the two groups; the Cp_{ss50} was lower in infants than in children. The combination of a large volume of distribution in infants and fixed clearance results in a longer mean residence time. After a single dose of relaxant, recovery of neuromuscular transmission depends on both distribution and elimination. The combination of a longer mean residence time and a greater sensitivity for vecuronium explains the prolongation of neuromuscular blockade in infants. Little or no 3-hydroxy vecuronium is formed after a single dose of vecuronium (0.1 to 0.2 mg/kg). Decreased clearance of vecuronium and the accumulation of 3-hydroxy vecuronium may contribute to prolonged spontaneous recovery times after infusions in ICU (Reich et al., 2004).

Infants vs. children. In a similar fashion, infusions of vecuronium in infants also act as long-acting rather than intermediate-acting agents. The clearance of vecuronium is low in infants (younger than aged 2 years), significant amounts of the metabolite 3-hydroxy vecuronium are found, and return to full neuromuscular transmission of TOF greater than 0.9 is quite slow (180 minutes) compared with a cisatracurium infusion, which takes only 30 minutes to attain the same level of neuromuscular transmission (Reich et al., 2004). A 45% decrease of vecuronium mean infusion rate of 54.7 ± 4.23 mcg/kg per hour is required in infants (aged 2 to 5 months) compared with that of the older children (aged 2 to 10 years) at 98.7 ± 7.07 mcg/kg per hour to keep block at 1 twitch. Recovery to TOF of greater than 0.7 is more rapid at 45 minutes for infants than 65 minutes for children. This faster recovery may be related to the decreased

total amount of vecuronium infused in the infants (Hodges, 1996). In the operating room with fentanyl and nitrous-oxide anesthesia, neonates (younger than 1 month) and infants (aged 1 to 12 months) require 40% less vecuronium at 62 ± 15 mcg/kg per hour compared with children (aged 3 to 10 years) at 154 ± 49 mcg/kg per hour and adolescents (older than age 13 years) and adults at 89 ± 13 mcg/kg per hour. Interindividual variation is quite large (Meretoja, 1989a, 1989b). These data correlate with the pharmacokinetic/pharmacodynamic studies in infants that reveal the increased volume of distribution, longer mean residence time and smaller Cp_{ss50} . Since the clearance is no different in infants than in children, the factors just mentioned explain the prolonged action of vecuronium in infants. Therefore, great interindividual variation makes routine monitoring of neuromuscular block in both the ICU and operating room essential; AMG is one convenient and reliable method in neonates and infants (Hodges, 1996).

Children vs. adults. An infusion rate of 144 mcg/kg per hour (2.4 mcg/kg per minute) vecuronium is required to maintain approximately 95% neuromuscular blockade in children during narcotic and nitrous-oxide anesthesia. These infusion rates are several times higher than those in adults (aged 18 to 85 years) (D'Hollander et al., 1982b). Young adults required 54 mcg/kg per hour (0.9 mcg/kg per minute) to maintain 95% neuromuscular blockade. This suggests that clearance is more rapid in children than in adults, and children do recover more rapidly from vecuronium infusions than do adults (Table 7-29). Several groups have described long-term vecuronium infusion requirements in adults with multiple organ failure in the ICU (Segredo et al., 1992). Infusion rates of about 1.6 mcg/kg per minute were required, and the degree of block gradually increased, a sign of accumulation. Increasing vecuronium infusion requirements, by contrast, may be seen during very prolonged infusions (i.e., lasting 3 to 14 days). These increased requirements could not be clearly associated with various pathophysiologic states, concurrent drug administration, or biochemical abnormalities. Proliferation of extrajunctional cholinergic receptors resulting from prolonged nondepolarizing blockade has also been offered as an explanation (Hogue et al., 1992; Martyn et al., 1992).

Patients with organ failure. Adults with liver failure have a decreased clearance (50%) of vecuronium and time to recovery to T_{50} is twice (130 minutes) and the RI (25% to 75%) is three times (68 minutes) that of normal patients in spite of the Cp_{ss50} being equal (Lebrault et al., 1985). The similarity of Cp_{ss50} suggests that patients with cirrhosis have normal sensitivity to vecuronium. Despite the prolonged duration of action of vecuronium in patients cirrhosis, it was still shorter than that of pancuronium in patients free of liver disease. No studies are available in pediatric patients with liver failure.

Vecuronium is only slightly dependent on renal elimination (10% to 30%), and it is minimally affected by renal failure. Some adult studies demonstrated a longer duration of neuromuscular block in this patient population (Lynam et al., 1988). The increased duration is related to both a decreased plasma clearance and a prolonged elimination half-life of vecuronium in the renal failure group. Similarly, Bencini et al. (1983) found a 50% decrease in clearance, an increase in volume of distribution, and a 50% increase in elimination half-life. The duration of action was not reported. Metabolites of vecuronium were not measured in these adult studies.

Chronic phenytoin therapy reduces the effect of vecuronium by mechanisms that include both increased vecuronium metabolism and reduced sensitivity of the patient to circulating concentrations of vecuronium (Wright et al., 2004).

Rocuronium

ED₉₅, onset, intubating conditions, and recovery. Rocuronium (ORG 9426), an aminosteroid, with no metabolites, has a chemical structure similar to vecuronium (with active metabolites). Rocuronium has one eighth to one tenth the potency of vecuronium. The lesser potency of rocuronium produces a more rapid onset of block in comparison with equipotent doses of other drugs (i.e., equal multiples of the ED₉₅) (Kopman, 1989). [Table 7-23](#) shows the ED₉₅ for infants and children for rocuronium. Bolus administration of 0.6 mg/kg of rocuronium at two times ED₉₅ is associated with a transient increase in heart rate of about 15 beats/min and produces complete neuromuscular blockade (at the adductor pollicis) in infants and children in 50 and 80 seconds, respectively (Woelfel et al., 1992; O'Kelly et al., 1994). Increasing the dose to 0.8 mg/kg in children shortens this time to an average of 30 seconds (O'Kelly et al., 1994). Low-dose rocuronium for tracheal intubation in children during inhalational induction is 0.3 mg/kg (ED₉₅) and allows acceptable intubating conditions in 95% of children (aged 2 to 7 years) with sevoflurane anesthesia within 2 minutes, or in children (aged 1 to 3 years) of age in 60 seconds (Eikermann et al., 2002). Another study shows that children (aged 4 to 6 years) have good intubation conditions in 90 seconds, 80% of the time (Hung et al., 2005). Recovery to TOF of greater than 0.8 occurs in 24 ± 8 minutes with a low dose of rocuronium (0.3 mg/kg) (Eikermann et al., 2002). Rocuronium 0.3 mg/kg with halothane anesthesia in children (older than 1 year of age) shows a slower onset than the larger dose, but does not cause a prolonged block (Driessen et al., 2002).

Recovery in infants. There is significant variability in time to recovery with 0.6 mg/kg of rocuronium in infants compared with children; and time to T₂₅ is almost twice as long at 41.9 minutes in infants (older than 10 months) compared with children (aged 1 to 5 years) at 26.7 minutes (Woelfel et al., 1994; Driessen et al., 2005). Prolonged recovery to T₇₅ and TOF of greater than 0.7 with both 0.45 mg/kg and 0.6 mg/kg of rocuronium in infants 0 to 1 months, 2 to 4 months, and 5 to 12 months under isoflurane anesthesia can be seen in [Table 7-26](#) (Rapp et al., 2004a). Even the low dose of 0.3 mg/kg of rocuronium with halothane nitrous-oxide anesthesia has a prolonged recovery to T₂₅, T₇₅, RI, and TOF of greater than 0.7 in the 0 to 6-month age group compared with those children older than 2 years of age (Driessen et al., 2000). This age-related difference is similar to that observed with vecuronium (Meretoja, 1989a). Both of these drugs are long-acting NMBAs instead of an intermediate-acting agent in the infant ([Fig. 7-51](#)). This is true for infants with balanced anesthesia (Taivainen et al., 1996).

Recovery in children vs. adults. Time to appearance of the fourth twitch after 1 mg/kg rocuronium is more rapid in children than adults, with ranges from 27 to 62 minutes in children (younger than 5 years of age) vs. 37 to 94 minutes in adults. In addition, once PTC is detected, recovery to one twitch in the TOF is also more rapid in children, at 7 minutes compared with 16 minutes in the adults (Baykara et al., 2002). No data on PTC in infants are presently available. Steady-state target-controlled infusions

of rocuronium in infants, children, and adults revealed infants had the lowest infusion rates of rocuronium and children had the greatest (Saldien et al., 2003). The data are shown in [Table 7-28](#).

Rapid onset of action with minimal tachycardia and intermediate duration of action in children (older than age 2 years) makes rocuronium an attractive neuromuscular blocking drug. However, in infants rocuronium functions as a long-acting nondepolarizing agent and the recovery time is quite variable. The monitoring device AMG has been shown to be practical even in the neonate and small infant and should be used (Driessen et al., 2005).

Infusions of rocuronium in ICU patients are variable, with rates reported from 0.3 to 2.2 mg/kg per hour (5 to 36.6 mcg/kg per minute), so use of neuromuscular monitoring equipment is highly recommended. In the operating room, infusion rates in children are influenced by inhalational anesthetics. Values range when using nitrous oxide from 16.7 ± 2.3 mcg/kg per minute for fentanyl anesthesia, 13.6 ± 3.7 mcg/kg per minute for halothane, 13.1 ± 5.1 mcg/kg per minute for isoflurane, and 8.49 ± 1.6 mcg/kg per minute for sevoflurane. The rocuronium infusion rate required to maintain stable 90% to 99% T₁ depression is reduced 20% with halothane and isoflurane, and by 50% with sevoflurane. No data are available for rocuronium infusions in children with desflurane. However, adult studies show no differences between isoflurane, sevoflurane, and desflurane with respect to potency (121 to 136 mcg/kg), infusion rate (6.1 to 6.3 mcg/kg per minute) or recovery (26 to 28 minutes) from rocuronium (Bock et al., 2000).

Intramuscular rocuronium. A multicenter study evaluated the intubating conditions, onset, and duration of intramuscular rocuronium in infants (1 mg/kg) and children (1.8 mg/kg) under halothane anesthesia. Conditions were not satisfactory in a consistent manner in this patient population. Rocuronium delivered intramuscularly is not an adequate alternative to intramuscular succinylcholine when rapid intubation is necessary (Kaplan et al., 1999).

Organ failure. A single bolus dose of rocuronium 0.3 mg/kg in children (older than 1 year of age) with renal failure does not cause a prolonged block, but it has a slower onset, 139 ± 71 vs. 87 ± 43 seconds, than in healthy children (Driessen et al., 2002).

No change in clearance is found in adults with renal disease or cirrhosis for patients receiving 0.6 to 0.8 mg/kg of rocuronium.

Long-Acting Agents

Pancuronium

Pancuronium, a steroidal bis-quaternary muscle relaxant, is still used for infants and children because of its predictable neuromuscular blocking action and associated cardiovascular stimulating properties. Older children require a larger dose than do infants and small children ([Table 7-36](#)) (Goudsouzian, 1974; Meretoja, 1990; Blinn et al., 1992).

Sixty-seven percent of pancuronium is recovered within 24 hours in the urine (Duvaldestin, 1982). About 25% of pancuronium appears in the urine in the form of the 3-hydroxy metabolite, and less than 5% each appeared in the form of the 17-hydroxy and 3,17-dehydroxy metabolites. Approximately 11% of the pancuronium was excreted in the bile.

TABLE 7-36. Cumulative Dose-Response Relationship of Pancuronium

Age	ED ₅₀ (mg/kg)	ED ₉₅ (mg/kg)
3 to 6 mo	24 ± 7	45 ± 7
7 to 12 mo	30 ± 5	52 ± 9
1 to 3 yr	34 ± 9*	62 ± 18*
4 to 6 yr	29 ± 8	62 ± 13*

Data from Blinn A et al: Pancuronium dose-response revisited, *Paediatr Anesth* 2:153, 1992.

*Statistically significant difference from the 3- to 6-month age group (analysis of variance).

Antagonists for Neuromuscular Blocking Agents: Anticholinesterases and Sugammadex

Doses of Anticholinesterase Drugs in Infants and Children

Three anticholinesterases are available to antagonize neuromuscular blockade: neostigmine, edrophonium, and pyridostigmine. Reviews by Bevan et al. (1992) and Aquilonius and Hartvig (1986) are available on the mechanisms of action of these drugs. When the enzyme acetylcholinesterase, which breaks down ACh, is inhibited, the concentration of ACh increases at the motor end plate and competes with the non-depolarizing NMBA. In addition, anticholinesterases may also increase the release of ACh from the presynaptic nerve terminals, block neural potassium channels, and have a direct agonist effect (Bevan et al., 1992).

Fisher et al. (1983, 1984) examined the dose of neostigmine and edrophonium required in infants, children, and adults to reverse a 90% blockade from a continuous d-tubocurarine infusion. In infants and children, 15 mcg/kg of neostigmine produced a 50% antagonism of the d-tubocurarine blockade; in adults, 23 mcg/kg was required. The duration of antagonism was equal in all three age groups, although the elimination half-life was clearly shorter in infants. A larger dose would give a higher sustained blood concentration. The dissociation between the elimination half-life and the duration of antagonism may result from the carbamylation of cholinesterase by neostigmine.

In infants, 145 mcg/kg of edrophonium produced a 50% antagonism of the d-tubocurarine blockade; for children and adults, 233 mcg/kg and 128 mcg/kg, respectively, were required. The volume of distribution of edrophonium is similar in all age groups. The elimination half-life of edrophonium is shorter in infants than in children or adults; hence, clearance is more rapid in infants.

Meakin et al. (1983) compared the rate of recovery from pancuronium-induced neuromuscular blockade after various doses of neostigmine (0.036 or 0.07 mg/kg) or edrophonium (0.7 or 1.43 mg/kg) in infants, children and adults. In the first 5 minutes, recovery of neuromuscular transmission was more rapid after edrophonium than after neostigmine in all age groups; recovery was more rapid in infants and children than in adults. By 10 minutes, there was no difference in neuromuscular transmission achieved in infants and children with either reversal agent (at either dose); adults had lower neuromuscular transmission at the lower dose (0.036

mg/kg) of neostigmine. If speed of initial recovery is a critical issue, edrophonium is better than neostigmine, and a high dose of neostigmine is better than a low dose. At 30 minutes after injection of either reversal agent (at any dose), there was no difference between neuromuscular transmission among age groups. Another study shows no advantage in increasing the neostigmine dose more than 20 mcg/kg to antagonize a rocuronium block (at only 10% recovery of the first twitch at which three or four twitches are present), and reaffirms that recovery is more rapid in children than adults (Abdulatif et al., 1996). Debaene et al. (1989) document that recovery with neostigmine 30 mcg/kg for infants and children and 40 mcg/kg for the adults under halothane from vecuronium also produces a more rapid response in children.

Edrophonium (0.5 to 1 mg/kg) has a more rapid effect than neostigmine (50 to 70 mcg/kg) when the block has recovered to three or four twitches, but it is not as effective for a profound block (only one twitch present). Pyridostigmine (350 mcg/kg) is rarely used clinically.

Side Effects of Anticholinesterases

Cardiovascular effects. The muscarinic effects of the anticholinesterases are blocked by administration of either atropine (7 to 10 mcg/kg) or glycopyrrolate (5 mcg/kg). An increase in heart rate should be observed from glycopyrrolate before administration of edrophonium because of its rapid onset; atropine can be administered at the same time as edrophonium.

Nausea and vomiting. Conflicting reports are available on the incidence of postoperative nausea and vomiting (PONV) related to anticholinesterase administration. Some evidence suggests that this incidence is dose dependent, with the lower dose of neostigmine 1.5 mg in adults having a lower incidence of PONV. The well-known risk of residual neuromuscular block far outweighs the concern for nausea and vomiting, especially in infants and children.

Sugammadex

Sugammadex appears to be a novel reversal agent that rapidly and effectively reverses rocuronium-induced neuromuscular blockade in less than 5 minutes, similar to that of anticholinesterases when administered at appropriate times. Sugammadex, a γ -cyclodextrin, is highly water soluble with a hydrophobic cavity that encapsulates steroidal neuromuscular blocking drugs, rocuronium at a rate greater than that for vecuronium, which has a greater rate than pancuronium (Figs. 7-58 and 7-59). Efficacy and safety have been demonstrated for sugammadex in infants (28 days to 23 months old), children (aged 2 to 11 years), adolescents (aged 12 to 17 years), and adults (aged 18 to 65 years) as a method for eliminating rocuronium (0.6 mg/kg). Sugammadex (0.5, 1, 2, or 4 mg/kg) was compared with placebo at reappearance of the second twitch of TOF with AMG monitor. Time to TOF of greater than 0.9 was 21, 19, 23.4, and 28.5 minutes in infants, children, adolescents, and adults, respectively, after placebo administration. With sugammadex (2 mg/kg), the TOF of greater than 0.9 was attained in 0.6, 1.2, 1.1, and 1.2 minutes, respectively, with no adverse events. The sugammadex plasma concentrations were similar for children, adolescents, and adults across the dose range. The drug was well tolerated, and no recurrence of blockade, inadequate reversal, significant

■ **FIGURE 7-59.** The sugammadex-rocuronium complex. (From Bom A et al.: *A novel concept of reversing neuromuscular block: chemical encapsulation of rocuronium bromide by a cyclodextrin-based synthetic host*, *Angew Chem* 41:266, 2002.)

QT prolongation, or other abnormalities were observed (Plaud et al., 2009). The encapsulated aminosteroid is excreted in urine; studies of adult patients in end-stage renal failure conclude that sugammadex appears to be safe in this patient population (Staals et al., 2008). Studies are ongoing at this time. Sugammadex also has a high affinity for vecuronium.

A 2009 review recommends the dose of 2 mg/kg sugammadex for shallow block, and 4 mg/kg for deep block in adults. A larger dose of 16 mg/kg may be administered 3 minutes after 1 to 1.2 mg/kg of rocuronium is administered (deep block), and recovery is rapid. No recurrence of block has been reported, the safety profile is unremarkable, no change in dose requirement has been found as a result of age or type of volatile anesthetic (Mirakhor, 2009). Another review recommends sugammadex to antagonize both deep and moderate rocuronium and

vecuronium block in adults and moderate block in children (aged 2 to 17 years). The drug is approved in Australia, Iceland, New Zealand, and Norway (Yang and Keam, 2009).

COMMONLY ADMINISTERED ANESTHETIC ADJUNCTS

Anticholinergic Agents

Atropine

Strong cholinergic stimulation, such as that which occurs from halothane and succinylcholine, can produce profound bradycardia and reduce cardiac output in infants. The primary purpose of atropine in pediatric anesthesia is to protect against cholinergic stimulation; its secondary purpose is to inhibit the production of secretions.

If atropine is administered intravenously in incremental doses, more atropine (on a weight basis) is needed to accelerate the heart rate in children younger than 2 years; however, acceleration uniformly occurs with 14.3 mcg/kg (Dauchot and Gravenstein, 1971). Infants need higher doses of atropine to increase heart rate compared with adults (Palmisano et al., 1991). The onset of the chronotropic effects of atropine appears to be related to the underlying heart rate at the time of administration of atropine. Children with slower heart rates have longer onset times than do children with faster heart rates (Zimmerman and Steward, 1986). Although atropine can increase heart rate and cardiac output, it does not appear to change the neuromuscular blocking onset time of atracurium (Simhi et al., 1997). A dose of 30 mg/kg appears to be vagolytic in infants, children, and adults. This dose provides adequate protection against a cholinergic challenge. In a study of 20 healthy children aged 1 to 36 months undergoing elective surgery, McAuliffe et al. (1997) noted that 20 mcg/kg intravenously caused a variable increase in heart rate and cardiac output in anesthetized children. In 40 children ranging from 2 to 6 years in age, intratracheal atropine (20 mcg/kg) produced only a modest increase in heart rate after 5 minutes (Jorgensen and Ostergaard, 1997). However, 50 mcg/kg increased heart rate rapidly (Howard and Bingham, 1990). The site of injection has a role in the onset time of atropine effect. In a randomized study of children 1 to 10 years of age who were anesthetized with nitrous oxide, oxygen, and halothane, Sullivan et al. (1997) noted that a subglottal injection resulted in a faster onset time than either a deltoid or vastus lateralis intramuscular injection.

In all age groups, 5 to 10 mcg/kg atropine minimally decreases salivation (Gaviotaki and Smith, 1962). Children with Down syndrome may have an increased sensitivity to atropine; the pupils dilate in response to atropine, and large increases in heart rate occur after repeated doses of atropine (Berg et al., 1960; Priest, 1960; Harris and Goodman, 1968). In a retrospective study by Kobel et al. (1982), however, patients with Down syndrome were no more sensitive to intravenous atropine than were other patients.

Glycopyrrolate is another anticholinergic agent. It is a quaternary amine that penetrates the CNS less than atropine. It inhibits the muscarinic action of ACh at postganglionic parasympathetic neuroeffector sites in smooth muscle secretory glands and in the CNS. Adverse reactions include tachycardia; palpitations; restlessness; delirium; dry, hot skin; myostasis;

xerostomia; and urinary retention. The intravenous dose is usually 0.005 to 0.01 mg/kg.

Scopolamine is a nonselective muscarinic antagonist, which has both peripheral antimuscarinic properties as well as central sedative, antiemetic, and amnesic effects. The pharmacokinetics and dynamics of scopolamine for clinical use have been reviewed by Renner and colleagues (2005). It has been used clinically as a premedication and as an antiemetic. Scopolamine has a short half-life—approximately 70 minutes after intravenous administration—and has dose-dependent adverse effects. The transdermal delivery system was developed to minimize the drug's adverse effects. The drug is also well absorbed after intranasal and ocular administration. The dose of scopolamine for intravenous, intramuscular, and subcutaneous administration is 6 to 10 mcg/kg.

Analgesic Agents

Ketorolac

Ketorolac is a nonsteroidal antiinflammatory drug. The analgesic properties of nonsteroidal antiinflammatory drugs are thought to be related to their ability to attenuate the hyperalgesic state caused by prostaglandins as opposed to producing analgesia directly. Ketorolac may act both peripherally and centrally. Ketorolac is an enantiomeric compound. The pharmacokinetics of ketorolac were described after single and continuous infusion (Olkola and Maunuksela, 1991; Gillis et al., 1997; Hamunen et al., 1999; Kauffman et al., 1999; Dsida et al., 2002; Kokki et al., 2002; Zuppa et al., 2009). Ketorolac has also been administered intranasally to adults (Brown et al., 2009).

In a study of 43 pediatric surgical patients, Dsida et al. (2002) noted no age-related differences in the pharmacokinetics, and the kinetic profile was similar to that reported for adults. In a pharmacokinetic study of the stereoisomers of ketorolac in children, Kauffman et al. (1999) noted that concentrations of the S⁻ enantiomer were lower than those of the R⁺⁺ enantiomer and that the S⁻ enantiomer had a shorter half-life, greater clearance, and larger volume of distribution. Similar findings were noted by Lynn and colleagues (2007). These differences in the enantiomer kinetic profile appear to be similar for children, adolescents, and adults (Fig. 7-60) (Hamunen et al., 1999). In addition to its analgesic properties, ketorolac may have antiemetic properties (Munro et al., 1994). In children undergoing ureteral reimplantation procedures, ketorolac can decrease the incidence and severity of postoperative bladder spasms, and in children undergoing low-risk cardiac surgery, ketorolac did not affect serum creatinine values differently than the control group of children who did not receive ketorolac (Park et al., 2000; Inoue et al., 2009). A major determinant to the use of ketorolac has been the potential that nonsteroidal agents affect bone healing. In a study of 349 adolescent patients undergoing posterior spinal fusions, Sucato et al. (2009) noted that the incidence of pseudoarthrosis was the same in adolescents given ketorolac to those who did not receive nonsteroidal antiinflammatory drugs.

Acetaminophen (Paracetamol)

Acetaminophen (paracetamol in European countries and the United Kingdom), N-acetyl-p-aminophenol, was first used widely in 1949 and has been available in the United States

without prescription since 1955. Its analgesic and antipyretic action may be related to its inhibition of prostaglandin synthesis in the CNS. Adult absorption from the gastrointestinal tract is rapid, with maximum levels at 30 to 60 minutes and a half-life of 2 hours. Acetaminophen is metabolized in the liver primarily by conjugation. Large doses result in the formation of hepatotoxic metabolites generated by the cytochrome P450 CYP2E1 system. Although the immaturity of the P450 system appears to increase the margin of safety for acetaminophen use in infancy, there have been reports of hepatotoxicity in infants (Greene et al., 1983). For accidental overdosing of a single dose, use of the Rumack-Matthew nomogram has become standard in deciding whether N-acetyl cysteine is appropriate. Dosing above 140 mg/kg per day for several days has been suggested to carry significant risk of liver damage (Cranswick and Coghlan, 2000).

It has been reported that therapeutic concentrations of acetaminophen for antipyresis are 10 to 20 mg/L to achieve 50% of maximal fever reduction (Rumack, 1978). Information of the ideal analgesic concentrations for acetaminophen is incomplete. Anderson and Holford (1999) modeled acetaminophen pharmacodynamics for analgesia after tonsillectomy. The population-based model in 120 children, with a mean age of 8 years and a mean weight of 34 kg, suggested that a mean pain score of 3.6 of 10 would be found with an acetaminophen concentration of 10 mg/L (Anderson et al., 2001). A subsequent study by the same authors reported that an acetaminophen concentration of 10 mg/L was associated with a pain score reduction of 2.6 out of 10 in children after tonsillectomy (Anderson et al., 2001). Using a different paradigm, Korpela et al. (1999) reported that children's pain scores in the postoperative recovery unit were significantly lower with rectal acetaminophen doses of 40 or 60 mg/kg compared with scores for children who received placebo or 20 mg/kg. Rescue morphine use was related to acetaminophen doses, with reduction in the number of children needing rescue medication reaching significance at the 40 and 60 mg/kg dose groups. Most surgeries were herniorrhaphies or orchiectomies. These authors suggest that concentrations with doses of 40 mg/kg rectal acetaminophen would be expected to be in the range of 13 to 17 mg/L.

Acetaminophen is the most widely used analgesic in pediatric anesthesia. An intravenous formulation (propacetamol) has been in use in Europe for over 10 years and for a somewhat shorter time in the United Kingdom, while in the United States only the oral and rectal formulations have been available. Acetaminophen's pharmacokinetics has been studied in children, infants, and neonates. Reports from multiple investigators of rectal acetaminophen dosing establish that higher doses are needed to achieve concentrations in the 10 to 20 mg/L range. Rectal absorption is also erratic, with longer onset times for analgesia compared with those for oral administration (Anderson; Montgomery et al., 1995; Birmingham et al., 1997; Cormack et al., 2006).

Arana et al. (2001) reviewed the use of paracetamol in infants. Metabolism by conjugation is the most important pathway, with sulfation most important in neonates because glucuronidation is deficient for several weeks. Oxidation via the cytochrome P450 system is a minor pathway, but it can generate N-acetyl-p-benzoquinone imine, which is hepatotoxic. Most reports suggest infants generate less of this compound, perhaps explaining the wider margin of safety for acetaminophen in infants. Elimination half-life averages 3.5 hour, compared

■ **FIGURE 7-60.** Concentrations (mean \pm SD) of S-ketorolac (brown circles) and R-ketorolac (blue circles) in plasma after intravenous administration of 0.5 mg/kg of racemic ketorolac tromethamine to 18 children, 28 adolescents, and 18 adults. (From Hamunen K et al.: Stereoselective pharmacokinetics of ketorolac in children, adolescents, and adults, *Acta Anaesthesiol Scand* 43:1041, 1999.)

with 1.9 to 2.2 hours in adults. Premature infants showed even longer half-lives of 11 hours in infants with 28 to 30 weeks' gestation and 4.8 hours in infants with 32 to 36 weeks' gestation. Clearance is reduced in neonates, so dosing intervals may need to be longer (8 to 12 hours rather than 4 to 6 hours). The intravenous prodrug, propacetamol, which is hydrolyzed to acetaminophen, shows measurable amounts of acetaminophen immediately after intravenous injection in neonates, infants, and children, suggesting the plasma esterases are active even in newborns. Maximum increases in pain thresholds were found 2 hours after maximum plasma concentrations but correlating with peak cerebrospinal fluid concentrations, implying a CNS site of action. This review also reports several studies that suggest higher rectal dosing at 30 to 40 mg/kg are needed to get concentrations in the 10 to 20 mg/L range. Only premature infants at 28 to 32 weeks' gestation achieved these levels from rectal doses of 20 mg/kg.

Anderson et al. (2002b) gathered pooled data of acetaminophen concentrations from six studies of premature infants, neonates, term infants, and children who received acetaminophen orally or rectally. Of the 283 children included, 124 were younger than 6 months of age. A NONMEM analysis using a one-compartment model and a "one fourth power" model found a volume of distribution of 66.6 L and a clearance of 12.5 L/hr per 70-kg person. Weight and age were the covariates most important to account for the pharmacokinetic variability. The volume of distribution decreased from 109.7 L/70 kg at 28 weeks postconception to 72.9 L/70 kg at 60 weeks postconception. Clearance increased from 0.74 L/hr per 70 kg at 28 weeks postconception to 10.8 L/hr per 70 kg at 60 weeks postconception. Using these parameters to achieve a mean C_{ss} above 10 mg/L at its trough, the authors suggest oral dosing of 25 mg/kg per day at 30 weeks postconception, 45 mg/kg per day at 34 weeks postconception, 60 mg/kg per day at 60 weeks postconception, and 90 mg/kg per day at 6 months of age. Especially for the higher dose recommendations, Anderson and colleagues caution that the effect of these dose levels on the formation of hepatotoxic metabolites from the CYP2E1 pathway are unknown, and that the dose schedule should be limited to fewer than 3 days.

In the United States, clinical trials of an intravenous formulation of acetaminophen that would have advantages for use in the perioperative period are currently underway. One gram of propacetamol generates 0.5 grams of acetaminophen. Since similar formulas have been available for several years in Europe and the United Kingdom, some information for children and infants is available to guide dosing. Allegaert et al. (2004) used a population analysis of 48 neonates; 30 infants were studied after a single dose of 20 or 40 mg/kg propacetamol, and 18 received multiple doses with a 30 mg/kg load and then 20 mg/kg at 6-hour intervals (for 36 weeks postconception or older), 8-hour intervals (for 32 to 36 weeks postconception), or 12-hour intervals (for younger than 32 weeks postconception). The volume of distribution was 70.4 L/70 kg, and clearance increased from 2.85L/h per 70 kg at 27 weeks postconception to 7.05 L/h per 70 kg at 42 weeks postconception. Tables of model predictions to keep acetaminophen concentration above 10 mg/L suggest loading with 40 mg/kg propacetamol with maintenance doses of 10 to 15 mg/kg at 4-hour intervals for infants past 30 weeks postconception (6-hour intervals in 28-week prematures).

Recently Anderson and colleagues (2005) did NONMEM population-based modeling of propacetamol in 144 children (aged 27 weeks postconception to 14 years) based on pooled data from

seven studies. Size was used as the primary covariate. The data fit a three-compartment (depot, central, and peripheral) linear model best. Central volume was 24 L/70 kg, and peripheral volume was 30 L/70 kg, with clearance of 16 L/hr per 70 kg. Clearance increased from 1.87 L/hr per 70 kg at 27 weeks postconception to 84% of mature values (16.3 L/hr per 70 kg) by age 1 year. Peripheral volume of distribution decreased from 45 L/70 kg at 27 weeks postconception to mature values (30.4 L/70 kg) by 6 months of age. They also confirmed that the relative bioavailability of propacetamol was 0.5 compared with oral acetaminophen elixir. A mean acetaminophen concentration of 10 mg/L can be achieved in children aged 2 to 15 years with doses of 30 mg/kg propacetamol every 6 hours. In young infants, maintenance doses should be decreased according to postconceptual age because of lower clearance to 9 mg/kg (28 weeks), 11 mg/kg (30 weeks), 14 mg/kg (34 weeks), 18 mg/kg (40 weeks), 23 mg/kg (3 months), and 27 mg/kg (6 months).

5-HT₃ Antagonists

Ondansetron

Ondansetron is a serotonin 5-hydroxytryptamine₃ (5-HT₃)-receptor antagonist. The mechanism of action, although not totally elucidated, appears to block the effects of serotonin on 5-HT₃ receptors on vagal afferents. Ondansetron is well absorbed orally and has an oral bioavailability of 60%. Ondansetron is metabolized in the liver by CYP1A2, CYP2D6, and CYP3A4 (Sweetland et al., 1992; Gregory et al., 1998). After oral administration, peak plasma levels occur in 1 to 2 hours. In adults, after oral, intramuscular, or intravenous administration, the volume of distribution and half-life are 140 L/kg and 3.5 hours. In children, the half-life ranged from 2.5 to 3 hours, the volume of distribution ranged from 1.9 to 2.4 L/kg, and the clearance ranged from 6.6 to 15.6 mL/kg per minute (Bryson et al., 1991; Spahr-Schopfer et al., 1995). The major clinical use in anesthesia has been for prophylaxis and treatment of postoperative nausea and vomiting. Both large-scale studies and meta-analyses noted ondansetron to be a superior prophylactic drug compared with placebo, droperidol, and metoclopramide (Patel et al., 1997; Domino et al., 1999; Lim et al., 1999). The addition of dexamethasone to prophylactic ondansetron further increases the antiemetic efficacy of the drugs (Splinter et al., 1998). When used for treatment of postoperative nausea and vomiting, ondansetron (0.1 mg/kg, maximum 4 mg) appears to be superior to placebo (Khalil et al., 1996; Culy et al., 2001).

Granisetron

Granisetron, with an elimination half-life of 9 to 12 hours, has been reported to be effective at a dose of 40 mcg/kg when administered either orally or intravenously (Fujii et al., 1998, 1999a, 1999b, 2001; Fujii and Tanaka, 1999, 2001, 2002).

Tropisetron

Tropisetron is another 5-HT₃-receptor antagonist whose half-life is two to three times longer than that of ondansetron. In studies of children, doses ranging from 0.1 to 0.2 mg/kg were found to be effective for postoperative nausea and vomiting (Ang et al., 1998; Holt et al., 2000; Jensen et al., 2000).

Dolasetron

Dolasetron, a highly potent and selective 5-HT₃-receptor antagonist, appears to provide prophylactic antiemetic efficiency similar to that of ondansetron (Sukhani et al., 2002; Olutoye et al., 2003). Dolasetron appears to have an active metabolite that has a half-life of about 8 hours. In a pharmacokinetic study of 30 children, the kinetics of the metabolite were similar after both intravenous and oral administration. The volume of distribution, clearance, and half-life were 5.2 L/kg, 22.1 mL/kg per minute, and 5.7 hours, respectively. Bioavailability has been estimated at 59% (Lerman et al., 1996).

SUMMARY

The pediatric anesthesiologist should have an appreciation of the pathophysiology of the child's disease and a firm understanding of how developmental changes affect the pharmacology of anesthetic agents. In contrast to inhalational anesthetics, the

effects of intravenous agents are in part delivered by pharmacokinetic parameters; that is, volume of distribution and clearance. Consequently, drug dosages are often age-dependent and need to be individualized. The anesthetic management of the infant and child requires a careful approach; both knowledge of pharmacologic and physiologic development and monitoring of neuromuscular function are essential.

The authors are indebted to Dr. Jerrold Lerman and Dr. D. Ryan Cook for their previous contribution to this chapter in the seventh edition of *Smith's Anesthesia for Infants and Children*.

Surgery and anesthesia are causes for considerable emotional stress in both parents and children. Because the consequences of this stress occur in the immediate postoperative period and may remain long after the hospital experience has passed, one of the main tasks of the pediatric anesthesiologist is to ensure the psychological, as well as the physiologic, well-being of patients (Chapman et al., 1956; Kain and Mayes, 1996; Kotiniemi et al., 1997a, 1997b; Holm-Knudsen et al., 1998; Aono et al., 1999; Kain et al., 1999a, 1999b, 2006a). To minimize the emotional stress of anesthesia and surgery, the anesthesiologist must understand the psychological developmental milestones of childhood and anticipate situations that a child may find threatening. The latter can often be accomplished with preoperative education, a careful and thoughtful preoperative visit, and the administration of preoperative sedation when other measures are inadequate. During the preoperative visit with the patient, the anesthesiologist can optimally evaluate the levels of anxiety of both the parent(s) and the child, while assessing the child's medical condition. Of interest is that anesthesiologists are best at predicting which child in the preoperative holding area will be most anxious during induction of anesthesia (MacLaren et al., 2009). In this chapter, the psychological facets of hospitalization and surgery for children and the psychological and medical preparation of pediatric patients for anesthesia and surgery are discussed. A summary of premedications used for children undergoing anesthesia is included.

PSYCHOLOGICAL PREPARATION FOR ANESTHESIA AND SURGERY

More than 4 million children undergo surgery in the United States each year, and it is estimated that 50% to 75% of these children experience significant fear and anxiety before their

operations (Corman et al., 1958; Vernon et al., 1965; Melamed and Siegel, 1975; Beeby and Hughes, 1980; Kain et al., 1996c). Based on behavioral and physiologic measures of anxiety, induction of anesthesia in children has been identified as the most stressful point during the entire preoperative period (Kain and Mayes, 1996). Appropriate understanding and management of fear and anxiety before surgery are important, because if not managed well, they can lead to both psychological and physiologic adverse outcomes, including postoperative maladaptive behavioral changes and increased postoperative pain and analgesic requirements. As an indicator of the importance of preoperative anxiety, a panel of 72 anesthesiologists ranked various clinical outcomes with low anesthesia morbidity according to importance and frequency (Macario et al., 1999). The three clinical outcomes with the highest combined scores were incisional pain, nausea and vomiting, and preoperative anxiety. Thus, it is important to understand the psychological issues involved when a child undergoes surgery.

Incidence and Definition

Although the exact prevalence of preoperative anxiety in children is difficult to assess because of issues related to measurement and developmental variations, it is estimated that up to 75% of children are reported to exhibit significant psychological or physiologic manifestations of anxiety during the preoperative period (Corman et al., 1958; Vernon et al., 1965; Melamed and Siegel, 1975; Beeby and Hughes, 1980; Kain et al., 1996c). That is, every year up to 3 million children in the United States exhibit significant fear and anxiety before undergoing surgery.

Preoperative anxiety is operationally defined as a subjective feeling of tension, apprehension, nervousness, worry, and vigilance that is associated with increased autonomic nervous

system activity (Burton, 1984; Kain and Mayes, 1996). Children are threatened by anticipated parental separation, pain or discomfort, loss of control, uncertainty about “going to sleep,” and masked strangers working in a technical, sterile, non-child-focused environment. Younger children tend to be concerned about separation from parents, and older children are more anxious about the anesthetic and surgical processes. The stress and anxiety experienced by children during induction of anesthesia represent an interaction between child-related factors and environmental conditions in the operating room. Child-related factors include age and developmental maturity, previous experience with medical procedures and illness, individual capacity for affect regulation and trait anxiety, and parental trait anxiety (Lumley et al., 1990, 1993; Kain et al., 1996c; Davidson et al., 2006).

Environmental factors related to the operating room include factors such as interactions with the medical staff, intensity of lights, level of noise produced by the staff and instrument preparation, and the number of medical personnel who interact with the child. Children may appear frightened or agitated, breathe deeply, tremble, stop talking or playing, or start to cry. Other children may become nauseated, wet themselves, have increased motor tone, or attempt to escape from the operating room personnel (Burton, 1984; Kain and Mayes, 1996). These behaviors, which are likely to prolong the induction of anesthesia, give children a sense of control over the situation and therefore diminish the sense of helplessness.

Identification of Children at Risk

The first step in psychologically preparing children to undergo surgery is to identify those children who are at a particularly high risk to develop extreme anxiety and fear before surgery. This is particularly important in an environment that is sensitive to hospital and operating room costs. To date, studies looking into risk factors that affect the behavioral responses of children during the preoperative period have identified several categories, including age, temperament and developmental stage of the child, trait (baseline) and state (situational) anxiety of the parent, various demographic characteristics of the child and parent, and quality of previous experience of the child with medical procedures.

Young children, between the ages of 1 and 5 years old, are reported to be at the highest risk for developing significant anxiety before anesthesia and surgery (Brophy and Erickson, 1990; Lumley et al., 1993; Vetter, 1993; Kain et al., 1996a, 1996c). At this age, children are particularly vulnerable because they are young enough to be dependent on their parents, yet old enough to recognize parental absence. Additional factors that enhance the vulnerability of this age group include the degree of inexperience in social contact, ability to communicate and benefit from psychological preparation, and ability to relieve anxiety through play (Hyson, 1983). Although the younger child may not have the cognitive ability to anticipate potential dangers or painful situations during induction of anesthesia, the older child (older than age 6 years) may anticipate pain and fear “going to sleep” (Sparrow et al., 1984). Older children may also rely on a number of coping strategies, including verbal questioning and cognitive mastery (e.g., learning about heart monitors or about what surgeons do) to mediate their anxiety.

Children who have high trait anxiety and who have experienced poor-quality medical encounters in the past are at a particularly high risk to develop high anxiety during the preoperative period (Kain et al., 1996a, 1996c; Davidson et al., 2006). Interestingly, a child who must undergo repeated surgical procedures may respond with either higher-than-expected preoperative anxiety levels or lower-than-expected preoperative anxiety levels. Based on a conditioned learning model, the preoperative situation presents unconditioned fear stimuli that occur repeatedly over short intervals. Thus, children’s previous surgical and medical histories may either exacerbate or attenuate their fear conditioning, and the quality of the previous medical experience (e.g., how distressing it was to the child) is more crucial than its occurrence (Box 8-1).

Several investigations indicate that children who have a shy and inhibited temperament show higher levels of fear and anxiety on the day of surgery compared with other children (Melamed and Ridley-Johnson, 1988; Kain et al., 2001). Conversely, children who have a more socially adaptive temperament are less anxious in the perioperative settings (Kain et al., 2001). Temperament in a child refers to individual patterns of behavior and has been compared with personality traits in adults (Buss et al., 1973; Buss and Plomin, 1975). Kagan et al. (1987) reported that temperament characteristics can be used to predict how a child responds emotionally in a stressful situation; for example, children who are “shy” or “inhibited” tend to become more anxious in novel settings, as suggested by the adrenocortical response and elevated heart rate.

A child’s anxiety before surgery is strongly affected by the state and trait anxiety of the parent (Kain et al., 1996c, 2001). Parental anxiety mediates the child’s response to stressful situations through two pathways (Kain and Mayes, 1996). First, whereas some parents may act as stress reducers for their children, parents who are anxious themselves are typically less available to respond to their children’s needs. Indeed, in these cases the child’s distress may further compound parental anxiety, thus diminishing the parent’s ability to respond effectively. The second pathway of the effect of parental anxiety on a child’s response reflects the genetics of parental disposition and anxiety.

Box 8-1 Risk Factors for Preoperative Anxiety

CHILD RELATED

- Young age (1 to 5 years of age)
- Poor previous experience with medical procedures and illness
- Shy and inhibited temperament
- Lack of developmental maturity and social adaptability
- High cognitive levels
- Not enrolled in daycare

PARENT RELATED

- High trait and state anxiety
- Divorced parents
- Multiple surgical procedures for parents

ENVIRONMENT RELATED

- Sensory overload
- Conflicting messages
- Operating

Previous research has illustrated that mothers who were more anxious in the surgical setting had children who were also more anxious and that these mothers were less able to respond to their children's anxiety (Kagan et al., 1987).

Divorced parents, parents with lower educational levels, and parents of children who were not enrolled in a daycare setting rate themselves as significantly more anxious preoperatively (Kain et al., 1996a, 1996c). Finally, parents of children who are younger than 1 year old, parents who themselves underwent multiple hospitalizations, and parents of children who underwent multiple admissions all report being more anxious (Litman et al., 1996; Shirley et al., 1998). Preoperative anxiety in young children undergoing surgery can be managed with behavioral or pharmacologic (preoperative sedative medication) interventions, or both (Fig. 8-1).

Psychological Preparation Programs

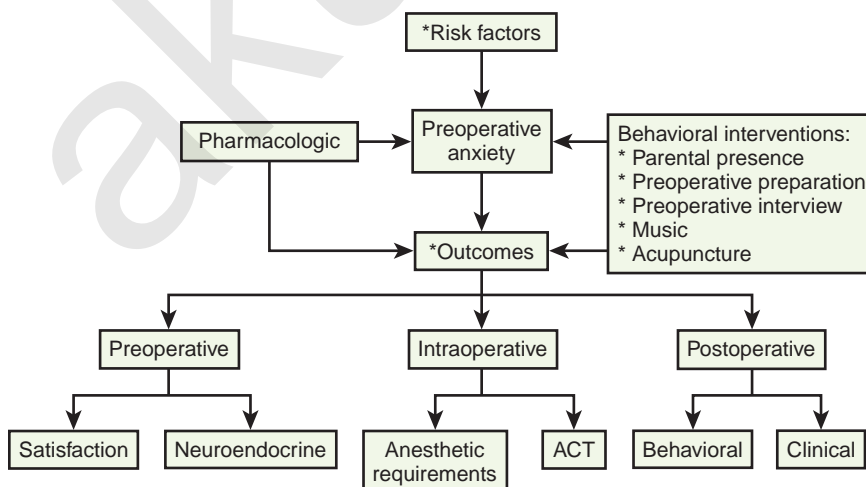

The concept of psychological preparation of children and parents who undergo surgery was introduced almost 50 years ago (Mellish, 1969; Robinson and Kobayashi, 1991). Earlier programs provided the child with information regarding the surgical and anesthetic procedures and sought to develop a rapport between the medical staff and the child (Melamed and Siegel, 1975; Melamed et al., 1976, 1978). In the 1970s, modeling preparation programs were introduced to multiple hospitals in the United States. These modeling programs included the use of illustrated books, video programs, and puppet shows (Melamed and Siegel, 1975; Melamed et al., 1976, 1978). The theory behind these programs was that children would be prepared for the surgical experience by observing other children who underwent similar procedures. During the 1990s, the idea of family-centered care was introduced to medicine in general and to the area of preoperative preparation in particular (Melamed, 1993). Coupled with the development of the child-life discipline and the teaching of coping skills, this concept dominates the preparation programs in current use. Child-life specialists are individuals who facilitate the child's coping and the perioperative adjustment of children and parents by providing play experiences using modeling techniques (AAP statement, 1993). Child-life specialists incorporate descriptions of the perioperative

sensations children experience and provide opportunities to examine, rehearse, and play with perioperative equipment to be used in their care. Child-life specialists also aim to establish supportive relationships with children and parents and to teach relaxation skills, as well as present information to the child and parent about the anesthetic and surgical procedures (AAP statement, 1993).

The regularity with which preparation programs aimed at children undergoing surgery are being used has changed over the past decades. Although these programs were scarce in the 1970s and 1980s, they became quite popular in the 1990s. In fact, in 1996 about 80% of all major acute care children's hospitals in the United States offered such programs to children and their parents (O'Byrne et al., 1997). Unfortunately, the number of comprehensive preparation programs has been reported as decreasing over the past few years; this new trend is likely the result of new economical constraints in the perioperative environment.

O'Byrne et al. (1997) state that the type of preparation program used varies significantly among different children's hospitals in the United States. About 89% of children's hospitals are reported to provide narrative preparation, 87% provide operating-room tours, 86% provide play therapy, and 84% provide printed material. More comprehensive preparation, such as child-life preparation is provided at about 50% of children's hospitals, and relaxation is taught at about 40% of the hospitals. Interestingly, a panel of experts indicated their consensus regarding the effectiveness of psychological preparation programs before surgery. On a scale of 1 (least effective) to 9 (most effective), child-life preparation was ranked the most effective, followed by play therapy, an operating-room tour, and printed material (O'Byrne et al., 1997).

Although the effectiveness of preparation programs in reduction of anxiety in the holding area is well established, their effectiveness for reducing anxiety during the induction process is questionable (Kain et al., 1996a, 1998a). Methodologic flaws, such as the absence of an appropriate outcome instrument and small sample size, hinder many of the studies that report reduced anxiety in children. In fact, a study that included a validated outcome measure has clearly documented that although a comprehensive psychological preparation program (i.e., child life) is effective in reduction of anxiety in the holding area, it is

■ **FIGURE 8-1.** Operational view of preoperative anxiety in children. ACT, Anesthesia control time.

not effective during the induction of anesthesia or in the recovery room (Kain et al., 1998a). It is likely that the extreme anxiety experienced during induction of anesthesia inhibits children's abilities to process and implement of the content of the preoperative-preparation program.

Considerations in Choosing a Preparation Program

It is vital to realize that psychological preparation programs have to be tailored based on the individual needs of each child. That is, a preparation program that is appropriate for a 3-year-old child is not appropriate for a 12-year-old child. Thus, once the type of the preparation has been chosen (e.g., child-life vs. a tour of the operating room), the preparation has to be individualized based on developmental considerations of the child.

Timing of the preparation in relation to the day of surgery is a significant factor. That is, children aged 6 years and older benefit most if they participate in the program more than 5 to 7 days before surgery and benefit the least if the program is given 1 day before surgery (Melamed et al., 1976; Robinson and Kobayashi, 1991; Kain et al., 1996a). This extended interval between the preparation and the surgery is needed for older children to have adequate time to process new information provided to them during the preparation process (Melamed et al., 1983; Kain et al., 1996a, 1998a). Typically, older children prepared 1 week ahead of surgery show an immediate increase in the anxiety during the preparation period, with a gradual decrease until the time of surgery (Melamed et al., 1983). Interestingly, there may be a negative effect of a preparation program on younger children. This may be a result of the inability of children younger than age 3 years to separate fantasy from reality (Melamed et al., 1976; Robinson and Kobayashi, 1991). From ages 3 to 6 years, children experience increased ability to separate fantasy from reality, and by the age of 6 years, this distinction of fantasy vs. reality is typically completed (Piaget, 1955).

It is particularly challenging to design a preparation program for children who have been previously hospitalized. Information about what occurs on the day of surgery does not provide new information for these children. Studies have documented that simple modeling and play programs are not beneficial for these children and may actually sensitize these children (Melamed et al., 1983; Faust and Melamed, 1984). Alternative psychological programs, such as teaching extensive, individualized coping

skills combined with actual practice, are more helpful for these children (Melamed et al., 1983; Kain et al., 1996a). These alternative programs should be based on the particular experiences the child had during previous surgeries.

Parental Issues

Clearly, preoperative preparation should be directed to parents as well as to children. Multiple studies have reported that parents typically become very anxious when their child undergoes surgery, and parental anxiety was identified as a significant risk factor for increased preoperative anxiety in children (Pinto and Hollandsworth, 1989; Kain et al., 1996a, 1996c; Litman et al., 1996; Shirley et al., 1998; Cassady et al., 1999). Parents experience preoperative anxiety for reasons such as fear of separation and bodily harm to their children, guilt, and financial stress (Cassady et al., 1999). Indeed many parents are more anxious about their children's health than their own (Kain et al., 1997d). Mothers are more prone to preoperative anxiety than are fathers, particularly when a child is younger than 1 year old or when they are coping with a child's first surgical experience (Litman et al., 1996; Shirley et al., 1998). Previous research has also documented that women are significantly more concerned with risks and side effects in general, although men specifically articulate a fear of death twice as often as women.

Parents who undergo a preoperative preparation program or who have viewed a preoperative videotape featuring factual information about anesthesia show reduced preoperative anxiety on the day of surgery, but this reduction in anxiety is transient and does not extend to the anesthetic induction, the recovery room, or 2 weeks postoperatively (Table 8-1) (Pinto and Hollandsworth, 1989; Kain et al., 1996a; 1998a; Cassady et al., 1999). Nonetheless, the use of videotapes has received increased attention as a supplementary educational modality for parents, because the tapes are informative, perhaps anxiolytic, and cost effective in certain settings (Pinto and Hollandsworth, 1989; Karl et al., 1990; Cassady et al., 1999; Cassady and Kain, 2000).

Future of Preparation Programs

Most surgeries in the United States are currently conducted on an outpatient basis, and as a result, many children receive preparation for surgery on the morning of the procedure. A major

issue with this approach is that because of production pressure, health care providers rarely spend more than a few minutes with the child before surgery (Kain et al., 2009a). As such, a different approach is needed.

The absence of cost-sensitive preoperative preparation programs will inevitably be filled by technological advancements. The future will be characterized by the development and implementation of computerized multimedia displays and interactive technology. The latter offers particular appeal, because its multimodal capability can provide specific interventions for individuals with a wide range of medical problems and coping styles. The capacity, programmability, and rapid response of current interactive technology are suitable for such tasks, but the cost remains high. In the future, it is the hope that all children and their parents will be able to realize the benefits of specialized, technologically advanced, tailored educational systems programmed to meet their individual and cultural needs and coping styles.

Parental Presence

Parental presence during the induction of anesthesia has been suggested as an alternative to sedative premedication. Although there is general agreement about the desirability of parents visiting during their child's hospitalization, their presence during invasive medical procedures, such as induction of anesthesia, remains very controversial (Lerman, 2000; Kain, 2001). Potential benefits from parental presence include reducing the need for preoperative sedatives and reducing the child's anxiety and distress on separation to the operating room. Increased child compliance and reduced child anxiety during induction of anesthesia have been suggested to be benefits as well. Common objections to this practice include delays in operating-room schedules, crowded operating rooms, and a possible adverse reaction of the parent during the induction process.

A large-scale, nationwide survey indicated that there is a large variability in hospital policy in the United States toward parental presence in operating rooms. Thirty-two percent of the hospitals allow parental presence; 11% encourage parental presence; 23% have no formal hospital policy; and 26% do not allow it (Kain et al., 2004c).

The same survey reported that only 10% of anesthesiologists have parents present during induction of anesthesia in more than 75% of cases, and that 27% of anesthesiologists have parents present during induction in less than 25% of cases. About 50% of all anesthesiologists never have parents present during induction (Kain et al., 2004c). The reported prevalence of parental presence varies widely among the different geographic locations in the United States.

The survey showed that parental presence during induction of anesthesia was practiced most often in the northeast region and least often in the south-central region of the United States (Fig. 8-2). Interestingly, the findings in this survey are very much different from the findings in a nationwide survey conducted in 1995 (Kain et al., 1997c, 2004c) (Fig. 8-3). Overall, there was an increase in the rate of parental presence from 1995 to 2002, and the number of anesthesiologists who never allow parental presence dropped in every geographic region (Kain et al., 1997c, 2004c). These findings may represent a new trend in this practice in the United States.

Parental Perspectives

A number of surveys have indicated that most parents prefer to be present during the induction of anesthesia regardless of the child's age (Braude et al., 1990; Ryder and Spargo, 1991). Furthermore, a majority of parents believe that they are of some help to their child and to the anesthesiologist during the induction process (Ryder and Spargo, 1991). A study indicates that over 80% of parents chose to be present in the operating room when returning for a second operation regardless of whether they were present in the operating room in the first operation

(From Kain ZN et al.: *Trends in the practice of parental presence during inductions of anesthesia and the use of preoperative sedative premedication in the United States 1995–2002: results of a follow-up national survey*, *Anesth Analg* 98:1252–1259, 2004c.)

FIGURE 8-3. Practice of parental presence during induction of anesthesia as a function of geographic areas in the United States as of 2002. PPIA, Parental presence during induction of anesthesia. (From Kain ZN et al.: *Trends in the practice of parental presence during inductions of anesthesia and the use of preoperative sedative premedication in the United States 1995–2002*, *Anesth Analg* 98:1252–1259, 2004c.)

FIGURE 8-4. Data regarding the parental intervention choice in the subsequent surgery as a function of the initial surgery. For example, 28% of the parents who were assigned to the premedication group in the initial intervention chose to be in the premedication group in the subsequent surgery. PPIA, Parental presence during induction of anesthesia. (From Kain ZN et al.: *Parental intervention choices for children undergoing repeated surgeries*, *Anesth Analg* 96:970, 2003b.)

(Kain et al., 2003b). This preference for parental presence during induction shown by parents who had experience with other interventions, including preoperative midazolam, is similar to the preference for parental presence shown by parents of children undergoing surgery for the first time (Kain et al., 2003b) (Fig. 8-4). It is no surprise, therefore, that parental presence during the induction of anesthesia is associated with increased parental satisfaction regarding not only the separation process from their child but also with the overall functioning of the hospital (Kain et al., 2000).

Many parents report increased anxiety when they are present during induction of anesthesia (Vessey et al., 1994). An

investigation found, however, that anxiety after induction of anesthesia among parents who were present during induction did not differ significantly from anxiety among parents who were not present during the induction process (Kain et al., 2003a). This finding is in agreement with previous randomized controlled trials that have examined this issue (Bevan et al., 1990; Kain et al., 1996b, 1998b, 2000).

Parental physiologic responses during induction of anesthesia have been examined as well (Kain et al., 2003a). It was found that parental heart rate and skin conductance levels significantly increase as the parents walk to the operating room. Interestingly, once the induction begins, parental heart rate

FIGURE 8-5. Changes in parental heart rate (HR) from baseline measurement until after induction of anesthesia. Data are reported as mean (SE). *, Time points at which differences between groups are statistically significant ($P < .05$); OR, Operating room; PPIA, Parental presence during induction of anesthesia. (From Kain ZN et al.: Parental intervention choices for children undergoing repeated surgeries, *Anesth Analg* 96:970, 2003b.)

decreases, only to peak again once the parents have to leave the operating room. This second peak in heart rate is in agreement with previous data indicating that the most upsetting factors are seeing the child go limp during induction and then having to leave the child (Vessey et al., 1994). Parental blood pressure after induction of anesthesia was not elevated, and examination of parental data from a Holter monitor revealed no rhythmic abnormalities and no electrocardiographic changes indicative of ischemia (Fig. 8-5) (Kain et al., 2003a).

There have been isolated reports of parental presence resulting in disruptive behavior and even a report of the removal of a child from the operating room by a grandmother (Schofield and White, 1989; Bowie, 1993). In contrast, a 4-year experience with 3086 children in a free-standing ambulatory surgery center found that no parent needed to be escorted from the operating room (Gauderer et al., 1989).

Experimental Studies Involving Parental Presence

Early studies involving parental presence during induction of anesthesia indicated that the presence of a parent might lower the anxiety of the child (Schulman et al., 1967; Hannallah and Rosales, 1983). These studies, however, were nonrandomized, did not control for confounding variables, and lacked appropriate outcome measurement tools. It is important to note that measurement of a child's anxiety during induction of anesthesia is a complex issue that necessitates the use of a validated and reliable instrument of a child's anxiety. Such an instrument, the Yale Preoperative Anxiety Scale, was developed and validated a number of years ago (Kain et al., 1995, 1997b). Later studies that used appropriate sample size, eliminated confounding variables, and used appropriate end points and assessment instruments concluded that parental presence does not result in decreased anxiety on the part of the child during the induction process (Hickmott et al., 1989; Bevan et al., 1990; Kain et al., 1996b, 1998b, 2000; Kain, 2001). Further, parental presence during induction of anesthesia was also compared with the use of oral midazolam (0.5 mg/kg) administered 30 minutes before surgery (Kain et al., 1998b). The investigations concluded that the use of oral midazolam is significantly more

FIGURE 8-6. Anxiety of child across the perioperative period. Induction 1, Entrance to the operating room; Induction 2, Introduction of the anesthesia mask to the child. Premedication group was significantly less anxious compared with the parental presence and control groups at Induction 1 (*) and induction 2 (**). PPIA, Parental presence during induction of anesthesia; YPAS, Yale Preoperative Anxiety Scale. effective than parental presence in terms of both reducing a child's anxiety and increasing a child's compliance (Fig. 8-6) (Kain et al., 1998b).

However, it is clear that research related to the basic concepts underlying parental presence during induction of anesthesia has not changed during the past 2 decades and that the present body of research simply deals with the question of whether parents should be present during induction of anesthesia. Research interests should shift toward an emphasis on what parents actually do during induction of anesthesia rather than simply on their presence. A preliminary publication reports the development of an intervention that consists of an informational and modeling video, instructed graduated exposure and shaping exercises, coached distraction techniques,

supportive telephone coaching, and adherence checks (Kain et al., 2002b). This informative modeling intervention is directed at parents of children undergoing surgery and is quite extensive. Results show that children and parents who underwent the extensive parental-preparation program were significantly less anxious than were children whose parents were present during induction of anesthesia and who did not receive the preparation program. More data regarding this preparation program are needed.

Moreover, more recent studies have also attempted to illustrate which children may benefit most from parental presence. In a large-scale prospective cohort study of over 400 children, Kain and colleagues (2006c) demonstrated that children who were older, had lower levels of temperamental activity, and had less anxious parents who valued preparation and coping skills for medical situations benefitted from parental presence at anesthesia induction in terms of anxiety levels and cooperation ratings. In addition, calm parents were found to benefit anxious children during induction of anesthesia, whereas there were no benefits of parental presence when parents were highly anxious (Kain et al., 2006a). In fact, in this large cohort study, calm children who had overly anxious parents present at anesthesia induction were significantly more anxious than calm children who had no parental presence. Finally, it should be noted that the number of parents who are allowed into the operating rooms does not impact the anxiety of the child (Kain et al., 2009b). That is, a child's anxiety during induction is not higher or lower based on the presence of only one parent as opposed to both parents.

Satisfaction Issues

Previously, the medical community held the view that the only "real" outcomes are those that have an immediate and direct impact on patient morbidity and mortality. This view has changed dramatically, and issues such as patient satisfaction and quality of life are considered by many as equally important as morbidity (Ford et al., 1997). This new development is echoed in review articles in the anesthesia literature suggesting that patient satisfaction should serve as an important end point and indicator of overall quality of anesthesia care (Fung and Cohen, 1998).

Typically, parents are not aware of the events that take place inside an operating room. To parents, the most important thing is their child's safety. However, with anesthetic mortality rates approaching 1:100,000, safety is expected. In contrast, parents evaluate an anesthesiologist, in part, based on the separation experience with their child. That is, if their child is taken to the operating room upset and crying, their satisfaction and impression of the anesthesiologist and the surgery center may be poor.

A study evaluated parental presence during induction of anesthesia as a contributing factor to their satisfaction. The study also evaluated the effectiveness of parental presence when used in conjunction with oral midazolam (0.5 mg/kg) (Kain et al., 2000). The study has demonstrated that while parental presence did not provide added value in terms of reducing child's anxiety or increasing a child's compliance, it did improve parental satisfaction with both the separation process and the entire perioperative process (Kain et al., 2000). Thus, although experimental studies fail to demonstrate the effectiveness of parental presence with regard to anxiety reduction or increased compliance,

parental satisfaction seems to improve if the parents are present during the induction of anesthesia.

Medicolegal Issues

The practicing anesthesiologist should also be aware of legal issues associated with parental presence during induction of anesthesia—that is, the additional risks the anesthesiologist incurs because of the presence of a parent in the operating room. The legal literature is not clear with this issue. Of note, however, is a decision made by the Illinois Supreme Court with regard to parental presence during an invasive procedure. In its verdict, the Illinois Supreme Court stated that a hospital that allows a nonpatient to accompany a patient during treatment does not have a duty to protect the nonpatient from fainting (Lewyn, 1993). If medical personnel invite the nonpatient to be present during the treatment, however, the hospital has a legal responsibility toward the nonpatient. Thus, there is an important distinction between allowing parental presence and inviting parental presence. As a response to such possible litigation, a number of hospitals require parents to sign a separate consent form when they express the wish to be present during induction of anesthesia. In a nationwide survey, Kain et al. (2004c) reported that only 5% of all hospitals in the United States indicate that they routinely obtain a separate written consent for parental presence during induction of anesthesia.

Behavioral Interventions

Family-Centered Preparation

In the contexts of increased attention to family-centered care in the past decade and of the relationship between a parent and a child's anxiety, Kain and colleagues recently developed a multicomponent, behavioral preoperative-preparation program targeting the family as a whole, rather than the individual child (Kain et al., 2007). Termed ADVANCE (Anxiety-reduction, Distraction, Video modeling and education, Adding parents, No excessive reassurance, Coaching, and Exposure/shaping), this program consists of psychological techniques of shaping, exposure, and modeling with coaching in combination with empirically supported distraction techniques. A randomized controlled trial comparing ADVANCE with standard of care (no premedication or parental presence), standard of care plus parental presence at induction of anesthesia, or standard of care plus midazolam indicated that parents and children in the ADVANCE group exhibited significantly lower levels of preoperative anxiety in the holding area compared with all other groups and lower anxiety during anesthesia induction when compared with the standard-of-care and parental-presence groups (Kain et al., 2007). Moreover, children in the ADVANCE groups had a lower incidence of emergence delirium, required fewer analgesics in recovery, and had a shorter length of stay in recovery as compared with children in the other three groups.

Music

Music has well-established psychological effects, including the induction and modification of moods and emotions (Baeck, 2002; Kain et al., 2002a; Lipe, 2002). Kane, in 1914, is reported to have been one of the first individuals to provide intraoperative

music to distract patients from “the horror of surgery.” It was not until about 1960, however, that a group of dentists reported that 65% to 90% of their patients needed little or no anesthesia for dental extractions with the routine use of music during dental surgery (Gardner and Licklider, 1959; Gardner et al., 1960). Music has gained popularity as a part of complementary medicine directed at patients undergoing medical and surgical procedures (Wang et al., 2002a, 2002b, 2003).

The role of music as a therapeutic modality for the treatment of preoperative anxiety in adult patients has been evaluated in several studies. Although a number of studies conducted in this area were hindered by multiple methodologic flaws, the anxiolytic effects of perioperative music are well documented in adults (Standley, 1986; Thompson and Kam, 1995; Miluck-Kolasa et al., 1996; Wang et al., 2002a). As indicated earlier, the anxiety experienced by a child during the induction period is related to personality factors, as well as to operating room factors such as bright lights and high noise levels. Several studies that have assessed noise levels in the operating room concluded that while overall sound levels are not excessive, loud intermittent noises up to 108 dB are present intermittently (Hodge and Thompson, 1990; Nott and West, 2003). Cohen (1970) classified noises as just audible (10 dB), very quiet (50 dB, comparable with light traffic at 30 miles/hr), moderately loud (70 dB, comparable with a dishwasher), very loud (90 dB, comparable with a food blender), and uncomfortably loud (130 dB, comparable with a rock-and-roll band). Interestingly, a sudden noise with a level as little as 30 dB above the background noise (e.g., an SpO₂ alarm) might cause an immediate startle response, which is associated with an activation of the sympathetic system, and an anxiolytic response (Falk and Woods, 1973). A study introduced an intervention that consisted of dimmed operating room lights (200 lux) and soft background music (Bach’s “Air on a G String” at 50 to 60 dB), and only the attending anesthesiologist was allowed to interact with the child during induction (Fig. 8-7) (Kain et al., 2002b). The number of medical personnel interacting with the child is of particular importance, as it is not uncommon that the surgeon, the circulating nurse, the anesthesia resident, and the anesthesiologist attending all try to help the child through the induction process. This may result in conflicting messages and increased anxiety on the part of the child. This study found that this combination of music, dim light, and only the attending anesthesiologist interacting with the child was effective and that the children who received this intervention exhibited significantly less anxiety during induction of anesthesia (Kain et al., 2002b).

To date, most reported studies of music therapy in the medical literature describe interventions that consist of patients passively listening to music. Studies that examined live-participation music therapy with children undergoing surgery concluded that this type of music therapy resulted in reduced anxiety in children undergoing surgery (Chetta, 1981; Robb et al., 1995). These studies, however, were limited because of a small sample size and a lack of reliable and valid outcome measures. A more recent trial that used an appropriate sample size and a reliable instrument for measuring outcome indicated some complexities related to this issue (Kain et al., 2004b). The study found that both at separation from parents and on entrance to the operating room, only children who received music therapy from one of the therapists involved in the study were significantly less anxious than the control group. This anxiolytic effect was present only in the holding area and

FIGURE 8-7. Levels of anxiety manifested by children during the perioperative period. Anxiety was assessed by the modified Yale Preoperative Anxiety Scale (m-PAS). Observed anxiety differed significantly between the two groups ($F[1,67] = 6.3, P = .014$). LSSG, Low sensory stimulation group; OR, Operating room. *, $P = .03$; **, $P = .003$. (From Kain ZN, Wang SM, Mayes LC, et al.: *Sensory stimuli and anxiety in children undergoing surgery: a randomized controlled trial*, *Anesth Analg* 92:897–903, 2001.)

at separation but not during induction of anesthesia. Thus, it can be concluded that the provision of live-participation music therapy is quite expensive, and considering the results of the more recent study, it is doubtful as to whether this modality should be routinely used to reduce preoperative anxiety in all children undergoing surgery.

Acupuncture

Acupuncture originated in China between the years 2000 and 100 BCE (Hsu, 1996). Despite the slow progression of scientific evidence, acupuncture and related techniques have become very popular in the western medical culture over the last few decades.

Several studies have examined whether acupuncture is an effective treatment modality for preoperative anxiety. Wang and Kain (2001a, 2001b) found that both healthy volunteers and adult patients undergoing routine outpatient surgery report lower levels of state anxiety after auricular acupuncture provided in specific points. This effect started as early as 30 minutes after insertion of the acupuncture needles. The use of acupuncture as a treatment for parental anxiety was examined as well. Wang and Kain randomized mothers of children who were scheduled for surgery to an acupuncture intervention group or a sham acupuncture control group (Fig. 8-8). The intervention was performed at least 30 minutes before the child’s induction of anesthesia and all mothers were present during induction of anesthesia (Wang et al., 2004).

The investigators found that after induction, maternal anxiety in the acupuncture group was significantly lower, and children whose mothers received the acupuncture intervention were significantly less anxious on entrance to the operating room (Wang et al., 2004). Thus, auricular acupuncture may have various uses in the pediatric perioperative environment.

■ **FIGURE 8-8.** Auricular acupuncture points that are used to treat parental anxiety. (From Wang S, Maranets I, Weinberg M, et al.: *Parental auricular acupuncture as an adjunct for parental presence during induction of anesthesia*, *Anesthesiology* 100(6):1399–1404, 2004.)

In addition to acupuncture, Wang and colleagues (2005) have also examined parental acupressure as an intervention for preoperative anxiety and found that acupressure at the Yintang point significantly reduced parental self-reported anxiety in the preoperative holding area.

Preoperative Interview

Anesthesiologists undoubtedly have the ability to increase or decrease the anxiety levels of patients; therefore, one should consider the preoperative interview as a psychological intervention that is administered routinely to parents and children (Egbert et al., 1963; Kain et al., 2002a). The anxiety-moderating effect of anesthesiologists is dependent on multiple variables, such as environmental stimuli and the coping style of the parent. That is, patients undergoing surgery generally ask for all relevant information to be provided to them, although some patients and parents have a coping style that is information-seeking, whereas others have a coping style that is information-avoiding (Miller, 1995; Kain et al., 1997a, 1997d). The challenge for the anesthesiologist is to identify the individual coping style of a parent without the benefit of using structured psychological instruments during the preoperative visit.

The impact of information given in the preoperative setting on the anxiety of patients was examined by Miller and Mangan (1983). They found that adult patients who were given extensive information preoperatively were more anxious and uncomfortable. In contrast, no increase in preoperative anxiety was

demonstrated in a study that involved English and Scottish men undergoing elective herniorrhaphy who were presented with detailed risk information (Kerrigan et al., 1993). Similarly, a study that involved parents of children undergoing surgery found that the provision of detailed anesthetic information in the setting of a randomized controlled trial did not increase the anxiety of the parents (Kain et al., 1997d). In terms of information desired by children, Fortier and colleagues (2009) recently demonstrated that the majority of children report a strong desire for comprehensive preoperative information, particularly information about pain; however, the impact of providing such information on perioperative outcomes, including anxiety, is not known. Thus, the practicing anesthesiologist should be aware of these data and provide information in the perioperative settings as dictated by the settings and the needs of the parents and the children.

BEHAVIORAL OUTCOMES OF PREOPERATIVE ANXIETY IN CHILDREN

Postoperative Behavioral Changes

Epidemiology

In 1945, Levy described 25 cases of children who developed significant fear of physicians after tonsillectomy. Vernon et al. (1966) developed a structured parental instrument (Posthospitalization Behavior Questionnaire [PHBQ]) that addressed the issue of postoperative behavioral changes in children. Earlier studies that used the PHBQ reported that up to 88% of all children undergoing anesthesia and surgery develop new behavioral changes postoperatively (Vernon et al., 1966; Peterson and Shigetomi, 1982; Thompson and Vernon, 1993). More recent studies conducted in the United States and Europe documented that up to 54% of young children undergoing outpatient surgery experience general anxiety, nighttime crying, enuresis, separation anxiety, and temper tantrums 2 weeks postoperatively (Fig. 8-9) (Kain et al., 1996c; Kotiniemi et al., 1996, 1997a; Kain, 2000). Nearly one-fifth of children continue to demonstrate maladaptive behavior changes 6 months postoperatively, and in 6% of children these behaviors persist at 1 year (Kain et al., 1996c).

Nightmares and waking up crying are particularly common problems after surgery in children, and the incidence of these behaviors is as high as 20% 2 weeks postoperatively (Kain et al., 1996c). The effect of outpatient surgery on postoperative sleep patterns was also addressed in a study that used actigraphy, which is an objective measure that aims to quantify sleep (Kain et al., 2002c). The study found that 47% of all children developed postoperative sleeping problems as assessed by either actigraphy or the PHBQ (Kain et al., 2002c). Fourteen percent of children experienced a decrease of at least 1 standard deviation in percentage sleep as assessed by actigraphy (Fig. 8-10) (Kain et al., 2002d).

Considering the dramatic changes that have occurred with health care delivery, this relatively high incidence of postoperative behavioral changes is surprising (Kain, 2000). That is, considering that these were studies that were conducted with outpatients, a lower incidence would be expected. It is important to appreciate, however, that because of economic issues, outpatient surgery for children is being performed with high levels of medical acuity. Children with similar issues underwent

FIGURE 8-9. The incidence of postoperative behavioral changes as a function of time after surgery. (From Kain ZN, Mayes LC, O'Connor T, et al.: *Preoperative anxiety in children: predictors and outcomes*, Arch Pediatr Adolesc Med 150:1238–1245, 1996c.)

FIGURE 8-10. Postoperative sleeping disturbances during the first five postoperative nights, as determined either by actigraphy or the PHBQ. (From Kain ZN, Mayes LC, Alexander GM, et al.: *Sleeping characteristics of children undergoing outpatient elective surgery*, Anesthesiology 97:1093–1101, 2002.)

inpatient surgery just a few years ago; it may be that efforts to improve the psychological climate of hospitals have been neutralized by other variables.

Predictors

Several studies report that young age is a significant risk factor for the development of postoperative behavioral changes. In 1945, Levy noted a marked reduction in the emotional reaction after surgery in children older than age of 3 years, when the incidence of the new-onset behaviors dropped from 50% to 10%. More recent investigations confirm this observation and report that these postoperative behavioral changes are most common

between the ages of 1 and 4 years (Vernon et al., 1965; Kain et al., 1996c). At these ages, children are particularly vulnerable because of issues such as separation anxiety, social inexperience, limited ability to communicate and benefit from psychological preparation, and limited ability to relieve anxiety through play (Kain, 2000).

Increased anxiety of the child and of the parent in the holding area and during induction of anesthesia are both good predictors for later emergence of maladaptive postoperative behaviors (Eckenhoff, 1958; Kain et al., 1996c, 1999a, 2004a, 2006a; Lumley et al., 1993). Meyers and Muravchick (1977) compared postoperative behavioral responses in a group of children who underwent a “steal induction” with a group of children who underwent an “awake” induction. One month after the children were discharged from the hospital, the investigators reported that the rate of behavioral changes was 88% in the awake group and 58% in the steal group. Kain et al. (1999a) confirmed these previous findings and observed that extreme anxiety during induction of anesthesia and forcing the child to the table is associated with a significantly increased occurrence of negative postoperative behavioral changes. Several reports indicate that these behavioral changes are significantly more common among children undergoing tonsillectomy and genitourinary surgery (Manley, 1982; Kain et al., 1996c). Finally, positive behavioral changes have also been reported after surgery, particularly in children with chronic conditions (e.g., recurrent otitis media) that have been improved by the surgery (Kain et al., 1996c; Kotiniemi et al., 1996).

The issue of anesthetic techniques (intravenous vs. mask) has not been demonstrated to be a significant predictor of the incidence of postoperative maladaptive behavioral changes (Kotiniemi and Ryhanen, 1996). In addition, the type of anesthetic used (sevoflurane vs. halothane) has not been shown to predict the incidence of postoperative negative behavioral changes (Kain et al., 2005). Although a history of previous surgery predicted increased incidence of postoperative maladaptive behavior in one study, other studies did not confirm this finding (Lumley et al., 1993; Kain et al., 1996c; Kotiniemi et al., 1997b). It is likely that the quality of surgical experiences is an

important predictor, not simply the history of surgery. Quality of past medical experience as a predictor of future anxiety of the child has been reported in studies exploring the issue of preoperative anxiety (Kain et al., 1996c).

Interventions

Preparation Programs

The impact of preparation programs on the incidence of postoperative behavioral changes is not clear. Vernon and Thompson (1993) completed a meta-analysis of published studies that evaluated the effects of preoperative behavioral preparation programs on postoperative behavior. The meta-analysis concluded that on the average, children who received preoperative interventions tended to have less postoperative maladaptive behavioral changes than did control subjects. In contrast, Kain et al. (1998a) compared several types of preoperative preparation programs in children and found no effect of preoperative preparation on the incidence of postoperative behavioral changes.

Parental Presence

The impact of parental presence during induction of anesthesia on the incidence of postoperative behavioral changes was evaluated (Kain et al., 1996b). To date, all studies concluded that the presence of a parent during induction does not have an impact on the issue of postoperative behavioral changes (Kain et al., 1996b; Kain, 2000).

Sedatives

Investigations that looked into the association between preoperative sedative premedication and postoperative behavioral changes report contradictory findings. Two investigations report some beneficial effects of premedication on postoperative behavior, but others report no effect (Padfield et al., 1986; Parnis et al., 1992; Payne et al., 1992). Furthermore, an investigation found a higher incidence of negative postoperative behavioral changes in children who were premedicated (McGraw and

Kendrick, 1998). These contradictory results may be explained by the methodologic complexity of this issue. Confounding variables such as the age of the child, surgical procedure, postoperative pain, and recent stressful major life events must be considered. An investigation by Kain and others (1999b) addressed all of these methodologic issues and screened all children for recent stressful life events. The investigators found that a significantly smaller number of children who were premedicated with oral midazolam before surgery demonstrated negative behavioral changes on postoperative days 1 through 7 (Fig. 8-11). Postoperative behaviors that were most improved included apathy and withdrawal, separation anxiety, and eating disturbances. At the second postoperative week, however, there were no significant differences between the placebo and midazolam groups. Thus, it can be concluded that in addition to its significant beneficial preoperative effects, sedative premedication improves immediate postoperative behavioral outcomes in young children undergoing general anesthesia and outpatient surgery.

Clinical Outcomes

Five decades ago, Janis (1958) proposed that moderate levels of preoperative anxiety in adult patients were associated with good postoperative behavioral recovery and that low and high levels of preoperative anxiety were associated with poor behavioral recovery. Although Janis' theory is intriguing, his studies were based on descriptive data from nonrandom, limited samples and retrospective reports of questionable validity. Subsequent studies have been critical of Janis' methodology and have reported a linear rather than a curvilinear relationship between anxiety level and postoperative behavioral recovery (Johnson et al., 1971; Johnston, 1980; Johnston and Carpenter, 1980; Newman, 1984; Pick et al., 1994). That is, low levels of preoperative anxiety are associated with good postoperative behavioral recovery, whereas high levels of preoperative anxiety are associated with poor postoperative behavioral recovery. To date, the literature on adults indicates that intensity of pain, analgesic requirements, postsurgical complications, length of hospital stay,

■ **FIGURE 8-11.** The effect of oral midazolam on the incidence of postoperative behavioral outcomes. (From Kain ZN, Mayes LC, Caramico LA: Postoperative behavioral outcomes in children: effects of sedative premedication, *Anesthesiology* 90:758–765, 1999b.)

poor patient satisfaction, and blood cortisol levels have all been reported to be associated with high levels of preoperative anxiety (Devine, 1992; Johnston and Voge, 1993; Contrada et al., 1994; Kiecolt-Glaser et al., 1998).

Many reviews of this research have appeared that, although critical of the methodology of a large number of studies, concluded that high preoperative anxiety is associated with impaired postoperative recovery (Mumford et al., 1982; Mathews and Ridgeway, 1984; Rogers and Reich, 1986; Anderson, 1987; Suls and Wan, 1989; Johnston and Wallace, 1990; Kincey and Saltmore, 1990; Devine, 1992; Johnston and Voge, 1993; Contrada et al., 1994; Kiecolt-Glaser et al., 1998).

The fact that low preoperative anxiety is predictive of good postoperative outcome underlies many interventions in which the aim is to reduce preoperative anxiety. As with the cohort studies described earlier, preparation studies have used diverse postoperative outcome measures, including pain, analgesic requirements, length of hospital stays, patient satisfaction, cortisol levels, blood pressure, heart rate, and behavioral indices of recovery (Mumford et al., 1982; Andersen and Masur, 1983; Mathews and Ridgeway, 1984; Anderson, 1987; Johnston and Voge, 1993). Reviews of this research concluded that psychologically prepared adult patients have improved postoperative recovery results (Mumford et al., 1982; Suls and Wan, 1989; Johnston and Wallace, 1990; Devine, 1992; Johnston and Voge, 1993; Contrada et al., 1994; Kiecolt-Glaser et al., 1998).

In contrast to the adult literature, there is a paucity of peer-reviewed, published-outcome data regarding the question of whether heightened preoperative anxiety impairs postoperative recovery in children undergoing surgery. A large-scale study assessed this question with convergent clinical, neuroendocrinologic, and behavioral measures and found that increased preoperative anxiety in children is associated with impaired postoperative behavioral and clinical recovery. Analysis of the

data indicated that children who were more anxious preoperatively showed poorer immediate clinical recovery (Kain et al., 2002c). The study also found a significant relationship between preoperative anxiety and postoperative pain and postoperative behavioral recovery. That is, children who were more anxious preoperatively were in more pain postoperatively and had a higher incidence of postoperative behavioral changes. More recently, Kain and colleagues (2004a, 2006a) demonstrated that preoperative anxiety was a predictor of emergence delirium, postoperative anxiety and sleep problems, and new behavioral problems after surgery.

SUMMARY

The perioperative period may be very stressful for the young child undergoing surgery. The fear and anxiety during this period are associated not only with immediate hardship to parents and children but also with outcomes such as parental satisfaction, as well as postoperative behavioral and clinical recovery. In this chapter, a variety of behavioral interventions have been described that can and should be used for the management of anxiety during this perioperative period. Although some interventions, such as preparation programs, are well established, others, such as parental presence, music, and acupuncture, are still under development. The individual clinician should have the knowledge of the risk factors, management, and outcome of this important clinical phenomenon.

		Summary	292

In addition to having a sound understanding of a child's medical disease and anticipated surgical procedure, the anesthesiologist must also appreciate the emotional stresses that affect both the child and parent. The preoperative meeting with the patient and his or her parents is not only a responsibility of the anesthesiologist but also an important opportunity to learn facts that could otherwise be missed. It is a chance to win the confidence of the patient and the parents, if they are present (Fig. 9-1).

A careful preoperative examination of the child and the child's medical record enables the anesthesiologist to assess the child's general state of health and to identify the presence of chronic, acute, or intercurrent diseases, as well as to recognize previous anesthetic problems (Black, 1999). From this knowledge, appropriate subspecialty consultation can be sought, the operative medical condition can be optimized for the surgery, and the anesthetic plans can be made. In addition to monitoring practices and anesthetic techniques, anesthetic plans should include provisions for the patient's postoperative care, particularly an analgesic plan. It is the general goal of the preanesthetic visit to anticipate potential complications before they occur, to avert them when possible, and, in so doing, to minimize the risks to the health of the child. The risk of anesthesia is assessed during the preoperative visit, and the child's parents should be informed of the plans for anesthesia and monitoring, and they should be apprised of the anticipated risk.

PREANESTHETIC VISIT

The preanesthetic visit should begin with a careful review of the medical record; particular attention should be paid to previous anesthetic agents and problems encountered, the successful and unsuccessful techniques used in the past for airway management, and any history of cardiorespiratory diseases or airway anomalies. A history of medical or environmental allergies should be elicited, and it should include questions specifically directed toward evaluating the presence of allergy to latex in children at risk, notably those with meningomyelocele or urogenital anomalies, those who undergo bladder self-catheterization, or those whose medical histories indicate a significant amount of latex exposure in the past (Holzman 1997; Porri et al., 1997; Hollnberger et al., 2002; Pires et al., 2002; Eustachio et al., 2003; Dehlink et al., 2009; Rendeli et al., 2006; Bostancy et al., 2007; Dieguez et al., 2007; Garcia 2007; Baker and Hourihane, 2008; De Queiroz et al., 2009). Results of laboratory tests should be reviewed, focusing on hematologic evaluations, renal function, and electrolyte profiles, as well as blood gas analysis and pulmonary function tests when appropriate.

The anesthesiologist must be aware of the child's current drug therapy and how it may interact with the anesthetic. The perioperative administration of bronchodilators, cancer chemotherapeutic agents, or anticholinesterases has significant implications for anesthesia (Schein and Winoker, 1975; Selvin,

FIGURE 9-1. An instructive approach to the anesthesia induction can be taken during the preoperative visit, enabling the anesthesiologist to gain the child's trust and confidence.

1981; Drummond, 1984). Corticosteroid administration is traditionally recommended for patients who receive chronic corticosteroid therapy and for patients who have received steroids in the past, although evidence for the necessity of doing so is lacking (see Chapter 36, Systemic Disorders). Current drug therapy must also include questions regarding the use of herbal medications. Potential complications in the perioperative period have been attributed to the use of complementary medicines. Table 9-1 summarizes the most commonly used herbal remedies (Ang-lee et al., 2001).

Many unusual syndromes occur in childhood, and they often have multisystem involvement; consequently, they have an important impact on anesthetic management. An important caveat in pediatric medicine is that when one congenital anomaly

exists, there is a significant likelihood of anomalies involving other organs. For example, infants with tracheoesophageal fistulas have an increased incidence of congenital heart disease, and some forms of radial dysplasia are associated with thrombocytopenia or atrial septal defects. The topic of congenital anomalies was extensively discussed in a review by Lynn (1985). The remainder of this section is a review of pediatric diseases that may be important to the anesthesiologist. Information regarding these problems may be forthcoming from the child's medical history, the physical examination, or both.

PHYSICAL EXAMINATION

The extent of the physical examination that the anesthesiologist performs depends on the circumstances. If a small infant scheduled for a minor operation has been crying and has finally dropped off to sleep, one can observe from the bedside the child's general nutritional state, skin color, character of respiration, and presence or absence of nasal discharge. Although the surgeon's or pediatrician's notes are helpful, they should not be a substitute for the anesthesiologist's independent examination.

Certain general principles are applied to the preoperative evaluation. When examining a child, the anesthesiologist should look for somewhat different signs than when examining an adult. Between the ages of 4 and 8 years, children must be examined for loose primary teeth. Finding an empty dental socket after an operation is not disturbing if one knows that the child lost the tooth before admission. There is always the danger of the recent onset of an upper respiratory tract infection with cough, rhinitis, and pharyngitis. If an infant or child has rhinitis, it may be challenging to determine whether it is because of an infection, seasonal allergies, or simply the result of crying. Enlarged cervical nodes and otitis media occur in association

TABLE 9-1. Pharmacologic Effects and Potential Perioperative Complications of Eight Commonly Used Herbal Remedies

Name of Herb	Common Uses	Potential Perioperative Complications
Echinacea, purple cone flower root	Prophylaxis and treatment of viral, bacterial, and fungal infections	Reduced effectiveness of immunosuppressants; potential for wound infection; may cause hepatotoxicity when used with other hepatotoxic drugs
Ephedra, ma-huang	Diet aid	Dose-dependent increase in heart rate and blood pressure; arrhythmias with halothane; tachyphylaxis with intraoperative ephedrine
Garlic, ajo	Antihypertensive, lipid-lowering agent, anti-thrombus forming	May potentiate other platelet inhibitors; perioperative bleeding
Ginkgo, maidenhair; fossil tree	Circulatory stimulant; Alzheimer's disease, peripheral vascular disease, and erectile dysfunction	May potentiate other platelet inhibitors; perioperative bleeding
Ginseng	To protect the body against stress and restore homeostasis	Perioperative bleeding; potential for hypoglycemia
Kavakava, pepper	Anxiolytic	Potentiate sedative effects of anesthetic agents; possible withdrawal syndrome after sudden abstinence; kavakava-induced hepatotoxicity
St. John's wort, goatweed, amber, hardhay	Treatment for depression and anxiety	Decreased effectiveness of cyclosporine, alfentanil, midazolam, lidocaine, calcium channel blockers, and digoxin
Valerian, vandal root, all heal	Anxiolytic and sleep aid	Potentiate sedative effects of anesthetic agents; withdrawal-type syndrome with sudden abstinence

From Skinner CM, Rangasami J: Preoperative use of herbal medicines: a patient survey, *Br J Anaesth* 89:792-795, 2002.

FIGURE 9-2. Unilateral nasal discharge can be from a foreign body like a bead (A), or a unilateral choanal atresia (B). (From Yellon RF, McBride TP, Davis HW: *Otolaryngology. In Zitelli J and Davis HW, editors: Atlas of pediatric physical diagnosis, ed 5, St Louis, 2007, Mosby.*)

with respiratory tract infections; clear, colorless rhinitis suggests crying or an allergic etiology.

Partial airway obstruction may result from infection, anatomic anomalies, or tumors. When possible, a diagnosis should be made before anesthesia is begun. Unilateral nasal discharge is unusual and suggests a foreign body (or, less often, choanal atresia) (Fig. 9-2).

Whenever possible the anesthesiologist should personally observe or palpate the location and size of the lesion, such as a laceration, tumor, or nevus, that may be the reason for surgery. A tumor may be the size of a pea or a melon, and a nevus may be a spot on a child's elbow or cover half a limb. The anesthesia cannot be planned intelligently without knowledge of these points.

Review of Body Systems (Table 9-2)

Central Nervous System

Disorders of the neuromuscular system only rarely escape notice during the history and review of systems; the purpose of the central nervous system (CNS) examination is primarily to assess the severity of the abnormality and the implications for anesthetic care.

Trauma is the most common cause of death in children, and most fatal trauma involves injury to the CNS. Head injuries often result in an altered level of consciousness, cerebral edema, and elevated intracranial pressure. Tumors of the brain

TABLE 9-2. Medical History and Review of Systems: Anesthetic Implications

System	History	Potential Anesthetic Implication
Central nervous and neuromuscular systems	Seizure	Medications: drug interactions, inadequate anticonvulsant therapy, drug-induced hepatopathology
	Head trauma	Elevated intracranial pressure
	Hydrocephalus	Anemia
	Central nervous system tumor	Elevated intracranial pressure
		Elevated intracranial pressure
		Chemotherapeutic drug interactions
Cardiovascular system	Developmental delay	History of steroid use
	Neuromuscular disease	Bulbar dysfunction
	Muscle disease	Risk of aspiration
		Altered response to relaxants
		Risk of malignant hyperthermia
		Risk of rhabdomyolysis and hyperkalemia
Cardiovascular system	Heart murmur	Risk of right-to-left air embolism of intravenous air bubbles
	Cyanotic heart defect	Need for SBE prophylaxis
		Right-to-left cardiac shunt
		Risk of right-to-left air embolism of intravenous air bubbles
		Hemoconcentration
		Need for SBE prophylaxis
Cardiovascular system	History of squatting	Teratology of Fallot
	Diaphoresis with feeding or crying	Congestive heart failure
	Hypertension	Coarctation of the aorta, renal disease, or pheochromocytoma

Continued

TABLE 9-2. Medical History and Review of Systems: Anesthetic Implications—cont'd

System	History	Potential Anesthetic Implication
Respiratory system	Prematurity Bronchopulmonary dysplasia	Increased risk of postoperative apnea Lower airway obstruction Reactive airways disease Subglottic stenosis Pulmonary hypertension
	Respiratory infection, cough Croup Snoring	Reactive airways and bronchospasm Medication history Subglottic stenosis or anomaly Obstructive sleep apnea Perioperative airway obstruction
	Asthma	β -Agonist or theophylline therapy History of steroid use
	Cystic fibrosis	Drug interactions Pulmonary toilet Pulmonary dysfunction and VQ mismatch Reactive airways disease
Gastrointestinal/hepatic systems	Vomiting, diarrhea	Electrolyte abnormality, especially hypokalemia Dehydration Risk of aspiration
	Growth failure	Low glycogen reserves/risk of hypoglycemia Anemia
	Gastroesophageal reflux	Risk of aspiration Reactive airways disease Anemia
	Jaundice	Altered drug metabolism Risk of hypoglycemia Coagulopathy
	Liver transplant recipient	Altered drug metabolism Immunosuppression Coagulopathy
Renal system	Frequency, nocturia	Occult diabetes mellitus Electrolyte disturbance Urinary sepsis
	Renal failure/dialysis	Electrolyte disturbance Hypervolemia or hypovolemia Anemia Medication history
	Kidney transplant recipient	Immunosuppression Poor toleration of hypotension Hypertension
Endocrine system	Diabetes	Insulin requirement Intraoperative hyperglycemia or hypoglycemia
	Steroid therapy	Adrenocorticoid suppression
Genitourinary system	Pregnancy	Teratogenic effects Risk of spontaneous abortion
Hematologic system	Anemia	Transfusion requirement Occult hemoglobinopathy
	Bruising, history of bleeding Sickle cell disease	Coagulopathy Anemia Need for hydration Limb tourniquet use
	Human immunodeficiency virus infection	Susceptibility to infection Infectious risk to medical personnel
Dental system	Loose primary teeth	Risk of aspiration if tooth avulsed

Modified from Coté CJ, Todres ID, Ryan JF: Preoperative evaluation of pediatric patients. In Ryan JF, Todres ID, Coté CJ, et al., editors: *A practice of anesthesia for infants and children*, New York, 1986, Grune & Stratton. (With permission from Elsevier.)
SBE, Subacute bacterial endocarditis; VQ, ventilation perfusion.

are the most common solid tumors of childhood and usually occur in the posterior fossa. They generally increase intracranial pressure as a mass effect but also often obstruct cerebrospinal fluid pathways, resulting in hydrocephalus. The anesthetic care of children with elevated intracranial pressure is discussed in Chapter 22, Anesthesia for Neurosurgery.

To ensure both therapeutic levels and the absence of toxic levels, serum levels of certain anticonvulsant drugs should be measured or should have been measured before elective surgery in children with chronic seizure disorders. Most anticonvulsants have a long plasma half-life; therefore, missing one dose in the perioperative period does not significantly diminish

the serum level and efficacy. Of the commonly used anticonvulsants, only phenobarbital, phenytoin, or valproate may be given intravenously in the perioperative period. Other commonly administered anticonvulsants, however, such as gabapentin, pregabalin, leviratracetam, or lamotrigene, are available only as oral medications. If a prolonged period without oral intake is anticipated (such as after abdominal surgery), a neurologist should be consulted about possible alternative parenteral drug therapy.

Conditions such as developmental delay and spastic cerebral palsy have important implications for anesthesia. In such children, the response to opioids and anesthetic agents is less predictable than that with healthy children. Many patients with cerebral palsy or intellectual impairment have difficulty managing oral secretions, and gastroesophageal reflux is particularly common in these children. They are at a greater risk of aspirating oral or gastric contents during induction. Cerebral palsy in older children often produces restrictive lung disease as a result of deformities of the spine and thoracic cage and from uncoordinated respiratory muscle function.

Neuromuscular diseases, such as congenital myotonia, muscular dystrophy, and the various forms of myositis, contraindicate the use of succinylcholine even in emergency airway management, although it is rarely used in current pediatric anesthetic practice (see Chapter 36, Systemic Disorders). In myotonia, succinylcholine produces a sustained contracture of skeletal muscle that may impede the ability to maintain a patent airway and ventilate the lungs. In other myopathies, such as clinically active dermatomyositis, succinylcholine produces life-threatening hyperkalemia. Some forms of muscular dystrophy (central core disease) are statistically associated with malignant hyperthermia, whereas others may result in a malignant hyperthermia-like syndrome that is equally life threatening (Guis et al., 2004; Rosenberg et al., 2007; Driessen and Snoeck, 2008; Hayes et al., 2008; Puel et al., 2008; Takagi and Nakase, 2008; Schwartz and Raghunathan, 2009). Although not all children with Duchenne's or other muscular dystrophies are genetically susceptible, Rosenberg and Heiman-Patterson (1983), as well as Takagi and Nakase (2008), recommend that precautions against malignant hyperthermia be taken in patients with this disorder because of rhabdomyolysis and hypermetabolism that may occur in myopathic children after exposure to triggering agents. For further discussion please refer to Chapter 37, Malignant Hyperthermia.

Cardiovascular System

Evaluation of the cardiovascular system is critical to the delivery of safe anesthesia. The physical examination seldom reveals an unexpected CNS lesion, but a careful history and auscultation of the child's chest often reveal a congenital cardiac lesion that may be unknown to the parents or the child's surgeon.

The history-and-systems review yields information regarding known cardiac anomalies of an acquired disease, cyanotic defects, or the presence of congestive heart failure. Symptoms of congestive heart failure may be insidious. In an infant, whose level of activity is not high, the symptoms of congestive heart failure or cyanosis are most likely limited to a few times of physical exertion, such as feeding and crying, and the only symptoms of congestive heart failure may be pallor and diaphoresis, which are subtle findings. Parents should be asked about diaphoresis during nursing or sucking. Resting

tachypnea and failure to thrive are also consequences of more advanced degrees of congestive heart failure, which may be the result of ventricular volume overload (most commonly, a ventricular septal defect, patent ductus arteriosus, or anomalous pulmonary venous return), either right- or left-sided outflow obstruction, or pulmonary hypertension.

Preoperative evaluation of a patient with a known or suspected heart defect that is physiologically significant should include a thorough history and physical examination; an electrocardiogram (ECG) and echocardiogram; determination of hematocrit value, a baseline oxygen saturation value (SpO_2); a chest radiograph; and a definitive understanding of the type of cardiac lesion, its degree of severity, and its physiologic effect on cardiac efficiency and oxygen delivery. Such patients should be examined meticulously and should not be accepted for anesthesia until they are in the best possible physical condition. For children with compromising lesions or those requiring cardiac medication, it is advisable to consult the cardiologist shortly before surgery.

The presence of polycythemia is uncommon in modern clinical practice but still should be ruled out in children with cyanotic heart disease; a hematocrit value of greater than 65% may be reduced by red blood cell pheresis or isovolemic hemodilution. Dehydration must be avoided, preferably through the use of controlled intravenous hydration beginning the night before surgery or by following the *nil per os* (NPO) guidelines and ensuring adequate oral intake of clear liquids up until 2 hours before surgery.

Particular care must be taken to rule out the existence of any infection, especially in the throat, ears, skin, or genitourinary tract. Bacteremia and infections of the teeth or gums should be controlled with appropriate antibiotics. The preoperative occurrence of fever or rhinitis or a significant preoperative exposure to a source of infection should be considered a possible indication for postponement of the operation.

Asymptomatic cardiac murmurs occasionally have implications for anesthesia. If they represent small ventricular septal defects or mild valvular disease, prophylaxis against bacterial endocarditis is indicated for procedures that may result in bacteremia, such as dental surgery, gastrointestinal or urogenital endoscopy, and nasotracheal intubation (Wilson et al., 2007). Atrial septal defects contraindicate the use of the sitting position for suboccipital craniotomies in order to minimize the risk of paradoxical air embolism (Fischler, 1992). The defects may also make intraoperative transesophageal echocardiography desirable in certain cases that have been associated with venous air embolism (e.g., posterior spine fusions or liver transplantation), so the movement of air from the pulmonary to the systemic circulation may be detected. If the anesthesiologist detects a previously undescribed murmur in these circumstances, a consultation with the cardiologist is indicated to further delineate the nature of the lesion (Fig. 9-3). Many congenital anomalies and syndromes are associated with cardiac defects or other cardiovascular problems; Box 9-1 provides an outline of these conditions.

Respiratory System

Chapter 3, Respiratory Physiology in Infants and Children, describes the anatomic and physiologic differences between the pediatric and adult respiratory systems. The differences in dimension and function predispose the child to perioperative airway

FIGURE 9-3. Sites for auscultation where murmurs are heard best. (From Beerman LB, Kreutzer J, Park SC: *Cardiology*. In Zitelli J, Davis HW, editors: *Atlas of pediatric physical diagnosis*, ed 5, St Louis, 2007, Mosby.)

Box 9-1 Pediatric Syndromes Associated with Cardiac Conditions

SYNDROMES ASSOCIATED WITH CONGENITAL HEART DISEASE

Apert's syndrome
 Asplenia syndrome (Ivemark's syndrome)
 Conradi's syndrome
 DiGeorge's syndrome
 Down syndrome (trisomy 21)
 Edwards' syndrome (trisomy 18)
 Ellis-van Creveld syndrome
 Goldenhar's syndrome
 Holt-Oram syndrome
 I-cell disease
 Laurence-Moon-Biedl syndrome
 LEOPARD syndrome (multiple lentiginos syndrome)
 Marfan syndrome
 Meckel's syndrome
 Noonan's syndrome
 Patau's syndrome (trisomy 13)
 Polysplenia
 Rubinstein's syndrome
 Sebaceous nevi syndrome
 TAR syndrome (thrombocytopenia-absent radius syndrome)
 VACTERL (vertebral, anal, cardiac, tracheal, esophageal, renal, and limb) association
 VATER (vertebral defects, imperforate anus, tracheoesophageal fistula, radial and renal dysplasia) association
 Williams syndrome

SYNDROMES ASSOCIATED WITH CARDIOMYOPATHY

Cretinism
 Duchenne's muscular dystrophy

Farber's disease
 Friedreich's ataxia
 Hunter's syndrome
 Hurler's syndrome
 Maroteaux-Lamy syndrome
 Myotonic dystrophy
 McArdle's disease
 Pompe's disease
 Stevens-Johnson syndrome

SYNDROMES ASSOCIATED WITH AUTONOMIC DYSFUNCTION OR ARRHYTHMIAS

Albright's osteodystrophy
 Guillain-Barré syndrome
 Jervell and Lange-Nielsen syndrome
 Riley-Day syndrome
 Shy-Drager syndrome
 Short QT syndrome
 Sipple's syndrome
 Wolff-Parkinson-White syndrome

SYNDROMES ASSOCIATED WITH THROMBOSES OR ISCHEMIC HEART DISEASE

Ehlers-Danlos syndrome
 Fabry's disease
 Grönblad-Strandberg syndrome
 Homocystinuria
 Progeria
 Tangier disease
 Werner's syndrome

obstruction, which mandates a critical preoperative evaluation of the airway. The upper airway of the child may be further compromised by many entities, including: tonsillar or adenoidal hypertrophy or both; craniofacial anomalies such as Crouzon's disease, Apert's syndrome, hemifacial microsomia, Goldenhar's syndrome,

Treacher Collins syndrome (or Pierre Robin syndrome); lingular hypertrophy (common in trisomy 21); Beckwith's syndrome and the various forms of mucopolysaccharidosis (Hurler's syndrome and Hunter's syndrome being the most common); isolated airway anomalies, such as cleft palate, laryngeal web or

cleft, laryngomalacia, or subglottic stenosis; or tumors, such as hemangiomas and lymphangiomas, which may occur anywhere along the airway. Cutaneous cervicofacial hemangiomas along a beard distribution are suggestive of an association with upper airway or subglottic hemangiomas (Orlo et al., 1997).

Acute upper respiratory tract infections provide a common dilemma for the anesthesiologist. The mere volume of publications that evaluate the risk of adverse events of anesthesia in children with upper airway infections speaks to the ongoing controversy (Tait and Malviya, 2005). In the best of all worlds, no child would be anesthetized electively during an acute respiratory illness. Although not all studies have identified acute respiratory illness as a cause of perioperative complications in children, there is compelling evidence that the occurrence of both intraoperative and postoperative hypoxemia and other airway complications are increased in children with upper respiratory tract infections (DeSoto et al., 1988; Cohen and Cameron, 1991; Kinouchi et al., 1992; Levy et al., 1992; Rolf and Coté, 1992; Parnis et al., 2001; Bordet et al., 2002; Elwood et al., 2003; Tait, 2005). There is also evidence that the incidence of bronchospasm is increased in the presence of upper respiratory infections in children who are intubated (Rolf and Coté, 1992; Rachel Homer et al., 2007; von Ungern-Sternberg et al., 2007). In a prospective study, Tait and colleagues (2001) noted that endotracheal intubation, a history of prematurity, reactive airways disease, parental smoking, airway surgery, and nasal congestion are all risk factors associated with respiratory complications in infants and children who have upper respiratory infections and who are undergoing anesthesia. Furthermore, the child with an acute respiratory disease exposes other patients and health care workers to their contagion, which may not be a trivial concern when these individuals are immunocompromised.

Other considerations, however, must be taken into account before making the decision to postpone surgery. For example, the relatively small risk to the child must be weighed against the expense and effort the family has made to come to the hospital, often from a distant locale and at the cost of lost income. Some children, particularly those seen for otolaryngologic surgery, appear to never be free from respiratory infections during much of the year. Postponement of surgery may not be practical in these circumstances. Indeed, one study indicates that myringotomy is therapeutic in these children and is not associated with an increased incidence of postoperative pulmonary complications (Tait and Knight, 1987).

The presence of acute disease of the lower airways, however, should generally delay elective surgery. The presence of fever, cough, and an abnormal auscultatory examination is reason for radiographic evaluation and possibly cancellation of scheduled surgery. Patients with a viral lower respiratory tract infection such as influenza may develop airway hyperreactivity that is indistinguishable from bronchial asthma and can last as long as 6 or 7 weeks from onset.

Chronic diseases of the lower respiratory tract occur in both children and adults. Asthma and cystic fibrosis are the most common chronic pulmonary diseases of childhood. A careful history and physical examination usually suffice in the preoperative evaluation of these diseases. If preoperative impairment is severe, however, or if the planned surgery is extensive, formal pulmonology consultation and pulmonary function testing may provide the anesthesiologist with information that can be used to provide optimal postoperative care. Children with asthma are commonly medicated with β_2 -adrenergic agents

and inhaled corticosteroids. Other first-line drugs include cromolyn sodium and leukotriene receptor antagonists; rarely are theophylline preparations administered at this time. However, when theophylline is a part of the patient's treatment, serum concentration of theophylline should be measured preoperatively to ensure blood levels in a therapeutic range (10-20 mcg/mL), and the anesthesiologist should be aware of potential interactions among theophylline, β_2 -adrenergic drugs, and halothane (although it is not often used). Asthmatic children who receive corticosteroids should also be considered for perioperative therapy with stress doses of corticosteroids if steroid therapy has been recent, although as previously stated, the evidence to support this convention is lacking. For those children who have required systemic steroids in the past, a short course of steroids beginning 1 to 2 days before the day of surgery may be beneficial (see Chapter 36, Systemic Disorders).

Severe kyphoscoliosis typically leads to significant restrictive lung disease. This is particularly true in cases of kyphoscoliosis that occur before the teenage years. Particularly in this age group, the cause of the kyphoscoliosis should be assessed, because it typically results from neuromuscular diseases such as cerebral palsy or muscular dystrophy or from anatomic anomalies such as hemivertebrae, which may be part of a syndrome that is associated with other congenital anomalies of importance to the anesthesiologist (e.g., VATER association). Preoperative testing of pulmonary function may be useful in predicting which children will require admission to an intensive care unit with or without mechanical ventilation postoperatively, but usually the decision to mechanically ventilate patients after spinal surgery is based on general preoperative condition, duration and difficulty of surgery, blood loss, and other surgical factors, rather than on the test of pulmonary function itself (see Chapter 26, Anesthesia for Orthopedic Surgery).

An infant who was born prematurely is often left with a residual chronic obstructive pulmonary disease called *bronchopulmonary dysplasia*, the consequence of both oxygen toxicity and ventilator-induced lung injury to immature lungs. The incidence and severity of this disabling condition have been dramatically reduced by the use of surfactant in neonatal intensive care units. Children with bronchopulmonary dysplasia exhibit a combination of fibrotic and cystic changes in the lung parenchyma with reactive small airways disease, with or without wheezing and air trapping. These children may respond to steroids and bronchodilators in varying degrees. More advanced bronchopulmonary dysplasia is associated with chronic hypoxia, carbon dioxide retention, pulmonary hypertension, and ultimately *cor pulmonale* (Berman et al., 1982).

As in the adult with chronic pulmonary disease, elective surgery is best delayed until preoperative cardiopulmonary function has been optimized. Children with severe bronchopulmonary dysplasia are usually treated with diuretics to reduce extravascular lung water; consequently, abnormal serum electrolyte levels are common preoperatively (e.g., hypokalemia, hyponatremia, or metabolic alkalosis). Arterial saturation should be maximized at all times to reduce pulmonary hypertension, and perioperative bronchodilator therapy should be considered. Alterations in anesthetic care include: judicious, if any, use of nitrous oxide to avoid exacerbation of pulmonary gas trapping and pulmonary vascular resistance; very conservative fluid therapy and restriction of sodium; and continuation of bronchodilator therapy. Postoperative mechanical ventilation may be required in this population.

Life-threatening apnea and bradycardia may occur after general anesthesia, most commonly in the preterm infant who is still younger than 45 weeks' or as old as 60 weeks' postconceptional age (the sum of gestational age and postnatal age) (Liu et al., 1980; Kurth et al., 1986; Wellborn et al., 1986). Hospital admission and respiratory monitoring are necessary for infants at risk, even after brief general anesthesia. Risk factors for postoperative apnea in preterm infants include: a history of mechanical ventilation, history of apnea and bradycardia, and anemia at the time of surgery (Kurth and LeBard, 1991; Wellborn et al., 1991; Spear, 1992; Malviya et al., 1993; Coté et al., 1995). In a meta-analysis of eight studies, Coté et al. (1995) reported that the postconceptual age required to reduce the risk of postoperative apnea to 1% was 54 weeks for infants born at 35 weeks' gestation and 56 weeks for infants born before 32 weeks' gestation. For further information, see Chapter 17, Neonatology for Anesthesiologists, Figure 17-10.

Congenital diseases of the lungs are usually recognized and surgically corrected in the newborn period. These conditions and their anesthetic management are discussed in Chapters 18 and 23, Anesthesia for General Surgery in the Neonate, and Anesthesia for General Abdominal, Thoracic, Urologic, and Bariatric Surgery.

Gastrointestinal System

The primary concern of the anesthesiologist is to assess the integrity of the gastroesophageal sphincter, the emptiness of the stomach, and, hence, the risk of aspiration on induction of or emergence from anesthesia. Gastroesophageal reflux occurs as an isolated entity in some otherwise healthy infants. Parents describe regular spitting up after meals, and there may be a history of recurrent lower respiratory tract infections, small airways disease, wheezing, or esophagitis that points to the diagnosis. Gastroesophageal reflux is very common in the child with developmental delays. After repair of tracheoesophageal fistulas, abnormalities of esophageal motility and decreased competence of the gastroesophageal sphincter are often present, increasing the risks of vomiting and aspiration on induction of anesthesia. Children who fall into these categories should be considered to have a "full stomach."

Renal System

Renal failure is uncommon in childhood. Chronic renal failure is typically managed with either peritoneal dialysis or, in the older child, hemodialysis. The evaluation of the child with preoperative renal disease includes serial measurements of blood pressure to assess the adequacy of antihypertensive therapy; careful determination of vascular volume; and measurement of serum levels of electrolytes, urea nitrogen, creatinine, phosphate, calcium, and magnesium, as well as hematocrit value. Electrolyte levels should be within a reasonably normal range; if significant derangement exists, additional electrolyte therapy or dialysis should be performed before elective surgery. The acceptable lower limit of hematocrit is generally considered to be about 20% with chronic renal failure. Such an assumption of adaptation, however, is controversial because the blood levels of 2,3-diphosphoglycerate in these children are not necessarily increased, depending on the chronicity of anemia or recent history of dialysis.

Milder degrees of renal dysfunction may also affect anesthetic care. In small children with mild or moderate underlying renal

disease, clinically significant hypervolemia may occur without compensation by augmented urine output, and an excessive sodium or free-water load further deranges the serum electrolyte level. Particular caution is important in the management of fluids in children, and central venous pressure monitoring is required during major surgery in which significant blood loss or fluid shifts are anticipated (see Chapter 5, Regulation of Fluids and Electrolytes).

Hematologic System

Underlying disorders of the hematologic system are not common. The systems review should include an inquiry into unusual bleeding in the family's or child's medical history to explore possible genetic coagulopathies. A report of excessive bleeding from a circumcision or tonsillectomy should raise the possibility of thrombocytopenia, von Willebrand's disease, or one of the inherited factor deficiencies and is a reason to measure platelet count, bleeding time, and coagulation time (see Chapter 36, Systemic Disorders).

Sickle cell disease typically produces no symptoms in early childhood, so a systems review is unlikely to detect its presence. For this reason, children of African heritage should be screened for sickle cell disease before surgery. A positive result should be followed by a hemoglobin electrophoresis to confirm the diagnosis or to define other hemoglobinopathies. The anesthetic plan may then be altered to ensure preoperative and postoperative hydration and to provide a high concentration of inspired oxygen. To prevent ischemia and subsequent sickling in the operated limb, the use of a tourniquet during orthopedic surgery is contraindicated when sickle cell disease or trait is present. This has become controversial, however.

In a report by the Preoperative Transfusion in Sickle Cell Disease Study Group, aggressive treatment (transfusion to a hemoglobin S level of less than 30%) was compared with a more conservative management regimen (hemoglobin maintained at 10 g/dL). The conservative approach was equally as effective as the aggressive approach in preventing serious complications but was associated with half the number of transfusion-associated complications (Vichinsky et al., 1995). A hematologic consultation should be sought or institutional protocols be developed for children with hemoglobinopathies who are undergoing anesthesia (see Chapter 36, Systemic Disorders).

THE CHILD WITH PHYSICAL OR MENTAL DISABILITIES

One of the most important principles in dealing with all types of physically and/or mentally disabled children is to be considerate. In any situation involving the care of patients with disabilities, it is appropriate to show appreciation for the position of the families and the dedication they show and deprivation they endure, usually with remarkably little complaint. It is often inspiring to learn about their abilities to cope with misfortune.

Brain Damage

Children who survive severe hypoxic or traumatic brain damage and children with postinfectious encephalopathy may need to undergo various surgical procedures. Preoperative evaluation

should include determination of the type and degree of the original neurologic lesion and the patient's present neurologic status. Patients with severe neurologic lesions may depend on implanted ventriculoperitoneal shunts, and shunt patency should be ensured before the administration of anesthesia. Signs and symptoms of a blocked shunt include an abnormally low or high heart rate or blood pressure, headache, vomiting, irritability, and drowsiness. At some point in the child's past, pulmonary management may have required a tracheostomy, which, if still present, may simplify the induction of anesthesia. However, if the patient was decannulated in the past, the upper airway may have been rendered stenotic.

Because they may have difficulty swallowing, these patients often aspirate secretions, and atelectasis or pneumonia may develop. Consequently, a chest radiograph may be indicated to determine the presence and degree of ventilatory compromise. The same patients commonly have gastrostomy tubes for feeding, which should be identified, drained before the induction of anesthesia, and then left open throughout the operative period to prevent gastric distension.

Old injuries, strictures, flexions, deformities, and scars should be noted, with careful descriptions made of signs of recent injuries, pressure sores, or self-inflicted scratches and marks that might otherwise be attributed to anesthetic care. During anesthesia, added care is taken to protect all parts of the body from abnormal pressure and positioning.

Cerebral Palsy

Special consideration is needed when caring for patients with the diagnosis of cerebral palsy, spastic diplegia, or quadriplegia (Nolan et al., 2000). Inexperienced personnel commonly make the serious mistake of assuming that patients with spastic diplegia or quadriplegia also suffer from cognitive impairment, which may not be true. *Cerebral palsy* is a general term applied to several different forms of neuromuscular disability, arising from various anatomic lesions of the brain and not always involving intellectual impairment (Stiles, 1981). The treatment of patients with cerebral palsy should include careful assessment of their level of intelligence. When in doubt, as with all patients who have difficulty communicating, one should assume that they can both hear and understand what is said.

Developmental Delay, Cognitive Dysfunction, and Psychological Disorders

The term *mental retardation* is one of the broadest in medicine, encompassing many different forms, and it is pejorative in its tone. The anesthesiologist is encouraged to use more sensitive terminology, such as *cognitive dysfunction*, *developmental delay*, or *intellectual impairment*, to name a few more acceptable terms. Trisomy 21 (or other trisomies), autism, and phenylketonuria are well-known forms of this affliction; information on more obscure forms may be found in special texts, such as that of Katz and Steward (1993). Developmental delays that are genetic bear no specific outward stigmata or congenital anomalies, and anesthesia is adapted to the child's level of consciousness and cooperation. Trisomy 21 and other chromosomal forms of intellectual impairment are often associated with congenital heart defects, as well as other congenital organ defects. Trisomy 21 is

also commonly associated with blunting of the styloid process of the second cervical vertebra, which combined with the ligamentary laxity of the syndrome allows atlanto-occipital subluxation, or dislocation on marked flexion of the head and neck, resulting in spinal cord injury (Moore et al., 1987; Williams et al., 1987). For more on this subject, see Chapter 36, Systemic Disorders.

Children with autism are difficult to deal with and are sometimes wildly resistant to any intervention. These patients may appear to be remarkably alert, but they also appear to be locked within themselves. The management of the autistic child must be individualized to the dynamics particular to each child's circumstances (Rainey et al., 1998; van der Walt and Moran, 2001). As for other intellectually impaired children, the presence of a parent at induction often has a soothing effect. Premedication with oral midazolam or clonidine is often effective for sedating these children and improving cooperation.

Hyperactivity and Lack of Cooperation

Hyperactive, aggressive, resistant, and uncooperative children offer challenging situations to the anesthesiologist. Such attitudes are seen in pure behavioral syndromes without developmental handicaps, as well as in various forms of neurologic disease or posthypoxic encephalopathy.

The history is carefully reviewed to determine the extent of the hyperactivity and factors that affect the behavior. Parents or attendants are questioned as to which approaches have succeeded in the past and which have not. Trial-and-error methods are not advisable. Oral premedication with midazolam, clonidine, or ketamine may be helpful. Intramuscular ketamine (2 to 4 mg/kg) may be used as a last resort (Hannallah and Patel, 1989).

DRUG ABUSE IN THE CHILD AND ADOLESCENT

Abuse of illicit drugs is unfortunately not limited to adults. Drugs such as cocaine, marijuana, and lysergic acid diethylamide (LSD) are of social and medical concerns. In 1993, about 1 in 3 high school seniors in the United States (35.5%) had used marijuana in their lifetime (Fig. 9-4) (Johnston et al., 1994). A survey of schoolchildren in Great Britain showed that 15.8% of boys have been offered the drug Ecstasy and that 5.7% have

FIGURE 9-4. Percentage of high school seniors in the United States who have used marijuana and other illegal substances in their lifetime.

taken it (Milroy, 1999). A survey among college students in Great Britain indicated that the most commonly used drugs are marijuana (59%), amphetamines (19%), cocaine (18%), and LSD (18%) (Christophersen, 2000). Because drug abuse may result in increased morbidity and mortality, a thorough understanding of the consequences of drug abuse is essential for the practicing anesthesiologist.

Cocaine

Cocaine is an alkaloid derived from the leaves of the South American shrub, *Erythroxylum coca*. Cocaine can be abused via every possible route, including oral, nasal, intravenous, and rectal. The hydrochloride form can be chemically altered to the base form, which is then concentrated by extraction in ether or baking soda (Perez-Reyes et al., 1982; Fleming et al., 1990). The residue from this method is a form of cocaine base commonly called *crack* (based on the cracking sounds it makes when heated) (Fleming et al., 1990; Julien, 1994). High levels of cocaine may persist in a person for 6 hours after nasal administration (Inaba et al., 1978). The metabolism of cocaine occurs primarily through plasma and hepatic cholinesterase, and patients with pseudocholinesterase deficiency are at increased risk for cocaine toxicity. Less than 5% of ingested cocaine is excreted unchanged in the urine (Inaba et al., 1978). Ecgonine methyl ester and benzoylecgonine constitute over 80% of cocaine metabolites and are detected in the urine for 14 to 60 hours after cocaine use.

Medical Complications

Myocardial ischemia and infarction have been described among young cocaine users with no other known cardiac risk factors (Box 9-2) (Mittleman et al., 1999; Feldman et al., 2000). The pathophysiologic basis for cocaine-related cardiac effects is not clear, and multiple mechanisms have been postulated, including increases in myocardial oxygen demand, accelerated atherosclerosis, thrombus formation, coronary vasospasm and vasoconstriction, and abnormally enhanced platelet aggregation (Pitts et al., 1997). Endothelin-1, a potent vasoconstrictor, is released by cocaine and may play a significant role in vasospastic angina, acute myocardial infarction, and sudden cardiac death (Wilbert-Lampen et al., 1998). Cocaine abuse has also been associated with ventricular hypertrophy, myocardial depression, and cardiomyopathy (Ghuran and Nolan, 2000). Dysrhythmias associated with cocaine use include sinus tachycardia, ventricular premature contractions, ventricular tachycardia or fibrillation, and asystole (Mouhaffel et al., 1995). Dilated cardiomyopathy, myocarditis, and congestive heart failure have also been reported secondary to cocaine use (Kloner et al., 1992; Mouhaffel et al., 1995). In addition, there is an increased incidence of hemorrhagic cerebrovascular accidents in patients who abuse cocaine (Brust, 1993). The smoking of crack cocaine produces alteration in pulmonary function, as would be expected.

Anesthetic Management

Identification of the cocaine user during the preoperative assessment presents a special challenge to the anesthesiologist, because self-reporting of drug abuse is notoriously unreliable. The nasal mucosa may show signs of ulceration. Extremities should be examined for sclerosis of peripheral veins and needle

Box 9-2 Medical Complications of Cocaine Abuse

- Cardiac
- Myocardial ischemia/infarction
- Arrhythmias
- Cardiomyopathy
- Myocardial depression
- Neurologic complications
- Seizures
- Cerebral infarctions
- Subarachnoid hemorrhage
- Intracerebral bleed
- Obstetric complications
- Preterm labor
- Premature rupture of membranes
- Abruptio placentae
- Precipitate delivery
- Sudden infant death syndrome
- Pediatric complications
- Prematurity
- Congenital anomalies
- Neurobehavioral abnormalities
- Partial ankyloglossia
- Necrotizing enterocolitis
- Pulmonary complications
- Cocaine-induced asthma
- Hypersensitivity pneumonitis
- Chronic cough
- Pulmonary edema
- Pneumothorax
- Pulmonary hemorrhage

marks from intravenous injections. Auscultation over the lungs is important to exclude cocaine-induced asthma, and a careful cardiovascular and neurologic examination is necessary (Fleming et al., 1990; Kain and Rosenbaum, 1994).

When cocaine use is suspected or confirmed, preoperative laboratory tests include: complete blood cell count with a platelet count to rule out thrombocytopenia; ECG to identify signs of rhythm disturbance or myocardial ischemia; chest radiography to rule out any pulmonary or cardiac involvement; and abdominal radiography—cocaine and heroin addicts may experience pseudo-obstruction.

Induction and Maintenance of Anesthesia

Of concern is that ketamine should be used with extreme caution in these patients because it can markedly potentiate the cardiovascular toxicity of cocaine. Because both cocaine and succinylcholine undergo metabolism by plasma cholinesterase, the use of succinylcholine may result in prolonged paralysis, an increased anesthetic requirement for volatile anesthetics may be present in the acutely intoxicated patient, and the temperature rise and sympathomimetic effects associated with cocaine can mimic malignant hyperthermia (MH), so it may be difficult to differentiate between the MH and the influence of cocaine.

Acutely Intoxicated Patient

General stabilization and hemodynamic control should precede induction of anesthesia. Propranolol was used successfully in the past to treat the β -adrenergic cardiac effects of cocaine

(Fleming et al., 1990). Propranolol may worsen coronary vasoconstriction and should not be used if the patient is experiencing chest pain. Intravenous nitroglycerin, which has been shown to reverse both cocaine-induced hypertension and coronary vasoconstriction, may be the preferable drug. Furthermore, Brogan et al. (1991) reported that sublingual nitroglycerin, in a dose sufficient to reduce the mean arterial pressure by 10% to 15%, reverses cocaine-induced coronary artery vasoconstriction. Labetalol, hydralazine, and esmolol have been documented to adequately control cocaine-induced hypertension (Hollander, 1995).

Clinical experience and experimental evidence support the use of benzodiazepines as a first-line treatment for cocaine-intoxicated patients (Hollander, 1995). In addition to anxiolytic effects, benzodiazepines may lower blood pressure and heart rate, thereby decreasing myocardial oxygen consumption. Benzodiazepines are recommended for patients who are experiencing cocaine-associated chest pain and cardiac ischemic changes, as well as for patients who are having convulsions. In addition, although no clinical data exist to support the use of acetylsalicylic acid (aspirin) in patients with cocaine-associated ischemia, some experimental evidence supports the use of aspirin (Rezkalla et al., 1993).

Amphetamine-Related Designer Drugs

The term *designer drugs* includes compounds that have been chemically altered from federally controlled substances to produce special effects and to bypass legal regulation. The largest group consists of the methylenedioxy derivatives of amphetamine and methamphetamine. Amphetamine designer drugs produce indirect sympathetic activation by releasing norepinephrine, dopamine, and serotonin from terminals in the central and autonomic central nervous system (Albertson et al., 1999; Christophersen, 2000). The best known and most widely used designer drug is 3,4-methylenedioxymethamphetamine (MDMA, or Ecstasy), which chemically resembles a combination of amphetamine and mescaline (Milroy, 1999). The drug can be ingested orally, injected, smoked, or snorted. The onset of action is directly related to the route of administration, and for an oral dose, onset usually occurs in 20 to 45 minutes and lasts up to 6 hours (Milroy, 1999). Ecstasy is metabolized by the liver and excreted by the kidneys.

Most people who use Ecstasy experience no complications, but a number of deaths have occurred as a result of hyperthermia or idiosyncratic reactions to the drug. The most commonly seen reaction to severe or toxic ingestion of Ecstasy is a syndrome of altered mental status, tachycardia, tachypnea, profuse sweating, and hyperthermia (Henry, 2000). This constellation of symptoms closely resembles that caused by acute amphetamine overdose, which is not surprising given the chemical similarity of MDMA. Reported severe complications from ingestion of Ecstasy include hyperthermia, rhabdomyolysis, renal failure, cardiovascular collapse, disseminated intravascular coagulation, hepatic failure, hyponatremia, urinary retention, cerebral infarct, and cerebral hemorrhage (Hall, 1997a; Milroy, 1999; Ghuran and Nolan, 2000; Henry, 2000; Reneman et al., 2000). Liver damage was recognized among the first deaths in the United Kingdom and seems to be a function of hyperthermia and the resulting shock and disseminated intravascular coagulopathy (Henry, 2000).

The usual presentation in cases of acute toxicity includes hyperthermia, muscle rigidity, and a rise in creatinine kinase (CK) (Hall, 1997b). These patients may deteriorate toward multiple-organ failure, requiring intensive cardiovascular and respiratory support. These patients should be treated with active cooling and dantrolene given over 72 hours (Dar and McBrien, 1996). MDMA-induced hyperthermia results from augmentation of central serotonin function by stimulation of neuronal serotonin release (Dar and McBrien, 1996). Interestingly, Rittoo and Rittoo (1992) suggest that serum MDMA concentrations be measured in the admission blood sample of young adults who develop hyperthermia during general anesthesia. They also raise the question of whether patients who develop hyperthermia after Ecstasy use are at higher risk for the development of severe hyperthermia after general anesthesia.

Management is aimed at controlling symptoms. Benzodiazepines are suggested for agitation or seizures, and dopamine or norepinephrine is recommended for hypotension unresponsive to fluid challenges. Also suggested are phentolamine or nitroprusside for hypertension, lidocaine for ventricular dysrhythmias, and aggressive cooling and possibly the use of dantrolene (Milroy, 1999; Ghuran and Nolan, 2000; Henry, 2000). Additionally, the use of bicarbonate for rhabdomyolysis and correction of electrolyte abnormalities may be needed in the management of these patients.

Marijuana

Marijuana is the most commonly used illegal drug. The hemp plant *Cannabis sativa*, from which marijuana grows throughout the world, flourishes in most temperate and tropical regions. Marijuana is commonly ingested by smoking, which increases the bioavailability of the primary psychoactive constituent, tetrahydrocannabinol (THC) (Musty et al., 1995; Hall and Solowij, 1998). Inhalation of marijuana smoke produces euphoria, signs of increased sympathetic nervous system activity, and decreased parasympathetic nervous system activity (Schwartz, 1987). At high doses, however, sympathetic activity is inhibited and parasympathetic activity is increased, leading to bradycardia and hypotension. Reversible ECG abnormalities have been reported, as have increases in supraventricular and ventricular ectopic activity (Ghuran and Nolan, 2000). The clinical relevance of this finding is unclear.

Pharmacologic effects of inhaled marijuana occur within minutes but rarely persist longer than 2 to 3 hours. The likelihood that an acutely intoxicated patient would come to the operating room is small. Severe tachycardia should be controlled preoperatively with labetalol or esmolol. Animal studies have demonstrated decreased dose requirements for volatile anesthetics, barbiturates, and ketamine after the intravenous injection of THC. Possible intraoperative complications include bronchospasm secondary to airway irritability by the marijuana smoke, although marijuana is a bronchodilator.

Phencyclidine and Lysergic Acid Diethylamide Abuse

Phencyclidine (PCP) was developed in 1956, and it was briefly used as an anesthetic in humans before being abandoned because of the high incidence of bizarre and serious psychiatric reactions, including agitation, excitement, delirium, disorientation,

and hallucinatory phenomena (Abraham et al., 1996). If taken orally, the effects of PCP develop in 1 to 2 hours and last from 8 to 12 hours. The mechanisms of action of both PCP and LSD are quite complex and include agonist, partial agonist, and antagonist effects at various serotonin, dopaminergic, and adrenergic receptors (Abraham et al., 1996). No data exist that examine PCP and its effect on patients undergoing general anesthesia, but anesthesiologists should be familiar with the management of issues related to PCP, because this product is a structural analogue of ketamine (Jansen, 1993).

The CNS effects of LSD begin approximately 15 to 30 minutes after intake and last about 6 to 12 hours (Abraham et al., 1996). The psychological effects related to LSD are intense and include alterations in mood and emotion, euphoria, dysphoria, and visual hallucinations (Abraham and Aldridge, 1993). LSD abuse is associated with only a mild sympathetic discharge that does not resemble those of cocaine, Ecstasy, or amphetamines (Ghuran and Nolan, 2000). These patients may also experience severe attacks of anxiety and panic. Anesthesia and surgery may precipitate these uncontrollable panic responses; diazepam or midazolam may be useful for the management of such responses. Postoperative hallucinations in patients undergoing general anesthesia have been reported as well (Morris and Magee, 1995).

PREOPERATIVE PREGNANCY TESTING

Although the pregnancy rates for teenagers fell to record lows for the United States in 2002, teen pregnancy rates have since risen, and teen pregnancy remains a significant public health concern and poses a dilemma for pediatric anesthesiologists. The birth rate for the youngest teenagers is about 0.7 birth per 1000 females aged 10 to 14 years and about 44 per 1000 for girls aged 15 to 19 years (Martin et al., 2003). At least 5% of girls are or have been pregnant by the time they reach their nineteenth birthday, and a substantial percentage of girls who are screened for elective or emergency surgery in their teen years have unsuspected or unrecognized pregnancies. General anesthesia and surgery in this population place the patient at risk for spontaneous abortion and the fetus at risk of exposure to known teratogenic substances during both anesthesia and the perioperative period, when the patient is no longer under the control of the anesthesiologist. It is this knowledge that leads many anesthesiology departments to have a policy of routinely screening postmenarchal girls for pregnancy.

On the other hand, routine pregnancy screening opens a Pandora's box of legal, ethical, and practical concerns. Some of the issues are discussed in the following paragraphs.

If an unsuspected (and, chances are, unwanted) pregnancy is discovered, the disclosure of this information to the patient and her family is a challenging task best done by a physician who is well acquainted with the family. The likelihood is that the anesthesiologist, and often the surgeon, have little personal knowledge of the patient and the family. How to best disclose test results and then ensure appropriate high-risk obstetric care must be prospectively determined before embarking on a testing program.

Complicating test result disclosure further is the fact that in the United States, the Health Insurance Portability and Accountability Act (HIPAA) restricts the disclosure of confidential medical information to a third party (parent) without the

consent of the patient (pregnant child). This creates a challenging logistical problem for the anesthesiologist.

The fact that there is a teenage pregnancy may imply a previous criminal offense against the child, such as rape or incest. Because of mandatory reporting requirements when child abuse is suspected, there may be criminal legal overtones to a positive pregnancy test that the anesthesiologist must address.

Finally, although the recognition of an unsuspected teen pregnancy may be a theoretically advantageous accomplishment before elective anesthesia, the fact is that within a hospital there are many more potentially injurious events that can occur to a fetus, including exposure to ionizing radiation, teratogenic antibiotics, and antineoplastic agents. A pregnancy screening program makes more sense if instituted on a hospital-wide basis rather than strictly within a preoperative screening program. Hospital-wide institution of such a program relieves the anesthesiologist of the burden of test-result disclosure and institution of appropriate social services.

PREOPERATIVE ORDERS

After the medical history and physical examination have been completed, preoperative orders are written.

For preoperative fasting, the anesthesiologist must consider the patient's age, size, and general medical condition, as well as the scheduled time of surgery if it is known (Table 9-3). The younger the child, the smaller the glycogen stores; therefore, the occurrence of hypoglycemia with prolonged intervals of fasting is more likely. For this reason, fasting time is reduced in the infant and young child. In general, solid food and milk products are prohibited within 8 and 6 hours, respectively, before surgery (generally after midnight); breast milk is prohibited within 4 hours of surgery; and clear liquids are prohibited within 2 hours of surgery. Liquids such as apple or grape juice, flat cola, and sugar water may be encouraged up to 2 hours before the induction of anesthesia. Ample experience has shown that shortened fasting times are safe, diminish preoperative anxiety and agitation, and may reduce the volume of gastric contents (Coté, 1990; Miller et al., 1990; Schreiner et al., 1990; Emerson et al., 1998; American Society of Anesthesiologist Task Force on Preoperative Fasting, 1999; Ferrari et al., 1999). When surgery is to be delayed beyond the anticipated time, it is important that small infants, generally those younger than 12 to 18 months old, are offered clear fluids or given intravenous fluids to prevent dehydration or hypovolemia.

TABLE 9-3. Fasting (NPO) Guidelines for Elective Surgery in Infants and Children

Substance	Minimum Hours of Fasting
Solid food	8
Commercial formula	6
Milk or milk products	6
Citrus juices	6
Breast milk	4
Clear liquids	2

Regardless of how long the patient fasts, there remains a defined population of children who are at an increased risk for regurgitation and aspiration of stomach contents. This group of children includes patients who have not fasted the requisite length of time and have sustained a severe injury during this period and children with esophageal dysmotility, incompetent gastroesophageal sphincters (gastroesophageal reflux diseases), delayed gastric emptying times, and abdominal conditions that are associated with ileus, vomiting, and electrolyte disorders. In addition, children with medical disorders that are associated with fluid and electrolyte abnormalities (such as diabetic ketoacidosis) are at risk for regurgitation and aspiration secondary to delayed gastric emptying.

In children at risk for aspiration, appropriate medical evaluation is important and preanesthetic medication with a nonparticulate antacid such as sodium citrate/citric acid (0.5 mL/kg), metoclopramide (0.1 mg/kg), and/or H₂-blocking agents (e.g., ranitidine 2.5 mg/kg) may be considered.

Two issues related to the NPO guidelines that commonly arise involve the safety of clear-liquid fasting in overweight and/or obese children for the recommended 2 hours before surgery and gastric fluid volume in children who have been chewing gum before the induction of anesthesia. Cook-Sather and colleagues (2009) noted in a study of ambulatory surgical patients, in which 27% of the patients were overweight or obese, that weight and obesity did not change the ratio of the patients' gastric fluid volume to their ideal body weights. Thus, the 2-hour fasting interval is appropriate in overweight and obese patients.

Chewing gum has the potential to increase gastric fluid volume and acidity. In adults who chewed sugared or sugarless gum before surgery, gastric fluid volume and pH did not change (Dubin et al., 1994). However, Schoenfelder et al. (2006) noted that children who chewed gum had larger gastric volumes than those children who did not. The significance of these findings remains unclear in that the incidence of aspiration is still exceedingly low.

PREANESTHETIC MEDICATIONS

Preoperative anxiety not only is an unpleasant experience for the patient but also makes the induction and recovery from anesthesia more complicated (Holm-Knudsen et al., 1998; Aono et al., 1999; Kain et al., 1999; Zuwala and Barber, 2001; Wollin et al., 2003). Indeed, inadequate preoperative premedication not only results in stormier anesthetic inductions, but also greater postoperative pain and behavioral abnormalities in children that persist long after surgical recovery occurs (Kain et al., 2006). In addition to allaying the anxieties of surgery, separation, pain, and body disfigurement, premedication should therefore allow a smoother and safer induction of anesthesia. The issue of which child should be premedicated and what agent should be used, and whether a parent may be present during induction of anesthesia must be considered according to the specific needs of each child and within the context of the anesthetic practice and clinical setting (Coté, 1999; McCann and Kain, 2001; Leelanukrom et al., 2002; Caldwell-Andrews et al., 2005; Kain et al., 2007a; 2007b).

Which is the best agent to use for premedication? The sheer volume of articles on the subject attests to the lack of an ideal agent or combination of agents as premedication for children.

Most preoperative medication is dictated by tradition. As Beecher remarked more than 50 years ago, "Empirical procedures firmly entrenched in habits of good doctors seem to have a vigor and life, not to say an immortality of their own" (1959).

The remainder of this chapter offers a discussion on the various premedications according to their drug classification. In selecting premedication, three important factors must be remembered:

1. A child's major fear concerning hospitalization is pain from needles and injections. Often hospitalization is synonymous with needles. Many children remember the premedication injection more than they do the pain associated with the operative procedure. Thus in selecting a premedication agent, most any route of administration is preferable to intramuscular injection.
2. Children who undergo regular hospitalizations need as much, or more, preoperative medication than patients undergoing anesthesia for the first time. Previous hospital experiences have formed the basis of their fears, so questions directed at determining their past experiences are invaluable. The previous anesthetic record should be reviewed, with careful attention given to the premedication agent and its effect.
3. The effects of premedications in children vary significantly. Some children may be sedated, others may be excited and restless after drug administration. In addition, to obtain a given level of sedation, some children may need half a recommended dose, and others may need twice the recommended dose. Therefore the dosages in Table 9-4 are intended to serve only as useful guidelines.

Anticholinergic Agents

Anticholinergic agents are mentioned in this chapter only for historical reference; in years past they were routinely administered to prevent unwanted autonomic vagal reflexes or bradycardia associated with airway instrumentation, nasopharyngeal stimulation, and anesthetic drugs (particularly halothane and morphine). Before that use, these compounds were administered to block the excessive secretions that were caused by the administration of diethyl ether at induction of anesthesia. At present they are uncommonly used and have few indications; fewer still are the indications that cannot wait until the patient has had anesthesia induced and intravenous access established, allowing intravenous administration of an anticholinergic. As with all pharmacologic agents, the use of anticholinergic agents—whether as an antisialagogue premedication

TABLE 9-4. Guidelines for Commonly Used Preanesthesia Medications in Children

Medication	Route of Administration		
	Oral	Intravenous	Transmucosal
Midazolam (mg/kg)	0.5-1	0.1	0.2-0.3 (nasal)
Morphine (mg/kg)		0.05-0.1	
Fentanyl (mcg/kg)		0.5-1	10 (oral transmucosal)
Ketamine (mg/kg)	5-10	1-2	5-10
Clonidine (mcg/kg)	2.5-5	1-2	

or as a vagolytic agent during surgery—should be governed by specific considerations of the potential side effects (temperature elevation, flushing, dry mouth, tachycardia, and CNS irritability) that can be significant.

Although atropine is the most commonly used agent, scopolamine and glycopyrrolate may also be used to premedicate children. Atropine, in doses of 0.02 mg/kg (0.03 mg/kg in infants), is an extremely effective vagolytic agent.

Oral atropine has been shown to be effective in preventing the adverse cardiovascular changes during induction of anesthesia (Miller and Friesen, 1987). Although injection is avoided with the use of oral atropine, the timing of its use relative to the operative procedure must still be anticipated.

Glycopyrrolate is a quaternary ammonium complex that does not cross the blood-brain barrier. As a result, it has a minimal CNS effect. It causes less tachycardia than atropine, but it is as effective as atropine at half the dose (0.01 mg/kg) as a vagolytic and antisialagogue. Studies in children have shown that glycopyrrolate reduced gastric fluid volume and altered its pH (Brock-Utne et al., 1978; Stoelting, 1978).

Opioids

Opioid premedication, once routinely administered as an intramuscular morphine injection in children, is nearly as uncommon and unnecessary as anticholinergic premedication. Opioid premedication can result in unpleasant dysphoria and an increased incidence of preoperative and postoperative vomiting. When given, opioids can be administered via the oral, rectal, intravenous, intramuscular, or transmucosal route. Interest in the use of opioids as preanesthetic medications has focused on the intranasal and oral transmucosal forms of administration (Leiman et al., 1987; Henderson et al., 1988; Nelson et al., 1989). The advantage of the latter technique is that the dose of premedication can be titrated to effect. Oral transmucosal fentanyl (OTFC) appears to have a relatively short onset time without adversely increasing gastric pH, but it does slightly increase gastric volume and delays the time that children need to tolerate postoperative fluids (Stanley et al., 1989; Ashburn et al., 1990).

Pharmacokinetic studies have demonstrated that OTFC is absorbed well through the buccal mucosa (Streisand et al., 1991). In volunteers administered an oral drink of both fentanyl and OTFC, OTFC produced higher and earlier peak plasma concentrations, as well as increased bioavailability (50% versus 30%), compared with swallowed fentanyl. In blinded studies of children in which OTFC (15 to 20 mcg/kg) was compared with placebo, OTFC is superior to placebo in allowing children to separate from parents and undergo inhalation induction of anesthesia (Moore et al., 2000; Tamura, et al., 2003). However, it was associated with considerable untoward side effects, including nausea and vomiting, oversedation, and oxygen desaturation (Nelson et al., 1989; Streisand et al., 1989, 1991; Ashburn et al., 1990; Goldstein-Dresner et al., 1991; Moore et al., 2000). The postoperative nausea and vomiting are not attenuated by intraoperative intravenous droperidol (50 mcg/kg) (Freisen and Lockhart, 1992). Because of the high incidence of reported side effects, as well as the need for continuous pulse oximetry while and after this drug is administered, OTFC as a preoperative sedative in children has not gained widespread use or popularity.

Hypnotics

Midazolam is a water-soluble benzodiazepine with a more rapid onset time and a shorter duration of action than diazepam. Its water solubility allows better absorption after intramuscular injection and eliminates the venous irritant properties associated with diazepam (Ghoneim and Korttila, 1977). Midazolam's peak plasma concentration occurs 45 minutes after intramuscular injection, but its anxiolytic effects occur in as little as 5 minutes. Its duration of action is usually 2 hours, with a range of 1 to 6 hours (Reves et al., 1985).

Now approved as a premedication for children and marketed as an oral preparation, midazolam has become the most commonly administered premedication before routine surgery in virtually every pediatric center; it is now the gold standard with which other premedications are compared. A national survey of over 5000 anesthesiologists has indicated that midazolam is the preoperative sedative of choice in more than 90% of all routine cases in children (Kain et al., 1997; Brosius and Bannister, 2002). The experience with midazolam is extensive and demonstrates the drug to be highly effective in alleviating anxiety, increasing cooperation, and diminishing antegrade recall without affecting retrograde memory (Payne et al., 1991a; Parnis et al., 1992; Twersky et al., 1993; Gillerman et al., 1996; McCann and Kain, 2001; Millar et al., 2007). Premedication with midazolam is safe and free of side effects, and it does not prolong recovery times (Payne et al., 1991b; Sievers et al., 1991; McMillan et al., 1992; Weldon et al., 1992; Davis et al., 1995; Viitanen et al., 1999; Brosius and Bannister, 2002). Finally, midazolam premedication smoothes the postoperative recovery of children and diminishes the incidence of delirium (Ko et al., 2001).

Nasal midazolam has also been reported to be highly effective in reducing anxiety in children within 10 to 12 minutes of administration (Griffith et al., 1998; Gautam et al., 2007). Furthermore, Davis et al. (1995) demonstrated that nasal midazolam (0.2-0.3 mg/kg) administered to patients undergoing myringotomies led to reduced preoperative anxiety and did not prolong recovery time and hospital discharge time. A drawback of nasal midazolam, however, is that more than 50% of children cry at administration because it irritates the nasal passages. The only rationale for administration of nasal midazolam is if a child without intravenous access cannot or will not swallow the oral preparation. Occasionally, younger children who refuse to take oral or nasal midazolam are more inclined to accept the midazolam rectally (McCann and Kain, 2001). Midazolam administered rectally in doses of 0.5 to 1 mg/kg effectively reduces the anxiety of children before induction of anesthesia.

Other benzodiazepines have not gained the popularity of midazolam nor have shown any advantage over the use of midazolam. Studies of flunitrazepam in children are limited, but it appears to be an effective pediatric premedication (Richardson and Manford, 1979). As with other benzodiazepines, flunitrazepam can be administered as a rectal premedication. In a double-blind, placebo-controlled study, 0.04 mg/kg of rectal flunitrazepam provided better sedation and mask-acceptance scores without prolonging recovery from anesthesia (Esteve and Saint-Maurice, 1990). Triazolam has been used as a preanesthetic medication in adults (Yamakage et al., 2002) but its use in children has not been evaluated, nor has it been compared with conventional agents.

Ketamine

In high doses (4 to 12 mg/kg), intramuscular ketamine has often been used to induce and maintain anesthesia in children (Wyant, 1971). Hannallah and Patel (1989) demonstrated that at low doses (2 mg/kg), intramuscular ketamine can facilitate inhalation induction of anesthesia. In this study of uncooperative children undergoing tympanostomy tube insertion, low-dose intramuscular ketamine was very effective in completing a mask induction with halothane in a shorter time than in cooperative children who did not need premedication. Although the induction time was shorter in the group receiving ketamine, ketamine did prolong the hospital discharge times.

As an alternative to intramuscular administration, rectal, nasal transmucosal, and oral routes of ketamine administration have been described. Rectal administration of ketamine has been reported in children undergoing a wide variety of surgical procedures. Van der Bijl and colleagues (1991) compared rectal administration of midazolam (0.3 mg/kg) with rectal administration of ketamine (5 mg/kg). Thirty minutes after the administration of either drug, good anxiolysis, cooperation, and sedation were achieved. In doses of 8 to 10 mg/kg, Saint-Maurice et al. (1979) noted that the interval from rectal administration to loss of verbal contact and acceptance of the facemask was 7 and 9 minutes, respectively.

Nasal transmucosal ketamine is an effective means of premedicating children. Weksler and colleagues demonstrated that 6 mg/kg of nasal ketamine administered 20 to 40 minutes before surgery achieved satisfactory sedation in 78% of the patients, whereas smaller doses of 5 mg/kg produced comparable sedation and ease of separation from parents as nasal midazolam (Weksler et al., 1993; Gautam et al., 2007).

Oral ketamine, of course the most acceptable route in most situations, has been used for nearly 20 years as a preoperative anesthetic medication in healthy children who are undergoing routine surgical procedures and in children undergoing corrective surgery for congenital heart defects (Stewart et al., 1990). Gutstein et al. (1992), in a double-blind, prospective study, evaluated placebo and oral ketamine at both 3 and 6 mg/kg doses as a preanesthetic medication in children. At some time during the study, 100% of the children administered 6 mg/kg were sedated as opposed to 73% of the children administered 3 mg/kg. In both groups of children who received ketamine, the onset of sedation occurred in 12 minutes, and in the 6 mg/kg group, 67% of patients were sufficiently sedated to have an intravenous cannula inserted. Similarly, the combination of oral midazolam and oral ketamine has a very high success rate of satisfactory anxiolysis compared with a somewhat lower success rate for either drug alone (Funk et al., 2000; Ghai et al., 2005). Postanesthesia care-unit discharge time of children who received orally administered ketamine is reported not to be prolonged compared with orally administered midazolam, provided that the duration of surgery is longer than 30 minutes (Funk et al., 2000). Oral ketamine has also been found to be an effective premedication in alleviating the distress of invasive procedures in pediatric oncology patients (Tobias et al., 1992). An oral transmucosal lozenge containing ketamine was under development for some time as a surgical premedication, and was found to be equally effective as oral midazolam; the present status of this drug development project is unknown at the time of this writing (Horiuchi et al., 2005).

Alpha-2-Adrenoreceptor Agonists

The role of α_2 -adrenoreceptor agonists for both premedication of children before surgery and as analgesics during and after surgery is continuing to evolve. In adults, α_2 -adrenoreceptor agonists have been shown to provide perioperative sedation, postoperative analgesia, improved perioperative hemodynamic stability, and reduced anesthetic requirements (Ghignone et al., 1987; Wright et al., 1990; Carabine et al., 1991). The MAC-sparing effect of premedication with 1 to 10 mcg/kg of oral clonidine has been demonstrated (Nishina et al., 1996; 1997; Inomata et al., 2002).

Clonidine

In a double-blind, randomized study, Mikawa and colleagues demonstrated that in children, oral clonidine produces sedation in a dose-dependent manner, and that at a dose of 4 mcg/kg, clonidine provides satisfactory sedation, a better quality of child/parent separation, and better mask acceptance than does standard oral diazepam premedication (0.4 mg/kg) (1993). Fazi and colleagues (2001) showed that oral clonidine was generally inferior to oral midazolam; however, clonidine 4 mcg/kg was associated with faster awakening than midazolam 0.5 mg/kg. These authors found that after clonidine premedication, children were more distressed and agitated during inhalation induction and had higher pain scores and greater analgesic requirements in the postoperative period. Yet few other citations in the literature have found similar results. Virtually all other authors have shown that oral clonidine in doses of 4 to 5 mcg/kg is comparable in efficacy with oral midazolam 0.5 mg/kg; whereas the onset of sedation tends to be less after the use of clonidine, the degree of sedation tends to be greater (Inomata et al., 2002; Bergendahl et al., 2004; Almenrader et al., 2007a; 2007b). Clonidine may be a useful premedication in children who have previously experienced delirium, agitation, or paradoxical reactions to midazolam or other benzodiazepines in the past (Stella and Bailey, 2008).

Importantly, clonidine premedication has beneficial effects that go beyond the preoperative period. It has become clear both from clinical experience and from clinical research that the analgesic effect of clonidine persists well into the postoperative period, reducing measures of surgical pain in children (Schmidt et al., 2007). This may be closely related to why the incidence of emergence delirium is reduced following clonidine premedication (Ko et al., 2001; Bock et al., 2002; Malviya et al., 2006) and is not after midazolam premedication (Breschan et al., 2007), and why the neuroendocrine stress response to surgery is attenuated in those children who were premedicated with clonidine (Kain et al., 2000).

Clonidine, therefore, is emerging as a premedication that is equal in sedative efficacy to midazolam, but that possesses salutary effects over and above midazolam. Its role in pediatric anesthesia will continue to evolve and be better defined in the future.

Dexmedetomidine

Dexmedetomidine is another α_2 -agonist that has an α_2 selectivity that is seven to eight times greater than clonidine. Although approved to be used as an infusion for sedation of adult intensive care unit (ICU) patients, dexmedetomidine has also been used as a premedication, an anesthetic adjuvant, a procedural sedation agent, and a treatment for postoperative

shivering and agitation resulting from an emergency situation. In addition, when applied to intra-articular surfaces after orthoscopic surgery, dexmedetomidine enhances postoperative analgesia and decreases the need for postoperative analgesic agents (Ibacache 2004; Easley et al., 2007; Yuen et al., 2007, 2008; Mason et al., 2006, 2008; Al-Metwalli et al., 2008; Heard et al., 2008; Mahmoud et al., 2009; Talon et al., 2009). As a premedication, Yuen and colleagues (2007, 2008) have shown that 1.7 mcg/kg of dexmedetomidine intranasally can provide sedation in children but has an onset time and peak effect of 45 minutes and 90 to 150 minutes, respectively. In burn patients, Talon et al. (2009) suggested that 2 mcg/kg of dexmedetomidine was comparable with 0.5 mg oral midazolam with respect to preoperative sedation, conditions at induction, and emergence from anesthesia. The bioavailabilities of dexmedetomidine after oral and buccal administration were 16% and 82%, respectively (Anttila et al., 2003). Dyck et al. (1993) have reported that after intramuscular administration, peak concentrations of dexmedetomidine occur at 12 minutes and that the bioavailability is 73%.

SUMMARY

The pediatric anesthesiologist must recognize developmental differences in anatomy and physiology and also must understand and deal effectively with the emotional reactions and needs of children of various ages and developmental stages. Although premedication agents often alleviate the anxieties of anesthesia and surgery, these pharmacologic adjuncts cannot substitute for a thorough and thoughtful preoperative visit and discussion with the patient and family.

		Summary	321

The pediatric anesthesiologist is charged with caring for a diverse patient population. Anesthetizing a 500-g newborn can be immediately followed by the care of a 100-kg adolescent. This broad range of patient sizes requires an equally diverse and unique spectrum of equipment. This chapter focuses on the types of equipment that are used in pediatric anesthesia and highlights unique adaptations of equipment for pediatric use.

HUMIDIFIERS

During normal breathing, the nasal mucosa and upper airway serve as a reservoir for condensed water. This water is evaporated during breathing and reduces the heat expended by the body in warming and humidifying inhaled gases. In typical atmospheric conditions, air in the pulmonary periphery contains 44 mg of water per liter at 37° C (100% relative humidity). Breathing ambient air at a temperature of 22° C, water content of 10 mg/dL would require the addition of 34 mg/L of evaporated water. This evaporation results in a loss of energy with the resultant cooling of the respiratory mucosa. The caloric expenditure of humidification consumes approximately five times the energy required to heat the inspired gases; this may amount to 20% of the basal metabolic rate of an infant (Rashad and Benson, 1967). Nasopharyngeal humidification is bypassed with the placement of common airway devices such as tracheal tubes, tracheostomy tubes, and laryngeal masks. Benefits of heating and humidifying anesthetic gases include prevention of intraoperative hypothermia, decreased atelectasis, and improved mucociliary clearance. Consequences of overhumidification include impaired mucociliary clearance related to reduced mucus viscosity, atelectasis, accumulation of secretions, infection, thermal injury, and surfactant inactivation (Schiffmann, 2006). Partial humidification of gas in the anesthesia breathing circuit

takes place within the carbon-dioxide absorber, which uses an exothermic reaction that may raise the water vapor content to as much as 29 mg/L. Further humidification is accomplished by reducing the amount of fresh-gas flow, thereby increasing rebreathing of humidified gases and using a heat and moisture exchanger (HME, or “artificial nose”). The HME uses a fine mesh to cause condensation of exhaled water vapor. The HME may increase the resistance to breathing or the dead space for some infants and children, although these changes are usually tolerable. Low fresh-gas flow alone is often inadequate at maintaining humidity and temperature in infants and neonates, therefore active or passive humidification devices should always be incorporated when ventilating this population (Hunter et al., 2005). HMEs increase airway humidification and preserve temperature in anesthetized children at a lower cost than active humidification systems (Bissonnette and Sessler, 1989) and they require 80 minutes to achieve optimal saturation of the membrane, during which time they are less efficient. HMEs come in a variety of sizes, enabling selection based on size of the patient, so that dead space or resistance can be minimized. Specially designed HMEs filter out infectious pathogens and minimize the risk of cross-infection between patients (Wilkes et al., 2000).

Active humidification is the most efficient means by which to heat and humidify inspired gases (Bissonnette and Sessler, 1989). A servocontrolled, shielded heated wire in the fresh gas line helps to prevent cooling and condensation of the water as it passes through the inspiratory limb. The temperature should be regulated by a probe near the patient connection, because overheating of the inspired gases can produce injury to the airway (Klein and Graves, 1974). Active humidifiers may also increase the compression volume of the breathing circuit; thus, compensatory increases in the tidal volume during controlled ventilation may be necessary except in ventilators with compliance compensation (Coté et al., 1983).

ANESTHESIA BREATHING SYSTEMS

Since Philip Ayre's (1937) landmark article began the modern era of breathing systems for pediatric anesthesia, this has been a topic of controversy. Using Magill's technique of tracheal intubation for the repair of cleft lip and palate in infants, Ayre noted adverse results. Breathing through a "closed" high-resistance system, these infants often developed "rapid, 'sighing' respirations" and "ashy pallor and sweating." They exhibited a "dark, congested oozing at the site of operation." Postoperatively, the infants were "in varying degrees of shock: some...for days" (Ayre, 1937). The contribution of hypotension or hypovolemia to this picture remains unknown, because blood pressure was not measured, and blood loss was difficult to quantify by Ayre's account.

Ayre noted dramatic clinical improvement when he adopted an open T-piece breathing system. The T piece, an extremely simple device, consists of an inspiratory limb, a connection to the patient, and an expiratory limb. It has no unidirectional or overflow valves, and there is no breathing bag. The expiratory limb serves as a reservoir for fresh gas, a means of monitoring the infant's respirations, and if the distal end is intermittently occluded, a means of providing positive pressure ventilation. If the volume of the expiratory limb is one third of the tidal volume, rebreathing can be virtually eliminated during spontaneous ventilation with a fresh-gas flow that is twice the minute ventilation (Ayre, 1956). Ayre attributed the salutary effect of the T piece to marked reductions in resistance to gas flow and rebreathing.

Nonrebreathing and Partial Rebreathing Systems

Despite its apparent benefits, the T piece is far from ideal. The major flaws are its release of anesthetic gases into the operating room and its inability to provide assisted or controlled ventilation. A series of modifications occurred. Rees (1950) first proposed the addition of a breathing bag to the expiratory limb. Another system, the Magill attachment, which predated Ayre's publication, introduced fresh gas distal to a breathing bag and an overflow valve near the patient connection. These and other variations were brought together under a single classification scheme proposed by Mapleson (1954), in which each system was distinguished on the basis of the location of its fresh gas inflow and overflow valves relative to the patient connection.

These Mapleson circuits share the benefit of reduced resistance to breathing by virtue of the absence of unidirectional valves and canisters; the elimination of these components results in varying degrees of rebreathing that depend on the fresh-gas flow (Fig. 10-1, A). Rebreathing is not necessarily bad because it serves to conserve heat, humidity, and anesthetic gases. Yet in the absence of a mechanism by which to monitor the accumulation of carbon dioxide, the consequences of hypercarbia and respiratory acidosis probably outweigh these benefits.

Each circuit has different rebreathing characteristics depending on the locations of the fresh gas inflow, the overflow valves, and the fresh-gas flow rate; the respiratory rate (i.e., expiratory time) and tidal volume, carbon dioxide production, and the mode of ventilation (i.e., spontaneous or controlled) also contribute to the degree of rebreathing. The following sections describe the Mapleson A (Magill attachment) and D systems. The B and C systems are rarely used today. The Mapleson E

system is the T piece described in the previous section of this chapter.

Mapleson A System

The Mapleson A system results in no rebreathing during spontaneous ventilation when the fresh-gas flow is more than 75% of the minute ventilation; it requires a larger fresh-gas flow to eliminate rebreathing during controlled ventilation (Fig. 10-1, B) (Waters and Mapleson, 1961; Kain and Nunn, 1967). This design is impractical in the operating room, because the proximal location of the overflow valve makes it cumbersome for scavenging waste gases, difficult to adjust during head-and-neck surgery, and potentially dangerous, because the heavy valve could dislodge a small tracheal tube.

Mapleson D System

The Mapleson D system is characterized by a proximal fresh-gas inflow and a distal overflow valve. It is a modification of the T piece, in which a breathing bag and an overflow valve have been added to the distal expiratory limb. Although it requires slightly more fresh-gas flow to eliminate rebreathing during spontaneous ventilation than the Mapleson A system, it is the most economical during controlled ventilation (Waters and Mapleson, 1961). On balance, considering both spontaneous and controlled ventilation, the Mapleson D requires the lowest fresh-gas flow rates among all Mapleson circuits. This system has become the most widely used of the Mapleson circuits for pediatric anesthesia.

The precise flow dynamics in the Mapleson D system have been a subject of discussion that has resulted in a variety of complex recommendations (Mapleson, 1954; Waters and Mapleson, 1961; Nightingale et al., 1965; Bain and Spoerel, 1973; Rose et al., 1978; Spoerel et al., 1978; Rose and Froese, 1979). To eliminate rebreathing, higher fresh-gas flows are needed during spontaneous ventilation than during controlled ventilation. With spontaneous ventilation, rebreathing is eliminated by provision of fresh-gas flow equal to the mean inspiratory flow rate (Mapleson, 1954; Rose et al., 1978). If an inspiratory/expiratory ratio is 1:1 or 1:2, the mean inspiratory flow rate is 2 to 3 times the minute ventilation. Although Spoerel and others (Bain, 1979) have demonstrated that a normal arterial carbon dioxide tension (P_{aCO_2}) can be maintained during spontaneous ventilation at fresh-gas flows as low as 100 mL/kg per minute, an increased minute ventilation (and hence more respiratory work) is required to compensate for rebreathed carbon dioxide.

The recommendations for fresh-gas flow during controlled ventilation are complex and varied (Waters and Mapleson, 1961; Nightingale et al., 1965; Bain and Spoerel, 1973). This reflects the importance of several factors that were summarized by Rose and Froese (1979) (Fig. 10-2). When a high fresh-gas flow (greater than 100 mL/kg per minute) is used, the P_{aCO_2} is governed by minute ventilation (ventilation limited). At low fresh-gas flow (less than 90 mL/kg per minute), P_{aCO_2} is independent of minute ventilation, varying instead as a function of the amount of rebreathing, which is governed by the fresh-gas-flow rate (flow limited).

Additional important factors that govern the magnitude of rebreathing include carbon dioxide production, respiratory rate, and respiratory waveform characteristics (e.g., inspiratory flow, inspiratory and expiratory times, and expiratory

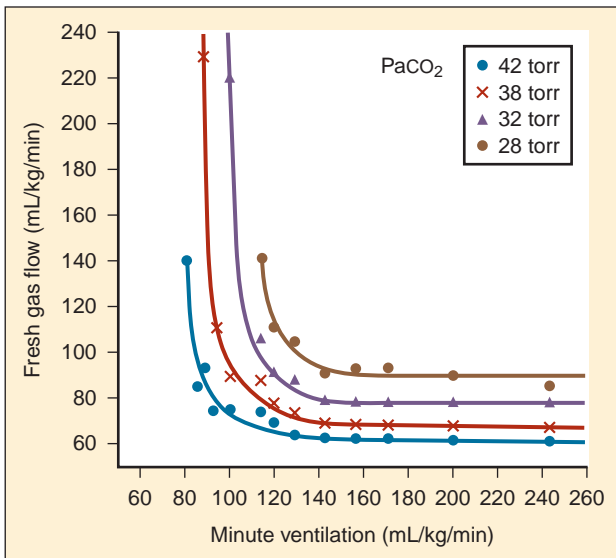

FIGURE 10-1. A, The Mapleson circuits. Each circuit is classified on the basis of the relative positions of the fresh-gas inlet, overflow valve, corrugated tubing, and reservoir bag in relation to the patient connection. **B,** Mapleson A system during spontaneous and controlled ventilation. (Adapted from Mapleson WW: *The elimination of rebreathing in various semiclosed anesthetic systems*, Br J Anaesth 26:323, 1954.)

pause) (Rose and Froese, 1979). Adjustments to the ventilatory pattern that allow the fresh-gas flow to constitute a larger proportion of the inspired gas (e.g., slow inspiratory time or low inspiratory flow) or that enable exhaled gases to be more completely washed out (e.g., long expiratory pause or slow rate) reduce the amount of rebreathing. With a Mapleson D circuit that has controlled ventilation and low fresh-gas flow

(flow limited), an attempt to reduce the P_{aco_2} by increasing the respiratory rate would reduce the expiratory pause and thus promote rebreathing (Fig. 10-3). In this situation, the increased ventilation is offset by increased fraction of inspired oxygen (F_{iO_2}), resulting in no net change in P_{aco_2} . To wash out the exhaled gas at this higher respiratory rate and take advantage of the increased minute ventilation, the fresh-gas

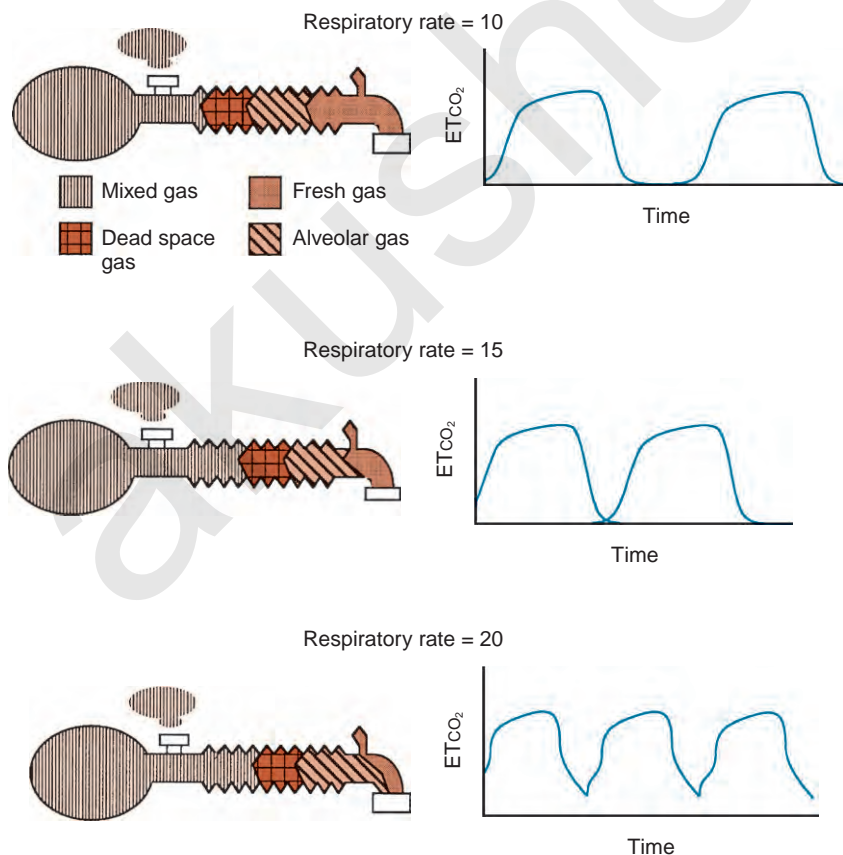

■ **FIGURE 10-2.** Fresh-gas flow as it relates to minute ventilation in the Mapleson D system.

flow must be increased. These fresh-gas flow and ventilatory recommendations are predicated for a normal metabolic rate and hence normal carbon dioxide production (Bain and Spoerel, 1977; Nightingale and Lambert, 1978). Conditions that increase carbon dioxide production (e.g., fever, catabolic state, or malignant hyperthermia) must be met with a proportional increase in fresh-gas flow or ventilation.

Bain Modification of Mapleson D

The Bain modification of the Mapleson D circuit incorporates the fresh-gas supply within the expiratory limb in a coaxial arrangement (Fig. 10-4) (Bain and Spoerel, 1972). This circuit is light and streamlined with only a single hose to the patient. It also provides some countercurrent warming of the inspired gases and effective scavenging of expired gases. Its major disadvantage lies in the inability to directly inspect the integrity of the inspiratory limb. Pethick (1975) described an indirect test of the Bain inspiratory-limb integrity in which the oxygen flush is passed through the circuit for several seconds. If the inspiratory limb is intact, the rapid flow of gas through it exerts a Venturi effect on the expiratory limb, resulting in a slight negative pressure and collapse of the breathing bag. With a leak from the inspiratory limb into the expiratory limb, the pressure in the latter rises, tending to inflate the reservoir bag. The rebreathing characteristics of the Bain circuit are identical to those of any other Mapleson D. The major reasons that proponents have advocated the use of these Bain circuits for pediatric anesthesia are their relatively lower resistance to breathing offered by an open system, the countercurrent warming of gases, and the low profile of a single hose attached to the patient.

The primary sources of resistance in an anesthesia delivery system are the tracheal tube, the valves, and the carbon dioxide absorber. With modern equipment, the tracheal tube represents a major source of resistance in the neonate (Cave and Fletcher, 1968; Brown and Hustead, 1969). Light-weight, large-diameter, modern disc valves exert resistance in two ways. There is a minimum, flow-independent resistance necessary to displace the valve, usually much less than 1 cm H₂O (Hunt, 1955). A much higher resistance

■ **FIGURE 10-3.** Influence of respiratory rate on rebreathing in the Mapleson D system.

■ **FIGURE 10-4.** The Bain modifications of the Mapleson D circuit provide a low-profile circuit and allow simple connections to the patient's airway.

may be required when the expiratory valve is wet. At high gas flows (more than 30 L/min), the valves also become a source of turbulent resistance proportional to the flow through them. Carbon dioxide canisters are also a source of turbulence. Their resistance is inversely proportional to the length of the path the gas must take through the resistor. Modern absorbers are short and wide to minimize this path of resistance.

Approximately a half century after Ayre introduced the T piece, the extent to which his work applies remains unclear. Perhaps the infants Ayre studied were subjected to the significant resistance imposed by the valves of that era. Although the neonate has a lower proportion of fatigue-resistant fibers in the diaphragm, infants as young as 2 weeks old have been shown to compensate for increases in resistance of 200% without changes in blood gases, at least for relatively short lengths of time (Muller et al., 1979). The benefits of the Mapleson systems must be weighed against their inherent problems on an individual basis. If a practitioner seldom uses Mapleson circuits and is unfamiliar with their characteristics, or if a practitioner has to make substantial alterations to an anesthesia machine to accommodate them, the additional risks of the situation must be considered. Even if a circle system is used for most children, it is important to understand the flow requirements of these circuits, as they continue to be used for resuscitation outside of the operating room and for transporting critically ill patients.

Circle Systems

The circle system is standard equipment on anesthesia machines that have been designed to meet the standards specified in ASTM 1850-00 (2005). When functioning properly, it enables lower fresh-gas flows than the Mapleson D circuit; a circle system conserves heat, humidity, and anesthetic agent. It also minimizes environmental pollution. Compared with the resistance of an endotracheal tube, the additional resistance imposed by the addition of unidirectional valves and a carbon-dioxide canister is trivial. Because the ratio of the patient's tidal volume to the volume of the inspiratory limb is small in young children, changes in the anesthetic concentration can take some time to reach equilibrium unless higher fresh-gas flows are used. It is important to be vigilant for the manifestations of stuck (resistance) or floating (rebreathing) unidirectional valves, because both have harmful consequences in small children.

Special circle-breathing systems have been designed for infants and children that incorporate the same components as the standard adult circuits but have been modified to minimize

dead space and resistance to breathing. Most incorporate short, narrow-caliber hoses and Y connections to minimize the weight and compliance of the circuit. These smaller hoses, along with smaller carbon dioxide absorbers, are also used to reduce the time needed to effect a change in the concentration of vapor or gases in the circuit.

ANESTHESIA MACHINES

Anesthesia machines serve two basic functions. The first function is to enable the anesthesia provider to control the concentrations of gases and anesthetic vapors delivered to the patient. The second function is to support both spontaneous and mechanical ventilation. There are no anesthesia machines specifically designed for pediatric applications, and for the most part, the available machines function as they do for adult care. There are, however, certain characteristics that should be sought in an anesthesia machine that is to be used for pediatric patients.

Gas and Anesthetic Vapor Delivery

Oxygen

All modern anesthesia machines are designed to ensure continuous oxygen delivery from either pipeline or cylinder supplies and to notify the user if the oxygen-supply pressure fails. Because pressure in the oxygen supply does not guarantee that oxygen is indeed flowing through the pipes, an oxygen analyzer located in the inspiratory limb of the anesthesia circuit is an essential safety monitor for every anesthetic (Dorsch and Dorsch, 2007). Indeed, an inspired oxygen-concentration monitor is considered to be the standard of care for every anesthetic according to the American Society of Anesthesiologists (2005) (Box 10-1).

The oxygen analyzer is also important when caring for the anesthetized pediatric patient, because certain clinical conditions mandate precise control of the delivered oxygen concentration, and the oxygen analyzer serves to confirm delivery of the desired oxygen concentration.

The inspired oxygen concentration (F_{iO_2}) is typically controlled by mixing oxygen with either air or nitrous oxide to achieve the desired result. When mixing oxygen and nitrous oxide, it is relatively easy to predict the resulting concentration of oxygen, because the ratio of the flows determines the percentage of inspired oxygen (1:1 oxygen/nitrous oxide is 50% oxygen, and a 1:3 ratio is 25% oxygen). When mixing air and oxygen, it is not as intuitive to predict the resulting oxygen concentration, because the air supply contains 21% oxygen. Furthermore, it can be difficult to minimize the oxygen concentration and use a low-flow technique. For example, if 200 mL/min of oxygen is delivered (minimum mandatory flow on some anesthesia machines), air flowing at 4 L/min results in a 25% concentration of oxygen. A table of flow ratios and resulting oxygen concentrations can be useful to guide flow settings, but the oxygen analyzer is an ideal tool to document the delivered oxygen concentration. When caring for pediatric patients, it is useful to have an anesthesia machine capable of delivering air only (no minimum oxygen flow), so that low concentrations of oxygen can be delivered without using excessive gas flows. Nitrous oxide and air are most commonly mixed with oxygen to control F_{iO_2} , but there are conditions in which helium or carbon dioxide are used.

Box 10-1 Standards for Basic Anesthetic Monitoring Committee of Origin: Standards and Practice Parameters

(Approved by the ASA House of Delegates on October 21, 1986, and Last Amended on October 25, 2005)

These standards apply to all anesthesia care although, in emergency circumstances, appropriate life support measures take precedence. These standards may be exceeded at any time based on the judgment of the responsible anesthesiologist. They are intended to encourage quality patient care, but observing them cannot guarantee any specific patient outcome. They are subject to revision from time to time, as warranted by the evolution of technology and practice. They apply to all general anesthetics, regional anesthetics and monitored anesthesia care. This set of standards addresses only the issue of basic anesthetic monitoring, which is one component of anesthesia care. In certain rare or unusual circumstances, 1) some of these methods of monitoring may be clinically impractical, and 2) appropriate use of the described monitoring methods may fail to detect untoward clinical developments. Brief interruptions of continual[†] monitoring may be unavoidable. These standards are not intended for application to the care of the obstetrical patient in labor or in the conduct of pain management.

STANDARD I

Qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthetics, regional anesthetics and monitored anesthesia care.

Objective

Because of the rapid changes in patient status during anesthesia, qualified anesthesia personnel shall be continuously present to monitor the patient and provide anesthesia care. In the event there is a direct known hazard, e.g., radiation, to the anesthesia personnel which might require intermittent remote observation of the patient, some provision for monitoring the patient must be made. In the event that an emergency requires the temporary absence of the person primarily responsible for the anesthetic, the best judgment of the anesthesiologist will be exercised in comparing the emergency with the anesthetized patient's condition and in the selection of the person left responsible for the anesthetic during the temporary absence.

STANDARD II

During all anesthetics, the patient's oxygenation, ventilation, circulation and temperature shall be continually evaluated.

Oxygenation

Objective

To ensure adequate oxygen concentration in the inspired gas and the blood during all anesthetics.

Methods

1. Inspired gas: During every administration of general anesthesia using an anesthesia machine, the concentration of oxygen in the patient breathing system shall be measured by an oxygen analyzer with a low oxygen concentration limit alarm in use.*
2. Blood oxygenation: During all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed.* When the pulse oximeter is utilized, the variable pitch pulse tone and the low threshold alarm shall be audible to the anesthesiologist or the anesthesia care team personnel.* Adequate illumination and exposure of the patient are necessary to assess color.*

Ventilation

Objective

To ensure adequate ventilation of the patient during all anesthetics.

Methods

1. Every patient receiving general anesthesia shall have the adequacy of ventilation continually evaluated. Qualitative clinical signs such as chest excursion, observation of the reservoir breathing bag and auscultation of breath sounds are useful. Continual monitoring for the presence of expired carbon dioxide shall be performed unless invalidated by the nature of the patient, procedure or equipment. Quantitative monitoring of the volume of expired gas is strongly encouraged.*
2. When an endotracheal tube or laryngeal mask is inserted, its correct positioning must be verified by clinical assessment and by identification of carbon dioxide in the expired gas. Continual end-tidal carbon dioxide analysis, in use from the time of endotracheal tube/laryngeal mask placement, until extubation/removal or initiating transfer to a postoperative care location, shall be performed using a quantitative method such as capnography, capnometry or mass spectroscopy.* When capnography or capnometry is utilized, the end tidal CO₂ alarm shall be audible to the anesthesiologist or the anesthesia care team personnel.*
3. When ventilation is controlled by a mechanical ventilator, there shall be in continuous use a device that is capable of detecting disconnection of components of the breathing system. The device must give an audible signal when its alarm threshold is exceeded.
4. During regional anesthesia and monitored anesthesia care, the adequacy of ventilation shall be evaluated by continual observation of qualitative clinical signs and/or monitoring for the presence of exhaled carbon dioxide.

Circulation

Objective

To ensure the adequacy of the patient's circulatory function during all anesthetics.

Methods

1. Every patient receiving anesthesia shall have the electrocardiogram continuously displayed from the beginning of anesthesia until preparing to leave the anesthetizing location.*
2. Every patient receiving anesthesia shall have arterial blood pressure and heart rate determined and evaluated at least every five minutes.*
3. Every patient receiving general anesthesia shall have, in addition to the above, circulatory function continually evaluated by at least one of the following: palpation of a pulse, auscultation of heart sounds, monitoring of a tracing of intra-arterial pressure, ultrasound peripheral pulse monitoring, or pulse plethysmography or oximetry.

Body Temperature

Objective

To aid in the maintenance of appropriate body temperature during all anesthetics.

Methods

Every patient receiving anesthesia shall have temperature monitored when clinically significant changes in body temperature are intended, anticipated or suspected.

Under extenuating circumstances, the responsible anesthesiologist may waive the requirements marked with an asterisk (); it is recommended that when this is done, it should be so stated (including the reasons) in a note in the patient's medical record.

[†]Note that "continual" is defined as "repeated regularly and frequently in steady rapid succession," whereas "continuous" means "prolonged without any interruption at any time."

Indications for Careful Control of F_{iO_2}

Studies have implicated arterial oxygen tension as one of several variables linked to retinopathy of prematurity (ROP) in preterm infants (weighing less than 1300 g) whose retinas are immature (Flynn et al., 1992). The contribution of brief episodes of intraoperative hyperoxemia to the development of ROP remains unknown, and oxygen concentrations greater than necessary should be avoided in this vulnerable population. It is not known whether there is any real impact on outcome dependent on whether air or nitrous oxide is used as the balance gas in these patients. Given the potential for nitrous oxide to interfere with deoxyribonucleic acid (DNA) synthesis, it may be prudent to avoid this gas in the developing neonate, although there are no definitive data indicating that nitrous oxide is dangerous for these patients.

During airway laser surgery it is desirable to reduce the inspired oxygen concentration to less than 30% to minimize the risk of igniting the tracheal tube or any other combustible materials. Because nitrous oxide also supports combustion, it should not be used in these cases. Air can be used alone or with small amounts of additional oxygen. Helium is also a useful balance gas in these cases, because it does not support combustion and can improve the flow of inspired gases beyond any obstructions in the airway (Pashayan et al., 1988). Specially adapted anesthesia machines capable of delivering inspired carbon dioxide to achieve hypercarbia or increased inspired nitrogen to produce hypoxia may be indicated in the care of the neonate with specific types of congenital heart disease (Tabbutt et al., 2001). The important aspect of caring for these patients is to maintain the balance of pulmonary and systemic blood flow by controlling pulmonary vascular resistance. Both hypoxic oxygen concentrations and carbon dioxide can be used toward this end.

In addition to the inspired oxygen analyzer, the pulse oximeter is also a mandatory patient monitor and facilitates reducing the F_{iO_2} comfortably. As the F_{iO_2} is reduced, the pulse oximeter becomes a better indicator of problems with oxygenation. Because the pulse oximeter only measures the saturation of hemoglobin, it is not useful for assessing the alveolar-to-arterial oxygen gradient when an enriched oxygen concentration is being delivered. If an inspired oxygen concentration of 25% or less is used, the pulse oximeter can rapidly indicate a problem with oxygen delivery to the blood by measuring the reduced oxygen saturation. As the F_{iO_2} is increased, the pulse oximeter becomes a delayed indicator of an oxygenation problem.

Anesthetic Vapor Delivery

All modern anesthesia machines deliver anesthetic vapor by vaporizing a controlled amount of liquid anesthetic and mixing it with the fresh gas entering the anesthesia circuit. The only exception is the Zeus anesthesia machine (Draeger Medical; Lubeck, Germany), which injects liquid anesthetic directly into the anesthesia circuit under closed-loop control. There are excellent sources of information on the details of vaporizer design; however, they are beyond the scope of this chapter (Dorsch and Dorsch, 2007).

The limitation of using fresh-gas flow to vaporize liquid anesthetic is that the rate of change of anesthetic vapor concentration delivered to the patient depends primarily on the total fresh-gas flow. This becomes important for the pediatric patient because inhaled inductions are commonly used. In this case, a

rapid and sustained increase in anesthetic vapor concentration is desired, and a high fresh-gas flow must be used. Typical settings are 3 L/min of oxygen and 7 L/min of nitrous oxide. These flows are wasteful in that most of the gas ultimately ends up in the scavenging system, but high flows are required to maintain the high inspired-agent concentration during induction. Once the desired concentration of anesthetic vapor is established in the breathing circuit, the fresh-gas flow can be reduced to the minimum rate necessary, a “low-flow” anesthesia technique. When attempting to minimize fresh-gas flows, both the inspired-oxygen monitor and the agent-concentration monitor should be used. The oxygen monitor confirms that adequate oxygen flow is being delivered. Measuring the exhaled-agent concentration helps assure proper depth of anesthesia. If the fresh-gas flow entering the circuit is reduced too early in the induction process, ongoing anesthetic uptake from the lungs may exceed the delivery of anesthetic vapor in the inspired gas and the concentration in the alveolus will fall.

Anesthesia Machine Ventilators

The most important advances in modern anesthesia machines germane to pediatric patients are improvements in anesthesia ventilators. For many years, anesthesia ventilators were not capable of delivering small tidal volumes precisely, did not function well at the higher respiratory rates required by children, and offered few if any modes of ventilation other than a volume-controlled mode. As a result, pediatric patients who were difficult to ventilate required an intensive-care-unit (ICU) ventilator in the operating room. Pressure-controlled ventilation has been an available mode of ventilation on many anesthesia machines for some time and has made it easier to ventilate a wider range of pediatric patients. The most modern anesthesia machines now incorporate ventilation capabilities that approach those of ICU ventilators. Not only are these modern anesthesia ventilators capable of accurately delivering small tidal volumes at high respiratory rates, but they offer a variety of ventilation modes and settings. Furthermore, the modern anesthesia ventilators are paired with flow sensors that are capable of monitoring delivered volumes precisely, even for small infants. In the past, setting the ventilator for small patients necessitated observing the chest for adequate expansion. Although there is no electronic or mechanical substitute for observing the patient, newer anesthesia ventilators are quite capable of ventilating even the smallest patients.

The standard ventilators used in pediatric intensive care units can be used in the operating room, but intravenous anesthesia techniques are typically required because anesthetic vapor delivery is either inefficient or simply not possible. Because anesthesia providers may not be familiar with the available ICU ventilators, it is best to have a respiratory therapist in attendance or immediately available if an ICU ventilator is brought to the operating room. Depending on the capabilities of the anesthesia machine, the added cost and complexity of using an ICU ventilator in the operating room, as well as the inability to administer a volatile anesthetic with the ICU ventilator, may be avoided. For those practitioners who care for small children routinely in the operating room, especially children with significant medical problems, a modern anesthesia machine with a capable ventilator becomes important.

Patients requiring nitric oxide need special adaptation of the breathing circuit. There are no anesthesia machines designed

specifically to facilitate nitric oxide delivery, and common practice is to introduce nitric oxide into the breathing circuit through an adapter. This special arrangement is therefore needed for patients receiving nitric oxide and for patients with significant pulmonary hypertension who may require nitric oxide for intraoperative management.

Controlled Ventilation

Controlled ventilation in the operating room can take the form of pressure- or volume-controlled ventilation (VCV). In either case, the goal is to provide all of the patient's ventilation needs with mechanical ventilation—no spontaneous ventilation efforts are expected. Controlled ventilation is commonly used for pediatric patients, especially very small patients, because the work of breathing imposed by the breathing circuit and small endotracheal tube makes effective spontaneous ventilation impossible.

Pressure-controlled ventilation (PCV) is commonly used for pediatric patients and has become the standard approach to pediatric ventilation in many centers. PCV has become popular because it compensates for some of the limitations of the circle anesthesia system for ventilating small patients. Traditionally, it has been difficult to deliver small tidal volumes reliably when using a circle system. Using VCV where the desired tidal volume is delivered by the ventilator is likely to result in hypoventilation because the compliance of the breathing system (i.e., the ventilator components, internal piping, and the breathing circuit itself) can reduce the delivered tidal volume significantly. When using PCV, the ventilator delivers whatever volume is required to achieve the set inspiratory pressure. The resulting tidal volume will depend entirely on the patient's lung compliance, independent of the breathing circuit. The impact of compliance on delivered tidal volume may not be completely apparent when using PCV, because the flow sensor is typically mounted on the expiratory valve and therefore measures both exhaled gas, as well as the gas that was compressed during inspiration in the breathing circuit and never delivered to the patient. Delivered tidal volume is also influenced by adjustments to the fresh-gas flow when using VCV with an older anesthesia machine. PCV obviates the need to be concerned about changing fresh-gas flow, because the ventilator's target is to deliver the set inspiratory pressure. At higher fresh-gas flows the ventilator can deliver less gas to achieve the desired pressure and vice versa. When using PCV, as long as the inspiratory pressure is set so that the desired tidal volume is achieved, the patient is ventilated effectively. The primary disadvantage of PCV is that the delivered tidal volume is not guaranteed. Any change in lung compliance is associated with a change in tidal volume, and inspiratory pressure needs to be adjusted if tidal volume is to be maintained.

The most important change to date in modern anesthesia machines is the ability to precisely deliver small tidal volumes accurately by compensating for breathing-circuit compliance and changes in fresh-gas flow. Newer anesthesia machines have ventilators that can precisely deliver small volumes at high rates (Stayer et al., 2000). Delivering small tidal volumes requires not only an accurate ventilator, but a means for compensating for the compliance of the breathing system and the interaction between fresh-gas flow and inspired tidal volume. Breathing-system compliance exists in any ventilator-circuit combination and results from the compression of gas within the breathing circuit as pressure builds in the circuit, as well as the elastic

expansion of the breathing-circuit tubing. Breathing-system compliance is expressed as milliliters of volume that are taken up per centimeter of water pressure, and it is determined by the internal volume of the breathing system and circuit, as well as the elastic properties of the circuit. Longer breathing circuits have an increased compliance primarily because of the greater internal volume. To better understand the impact of breathing-circuit compliance on delivered tidal volume, consider a case where the compliance value is 1 mL/cm H₂O and the inspiratory pressure is 20 cm H₂O. In that case, 20 mL of tidal volume delivered by the ventilator will not reach the patient. If the desired tidal volume is small, for example 100 mL or less, the fraction that does not reach the patient because of circuit compliance becomes a significant fraction of the desired tidal volume.

To compensate for the compliance of the breathing system, the preuse checkout must be performed to allow the ventilator to measure the compliance of the breathing system and then compensate for that compliance factor during VCV. To use these ventilators effectively, it is essential that the preuse checkout procedures be followed with the breathing-circuit configuration that is to be used during the procedure (Fig. 10-5, A) (Bachiller et al., 2008). Different anesthesia-machine vendors have different approaches to eliminate the interaction between fresh-gas flow and tidal volume. Some anesthesia machines (e.g., Draeger Medical; Lubeck, Germany) use a decoupling valve between the ventilator and the fresh-gas inflow so that the valve closes during inspiration. Other anesthesia machine designs (e.g., General Electric; Madison, Wisconsin) compensate for the fresh-gas flow by using closed-loop feedback between the inspiratory flow sensor and the ventilator.

Because modern anesthesia machines can now deliver and monitor small tidal volumes effectively, it is possible to use VCV routinely for pediatric patients. When using VCV, by definition, tidal volume is constant and pressure varies with changes in lung compliance. To protect the patient from high pressures caused by sudden changes in effective lung compliance (e.g., coughing or external pressure on the chest), a pressure limit can be set when using VCV. This limit should be set above the inspiratory pressure required to deliver the set tidal volume; otherwise, the desired volume will not be delivered.

Assisted Spontaneous Ventilation

Another advantage of modern anesthesia ventilators for pediatric patients is the advent of pressure-supported modes of ventilation. These modes are specifically designed to allow for spontaneous ventilation when an endotracheal tube or supralaryngeal airway is in place and the associated work of breathing would be an impediment to effective spontaneous ventilation. In pediatric patients the work of breathing is a major problem, because small endotracheal tubes impose a significant resistance to inspiration, the ventilator circuits and valves add to the work of breathing, and the anesthetized patients have reduced inspiratory force. In general, long periods of unassisted spontaneous ventilation during anesthesia are undesirable and can result in progressive atelectasis. Supported ventilation is an excellent method for allowing a patient to breathe spontaneously, and it has been demonstrated to improve gas exchange during anesthesia (von Goedecke et al., 2005).

Depending on the manufacturer of the anesthesia machine, assisted spontaneous-ventilation modes can have different names; however, the basic controls and implementations for the

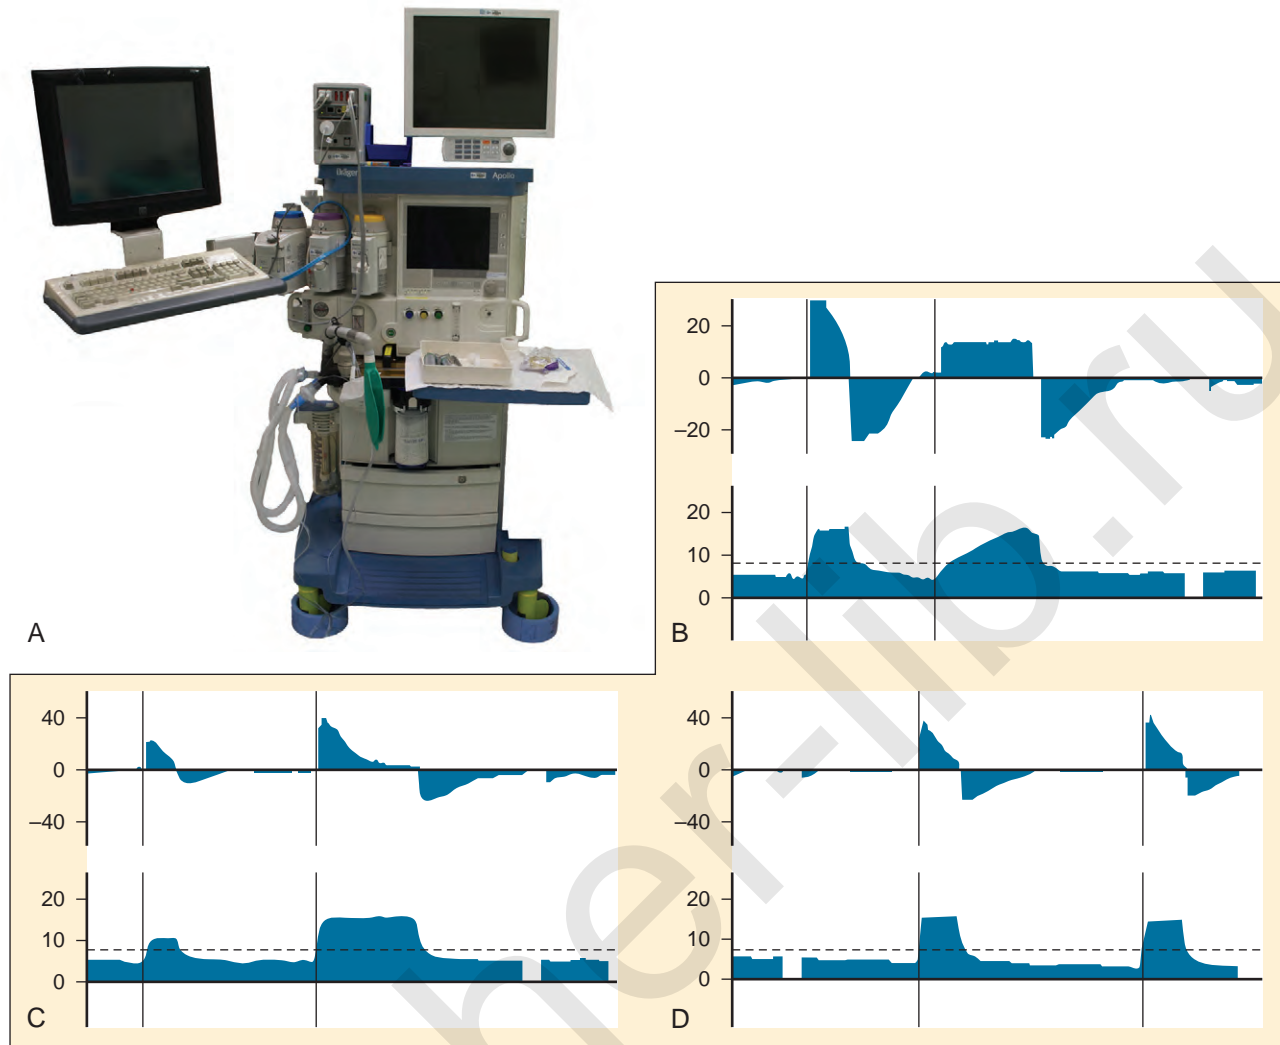

FIGURE 10-5. A, Modern anesthesia ventilator (Draeger Apollo Workstation) capable of pressure support ventilation and circuit compliance compensation. **B**, Typical flow (L/min) (*top*) and pressure (cm H₂O) (*bottom*) waveforms indicating mixed VCV and PSV. The vertical black spike indicates that a breath has been triggered by the patient. The mandatory volume breath is indicated by the constant inspiratory flow and ascending pressure waveforms and, in this case, was synchronized with the patient's inspiration. The pressure support breath is indicated by the constant inspiratory pressure and decelerating flow waveforms. **C**, Typical flow (L/min) (*top*) and pressure (cm H₂O) (*bottom*) waveforms indicating mixed PCV and PSV. The synchronized PCV breath can be distinguished from the pressure support breath by the magnitude and duration of the pressure waveform. **D**, Typical flow (*top*) and pressure (*bottom*) waveforms indicating PSV.

assisted part of the ventilation mode are similar. The common settings for the degree of ventilator assistance are the inspiratory flow needed to trigger a supported breath, the inspiratory pressure that will be provided when the patient initiates a breath, and any positive end-expiratory pressure (PEEP) that will be provided. The tidal volume that results from a supported breath depends on the inspiratory pressure provided by the ventilator and the amount of patient effort. Typical inspiratory support settings are between 5 and 15 cm H₂O above PEEP. The duration of a supported breath is typically determined by the patient. Once the inspiratory pressure is triggered, the ventilator supplies gas to maintain that pressure until the inspiratory flow falls to a predetermined fraction of the peak inspiratory flow (25% is common).

The most important ventilator control when using assisted spontaneous ventilation is the inspiratory flow that is needed

to trigger an assisted breath. The trigger setting tells the ventilator how much inspiratory flow the patient must generate to cause the ventilator to assist the spontaneous effort. Pediatric patients may require lower trigger settings than adult patients, which increases the chance of autotriggering. Supported breaths are usually flow-triggered, whereby support is initiated when inspiratory flow exceeds a preset threshold. If the threshold is very low (0.5 to 1 L/min), it is possible that a breath may be triggered by a practitioner leaning on the patient's chest or simply by small movements of gas in the breathing circuit. Monitoring the pressure waveform as well as the rate and regularity of triggered breaths can help identify when autotriggering is occurring. If there is a concern that autotriggering is occurring, the trigger threshold can be gradually increased until triggering stops. At that point the patient, as well as the pressure and flow waveforms, can be inspected to see if there are any

underlying spontaneous breathing efforts. The goal would be to determine whether there are sufficient spontaneous efforts to warrant using an assisted rather than a controlled mode of ventilation. If not, a mode of ventilation should be chosen with enough mandatory support to achieve the ventilation goals.

Three typical options for assisted spontaneous ventilation are listed as follows:

VCV plus pressure support: When using this mode, the user selects a volume to be delivered, the respiratory rate, the inspiratory/expiratory ratio, or the inspiratory time and PEEP as indicated. In addition, the user selects the inspiratory pressure for assisted breaths and the trigger threshold. The set respiratory rate and tidal volume determine the minimum mandatory ventilation the patient receives. If the patient initiates a breath within the window of a mandatory breath, the effort triggers a synchronized breath at the set tidal volume. If spontaneous efforts occur at a greater rate than the set mandatory rate, assisted breaths are triggered and provided at the set level of inspiratory-pressure support above PEEP. Observation of the pressure waveform allows the anesthetist to distinguish synchronized mandatory breaths from triggered pressure support breaths. The synchronized volume breath appears as a gradually ascending pressure waveform, whereas the pressure support breath appears as a square wave (Fig. 10-5, B).

PCV plus pressure support: When using this mode, the user selects an inspiratory pressure to be delivered, the respiratory rate, the inspiratory/expiratory ratio, or the inspiratory time and PEEP as indicated. In addition, the user selects the inspiratory pressure for assisted breaths and the trigger threshold. The set respiratory rate and inspiratory pressure determine the minimum mandatory ventilation the patient receives. If the patient initiates a breath within the window of a mandatory breath, the effort triggers a synchronized breath at the set inspiratory pressure. If spontaneous efforts occur at a greater rate than the set mandatory rate, assisted breaths are triggered and provided at the set level of inspiratory pressure support above PEEP. Observation of the pressure waveform allow one to distinguish synchronized mandatory breaths from triggered pressure support breaths. The synchronized pressure breath appears as a square wave at the set inspiratory pressure. The pressure support breath also appears as a square wave but typically at a lower maximum pressure and often a shorter inspiratory time (Fig. 10-5, C).

Pressure Support Ventilation (PSV): When this mode is selected, all of the breaths are supported at the set inspiratory pressure above PEEP. In that case, the minute ventilation that results is completely dependent on the inspiratory pressure setting, the patient's effort, and the patient's respiratory rate. Most of these modes allow for a minimum backup ventilation rate, whereby the ventilator delivers a breath if the patient does not trigger breaths at a rate that exceeds the backup rate. Untriggered breaths delivered by the backup setting alone may not result in an acceptable minute ventilation, because there is no patient effort to augment the delivered tidal volume. If a patient does not exceed the backup setting and trigger breaths when using PSV, it may be prudent to use a mandatory mode (VCV or PCV) with pressure support to ensure adequate minute ventilation (Fig. 10-5, D).

Warming Devices

Heat conservation is critical in the care of the newborn infant. A decrease of 2° C in the environmental temperature is sufficient to double the oxygen consumption of a full-term infant (Hill and Rahimtulla, 1965). To meet this increase in oxygen consumption, the neonate must double its minute ventilation. For a critically ill premature infant who is unable to mount this increase in ventilation, an oxygen debt and progressive lactic acidosis ensue (see Chapter 6, Thermoregulation: Physiology and Perioperative Disturbances). The rate of heat loss in newborn infants is four times that in adults because of a higher surface area-to-body weight ratio, increased curvature of body surfaces, and decreased insulation from skin and subcutaneous fat (Adamson and Towell, 1965). Special efforts must be made to maintain body temperature during anesthesia, especially in small infants undergoing operative procedures accompanied by large insensible heat losses.

Forced Warm-Air Device

The flow of warm air across a child's skin produced by a forced-air warming blanket prevents heat loss to the environment and may even effectively warm patients via radiant shielding and convection. Of all devices, this is one of the most effective and should be used in all cases where hypothermia is a possibility (Sessler et al., 1991; Camus et al., 1993; Kurz et al., 1993). Forced-air systems inject warm air through a connecting hose into a quiltlike blanket that has small holes on one surface. Warm air escaping through these holes provides conductive and convective warming to the patient. Different sizes of blankets permit maximum coverage of specific body areas over a range of patient sizes. The most effective units direct flow toward areas with major blood vessels, like the chest, axillae, abdomen, and groin, where convective heating is most effective (Giesbrecht et al., 1994). Like overhead radiant warmers and circulating-water blankets, forced-air systems can produce burns and overheating when used inappropriately (Truell et al., 2000). Maximum air temperatures on these devices are designed to minimize the risk of burns. Ensuring that the tube carrying the warm air to the blanket does not touch the patient also decreases the likelihood of thermal injury. Furthermore, directing warm air from the hose without the blanket ("free-hosing") has been associated with patient burns. Patients with compromised circulations are at a higher risk of burns even when the blanket is used correctly; the temperature should not be set to the highest setting in these patients, especially during prolonged surgery (Siddik-Sayyid et al., 2008). Blankets that are wet are ineffective at maintaining temperature and should be replaced (Lin et al., 2008).

Wrapping and Draping with Plastic Sheets

Because of their large surface area, infants have significant evaporative and radiant heat loss. Wrapping and draping the patient with special blankets is also effective in decreasing heat loss during prolonged surgery, especially when forced-air devices are impractical. Radiant heat loss can be decreased with the use of Webril cotton wrapping (Kendall Corporation; Boston, Massachusetts) covered with plastic bags over exposed extremities. For small infants with relatively large heads, cranial heat loss can be decreased up to 73% by wrapping the head in an

insulated hat or plastic bag. This is significant for neonates, because their brains are responsible for 44% of their total heat production (Rowe et al., 1983). The use of reflective blankets, made from the material used in outdoor survival apparel (e.g., space blankets), is also effective in reducing heat loss (Bourke, et al., 1984). Cutaneous heat loss is proportional to the surface area of the patient, making the percentage of skin surface covered far more important than the region of the body covered or the type of material used for passive insulation (Sessler et al., 1991).

Humidification of Inspired Gases

Humidification of inspired gases, as noted previously, is an important technique for conserving heat in anesthetized patients. Because 12% to 14% of body heat is lost through the respiratory tract, the use of warm, humidified gases decreases the potential heat drain in addition to preventing damage to the ciliated cells of the tracheobronchial tree caused by dry gases (Clarke et al., 1954). The humidifier should be servocontrolled, with a temperature sensor close to the patient to automatically shut off the heater when the preset temperature equals the patient's airway temperature, minimizing the risk of airway burns. Maximum temperature limits, causing automatic shut-off, should also be an integral aspect of the humidifier. Special anesthesia circuits with a heated wire in the expiratory limb minimizes condensation that can occur with humidifiers. HMEs (e.g., Humid-Vent) can provide 80% inspired humidity when 80 minutes of use is allowed to saturate the hygroscopic membrane (Bissonnette et al., 1989a, 1989b). Many HMEs are incorporated into breathing-system filters. These serve to minimize the passage of infectious materials to the breathing circuit and provide warmth and humidification of inhaled gases. The efficacy of various HME brands to perform these functions is variable. The internal volumes of these devices can range from 10 to 60 mL, and small volume filters are preferred in the neonatal population. HME filters may increase the work of breathing and dead space and should be accounted for when ventilating small children. Filtration efficacy is assessed by the penetrance of sodium chloride particles (0.1 to 0.3 μm); tests in pediatric HME filters show that their filtration ability is less than in adult filters. Based on these findings the Centers for Disease Control (CDC) recommend changing the breathing circuit for each new case. Berry and Nolte (1991) examined the efficacy of the Pall HME filter in preventing bacterial contamination of the circle-breathing system in a laboratory model and found it to be an effective microbial barrier between the patient and the circle system. They concluded that when using the Pall HME filter the components beyond the filter may be reused. However the reuse of single-use equipment is not recommended and use is borne by the individual practitioner or institution. To date there has not been a reported case of infection transmission between patients related to anesthesia-breathing systems with filters in place.

Face Masks

The most appropriate anesthesia face mask for a child spans vertically from the bridge of the nose to just below the lower lip, without compressing the nasal passages. It should contain the least volume (i.e., dead space) possible. The pediatric face mask should be constructed with a clear (nonlatex) plastic that

FIGURE 10-6. Plastic disposable face mask with pneumatic cushion.

allows recognition of cyanosis, the condensation of exhaled gas, and the presence of excess secretions or vomitus. A constant challenge in pediatric anesthesia, especially for small infants, is to find a face mask that conforms to the shape of an infant's face without a significant leak. During positive pressure ventilation the anesthesiologist often must twist or torque a face mask without applying undue pressure against a child's face to reduce the amount of air that escapes from within the mask. To achieve these purposes, a variety of face masks have been used in the pediatric population.

The most common anesthesia face mask in use today is the plastic disposable type that contains an adjustable pneumatic cushion, which when inflated or deflated with air can be altered to conform to the shape of a child's face. A variety of different manufacturers produce this type of face mask (Fig. 10-6). An alternative variety for use in pediatric patients is the Rendell-Baker-Soucek mask, which remains in use in many centers (Fig. 10-7). This mask is available in malleable rubber or non-latex silicone and allows an effective seal on a child's face while minimizing internal dead space. It was originally designed on the basis of anatomic molds taken from a large number of children (Rendell-Baker and Soucek, 1962).

FIGURE 10-7. Pediatric face masks. Various mask sizes are available for the wide range of pediatric patients. *Top row*, Four different Rendell-Baker-Soucek masks (From Willy Rusch, Kern, Germany); *Bottom row*, Disposable bubble masks (From Vital Signs, Totowa, New Jersey).

FIGURE 10-8. **A**, Oral airway devices for the spectrum of pediatric patients. **B**, The appropriately-sized oral airway device is chosen by placing it adjacent to the face to approximate its position in the oral cavity.

Oral and Nasal Airway Devices

Oral and nasal pharyngeal airway devices are used in pediatric anesthesia to improve patency of the upper airway and to facilitate delivery of oxygen or anesthetic gases to the lungs. Minimum requirements for these devices are noted in ANSI/ISO5364-08 (ANSI/ISO, 2008). The Guedel-type oral airway device is probably most commonly used in pediatric patients. It contains a central lumen for the passage of airflow and for suctioning of the posterior pharynx (Fig. 10-8, A). The oral airway device is primarily used to alleviate upper airway obstruction caused by tonsillar or adenoidal hypertrophy, or normal pharyngeal tissue obstruction, as often occurs in small infants (see Chapter 3, Respiratory Physiology).

Oral airway devices are usually manufactured from plastic or polyethylene and are latex-free. They are sized according to the total length of the device (50 to 80 mm, flange to tip, for most children) or based on an arbitrary scale designated by the manufacturer. The appropriate size is determined by placing the airway device adjacent to the child's face to approximate its position in the oral cavity. The appropriately-sized oropharyngeal airway device should extend from the corner of the mouth to the angle of the mandible (Fig. 10-8, B). When appropriately placed, its distal end snugly curves around the base of the tongue, without the proximal end protruding out of the mouth. Too small a device pushes the posterior portion of the tongue against the posterior pharyngeal wall, and too large a device may cause upper airway obstruction at the laryngeal inlet by compressing or distorting the epiglottis.

The oral airway device should be inserted in its normal orientation with the aid of a tongue depressor. In older children, insertion may be accomplished with the distal tip oriented cephalad and then turned 180 degrees when the tip has reached the posterior aspect of the palate. In younger children, this maneuver may push the tongue posteriorly and exacerbate airway obstruction.

Complications of using oral airway devices in children are not uncommon and usually occur during emergence. Lip or tooth damage is possible; a loose tooth may become dislodged and lost in the oral cavity, where it may accidentally travel into the bronchopulmonary tree. Compression of oral structures by the oral airway device may result in transient postoperative numbness and a sore throat.

The nasal airway device is made from soft, latex-free rubber to allow easy insertion through the nasal passage and into the nasal or oropharynx. It can be bathed in warm or cold water to decrease or increase its stiffness, respectively. Some nasal

airway devices contain an enlarged flange at the proximal end to prevent unintentional advancement into the nasal cavity. Others contain an adjustable ring that can be secured against the outside of the nasal opening. Nasal airways are available in sizes 12 to 36F (outer diameter, or OD) (Fig. 10-9). If required, a stiffer nasal airway can be fashioned out of a standard tracheal tube by cutting it off at the appropriate length. An anesthesia breathing circuit can be connected to any type of nasal airway device using an appropriately sized tracheal tube adaptor (Fig. 10-10). This technique may facilitate intubation in patients with difficult airways by allowing the administration of anesthesia and oxygen during airway manipulation via a modified nasal airway connected to the anesthesia breathing circuit (Holm-Knudsen et al., 2005). The use of an adaptor also permits delivery of continuous positive airway pressure (CPAP).

To avoid trauma and bleeding of the delicate nasal mucosa, the nasal airway device should be lubricated and gently inserted in a posterocaudal direction along the floor of the nasal cavity. A topical vasoconstrictor, such as 0.05% oxymetazoline, can be applied to the nasal mucosa before inserting the nasal airway device to shrink nasal mucosal tissue and reduce bleeding.

FIGURE 10-9. Nasopharyngeal airway devices.

■ **FIGURE 10-10.** Nasopharyngeal airway device modified with 1.5-mm tracheal-tube adapter.

Vasoconstrictors should be used in recommended doses, particularly because topical phenylephrine use has been associated with cardiac arrest and death in children. The circumstances of these arrests usually involve the topical administration of an unmeasured dose of phenylephrine with resultant hypertension. The anesthesiologists in these cases administered a β -blocking or calcium-channel blocking agent in response to the hypertension, with the consequence of pulmonary edema and cardiac arrest (Groudine et al., 2000). Hypertension secondary to α -agonists should be treated with α -antagonists and direct vasodilating agents. In children weighing up to 25 kg, the initial dose of phenylephrine should not exceed 20 mcg/kg (Groudine et al., 2000). Oxymetazoline can also cause hypertension, tachycardia, and peripheral vasoconstriction by stimulation of peripheral α_2 -receptors; some patients exhibit hypotension, bradycardia, and neurologic and respiratory depression related to stimulation of central α_2 -receptors. Current dosing guidelines recommend oxymetazoline use in children at 6 years of age, although it is safely utilized in children of all ages. A 0.025% solution is recommended for ophthalmic use (1 to 2 drops to affected eye every 6 hours) and a 0.05% solution for nasal use (2 to 3 sprays in each nostril twice a day). The proper diameter of the nasal airway device is determined by approximating the circular diameter of the nasal opening. The proper length of the nasal airway device is estimated by measuring the distance from the nares to the tragus of the ear. When appropriately placed, its distal tip should lie at the level of the angle of the mandible, between the posterior aspect of the tongue and above the tip of the epiglottis.

The most common complication resulting from inserting a nasal airway device is trauma to the nasal or pharyngeal mucosa that results in minor bleeding. Adenoidal tissue may be disrupted and may bleed into the oropharynx. Occasionally, a friable vessel is encountered in the nasal mucosa and bleeding is brisk. Sequential dilation of the nasal passage with nasal airway devices of increasing size is sometimes used in an attempt to minimize trauma during nasal intubation. Adamson et al. (1988) investigated the influence of dilation vs. no dilation on bleeding and found an increased incidence of hemorrhage with dilation and no difference in resistance to passage of the tracheal tube. There are two pathways that devices can take when placed into the nasal passage: a lower pathway below the inferior turbinate and an upper pathway between the middle and inferior turbinates. The middle turbinate is attached anteriorly to the cribriform plate and posteriorly to the ethmoid bone by a thin lamella, making it vulnerable to trauma and avulsion when an airway device is forcibly passed through the upper pathway. The lower pathway is therefore preferred, and airway devices should be inserted perpendicular to the patient's nare

and directed caudally to increase the likelihood of passage into the lower pathway (Hall and Shutt, 2003; Ahmed-Nusrath et al., 2008). Nasal airways should not be inserted in children with a coagulopathy, neutropenia, or suspicion of a traumatic basilar skull fracture.

Tracheal Tubes

The most commonly used tracheal tubes are made of nonreactive polyvinylchloride (PVC). Tracheal tubes should bear a designation that they comply with ANSI/ISO Standard 5361 (1999), which confirms that they are inert, as well as meet dimension, material, and product-marking standards. Biologically inert materials reduce the risk of airway inflammatory reactions.

PVC tubes are flammable and cannot be used in laser surgery performed on airways. A tube that is either nonflammable (e.g., metal) or laser-resistant (e.g., red rubber tube wrapped with aluminum foil or manufactured with special surface treatments) must be substituted (see Chapter 24, Anesthesia for Pediatric Otorhinolaryngologic Surgery). These special tubes should have a label indicating that they are intended for use in laser surgery. Patients with difficult airways or tracheal abnormalities often require a spiral wire-embedded silicone, or "anode," tube (Fig. 10-11). This tube has the flexibility to assume virtually any position, while the wire coil embedded in its wall preserves the lumen. Extreme caution must be taken with anode tubes, because their flexibility makes accidental extubation more likely.

In evaluating tracheal tubes for use in infants and children, their influence on dead space, resistance to breathing, and tracheal or laryngeal injury must be considered. Tracheal intubation reduces the dead space of the natural extrathoracic airway but can have a dramatic negative impact on the resistance to breathing (Glauser et al., 1961). Resistance to laminar flow through a tube is governed by the Hagen-Poiseuille Law, which dictates that resistance is proportional to the length of the tube and inversely proportional to the fourth power of the radius. Thus, small changes in the lumen of a tube can dramatically increase the resistance to flow through it. Assuming that flow is laminar and that all other variables are constant, one can predict that a reduction in internal diameter (ID) from 7.5 to 7.0 mm increases resistance 24%, whereas a reduction from 3.5 to 3.0 mm increases resistance by nearly 50%. Because luminal

■ **FIGURE 10-11.** Wire reinforced anode tube.

changes between the tracheal tube and the adapter promote turbulent flow, measured differences are even more exaggerated. The resistance to breathing through the natural airway of a neonate is greater than that through a 3.5-mm ID tracheal tube but significantly less than that through a 2.5-mm ID tracheal tube (Polgar and Kong, 1965). A small amount of secretions or debris can increase resistance substantially, yet these accumulations are difficult to avoid in small-lumen tubes. The use of 2.5-mm ID tracheal tubes should be restricted to situations in which no other tube fits.

Resistance to breathing is governed by the ID of a tube, but the potential for laryngeal or tracheal mucosal injury is related to the OD. Mild trauma to the airway, producing as little as 1-mm mucosal edema, can result in significant narrowing of the infant's airway. As little as 25 mm Hg pressure on the lateral wall of the trachea causes local ischemia and mucosal injury in adults and presumably in children as well (Nordin et al., 1977; Seegobin and van Hasselt, 1984).

Historically, uncuffed tracheal tubes have been used for children under 8 years. Based on the interpretation of statements by Eckenhoff (1951), the child's larynx was thought to be conical with a circular cricoid ring at its most narrow dimension and only assumed a more cylindrical shape as the child matured into an adult (Motoyama, 2009). A circular, uncuffed tracheal tube would then conform well to this narrow, circular portion of the airway. More recent data suggest that the cricoid is slightly elliptical with the rima glottidis (the vocal cords) as the narrowest point in the pediatric airway (Litman et al., 2003; Dalal et al., 2009). A snug-fitting tracheal tube would exert more pressure on the lateral mucosa of the trachea than in the anterior-posterior direction. (Motoyama, 2009). This conclusion might suggest the use of smaller, uncuffed tracheal tubes. However, smaller tracheal tubes would increase resistance to spontaneous breathing, make controlled ventilation more difficult caused by a larger leak around the tube, increase environmental pollution, and possibly risk increased rates of pulmonary aspiration.

Yet with the reduction in tube size necessary to pass the glottic opening and the fear of laryngeal and tracheal damage, cuffed tracheal tubes have not been recommended in young children in the past. With the regular use of mechanical ventilation and the advent of pressure-support anesthesia ventilators, increased tracheal tube resistance may be less of an issue for most children undergoing anesthesia. Tissue damage may be the result of overinflated cuffs or prolonged intubation in intensive care settings (Nordin, 1977; Holski, 1997). Several series, however, have demonstrated that cuffed, tracheal tubes perform as well or better than uncuffed tubes in children undergoing anesthesia with muscle relaxant, noting fewer required intubation attempts and no difference in the incidence of postoperative croup (Khine et al., 1997; Murat, 2001; Weiss et al., 2009).

The development of a new, microcuff tracheal tube (Kimberly-Clark Worldwide; Roswell, Georgia) may add additional advantages to management of the pediatric airway (Weiss and Dullenkopf, 2007). These tubes have an anatomically-based intubation depth mark for placement at the level of the cords, providing a margin of safety for tube-tip displacement with head flexion and extension (Weiss et al., 2006). Additionally, these tubes have a distally placed cuff with a smooth, thin membrane that allows the cuff to avoid the cricoid and larynx and facilitates lower inflation pressures to seal the trachea (Fig. 10-12, A).

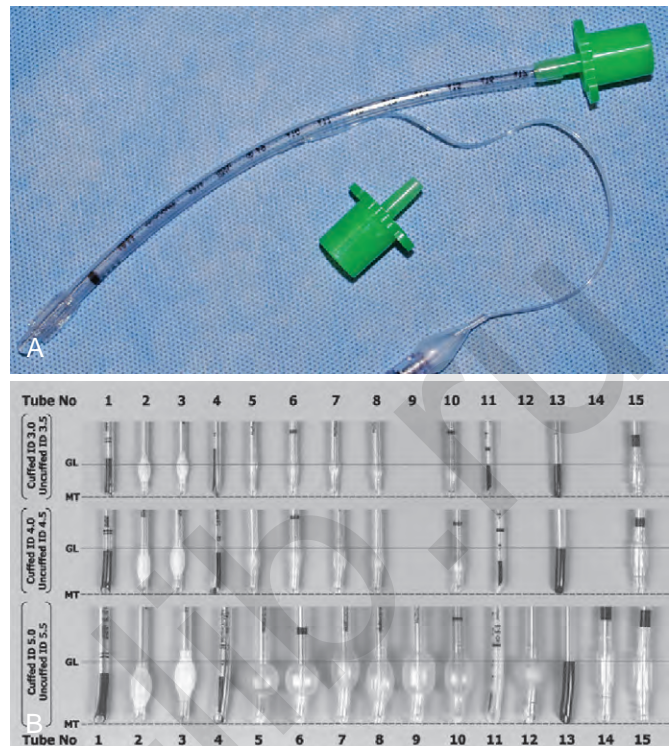

FIGURE 10-12. A, Microcuff tube. B, 3.0-, 4.0-, and 5.0-mm ID cuffed tracheal tubes and age-related corresponding (ID + 0.5 mm) uncuffed tracheal tubes are shown for each of the 15 tube brands. Age-related mid-tracheal placement of the tube tip according to the depth marking of the uncuffed tracheal tube results in laryngeal or even glottic level position of the cuff for all the cuffed tracheal tubes, (From Weiss M et al.: *Shortcomings of cuffed paediatric tracheal tubes*, Br J Anaesth 92(1):78, 2004.)

Whether cuffed tracheal tubes should replace uncuffed tubes in pediatrics is unclear. In a large, randomized, controlled, multicenter trial comparing cuffed with uncuffed endotracheal tubes, Weiss and others (2009) reported that in children from birth to 5 years of age undergoing general anesthesia, the incidence of postextubation stridor was similar for the cuffed tube group (4.4%) vs. the uncuffed group (4.7%). However, the rate of tube exchange was significantly greater in the uncuffed group (30.8%) compared with the cuffed group (2.1%). Unfortunately, some of the major shortcomings of cuffed tracheal tubes are the relative inconsistency of the distance of the distal tube tip to the lower and upper borders of the cuff, the ODs of the tubes, and the maximal cross-sectional area of the inflated cuff and depth markers for positioning of the tube at the appropriate depth of the trachea (Fig. 10-12, B; see Chapter 1, Special Characteristics of Pediatric Anesthesia, Table 1-1) (Weiss et al., 2004a).

A variety of tracheal tubes are available for special needs. A Ring, Adaire, Elwyn (RAE) tube has a preformed contour that facilitates access to the surgical field (Fig. 10-13, A). Oral RAE tubes were initially developed for cleft-palate surgery. The proximal end of the oral RAE tube rests over the middle of the mandible, whereas the proximal end of a nasal RAE tube rests on the forehead (Fig. 10-13, B; see Chapter 25, Anesthesia for Plastic Surgery, Fig. 25-12). These preformed tracheal tubes can be used for any type of head or neck surgery in which the operating room table is turned away from the anesthesiologist

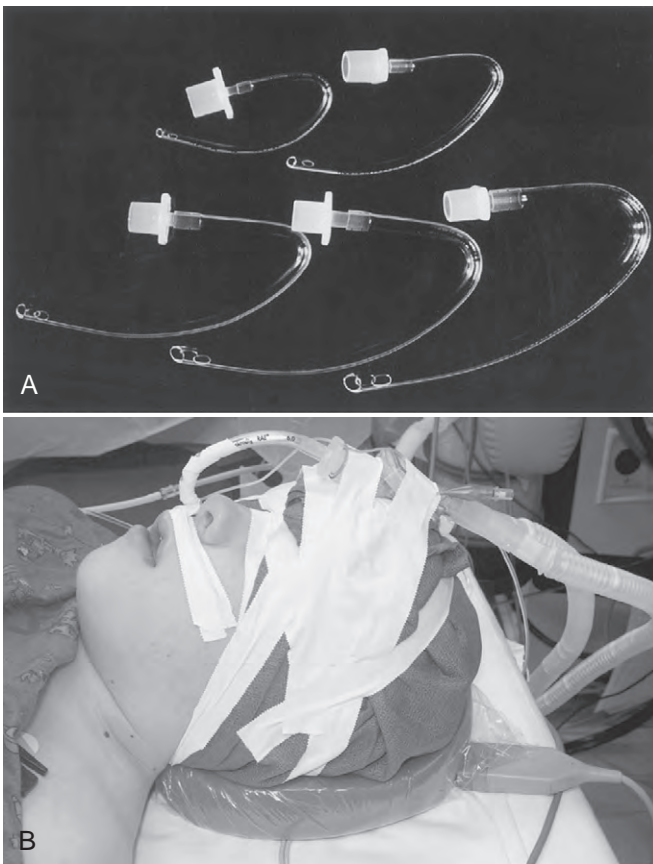

FIGURE 10-13. A, Oral RAE tubes. Preformed oral RAE tubes are made in a variety of sizes. They are especially useful in facial surgery. **B,** The nasal RAE tube is preformed to sit on the forehead for procedures in the oral cavity or neck. (From Litman RS: *Pediatric airway management*. In Litman RS, editor: *Pediatric anesthesia: the requisites*, St. Louis, 2004, Mosby.)

and the head is maintained in a neutral position. The greatest disadvantage of preformed tubes is that the flexion point is fixed. The length may be inappropriate, especially in patients whose cricoid diameter is unusually large or small, increasing the risk of endobronchial intubation or accidental extubation, respectively. Similarly, in a patient with a laryngeal or proximal tracheal stenosis, a standard tracheal tube of a caliber small enough to be admitted to the airway may be too short. Tubes of small caliber with extra length are commercially available for this purpose.

Double-Lumen Tracheal Tubes

A double-lumen tracheal tube is commonly used to attain lung separation in adults. Its advantages include rapid and easy separation of the lungs, access to both lungs to facilitate suctioning, the ability to rapidly switch to two-lung ventilation if needed, and the ability to administer CPAP or oxygen insufflation to the operative lung, when necessary. The smallest commercially available double-lumen tracheal tube is size 26F, which precludes its placement in children weighing less than 30 to 35 kg or younger than 8 to 10 years old (Table 10-1; see Chapter 23, Anesthesia for General Abdominal, Thoracic, Urologic, and Bariatric Surgery, Table 23-9). With this small,

TABLE 10-1. Comparative Diameters of Single-Lumen and Double-Lumen Tubes

FOB, Fiberoptic tube.

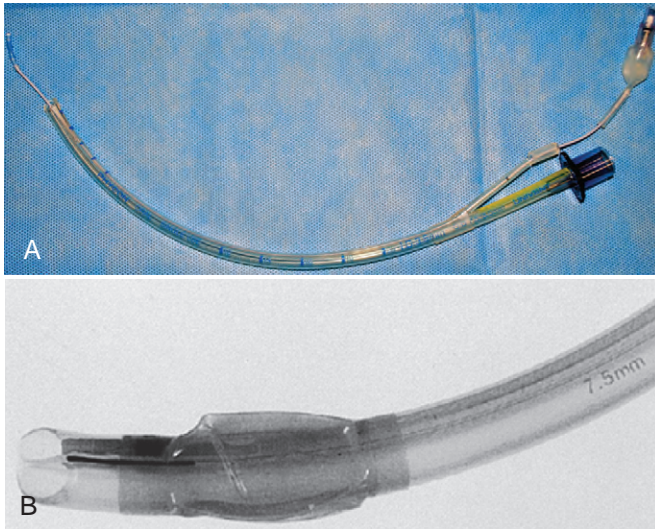

double-lumen tracheal tube, bronchoscopic confirmation of its appropriate location within the trachea and bronchus requires use of an ultrathin flexible bronchoscope (Wood, 1985).

Tracheal Tubes for One-Lung Ventilation

Because of mechanical difficulties of one-lung ventilation in small children, pediatric surgeons historically have used retractors and surgical packs to improve surgical exposure during thoracic surgery. With the increasing popularity of thoracoscopic surgical techniques in children, there is an increasing need to provide one-lung ventilation to facilitate surgical exposure (Rowe et al., 1994; Tobias, 1999; Hammer, 2001). The pediatric anesthesiologist has a number of choices for the provision of one-lung ventilation.

Univent Tracheal Tubes. The Univent Tracheal Tube (Fuji Systems Corporation; Tokyo, Japan) is a single-lumen tracheal tube with a moveable bronchial blocker built into its side wall (Fig. 10-14) (Kamaya and Krishna, 1985; Hammer et al., 1998; MacGillivray, 1988). The bronchial blocker contains a low-pressure high-volume cuff and has a central channel used to suction the blocked lung and to insufflate oxygen. The Univent Tracheal Tube is inserted into the trachea like a standard tracheal tube with the bronchial blocker withdrawn into the main tube. The bronchial blocker can then be advanced into the main-stem bronchus of the operative lung under bronchoscopic guidance. Rotation of the tracheal tube determines the direction that the blocker takes as it is advanced. Inflation of the endobronchial cuff on the balloon-tip catheter enables isolation of the operative lung. At the end of the procedure, the blocker tube can be withdrawn into the main tube, permitting postoperative ventilation without the need to change to a separate single-lumen tube.

Advantages of the Univent Tracheal Tube include ease of placement and the ability to easily change from one-lung ventilation to two-lung ventilation. In addition, unlike the standard double-lumen tracheal tube, the bronchial blocker can be pulled back into its channel with the Univent tube left in place

■ **FIGURE 10-14.** **A**, Univent tube. The bronchial blocker is incorporated into the tracheal tube to allow for isolation of one of the lungs during the anesthesia. The blocker can be withdrawn from the tube, and ventilation can be continued in the postoperative period without the need to exchange to a single-lumen tube. **B**, The blocker in the retracted state.

for postoperative ventilation. The Univent Tracheal Tube is available in sizes 3.5- (uncuffed), 4.5-, 6.0-, 6.5-, 7.5-, 8.0-, 8.5-, and 9.0-mm ID. The OD is larger than that of a conventional tracheal tube of the same ID. The IDs of the 3.5- and 4.0-mm ID Univent Tracheal Tubes limit the passage of a standard pediatric bronchoscope with an OD of 3.5 mm or greater, thereby requiring an ultrathin pediatric bronchoscope to visualize the bronchial blocker.

Selective Endobronchial Intubation

In infants and young children whose small size precludes placement of a double-lumen tracheal tube or a Univent tube, there are two additional options for one-lung ventilation: selective endobronchial intubation with a standard tracheal tube or placement of a separate “bronchial-blocker” device.

Endobronchial Intubation with a Standard Tracheal Tube. A tracheal tube can be inserted into either main bronchus with the use of bronchoscopic guidance or fluoroscopic guidance. In small neonates, an uncuffed tracheal tube can provide adequate isolation of the lungs. In older infants and children, a cuffed tracheal tube maintains an effective seal of the lungs while maintaining the tube in a proximal position within the main bronchus. A tube with a distally placed cuff facilitates this placement. The major disadvantage of selective endobronchial intubation is that it is not possible to quickly change from one-lung ventilation to two-lung ventilation because it requires repositioning the tracheal tube from the bronchus into the trachea and vice versa. Furthermore, with unintentional movement of the tracheal tube and minimal cephalad displacement, selective intubation may be lost because of bronchial extubation, a phenomenon that occasionally happens with surgery around the hilum of the lung.

Bronchial-Blocker Devices. A bronchial-blocker device consists of a small balloon that is purposefully inflated within the proximal portion of the main bronchus to isolate one of the lungs under bronchoscopic guidance. Several different devices can be used as bronchial blockers, including a Fogarty embolectomy catheter and the Arndt endobronchial blocker (Cook Critical Care; Bloomington, Indiana) (Fig. 10-15). The latter device contains a central channel that allows suctioning (for lung deflation) and the application of oxygen and CPAP. It is too large for use in neonates and infants.

A Fogarty embolectomy catheter contains a balloon at its distal end that can be placed within the proximal main bronchus to isolate the lung either with bronchoscopic or fluoroscopic guidance. A disadvantage of the embolectomy catheter is that the distal tip can be displaced proximally during the course of a surgical procedure, especially if the patient’s position changes. Total airway obstruction can result if the inflated balloon slips back into the trachea. Suctioning or application of CPAP is not possible because of the lack of an inner channel. The catheter is usually placed outside of the tracheal tube in small infants, so that the small lumen of the tube is not further compromised.

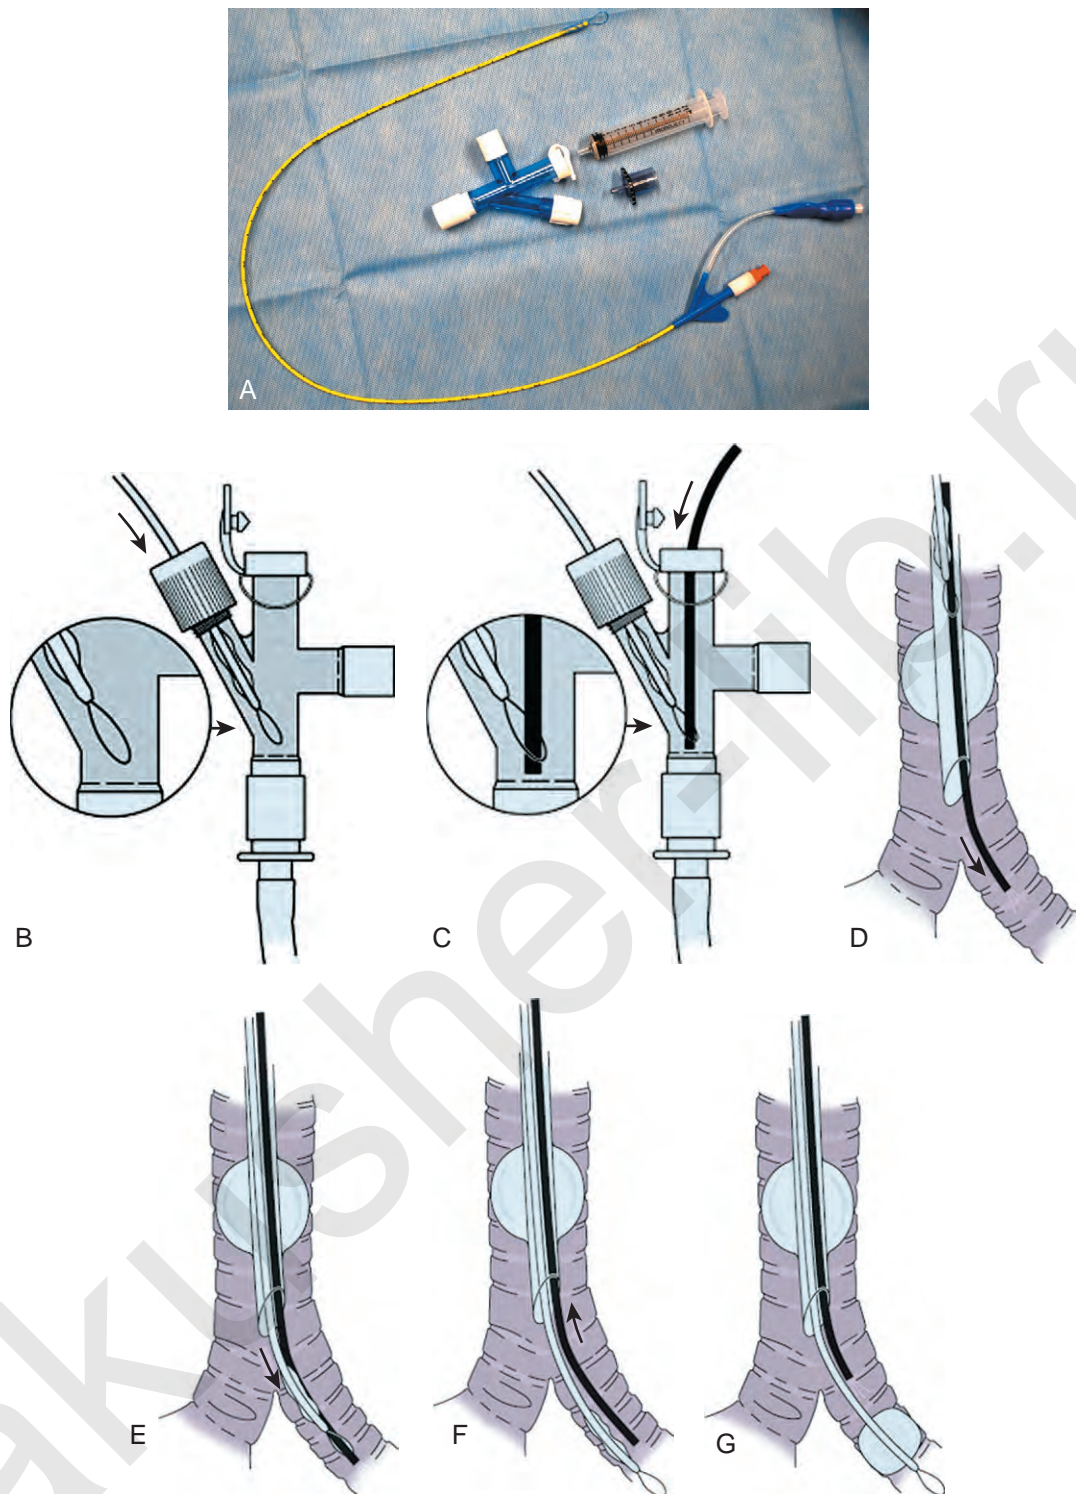

The Arndt endobronchial blocker is a bronchial blocker with an inflatable cuff and a central lumen, through which a wire with a looped end has been passed (Arndt et al., 1999; Hammer, 2002). The bronchial blocker is passed through a specialized adapter that is placed at the proximal end of the tracheal tube. This adapter contains the following four ports:

1. A connection to the tracheal tube,
2. A standard 15-mm adaptor for the anesthesia circuit,
3. A port for the bronchial blocker with a self-sealing diaphragm that can be tightened around the bronchial blocker to hold it in place, and
4. A port for the flexible bronchoscope.

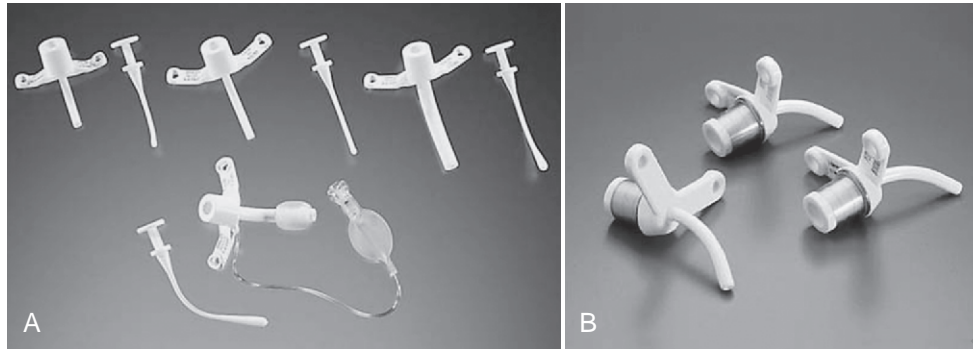

The bronchial blocker is passed through its port and placed at the entrance of the tracheal tube. The bronchoscope is passed through its port and then through the wire loop at the end of the bronchial blocker. The bronchoscope and bronchial blocker are then passed under direct vision as a single unit into the main bronchus of the operative side. The bronchoscope is withdrawn into the trachea, and the balloon is inflated under direct visualization. When correct placement has been confirmed, the wire loop is removed from the central channel. Once the wire guide is removed from the channel, it cannot be replaced. The Arndt endobronchial blocker is currently available in three sizes (5F, 7F, and 9F), with the 9F recommended for tracheal tubes of 7.5 mm and above, 7F for tracheal tubes of 6.0 to 7.0 mm, and 5F for tracheal tubes of 4.5 to 5.5 mm.

Tracheostomy Tubes

The three most common indications for tracheostomy in children are the need for prolonged mechanical ventilation (more than 50% of cases), upper airway obstruction (40%), and pulmonary toilet (10%) (Wetmore et al., 1999). Within each category are congenital, traumatic, metabolic, infectious, and neoplastic conditions that require tracheostomy. Although the underlying medical conditions may be numerous, the most common diagnoses in pediatric tracheostomy patients are bronchopulmonary dysplasia and neurologic disorders.

■ **FIGURE 10-15.** **A**, Arndt endobronchial blocker kit. The Arndt endobronchial blocker is inserted under fiberoptic guidance. **B**, With a special multiport adapter that is attached to the tracheal tube, the blocker is inserted through a side port into the main body of the connector. Ventilation with 100% oxygen is enabled through a second side port. **C**, A flexible bronchoscope is inserted through the remaining port, engaging the wire loop at the end of the bronchial blocker. **D**, The bronchoscope is advanced into the bronchus to be isolated. **E**, The blocker is advanced into the bronchus, sliding down the bronchoscope. **F**, The bronchoscope is withdrawn, leaving the blocker in place. **G**, The blocker's balloon is inflated, and placement is verified using the bronchoscope before it is withdrawn completely. (**B-G** Courtesy of Cook, Inc., Bloomington, Ind.)

■ **FIGURE 10-16.** Representative models of pediatric tracheostomy tubes include the Shiley (**A**) and the Bivona (**B**).

The ideal tracheostomy tube should be made of a material that causes minimal tissue reactivity, can be easily cleaned and maintained, and is available in a variety of shapes, diameters, and lengths (Fig. 10-16). The tube needs to be rigid enough to prevent kinking or collapse, yet soft enough to be comfortable for the patient. Early tracheostomy tubes were made of stainless steel or silver (Downes and Schreiner, 1985). These tubes had the advantages of causing minimal tissue reaction and averting tracheal collapse. Their rigidity caused significant discomfort to the patient because of injury to the tracheal mucosa. Most manufacturers use silicone tubes that have minimal tissue reactivity and conform to the structure of the airway. The ideal tube also contains an inner cannula that can be removed and cleaned. Modern tracheostomy tubes have a 15-mm male connector for the attachment of standard respiratory equipment. To improve the patient's comfort and ease of care, a low-profile swivel is commonly added to the tracheostomy tube. This allows unrestricted neck movement and easy care through a suction port. Tracheostomy tubes for infants are uncuffed; in larger children and adolescents, cuffed tracheostomy tubes are preferred. Attachments are available to promote verbal communication.

The appropriate tracheostomy tube is selected on the basis of ID, OD, and length (Table 10-2). The OD determines the size of the tube that may be inserted, whereas the ID determines the actual airway size. The diameter of the tube should be large enough to allow adequate air exchange, easy suctioning, and clearance of secretions. If the indication for tracheostomy is assisted ventilation, the size of the tube should be adjusted to prevent excessive air leak. Predictors of the appropriate tube size include the child's age and the size of a preexisting tracheal tube. A tube that is too large compromises the capillary blood flow in the tracheal wall, which may result in mucosal ischemia, ulceration, and development of fibrous stenosis. Overinflation of a cuffed tracheostomy tube for a prolonged period of time may produce similar injuries. This complication may be avoided by selecting the proper size of tracheostomy tube and adjusting the cuff pressure to less than 20 cm H₂O (Table 10-2). The choice of the tube size is also influenced by visualization of the size of the tracheal lumen.

The length of the tube is important, especially in neonates and infants. A tube that is too short may result in accidental decannulation or the development of a false passage. If a tube is too long, the tip may abrade the carina or become situated

in the right main bronchus. Some plastic tubes may be cut to the desired length as necessary. Extra-long, custom-made tubes may be helpful in unusual situations, such as tracheomalacia or tracheal stenosis, to span the diseased area.

Supralaryngeal Airways

Laryngeal Masks

Since the invention of the original laryngeal mask, the Laryngeal Mask Airway (LMA; LMA North America; San Diego, California) (Brain, 1983), several manufacturers have developed laryngeal masks of various designs for use in children (Fig. 10-17, Table 10-3). Examples include the Ambu AuraOnce (Ambu A/S; Ballerup, Denmark), air-Q (Cookgas; St. Louis, Missouri), and the Portex Soft Seal Laryngeal Mask (SS-LM; Portex; Kent, United Kingdom) (Fig. 10-18). Most of these masks share common features, such as a bowl-shaped inflatable cuff attached to an airway tube and a detachable or fixed 15-mm adaptor at the proximal end of the airway tube. Some designs have curved airway tubes, whereas others maintain the original straight configuration. Some of the new designs incorporate a separate gastric access channel to facilitate correct placement and to allow gastric decompression; however, only the Proseal LMA is available in all pediatric sizes (Fig. 10-19). Despite variations in design, one simple principle applies to the use of these devices in children. The incidence of problems with positioning laryngeal masks is inversely proportional to the age of the child; consequently, the use of laryngeal masks in infants and neonates requires an experienced provider with a high level of vigilance. Fiberoptic bronchoscopy and magnetic resonance imaging (MRI) studies in pediatric patients demonstrate a high incidence of malpositioning of the LMA in children (Keidan et al., 2000; Monclus et al., 2007). When placed properly, the distal cuff overlies the laryngeal inlet, and the aperture bars, when present, prevent the epiglottis from obstructing the lumen (Fig. 10-20). Once inflated through a pilot tube, the cuff creates a seal in the pharynx that permits both spontaneous and controlled ventilation without a large gas leak, provided the peak pressure is below 15 cm H₂O (Epstein and Halmi, 1994; Lardner et al., 2008). A variety of methods of LMA placement in children is possible. The original "Brain" (1990) technique requires that the mask be

*Shiley is manufactured by Mallinckrodt Inc., St. Louis, Missouri.

†Bivona is manufactured by Portex, Keene, New Hampshire.

‡FlexTend tubes feature a flexible, kink-resistant proximal extension that allows easier access and enables distal connections away from the infant's chin, neck, and chest.

§Bivona cuffed tubes are available in three different models: Fome-Cuf tubes (85 series) include a SidePort AutoControl Adapter that synchronizes cuff and ventilator pressure. A complete seal is possible for patients with high PEEP or high inspiratory pressure needs. Aire-Cuf tubes (65 series) feature a traditional air-filled cuff. TTS cuffs (67 series) feature an uncuffed tube profile when the cuff is deflated but provide the protection of a cuff when it is inflated.

¶Adjustable Hyperflex (HA series) is an instantly customizable, soft, flexible, kink-resistant, silicone tube with an adjustable neck flange. The flexible shaft adapts to the unique contours of each patient's anatomy. The Adjustable Hyperflex tube is primarily used as a measuring device and temporizing measure until the child can receive a permanent tube with a fixed neck flange. The 550 series is made of PVC that softens at body temperature. It features a long tube shaft and a traditional anatomic curve.

■ **FIGURE 10-17.** Classic LMA.

advanced across the hard palate with the cuff fully deflated, the distal aperture facing anteriorly, and the head in the classic “sniffing” position. The index finger of the right hand helps guide the LMA over the surface of the tongue while pressing the mask against the palate, thereby simulating the action of the tongue on a bolus of food. A water-based lubricant applied to the posterior surface of the LMA helps to decrease the resistance to insertion. On meeting the characteristic resistance of the upper esophageal sphincter, the cuff is inflated through the pilot tube. With cuff inflation, the tube usually moves outward a short distance as the tube centers itself over the laryngeal inlet. Inflation of the cuff to recommended maximum volumes and the use of clinical endpoints such as outward movement of the LMA may result in cuff pressures that are higher than the maximum recommended pressure of 60 cm H₂O (Maino et al., 2006). High cuff pressures are associated with increased incidence of leak around the LMA, excess mucosal pressures, and an increased incidence of sore throat (Wong et al., 2009). Only a fraction of the recommended volume is required to obtain an effective seal, and using a manometer to guide inflation has been shown to decrease leakage around the LMA by promoting more effective molding of the device to the airway (Licina et al., 2008).

The LMA can also be inserted with the cuff partially inflated or with the aperture facing posteriorly and then turned 180 degrees once it is in the larynx (Chow et al., 1991; O’Neill et al., 1994; Nakayama et al., 2002). Clinical evaluations of the different insertion techniques suggest that the rotational technique is an acceptable alternative to the standard approach and may improve placement success in children (Tsujiyama, 2001; Nakayama et al., 2002; Ghai et al., 2008).

Additional maneuvers that may facilitate ease of insertion include increasing head extension, performing a jaw-thrust maneuver, inserting the LMA slightly laterally in the pharynx to avoid the uvula, or using a laryngoscope to lift the tongue anteriorly (Brain, 1989; van Heerden and Kirrage, 1989; Cass, 1991). Nevertheless, in some children, insertion is difficult and

*Based on Mallinckrodt tracheal tubes.

associated with pharyngeal bleeding (Marjot, 1991). The LMA is usually placed in an anesthetized child; insertion in a conscious or sedated neonate is occasionally necessary in situations in which traditional mask ventilation and endoscopy is problematic (Denny et al., 1990; Markakis et al., 1992; Stricker et al., 2008). The LMA can be placed successfully in the prone pediatric patient in the case of accidental extubation and allows for rapid airway control without having to reposition the patient supine. (Dingeman et al., 2005).

■ **FIGURE 10-18.** A, Ambu AuraOnce. B, Air-Q airway.

■ **FIGURE 10-19.** The pediatric Proseal LMA.

■ **FIGURE 10-20.** When properly inserted, the distal outlet of the LMA is situated over the laryngeal inlet.

Diagnostic and interventional flexible bronchoscopy is facilitated with LMA use. After LMA placement, the airway is anesthetized with topical lidocaine, and the patient is allowed to breathe spontaneously. Adequate anesthetic depth is maintained with volatile or intravenous anesthetic (Nussbaum and Zagnoev, 2001; Yazbeck-Karam et al., 2003).

Laryngeal masks are critical tools in the management of the airways in children. They have been used successfully to rescue ventilation in patients who have difficult airways and can serve as conduits to intubation (Yang and Son, 2003; Batra, et al., 2006). Attaching a swivel connector (Swivel Connector, Ref. 60-60.305; VBM; Sulz, Germany) to the 15-mm end of an LMA facilitates ventilation during fiberoptic intubation through the LMA and subsequent LMA removal (Weiss et al., 2004b). The use of this adaptor significantly shortens apnea time and allows uninterrupted ventilation of the patient during tracheal tube placement and LMA removal. Despite its many benefits, the LMA has several limitations in children. Cuffed tracheal tubes do not pass through small LMAs, because the pilot balloon becomes lodged in the airway tube (Weiss and Goldmann, 2004). In order to place a cuffed tracheal tube, an uncuffed tube is first inserted and the LMA is removed; a tube exchange is then performed, leaving a cuffed tube. This added step can cause additional morbidity or mortality if the exchange should fail.

Standard tracheal tubes are similar in length to their corresponding LMA sizes. This similarity results in the tracheal tube disappearing into the airway tube before a significant length of tube can be slid over a fiberoptic scope into the trachea. This presents challenges with advancing the tube into the trachea and removing the LMA. Several techniques have been described to address this problem, including using a second tracheal tube or laryngeal forceps as a stabilizer, cutting the airway tube of the LMA to shorten its length, using an extra-long tracheal tube, or leaving the LMA in place after intubation (Benumof, 1992; Yamashita, 1997; Selim et al., 1999; Muraika et al., 2003; Osborn and Soper, 2003; Yang and Son, 2003; Machotta and Hoeve, 2008).

The air-Q is uniquely designed to facilitate tracheal tube placement in children of all ages (Fig. 10-18, B). This laryngeal mask is a curved device with a uniquely designed airway tube. The airway tube readily accommodates the pilot balloon of cuffed tracheal tubes in all its sizes, and the length is shortened, thereby ensuring that the tracheal tube is in the trachea when the proximal end disappears into the device (Table 10-3).

A limitation of the classic LMA is its inability to protect the airway against regurgitation of gastric contents into the trachea. In a 1992 study by Barker et al., in adults without significant risk for reflux or aspiration there was a 25% incidence of regurgitation of methylene blue into the laryngeal mask, though no tracheal soiling was noted. Pulmonary aspiration during LMA use remains an uncommon event, with the incidence reported to be approximately 2 in 10,000 (Brimacombe and Berry, 1995; Keller et al., 2004a).

In general, the smaller the size of the LMA, the higher the incidence of malpositioning, usually with the epiglottis contained within the grill of the LMA (Rowbottom et al., 1991; Mizushima et al., 1992; Dubreuil et al., 1993). Even in the presence of this type of malpositioning, ventilation is not usually impaired, although ventilation is more likely to become

problematic with small movements of the child or LMA when the initial position is not optimal. (Mason and Bingham, 1990; Rowbottom et al., 1991).

The Proseal LMA is designed to separate the alimentary and respiratory tracts. It integrates a drain tube placed lateral to the airway tube of the LMA and ending at the tip of the mask (Fig. 10-19) (Brain et al., 2000). When the Proseal LMA is placed correctly, the second tube is contiguous with the alimentary tract and is sealed against the upper esophageal sphincter, allowing the passage of a nasogastric tube and confirmation of adequate positioning of the device. The Proseal LMA forms a more effective airway seal and is associated with higher oropharyngeal leak pressures (11 to 18 cm H₂O higher) and less gastric insufflation than the classic LMA in children (Goldmann and Jakob, 2005; Lopez-Gil and Brimacombe, 2005; Wheeler, 2006; Lardner et al., 2008). The first-attempt success rate of placement is reported to be about 90% in children (Wheeler, 2006). The Proseal LMA may effectively separate the gastrointestinal system from the airway; however, much of the evidence for this comes from case reports and requires the assumption that the device position does not change after it has been assessed to be correctly placed (Keller et al., 2004b).

The Proseal LMA is available for use in all infants. The incidence of complications with the Proseal LMA is highest in the youngest patients (size 1.5), most of these relating to poor positioning of the LMA, obstruction, or laryngospasm (Bagshaw, 2002).

The choice of which laryngeal mask to use depends on the clinical application, cost, personal preference, and experience. The practitioner needs to examine these variables when selecting the mask to use in the surgical environment.

Cobra Perilaryngeal Airway

The Cobra Perilaryngeal Airway (Cobra PLA; Engineered Medical Systems, Indianapolis, Indiana) is another supraglottic device that aids in airway management. The Cobra PLA consists of a softened distal tip that has slotted openings for ventilation and is designed to be positioned in the hypopharynx overlying the laryngeal inlet (Fig. 10-21). It is secured in place by a more proximal cuff and has a proximal 15-mm connector that attaches to the anesthesia breathing circuit. The Cobra PLA is available in eight different sizes, five of which are suitable for pediatric age and weight ranges (Table 10-4). It is suitable for use during spontaneous or controlled ventilation, and the larger sizes can accommodate an appropriately sized fiberoptic bronchoscope and tracheal tube for difficult intubations.

The Cobra PLA is inserted in a similar manner to the LMA. A preliminary study in adults demonstrated that the Cobra PLA often requires readjustment up or down to affect adequate ventilation once inserted (Agro et al., 2003). A comparison examining the anatomic positions of the LMA Unique, Softseal LMA, and the Cobra PLA found that herniation of the arytenoids through the mask aperture bars was more common with the Cobra PLA than with the other devices (van Zundert et al., 2006). Polaner et al. (2006) assessed the orientation of the Cobra PLA using flexible bronchoscopy in infants and children. They found the airway to be acceptable in all children; however, the laryngeal view was nearly or completely obstructed in 76.9% of the patients who weighed 10 kg or less. A comparison of the Cobra PLA to the LMA Unique in children revealed higher seal pressures for the

FIGURE 10-21. The Cobra PLA consists of a distal softened tip that contains slotted openings for ventilation, a more proximal cuff to secure the airway, and a proximal 15-mm connector that attaches to the anesthesia breathing circuit. Cobra PLA, with similar insertion ease and times and less gastric insufflation. The fiberoptic view was found to be better based on the comparison of fiberoptic views immediately after induction to views before emergence (Szmuk et al., 2008). Airway obstruction secondary to epiglottic incarceration into the aperture bars has been reported and may be more likely if the device moves upward from the hypopharynx after insertion (Yamaguchi et al., 2006).

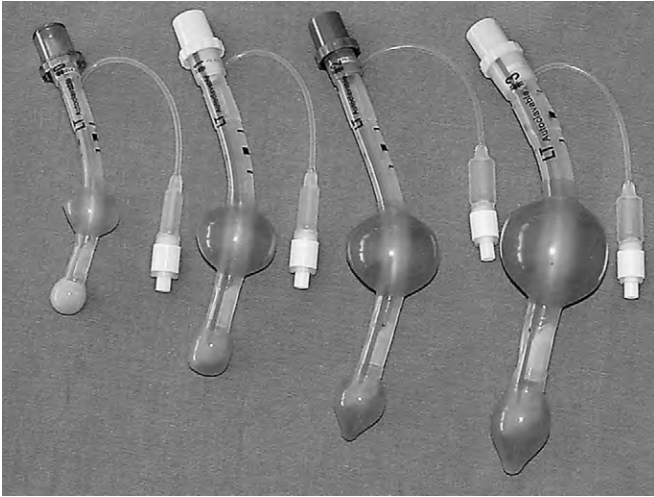

FIGURE 10-22. The laryngeal tube consists of an oval ventilation aperture placed between two distal low-pressure cuffs. The distal (esophageal) balloon is designed to seal the airway distally and protect against regurgitation. (Courtesy of VBM Medical Inc., Noblesville, Ind.)

Laryngeal Tube

The Laryngeal Tube (LT; VBM Medical; Noblesville, Indiana) is a single-lumen tube consisting of an oval ventilation aperture placed between two distal low-pressure cuffs and is inserted in a similar manner as the LMA (Fig. 10-22). The distal (esophageal) balloon is designed to seal the airway distally and protect against regurgitation. The proximal (oropharyngeal) balloon is designed to seal off the pharynx above the ventilation port. The two balloons are inflated sequentially via a unique connector at a pressure of 60 cm H₂O by using a manometer. There are seven sizes that encompass all age ranges. The LT is available in four designs: the standard LT reusable version, a disposable LT-D version, a reusable version with a gastric access channel (LTS-II), and the LTS-D, a disposable single use version with a gastric access channel (Table 10-5). Like the LMA and Cobra PLA, the LT is designed as an alternative to the anesthesia face mask and as a potential tool for providing ventilation in patients with difficult airways. It can be used during spontaneous or controlled ventilation. In adult studies, the rate of successful placement exceeds 90% (Cook et al., 2003). A prospective comparison of the LT with the LMA in children demonstrated similar insertion success rates

TABLE 10-5. Laryngeal Tube Sizing

Size	Patient	Weight/Height
0	Newborn	<5 kg
1	Baby	5-12 kg
2	Child	12-25 kg
2.5	Adult	125-150 cm
3	Adult	<155 cm
4	Adult	155-180 cm
5	Adult	>180 cm

and higher airway leak pressures with the LT (Genzwuerker et al., 2006). The LT allows higher positive inspiratory pressure than the classic LMA; like other supralaryngeal airway devices it is associated with more ventilation failures in children who weigh less than 10 kg (Genzwuerker et al., 2005). Removal of the LT in an anesthetized state reduces cough, hypersalivation, hypoxia, and tube displacement (Lee et al., 2007).

Flexible Fiberoptic Bronchoscopy

Fiberoptic intubation remains the gold standard for the management of difficult pediatric intubation. Miniaturization of fiberoptic and digital image technology has allowed the design of ultrathin bronchoscopes that facilitate intubation with tracheal tube sizes down to 2.5 mm ID (Fan et al., 1986; de Blic et al., 1991; Roth et al., 1994). In addition, the optical aspects of the equipment have improved with these smaller fiberscopes to allow better screen resolution. With the child sedated or anesthetized and breathing spontaneously, a fiberoptic bronchoscope that has been passed through a tracheal tube is inserted through the mouth or nose to visualize the larynx. The tracheal tube is advanced off the bronchoscope after its entrance into the trachea.

Some ultrathin bronchoscopes contain a working channel, but it is often too narrow to allow effective suctioning of secretions, so secretions and blood are more likely to obscure the view in smaller children. Furthermore, oxygen insufflation should be judiciously applied through this channel in small children because of the possibilities of generating dangerously high intrabronchial pressures and development of a tension pneumothorax (Iannoli and Litman, 2002).

Ventilation can be accomplished during bronchoscopy by the use of a special endoscopy mask (VBM Medical, Noblesville, Indiana) that incorporates a conduit for passage of the bronchoscope or by placement of a modified nasal trumpet in the nares.

Lighted Stylets

The lighted stylet (“light wand”) consists of a semirigid stylet with a bright light at the distal-most end (Fiberoptic Intubation Stylet, Anesthesia Medical Specialties; Santa Fe Springs, California; and Trachlight, Laerdal Medical, Armonk, New Jersey) (Fig. 10-23). The lighted stylet is prepared by inserting it inside a standard tracheal tube, the tip is then bent at a 60- to 120-degree angle, depending on the anatomy of the patient. The length of the bend may influence intubation success with the lighted stylet and should ideally be approximately equal to the distance from the thyroid prominence to the mandibular angle (Chen et al., 2003). After dimming of the operating room lights, a jaw thrust is performed with the non-dominant hand, and the lighted stylet is placed in the midline of the pharynx and advanced slowly. A characteristic glow is noted with transillumination at the cricothyroid membrane, and the tracheal tube is advanced off the stylet into the trachea. Difficulty with placement of the lighted stylet may be caused by entrapment in the vallecula or a nonmidline insertion. In this event, the stylet should be withdrawn and reoriented in the midline to reduce the risk of airway trauma before subsequent insertion attempts (Fisher and Tunkel, 1997). A transient disappearance of the transilluminated light, followed by a reappearance more distally suggests passage behind the larynx into the esophagus.

■ **FIGURE 10-23.** Using a lighted stylet, the endotracheal tube can be guided into the trachea with the use of the surface anatomy of the child and projection of the lighted stylet tip. (From Litman RS: *Pediatric airway management*. In Litman RS, editor: *Pediatric anesthesia: the requisites*, St. Louis, 2004, Mosby.)

The lighted stylet is useful when a child has an anatomically normal larynx that is difficult to visualize with direct methods. This may occur with micrognathia, temporomandibular joint disorders (or any condition that limits mandibular mobility), cervical spine instability, or facial trauma (Krucylak and Schreiner, 1992). It is particularly suited to children with limited neck and mandible mobility, but it is not useful in cases of fixed upper or lower airway obstructive pathology or in the presence of a foreign body.

Commercially made lighted stylets can be used in tracheal tubes as small as 4.5 mm ID. For small infants and neonates, a standard tracheal tube stylet can be combined with a 20-gauge fiberoptic illuminating light pipe (Storz Ophthalmics Inc., St. Louis, Missouri) attached to any standard fiberoptic light source (Davis et al., 2000). Few complications have been reported with lighted stylet use. However, arytenoid dislocation and dislodgement of the lighted stylet bulb have been described. The latter complication is less likely with newer stylet designs, and potential for arytenoid dislocation may be decreased by avoiding rotation of the stylet in the pharynx when it slides off the midline. The skill required for lighted-stylet guided intubation is easily acquired, and it remains a very useful adjunct in the management of children who present with difficult intubation.

Optical Stylets

The Shikani Optical Stylet (SOS) is a modification of the lighted stylet, which has a fiberoptic core that allows transmission of the image from the distal tip to an eyepiece (Fig. 10-24). It integrates a battery-operated light source and is manufactured in pediatric and adult versions. The pediatric version can accommodate tubes down to 2.5 mm ID. The SOS has an integrated oxygen insufflation port that allows the insufflation of oxygen. Similar to the lighted stylet, a jaw thrust with the nondominant hand facilitates the elevation of the epiglottis off the posterior pharyngeal wall and allows the SOS to be placed in the midline along the tongue base until the epiglottis and glottic opening are visualized. The device can be placed just past the vocal cords, and the tube can then be advanced into the trachea.

■ **FIGURE 10-24.** The Shikani Optical Stylet with a fiberoptic case that allows transmission of the image from the distal tip to an eyepiece.

The SOS combines the benefits of fiberoptics with a light wand and has been used successfully in patients who are difficult to intubate (Shukry et al., 2005). The SOS is limited by blood, secretions, and fogging, although fogging can be reduced by the application of an antifog solution or warming the device before use.

Bonfils Retromolar Scope

With mechanics of use similar to the SOS, The Bonfils Retromolar Scope is a rigid J-shaped optical stylet with a fixed anterior curve of 40 degrees. The manufacturer suggests a retromolar approach to the glottic opening to shorten the distance travelled to the glottis. Limited by blood, secretions, and fogging, the first-attempt success rate is reported to be about 70% in children (Bein et al., 2008).

Laryngoscopes

A variety of pediatric-sized laryngoscope blades are available (Table 10-6). The laryngoscope has three basic parts: a handle, a blade, and a light. The blade consists of a spatula, a flange, and a tip. Blades differ in length, width, and curvature. Laryngoscopes can be purchased with incandescent or fiberoptic light sources. Those with fiberoptic light sources provide extremely bright, highly focused light that occasionally can be obscured by the

TABLE 10-6. Laryngoscope Blade Types and Sizes

■ **FIGURE 10-25.** A, Miller blades and B, Phillips blades.

tongue and soft tissue. Selection of a particular laryngoscope is usually based on personal preference and experience, the size of the child, and the peculiarities of a specific airway problem.

Generally, the straight Miller or Phillips blade is used in children (Fig. 10-25). This blade allows the cephalad aspect of the larynx to be exposed more easily, because the base of the tongue can be lifted out of the line of sight, and the protruding epiglottis can be retracted with the tip. Wide blades and large-flange blades, like the Robertshaw, the Flagg, and the Wis-Hipple blades, allow the wide tongue of the small child to be flattened during laryngoscopy (Fig. 10-26) (Robertshaw, 1962). The length of a 1.5 Wis-Hipple blade is especially useful in toddlers (Fig. 10-27). For older children and young adults, longer straight blades (e.g., the Miller 2) or curved blades (e.g., the MacIntosh) allow the anesthesiologist to achieve good exposure and avoid prominent dentition (Fig. 10-28).

During laryngoscopy, neonates may rapidly develop hypoxemia secondary to apnea, decreased functional residual capacity, and increased oxygen consumption. The Oxyscope is a modified Miller blade that allows insufflation of oxygen into the pharynx and decreases the rapidity with which hypoxemia occurs during laryngoscopy (Fig. 10-29) (Todres and Crone, 1981).

Video Laryngoscopes

Video laryngoscopes of various designs are being manufactured for use in children. Much of the data regarding the efficacy of these devices comes from case reports and case series with

■ **FIGURE 10-26.** Robertshaw blade (top) and Flagg blade (bottom).

■ **FIGURE 10-27.** Two sizes of the Wis-Hipple blade are available.

very few data from prospective trials. The Bullard laryngoscope represents one of the early designs of an optically enhanced laryngoscope for pediatric use (Fig. 10-30). It incorporates fiberoptics and mirrors to provide an indirect glottic view and has been used successfully in children of all ages (Borland and Casselbrant, 1990). Video laryngoscopes can play an important role in the successful management of the child who is difficult to intubate by direct laryngoscopy. One issue that seems to apply to many of these devices is that even with full view of the glottic opening, guiding the tracheal tube into the trachea may sometimes be difficult.

Glidescope

The Glidescope (Verathon Medical, Bothwell, Washington, U.S.) is a plastic laryngoscope with a MacIntosh-style curved blade. The blade has an integrated digital video camera that transmits the image from the tip to a portable video monitor. The Glidescope Cobalt consists of a video baton with a disposable plastic blade; the camera is positioned at the inflection point of the blade, providing a wide-angled view on the monitor (Fig. 10-31) (Cooper et al., 2005). After sweeping the tongue to the

■ **FIGURE 10-28.** **A**, Miller blades. The top two blades compared with Wis-Hippel blades. Note that different manufacturers of the Miller blades have created slightly different nuances to the blade (i.e., the position of the bulb on the blade and the distance of the blade tip to the bulb). **B**, The four different sizes of the MacIntosh blade.

■ **FIGURE 10-29.** Oxyscope. This is a Miller O blade that is specially fitted; 2 to 3 L/min of oxygen is connected to the cannula on the left side of the blade, as shown. The oxygen is then directed by the lumen of this cannula into the trachea.

■ **FIGURE 10-30.** The Bullard laryngoscope allows a view of the larynx in children with limited ability to open their mouths and in cases where the larynx is positioned relatively anterior (cephalad).

left, the Glidescope is placed in the midline of the pharynx or slightly to the left to create space for the passage of the tracheal tube. Because the view of the larynx is not directly in the line of sight as in conventional laryngoscopy, a styleted tracheal tube with similar angulation as the blade or a hockey stick configuration is required for intubation and should be prepared before laryngoscopy. The manufacturer also provides a preformed rigid stylet (Gliderite Rigid Stylet) to facilitate intubation with the Glidescope. During passage of the tracheal tube, the laryngoscopist's attention should be directed to the passage of the styleted tube to minimize pharyngeal injury caused by blind advancement (Leong et al., 2008).

Storz Video Laryngoscope

The Storz Video Laryngoscope consists of a camera system that couples to several video blades. A Miller-type video blade is available for intubation in neonates and infants and has been used successfully after failed laryngoscopy in children (Hackell et al., 2009). A study in an infant mannequin compared the grade of view of the Miller-1 video blade to the standard Miller blade and demonstrated a one-grade improvement in view with the video blade (Wald et al., 2008; Xue et al., 2008; Fiadjoe et al., 2009). Because of the similarity in design of the Storz Video blades to standard blades, they allow documentation of the traditional direct laryngoscopy view while providing the option for visualization with video if the direct view is poor.

The Airtraq (Prodol Meditec SA; Vizcaya, Spain) is an indirect laryngoscope that uses a series of mirrors and prisms to provide a wide-angled view of the airway during intubation. The image is transmitted from a lens at the tip to a proximal viewfinder. The Airtraq incorporates a channel to house the tracheal tube during laryngoscopy (Fig. 10-32). The device is placed in the midline of the oropharynx, and the tip is advanced to the vallecula; the epiglottis may need to be elevated to obtain optimal exposure. Once adequate positioning has been obtained, the incorporated tracheal tube is advanced into the trachea. The Airtraq is currently manufactured in 4 sizes. The Airtraq

■ **FIGURE 10-31.** Glidescope video component (A) and blades (B). Three of the four blades are shown. From smallest to longest, the blade lengths (tip to handle) are 47, 82, and 102 mm. The widths of the camera, from the smallest to largest blade are 18, 20, and 27 mm.

■ **FIGURE 10-32.** The Airtraq, manufactured in four sizes, incorporates a channel to house the endotracheal tube during laryngoscopy.

■ **FIGURE 10-33.** A makeshift cricothyrotomy airway. Note the catheter is attached to the barrel of a 3-mL syringe. A 7.0-mm endotracheal-tube adapter is firmly placed in the barrel of the syringe. This can then be attached to an anesthesia circuit or jet ventilator.

has been reported to facilitate difficult intubation in a child; however, further study in a large cohort of pediatric patients is warranted to evaluate its efficacy (Lejus et al., 2009).

Cricothyrotomy

The need for a surgical airway is imperative if intubation fails and ventilation becomes impossible. For the anesthesiologist, cricothyrotomy is an approach to creating an airway with a percutaneous needle and a catheter. The technique involves the following five steps:

1. Skin preparation and neck extension
2. Palpation of the cricothyroid membrane
3. Needle puncture of the membrane with an intravenous catheter attached to a syringe
4. Aspiration of air, advancement of catheter, and aspiration of catheter for air
5. Attach catheter to a 3-mL syringe barrel and a 7-mm ID endotracheal-tube adapter (Fig. 10-33).

Numerous kits for cricothyrotomy are on the market (Coté and Hartwick, 2009). In truth, the usefulness of these devices in infants and small children is questionable.

Intravenous Equipment

Catheters

Intravenous catheters appropriate for the smallest premature infant and the largest adolescent patient are made by a wide variety of companies. The appropriate catheter is usually dictated

by the patient's size, expected fluid requirements, and the operator's preference. In general, a 22- or 24-gauge catheter suffices in the small infant. Patients with significant fluid requirements, such as neonates undergoing gastroschisis repair, may need two or three intravenous catheters. In older children, a 22- or 20-gauge catheter usually suffices. Butterfly needles inserted into tiny veins are not adequate for infusions during surgery because they are easily dislodged, but they are convenient for performing rapid intravenous induction in a young child or an anxious adolescent. Pain from butterfly insertion can be minimized when using a 25- or 27-gauge butterfly needle.

In accordance with Poiseuille's relationship, the resistance to flow through an intravenous catheter is related to the radius of the lumen, length of the catheter, and the viscosity of the fluid (Table 10-7). Although small differences exist between comparable catheters of various manufacturers, major flow reductions occur when they are lengthened to enable central venous cannulation (Hodge et al., 1986; Rosen and Rosen, 1986). Viscosity of the infused fluid (e.g., blood vs. crystalloid) imposes significant resistance changes only when small (smaller than 20-gauge) or long (more than 3 inches) catheters are used (Hodge and Fleisher, 1985; Rothen et al., 1992). For example, an 18-gauge catheter lengthened to 8 inches to enable central venous placement exhibits the flow characteristics of a short 24-gauge catheter.

Central venous catheters are manufactured in various sizes lengths and materials for pediatric use. Catheters are constructed from Silicone, PVC, polyethylene or polyurethane. Each of these materials has unique advantages and disadvantages; however, the most common adverse events related to catheter use are infection and thrombosis. Polyurethane catheters have been shown to have greater pressure tolerance than

TABLE 10-7. Catheter Sizes and Their Flow Rates

Catheter Size (Gauge)	Length (Inches)	Mean Flow Rate Range (mL/min)		
		Crystalloid (Gravity)	Crystalloid (Pressure)	Blood (Pressure)
24	0.75	14 to 15	42 to 47	20 to 30
22	1	24 to 26	65 to 77	44 to 50
20	1.25 to 2	38 to 42	103 to 126	69 to 81

Data from Hodge D III, Fleisher G: Pediatric catheter flow rates, *Am J Emerg Med* 3:403, 1985.

silicone catheters in experimental models and are less likely to rupture (Smirk et al., 2009). Polyurethane and polyethylene catheters may increase the risk of vessel perforation as compared with silicone and PVC catheters. Silicone catheters are soft and pliable and may be more difficult to insert percutaneously; PVC catheters are stiff on insertion and soften after insertion, making them easier to place (Welch et al., 1997; Macdonald and Ramasethu, 2007). Peripherally inserted central catheters (PICCs) catheters are typically single lumen, made from silicone or polyurethane, and available in sizes as small as 1.2 French for neonatal use. Central venous catheters are available in sizes as small as 2.5 French and are typically single or double lumen for neonatal use—triple-lumen catheters are available for older children (Macdonald and Ramasethu, 2007). Central venous access can be obtained in children using several vessels; they can be peripherally inserted into central veins (PICC lines) or can be inserted using the femoral, subclavian, or jugular veins. The central circulation can also be accessed in neonates through the umbilical vessels. The risk of complications with subclavian access is increased when compared with cannulation of the internal jugular vein. Internal jugular access is associated with less pneumothorax, less accidental arterial puncture, and fewer attempts to puncture the vein (Iovino et al., 2001). Ultrasound facilitates catheter placement in children and lessens the number of attempts for successful cannulation even in experienced operators (Verghese et al., 1999). In young children, the combination of Valsalva's maneuver, liver compression, and Trendelenburg's position produces the largest increase in jugular venous size, with Valsalva's maneuver being the most effective single maneuver to achieve this increase. The optimal positioning of central venous catheters remains a subject of debate; however, avoiding intracardiac placement decreases the risk of cardiac perforation and tamponade. Central venous placement is not without risks, including pleural effusion, pneumothorax and hydrothorax, pneumomediastinum, and hemothorax. A risk factor for perforation is catheter stiffness; the more perpendicular the catheter is with the vessel wall the higher the chance of perforation, particularly in catheters placed on the left side of the head and neck. Ideally, the catheter tip should be placed at the superior vena

cava-right atrial (SVC-RA) junction outside of the heart, and the catheter axis should parallel the axis of the vein into which it is inserted (Fletcher and Bodenham, 2000). Central catheters should be placed 1 cm outside the cardiac silhouette in premature infants and 2 cm away in full-term infants, and x-ray technology should be routinely used to diagnose catheter migration into the heart (Nowlen et al., 2002). The carina may provide an estimate of the SVC-RA junction in older children, but this may not be the case in neonates and small children (Yoon et al., 2005; Inagawa et al., 2007).

Intraosseous Access

Intraosseous access should be considered in children who need acute resuscitation and have challenging peripheral or central vascular access (ILCOR, 2005) (see Chapter 30, Anesthesia for the Pediatric Trauma Patient). The intraosseous route provides noncollapsible access to the central venous circulation, making it an ideal route to administer drugs and fluid to patients with cardiovascular compromise or shock. Onset times of drugs administered via this route are similar to those given intravenously. The preferred access site in children and infants is the anteromedial surface of the tibia, approximately 1 to 2 cm below the tibial tuberosity. Other sites that have been successfully used include the sternum, the iliac crest, the distal radius, and several others. Several companies manufacture intraosseous needles; however, access may be obtained with any styleted needle. Spinal needles of 18 or 20 gauge have been successfully used for access. After sterile preparation of the chosen site, the needle is inserted perpendicular to the skin and advanced using a rotating motion until a loss of resistance is felt. Once seated, the stylet may be removed, and successful positioning is confirmed with aspiration of marrow and the ability to flush without extravasation. Risks of intraosseous access placement include infection, extravasation of fluid and medication, injury to the growth plate, and fracture (Tobias and Ross, 2010).

A number of studies have determined that needleless intravenous catheters reduce the rate of needlestick injuries by up to 60% (Orenstein et al., 1995; Needlestick, 2000). In 2001, the U.S. Occupational Safety and Health Administration (OSHA) authored the Needlestick Safety and Prevention Act (HR 5178), which provides a legislative mandate that health-care facility employers provide employees with safety-engineered sharp devices (Federal Register on January 18, 2001).

Infusion Sets

Intravenous infusion sets must also be tailored to the patient and the planned surgical procedure. Microdrip infusion sets (60 drops/mL) allow the anesthesiologist to more accurately deliver small volumes of infusate to the small child compared with the standard 15 drops/mL infusion set. For an older child (older than approximately 10 years), the standard adult infusion set is adequate. The addition of extension tubes to all pediatric infusion sets permits the intravenous catheter to be placed in any available extremity and allows a small child to be moved down on the operating table for better surgical access. Insertion of multiple stopcocks in the infusion tubing allows precise volumes of blood or colloid to be administered and minimizes the need to use needles to access the infusion. The blood set is attached to the stopcock closest to the patient, and

a syringe is placed in the stopcock farthest from the patient. The stopcocks are opened to allow blood to flow into the syringe and then adjusted to allow an accurate volume of blood to be infused from the syringe into the patient. Before their use, all infusion sets should be “de-bubbled” to prevent air entrainment into the circulation, a task especially important in a premature infant, who is likely to have a patent foramen ovale or patent ductus arteriosus, or in a child with a known intracardiac defect or persistent patent foramen ovale. To decrease the incidence of accidental needlestick injuries, all manufacturers now offer injection ports throughout the length of the tubing that are accessible with standard syringes or specialized blunt adaptors. When these ports are accessed, care must be taken to avoid trapped air that often accumulates in these ports.

In the face of significant hypovolemia that results from brisk blood loss or other causes of severe intravascular volume depletion, the rapid infusion of blood or crystalloid may prevent an impending disaster. The speed of infusion is directly related to the driving pressure of the infusate and the resistance of the infusion. Unless small-bore infusion tubing is used to minimize infusion dead space, resistance of the infusion circuit is mainly related to the length and diameter of the intravenous catheter. Short catheters with large, IDs have less resistance than longer catheters with smaller diameters, irrespective of peripheral or central placement (Hodge and Fleisher, 1985). The driving pressure of the intravenous solution depends on the height of the fluid bag, gravity, or the mechanical force used to push the solution. A simple method to increase the fluid administration rate in neonates and small children uses the push-pull technique, as noted above. By drawing blood or fluid into a syringe, the fluid can be “pushed” into the patient with significant speed, especially in children weighing less than 40 kg (Stoner et al., 2007). Drawbacks of this technique include the need to manually perform the task and risk of infection that may increase as the same syringe is used repeatedly. Advantages include the ability to accurately deliver fluid at a brisk rate while manually sensing changes in system resistance that may indicate an intravenous catheter infiltration.

Pressurizing or mechanically pumping an intravenous solution or blood also dramatically increases the rate of infusion. By placing an inflatable sleeve over the infusion solution bag, the driving pressure of the solution can be markedly increased. By using a hand pump (C-Fusor, Smith Medical North America, Dublin, Ohio; Infu-Surg, Cardinal Health; Dublin, Ohio), the sleeve can be inflated incrementally to 300 mm Hg to drive blood or intravenous solution into the patient. Disadvantages with this system include the need to hand-inflate the pressurization device, the inability to accurately deliver small volumes of infusate, infiltration of infusate outside of the vein, and the risk of unintended infusion of air causing an air embolism (Linden et al., 1997). Special attention to removing residual air from the blood or infusion bags before spiking the bag is necessary. Before using a rapid-infuser system, the intravenous

line should be checked for free flow and patency of the vein. Accuracy of infusion volumes can be increased by using the pressure system to fill a push-pull syringe that has been set up instead of having to manually fill the syringe. Any residual air can be removed using the syringe system. Automated pressure infusers (Level 1 H-1200, Smith Medical North America, Dublin, Ohio; Ranger A1400, Arizant Healthcare; Prairie, Minnesota) eliminate the need for manual inflation through the use of high pressure air or electrical power to create the driving pressure. These devices have fluid warmers and air detectors as integral parts or as accessories and can deliver large volumes of warmed fluids rapidly through special, disposable infusion sets. Roller pump technology has also been used to rapidly infuse blood or intravenous solution. Integrated with an electromagnetic heater, air detector, and electronic flow control, high volumes of warmed fluids can be accurately delivered using this technology (Belmont Rapid Infuser; Billerica, Massachusetts). Because the risk of air is greater with high-pressure infusers, it is crucial that any automated apparatus used stops delivery of fluid if air is detected in the line. Hemolysis and hyperkalemia may also be a concern if rapid infusers are used to deliver blood through 24-gauge intravenous catheters (Miller and Schlueter, 2004).

SUMMARY

Advances in medical technology have resulted in the design and production of a plethora of new equipment for the care of the child. This proliferation comes with many challenges. Careful organization and supervision of anesthesia supply rooms are essential to prevent the presence of expired supplies or nonfunctional equipment, as well as ensure that supplies are not out of stock. Equally as important is the need to standardize certain types of supplies or equipment, from both cost and knowledge perspectives. Having multiple pieces of equipment or supplies that perform the same or nearly the same function is costly to buy and stock. Even more critical is the need to maintain the clinical competency of each anesthesia provider in the use of the variety of specialized equipment, and this is something that is exceedingly difficult as the variety of equipment and supplies expand. Recurrent educational opportunities may be needed, particularly for devices that are rarely used. Lack of familiarity caused by small differences in a particular piece of equipment may impede function, especially in an urgent or emergent situation. Simplifying equipment and supply lists as much as possible is warranted, although safe and effective clinical care demands an extensive selection for the pediatric anesthesiologist.

MONITORING

Most studies that have determined the rate of cardiac arrests resulting from anesthesia have found a threefold to fivefold greater risk among children than adults (Graff et al., 1964; Keenan and Boyan, 1985). In children younger than 1 year, the incidence increases to 9.2 to 17 per 10,000 anesthetics, or 10 times the adult incidence (Olsson and Hallen, 1988; Cohen et al., 1990). Factors contributing to cardiac arrests in anesthetized children are likely to be related to the cardiovascular or respiratory system (Salem et al., 1975). Flick and others (2007) have reviewed cardiac arrest data at the Mayo Clinic. The incidences of cardiac arrest and mortality during noncardiac procedures were 2.9:10,000 and 1.6:10,000, respectively. However, the incidence of cardiac arrest in children undergoing cardiac operations was 127:10,000. The incidence of other serious complications is also greater for infants than for adults in the operating room (Tiret et al., 1988) and in the postanesthesia care unit (PACU) (Cohen et al., 1990). These data indicate that children are a high-risk population and should be monitored with particular attention to cardiovascular and respiratory variables.

Guidelines for the intraoperative monitoring of patients under anesthesia have been published by the American Society of Anesthesiologists (ASA) (2005) (see Box 10-1). These standards mandate the continuous presence of an anesthesiologist or a nurse anesthetist throughout the conduct of anesthesia

and require continuous monitoring of oxygenation, electrocardiographic status, and adequacy of ventilation and circulation. The minimum standard for monitoring oxygenation includes an oxygen analyzer in the anesthesia breathing circuit, sufficient illumination to evaluate the patient's color, and a quantitative method such as pulse oximetry, except under extenuating circumstances. Tracheal intubation must be verified by physical examination and the qualitative detection of carbon dioxide in the exhaled gas. Regardless of whether endotracheal intubation has been performed, continuous capnography is required unless it is invalidated by the nature of the patient, procedure, or equipment. Furthermore, quantitative monitoring of the volume of expired gas is strongly encouraged. The ASA also recommends monitoring of ventilation using observation of chest excursion and the reservoir breathing bag, as well as auscultation of breath sounds. When ventilation is controlled by a mechanical ventilator, there should be in continuous use a device that is capable of detecting disconnection of components of the breathing system, and the device must give an audible signal when its alarm threshold is exceeded.

ASA monitoring standards for circulation mandate that every patient receiving anesthesia have continuous electrocardiography (ECG), and determination of arterial blood pressure and heart rate at least every 5 minutes. In addition, every patient's circulatory function should be evaluated continually, using at least one of the following methods: palpation of a

pulse, auscultation of heart sounds, monitoring of an intraarterial pressure tracing, ultrasound peripheral pulse monitoring, and pulse plethysmography or oximetry. Finally, a method by which temperature can be measured should be readily available, and the patient's temperature should be monitored when clinically significant changes in body temperature are intended, anticipated, or suspected.

Many of these provisions have been extended to the PACU. In standards adopted by the ASA in 1988 and updated in 2009, PACU monitoring should emphasize oxygenation, ventilation, circulation, and temperature assessment, with specific capability for quantitative determination of systemic oxygenation by pulse oximetry or its equivalent. Equipment should be readily available to enable the practitioner to meet these standards in all pediatric patients. The anesthesiologist is the ultimate monitor.

Physical Examination

Observation

The anesthesiologist can gain a tremendous amount of information from observation alone. Anesthetic depth can be inferred from the rate and pattern of respiration, and airway obstruction can be detected by chest wall retractions or "saw-saw" paradoxical motion. The skin and mucous membranes should be continually assessed to confirm adequate oxygenation, because a pulse oximeter reading can significantly lag behind other indices of hypoxemia when placed on an extremity (Reynolds et al., 1993), or it may not detect a pulse at all during intense vasoconstriction. In rare circumstances, pulse oximetry falsely indicates normal saturations during hypoxic conditions (Costarino et al., 1987).

Capillary refill can provide valuable information about the intravascular volume and cardiac output of a eutermic patient. A child with cool, mottled, poorly perfused extremities should be examined closely for additional evidence of hypovolemia or reduced cardiac output even if the systemic arterial pressure remains normal. Progression of this mottled appearance onto the trunk indicates the extreme vasoconstriction that may herald imminent cardiovascular collapse.

Auscultation

Continuous auscultation of heart and lung sounds by means of a precordial stethoscope is useful during all phases of general anesthesia, as well as during transport of the child between hospital locations. A precordial stethoscope allows the anesthesiologist to immediately detect changes in the rate and character of heart and breath sounds, and it often gives the first warning of a physiologic alteration (e.g., right main bronchial intubation, wheezing). Crisp heart tones are produced by the flow of blood through a briskly contracting heart. Myocardial depression initially results in a muffled and then in a distant quality to the heart tones. Careful auscultation may reveal arrhythmias or murmurs such as the mill-wheel murmur that results from a venous air embolus.

When selecting and placing a precordial or an esophageal stethoscope, one should consider the nature of the planned surgery, the proposed anesthetic, and any underlying patient condition that may affect auscultation. Breath sounds and heart tones are best heard when a precordial stethoscope is positioned near

the left sternal border between the second and fourth interspaces (above the nipple line). An esophageal stethoscope is reserved for patients whose anesthetic management includes endotracheal intubation and in whom a precordial stethoscope either provides inadequate information or violates the surgical field. The proper method for accurate placement of the esophageal stethoscope is to listen while simultaneously advancing the device and placing it at the level where the heart and lung sounds are maximal. In small infants, unintentional placement of the esophageal stethoscope into the stomach can easily occur.

Esophageal stethoscopes are contraindicated in patients with esophageal atresia or in those who have a disease process involving the proximal portion of the esophagus. They confer a rigid feel to the esophagus, which might be mistaken for the trachea (Schwartz and Downes, 1977). As a result, the esophageal stethoscope is relatively contraindicated in neck dissections where the trachea is a critical landmark, such as a tracheostomy.

Electrocardiography

In pediatric anesthesia, ECG is most useful for tracking the heart rate and diagnosing intraoperative rate-related arrhythmias, of which the two most common are bradycardia and supraventricular tachycardia. ECG is much less prone to movement-related artifact than the original pulse oximeter, although new pulse oximeter devices have eliminated most motion artifacts. In small infants, hypoxemia-related bradycardia may occur before the pulse oximeter reveals oxyhemoglobin desaturation. Conversely, resolution of hypoxemia is heralded by the transition from bradycardia to normal sinus rhythm. Premature ventricular contractions are commonly observed when halothane is used as the general anesthetic agent, especially during periods of hypercapnia or catecholamine release. The precordial stethoscope as a single monitor provides a much better indication of cardiac contractility and thus the overall hemodynamic status.

Electrolyte abnormalities may also be uncovered through the use of ECG. Hyperkalemia produces the characteristically prominent T waves. Hypocalcemia, which may occur during rapid administration of citrated blood products, prolongs the QT interval. Because ischemic changes in normal pediatric patients are rare, and because lead II provides a good view of atrial activity for arrhythmia diagnosis, the latter is recommended for the routine intraoperative electrocardiographic monitoring of pediatric patients.

In children, the normal heart rate varies with age (Table 11-1). The normal heart rate of the newborn ranges from 120 to 160 beats per minute, although lower rates (e.g., 70) are frequently observed during sleep, and higher rates (>200) are common during anxiety or pain. Heart rates tend to decrease with age and in parallel with decreases in oxygen consumption. In addition, many children have a noticeable variation in heart rate with respiration (i.e., sinus arrhythmia).

Systemic Arterial Pressure

Noninvasive Measurement

Blood pressure is easily measured noninvasively in children and small infants using oscillometry. In children, oscillometric measurements of systolic arterial pressure (Bruner et al., 1981;

TABLE 11-1. Normal Resting Heart Rates of Infants and Children

Age	Heart Rate (beats/min)	
	Mean	Range (± 2 SD)
0 to 24 hr	119	94 to 145
1 to 7 days	133	100 to 175

Friesen and Lichtor, 1981) and mean arterial pressure (Kimble et al., 1981) usually correlate well with the Riva Rocci mercury column method, as well as with direct arterial pressure measurement, but oscillometric measurements tend to underestimate the diastolic component. During routine uncomplicated cases, measurement of blood pressure should be performed every 3 to 5 minutes while the child is anesthetized—determinations that are too frequent can result in limb ischemia. The blood pressure cuff is most commonly placed on the upper arm but can be placed on the forearm, thigh, or calf. There is inconsistent correlation of measurements obtained between the upper and lower limbs.

The width of the blood pressure cuff should cover approximately two thirds of the total length of the upper arm (or other extremity portion to which it is applied). A cuff that is too small or too narrow incompletely occludes the artery, resulting in the premature return of detectable flow and hence falsely increasing the pressure measurement (Park et al., 1976; Kimble et al., 1981). The error can be as great as 30 mm Hg. A cuff that is too wide can dampen the arterial wave and result in a falsely low pressure, but the magnitude of this error is small (Kimble et al., 1981). Blood pressure increases gradually throughout childhood (Figs. 11-1 and 11-2) and depends on the height of the child: taller children demonstrate a higher blood pressure (Table 11-2). Blood pressure ranges in premature infants have been defined (Table 11-3) and vary depending on the health status of the infant and mother.

Direct Measurement

Direct measurement of blood pressure via an arterial catheter is indicated when there is a need for precise beat-to-beat blood pressure monitoring or for frequent determination of arterial blood gas values. This patient population may include children who are expected to develop unstable hemodynamics or those undergoing a surgical procedure that could result in profound hemodynamic alterations related to blood loss (i.e., total loss >50% estimated blood volume [EBV], or acute loss >10% EBV), fluid shifts (i.e., third space losses >50% EBV), deliberate

FIGURE 11-1. Age-specific percentiles of blood pressure measurements in boys, from birth to 12 months of age. Values for girls are slightly lower. hypotension, or nonpulsatile blood flow (e.g., cardiopulmonary bypass [CPB]). The respiratory indications for direct arterial monitoring include significant abnormalities in gas exchange caused by either preexisting disease or the procedure (e.g., thoracotomy). Rarely, direct arterial monitoring is necessary because of the inability to measure systemic arterial pressure by any indirect technique.

There are no absolute contraindications to placing an arterial catheter, but a risk-benefit analysis should be performed in patients with a hypercoagulable state or bleeding disorder. The radial artery is a favored site for arterial cannulation because the vessel is superficial and easily accessible. Other anatomic sites frequently used are the ulnar, dorsalis pedis, posterior tibial, and femoral arteries. The axillary artery has gained favor because of increased collateral blood flow compared with the brachial or femoral artery (Lawless and Orr, 1989; Cantwell et al., 1990; Greenwald et al., 1990; Piotrowski and Kawczynski, 1995). In general, the brachial artery should be avoided because of the risk for median nerve damage and poor collateral flow around the elbow. Umbilical vessels are an alternative site for cannulating the aorta and inferior vena cava in neonates. In determining a site, one needs to consider the history of that vessel (i.e., whether it has been cannulated before), its collateral flow, the experience of the person inserting the catheter, and special physiologic issues (e.g., whether it arises on an aortic root proximal to the ductus arteriosus) or surgical issues

†Values are mean ± standard deviation.

(e.g., whether it arises from a vessel likely to be clamped or sacrificed during the procedure). Cannulation of vessels with good collateral flow, such as the arch vessels of the wrist or foot, may reduce the risk for ischemic tissue damage distal to the catheter.

As the largest superficial vessel, the femoral artery can be cannulated most predictably in situations when intense peripheral vasoconstriction may accompany low cardiac output and blood pressure. In less dire circumstances, the selection of a vessel may reflect a variety of anatomic and physiologic characteristics exhibited by certain vessels. The pedal vessels exhibit pressure wave amplification that results in pressure determinations exceeding aortic values by as much as 30% (Park et al., 1983).

After palpation and localization of the artery with the non-dominant hand, one can cannulate the selected artery either by inserting the catheter directly into the artery using a catheter-over-needle device or by using the Seldinger technique. The Seldinger technique involves entering the vessel with a needle, placing a guidewire through the needle after the vessel is entered, removing the needle, and then placing the catheter over the wire into the vessel. A 22-gauge catheter is appropriate for peripheral artery cannulation in infants and children younger than 5 years, whereas a 20-gauge catheter may be substituted in older children. Aseptic technique should always be followed when placing an arterial line. When cannulating a peripheral artery, it is helpful to immobilize the extremity with a board.

A Doppler flow transducer is occasionally useful to locate an artery that is difficult to palpate. Surgical cutdown may be the preferred option when percutaneous placement is likely to be difficult or has failed. Indwelling arterial catheters are associated with several possible complications. Proximal emboli, distal ischemia, arterial thrombosis, and infection are common to all sites. Thrombosis of the radial artery is generally temporary, although it is more likely to persist after a cutdown (Miyasaka et al., 1976). Although small flush volumes (0.3 mL) in radial arterial catheters can be detected in the aortic arch vessels, cerebral infarcts have not been reported (Edmonds et al., 1980). The tip of an umbilical artery catheter should be placed in either a high (above the diaphragm) or a low (below L3) position to

avoid direct flushing into the renal arteries. Despite these precautions, as many as 10% of neonates exhibit hypertension as a late complication attributed to umbilical artery catheterization (Bauer et al., 1975; Plumer et al., 1976; Horgan et al., 1987). Minor complications of umbilical artery monitoring include vasospasm of the lower extremity vessels, which are more common with low tip placement. Major complications (e.g., necrotizing enterocolitis, renal artery thrombosis) occur independent of location (Mokrohisky et al., 1978; Umbilical Artery Catheter Trial Study Group, 1992). The rarity of clinical complications is remarkable given that the incidence of aortic thrombosis on removal of umbilical artery catheters approaches 95% in some series (Neal et al., 1972), although most series define the incidence at 12% to 31% of neonates (Symansky and Fox, 1972; Horgan et al., 1987; Seibert et al., 1987).

Systolic Pressure Variation

Systolic pressure variation is a noninvasive way to determine volume status and fluid responsiveness. It is defined as the difference between the maximal and minimal values of systolic blood pressure during a positive pressure breath. Initially during a positive pressure breath, there is a transient increase in systolic blood pressure (delta up) followed within four or five beats by a decrease in systolic blood pressure (delta down). Increases in intrathoracic pressure during positive pressure ventilation cause a decrease in systolic blood pressure because of decreased preload to the right ventricle, increased afterload to the right ventricle, and decreased afterload to the left ventricle. This decrease is greater during hypovolemia. Systolic pressure changes in response to respiratory variation have been used to determine hypovolemia (Greilich and Johnston, 2007).

The difference between the maximal systolic blood pressure and minimal systolic blood pressure during a respiratory cycle can help predict volume status. In fact, when this value is divided by the mean of the two systolic pressure values, it provides a percentage of respiratory change in arterial pulse pressure. The equation for this calculation is as follows:

$$\Delta PP\% = 100 \times (\text{maximum systolic pressure} - \text{minimum systolic pressure}) \div [(\text{maximum systolic pressure} + \text{minimum systolic pressure})/2]$$

where $\Delta PP\%$ is respiratory change in pulse pressure (mm Hg).

Michard and others (1999) demonstrated a strong relationship in adult ventilated patients between pulse pressure changes and cardiac output. Patients with pulse pressure changes (ΔPP) that are greater than 10% may be fluid responsive and benefit from the administration of intravenous fluids.

Changes in the pulse oximetry waveform (plethysmographic waveform amplitude) have been shown to predict fluid responsiveness (Pizov et al., 2010). Bedside use of this variable is challenging. The "pleth variability index" (Masimo Corp., Irvine, CA) automatically calculates the waveform amplitude variation and may predict fluid responsiveness noninvasively (Cannesson et al., 2008a, 2008b).

Central Venous Pressure

There are four relative indications for central venous catheterization: inadequate peripheral venous access, central venous pressure monitoring, infusion of hyperosmolar or sclerosing

substances, and a planned operative procedure with a high risk for hemodynamically significant venous air embolism. There is no absolute indication for central venous pressure monitoring in pediatrics. Unlike direct systemic arterial pressures, central venous pressure itself rarely provides the sole basis for therapeutic action. It does, however, provide useful information that, taken together with other data, help to form a management plan. The procedures for which this monitoring deserves consideration include large estimated blood loss or fluid shifts (>50% EBV), deliberate hypotension, cardiac surgery with CPB, situations in which the usual signs of hypovolemia are likely to be misleading (e.g., renal failure, congestive heart failure), and procedures with expected moderate blood loss or fluid shifts. The normal values for central venous pressure in children are similar to those in adults (mean, 2 to 6 mm Hg).

Every insertion site that has been used in adults can be used in children. Access to the central circulation can be achieved from the internal and external jugular, subclavian, basilic, umbilical, and femoral veins. The site selected depends on the experience of the operator and the indication for the catheter. If venous access is the only requirement, one might elect to use visible veins (e.g., basilic, external jugular) or those with a lower risk for complications (e.g., femoral). Situations that require true intrathoracic central venous placement also require placement of the catheter into the internal jugular vein or subclavian vein. The umbilical vein can be used in neonates for volume resuscitation, but the high frequency with which these catheters enter the branch portal veins introduces a significant risk for permanent liver injury if sclerosing or hyperosmolar solutions are infused. Because a catheter tip can erode through the wall of the right atrium, care must be taken to avoid intracardiac tip placement. The catheter should be advanced only until the orifice lies in the intrathoracic great vessels, and its position should be confirmed radiographically.

Catheters of various sizes (2.5 to 10 French), lengths, and composition are available for pediatric applications (Cook Critical Care, Bloomington, IN, and other companies). Selection is based on the size of the patient (Andropoulos et al., 2001) and the purpose of the catheter. The composition of the catheter depends on its intended use. Teflon is fairly resistant to thrombus formation, but concerns about perforation by catheters have prompted the development of softer catheter materials, especially for long-term use (e.g., Silastic and polyurethane). The catheters are generally inserted via the Seldinger technique, using landmarks that are similar to those used in adults.

There are no absolute contraindications to placing a central venous catheter, but each site has potential risks. All sites share the common complications of infection (site cellulitis, bacteremia), venous thrombosis with potential emboli, air embolism, catheter malfunction (occlusion, dislodgment, or fractures), dysrhythmias (when the catheter tip is in the heart), and bleeding. Universal precautions and sterile technique should be used when placing a central venous catheter. The risks involved in cannulating the internal jugular vein include carotid artery puncture, Horner's syndrome, pneumothorax, and injury to the thoracic duct when the left internal jugular vein is cannulated. The high approach to the internal jugular vein, at the midpoint of the sternocleidomastoid muscle, results in comparable success with fewer complications than lower approaches (Coté et al., 1979). Two-dimensional ultrasound scanning improves localization of the internal jugular vein and increases the success rate of central venous cannulation in adults and children

(Verghese et al., 2002; Hind et al., 2003). Using this device, Alderson and others (1993) reported an 18% prevalence of anatomic variations in children younger than 6 years that would preclude or significantly hinder the successful cannulation of the internal jugular vein using anatomic landmarks alone. In addition, Hong and colleagues (2010) reported that rotating the head away from the neutral position increases the degree of carotid artery and internal jugular vein overlap, and decreases the incidence of lateral positioning of the internal jugular vein to the carotid artery.

Mixed Venous Oxygenation and Monitoring

Mixed venous oxygenation is defined as the oxygenation saturation or content of venous blood from the pulmonary artery. The collection of a mixed venous sample requires a pulmonary artery catheter. The Fick equation for mixed venous oxygen saturation (Sv_{O_2}) depends on four variables: oxygen consumption ($\dot{V}O_2$), cardiac output, hemoglobin, and arterial oxygen saturation.

Normal values for mixed venous saturation range from 65% to 75%. A decrease in Sv_{O_2} occurs because of increased oxygen consumption (stress, pain, hyperthermia, shivering) or decreased oxygen delivery (anemia, decreased cardiac output, decreased Pao_2 , decreased Sao_2). An increase in Sv_{O_2} occurs because of a decrease in $\dot{V}O_2$ (hypothermia, anesthesia) or an increase in oxygen delivery (increased hemoglobin, increased cardiac output, increased Pao_2 , increased Sao_2). Mixed venous oxygenation is used to assess the balance between oxygen delivery and oxygen consumption for patients in the operating room and intensive care unit. It is a global index of tissue oxygenation.

A significant limitation of mixed venous saturation is that it requires the collection of blood from the pulmonary artery. This is a particular limitation in the smaller pediatric patients. Blood from the superior vena cava (central venous saturation [Scv_{O_2}]) and right atrium have been investigated as possible surrogate markers for mixed venous oxygen saturation, with mixed results.

Dueck and coworkers (2005) found a significant variation between central venous saturations and mixed venous saturations in the same patient, so individual values of Scv_{O_2} cannot be substituted for Sv_{O_2} values. However, although the absolute values do not correlate, there is a correlation between the trends in Scv_{O_2} values and in Sv_{O_2} values. Perez and colleagues (2009), in a retrospective pediatric study, identified a correlation between right atrial and mixed venous oxygen saturations. Scv_{O_2} is used clinically in pediatric patients. Continuous monitoring of Scv_{O_2} can be performed in neonates, infants, and children.

In infants, continuous monitoring of Scv_{O_2} can be achieved with a fiberoptic probe. One type of fiberoptic probe is designed as a percutaneous catheter from CeVOX (Pulsion Medical Systems AG, Munich, Germany). This 2-F probe is 31 cm in length and measures central venous oxygen saturations using spectrophotometry. Muller and coworkers (2007) described placing the catheter percutaneously through a 16-gauge single-lumen catheter in the femoral or subclavian vein. There were only three patients in this study, so accurate correlation with central venous blood samples cannot be determined.

The PEDIASAT system (Edwards Life Sciences) has been described in infants and children having orthopedic, craniofacial, and cardiac surgery. It comes in four sizes (4.5 F, 5 cm; 4.5 F, 8 cm; 5.5 F, 8 cm; and 5.5 F, 15 cm) and provides continuous readings of central venous oxygen saturation. Liakapolous and colleagues (2007) and Ranucci and colleagues (2008) demonstrated good correlation between Scv_{O_2} values from the PEDIASAT system when compared with co-oximetry values obtained from blood samples drawn from the distal port.

Artifact may limit the clinical usefulness of Scv_{O_2} catheters for intraoperative care. Manipulation of the catheter by the surgeon when the chest is open or direct light from the surgeon's headlight may alter the readings of the catheter.

Pulmonary Artery Catheters

Since its introduction in 1970, indications for the use of the flow-directed balloon-tipped pulmonary artery (Swan-Ganz) catheter in pediatric patients have been slow to evolve. Although the validity and value of the data that these catheters generate remain controversial in pediatrics, the technical difficulties and complications associated with their use are significant. Pulmonary artery pressure measurement can help guide therapy in children with elevated or volatile pulmonary vascular resistance, but the interpretation of the flow data they generate is hindered by several factors. First, the desired cardiac output varies according to age, disease state, and other elements of management that alter metabolic demand in complex ways, thereby introducing significant uncertainty in assigning a target value. Second, the prevalence of intracardiac communications that permit shunting of blood causes discrepancies in pulmonary and systemic blood flow that may vary continuously and are difficult to quantify. Finally, despite several studies demonstrating reasonable accuracy when thermodilution is compared with other methods of flow determination, such as the Fick equation (Freed and Keane, 1978) and dye dilution (Colgan and Stewart, 1977), the precision of these determinations in small infants is low and has a 25% intersample variability. In patients with congenital heart malformations, for example, measurement errors are introduced by shunting and complex anatomy, and the risks of improper placement of the flow-directed pulmonary artery catheter are increased. Alternatively, directly placed pulmonary artery catheters can provide the necessary information regarding pulmonary vascular resistance and residual left-to-right shunts, and left atrial catheters reflect filling and diastolic function of the left ventricle after cardiac surgery.

In some situations, pulmonary artery catheters provide useful information. In children who have severe coexisting pulmonary and circulatory failure, pulmonary artery catheters can help to quantify the hemodynamic impact of extreme respiratory support measures and guide complex fluid and pharmacologic regimens. They may also be useful in patients with underlying pulmonary hypertension or poorly compensated left ventricular dysfunction who undergo acute surgical stress (e.g., arteriovenous malformation clipping or aortic cross-clamping). Given the uncertainty about optimal systemic flow in a given child, mixed venous oxygen saturation may serve as a better indication of global perfusion. In the absence of left-to-right shunts, this sample is best obtained from the pulmonary artery.

Pulmonary artery catheters can be difficult to insert, especially in infants or in children with low cardiac output. They may be placed in any vein used for access to the central venous system, but the most reliable veins are the right internal jugular and the femoral. In infants and children smaller than 15 kg, it is technically difficult to place an introducer sheath in the neck vessels; the femoral veins are preferable. Multilumen catheters capable of thermodilution are available in two sizes, 5 and 7 F, with four options for the right atrium-to-pulmonary artery interluminal distance. Catheter recommendations are based on age (Table 11-4). The proper placement of these catheters can take a long time, and thus the assistance of fluoroscopy is recommended for infants and children less than 30 kg and for larger children who have a low cardiac output.

The risks of balloon-tipped pulmonary artery catheters are numerous and include the risks of central venous catheter placement discussed previously, as well as the complications seen in adult patients with pulmonary artery catheters: infection, air emboli, thrombus, pulmonary artery rupture, acute right bundle branch block, and intracardiac knots. Other complications are more common with children: misleading information, paradoxical systemic emboli, disruption of an intracardiac repair, and high-grade right ventricular outflow tract obstruction because of the relatively large balloon diameter. The presence of intracardiac and extracardiac malformations may result in an aberrant catheter course, leading to incorrect data and an increased risk for systemic emboli.

Cardiac output can be estimated in children through indicator dilution (e.g., thermodilution or dye dilution) and noninvasive techniques. Doppler determinations of aortic blood velocity can be used to quantify systemic flow if the angle of the incident ultrasound beam and the cross-sectional area of the aorta are reliably determined (Alverson et al., 1982). Transthoracic and transesophageal evaluations of Doppler cardiac output in children have proved to be less promising (Notterman et al., 1989; Muhiudeen et al., 1991). Thoracic bioimpedance, a method that estimates stroke volume on the basis of changes in thoracic impedance, has been applied to children as small as 3.6 kg. Although some correlation exists between bioimpedance and indicator dilution methods, reproducibility is poor (O'Connell et al., 1991). Further details and the complexities encountered in the measurement of cardiac output in children are beyond the scope of this chapter but have been reviewed previously (Tibby and Murdoch, 2002).

A noninvasive cardiac output monitor has been developed that determines cardiac output via the Fick principle for rebreathed CO₂ (Respironics; Novamatrix Medical Systems Inc., Wallingford, CT) (Capek and Roy, 1988). The noninvasive cardiac output monitor has been clinically validated in adults and

is approved by the U.S. Food and Drug Administration (FDA) for use, but it requires tidal volumes of 200 mL or greater (Guzzi et al., 2003; Watt et al., 2004).

Transesophageal Echocardiography

The value of transesophageal echocardiography (TEE) for monitoring hemodynamics and to evaluate preoperative and postoperative cardiac anatomy has been appreciated from the time of its introduction to the operating room. In the infancy of TEE in the late 1970s, an M-mode transducer was passed into the esophagus, plotting the distance of structures from the transducer on the y-axis and time on the x-axis (Frazin et al., 1976). Although they provided valuable information, M-mode images were too limited alone. In 1982, Schlüter and colleagues (1982) described their experience using a transducer capable of two-dimensional images mounted on a gastroscope. The usefulness of the images obtained was readily apparent, and since that time technology has catapulted the field of TEE to the forefront of cardiovascular monitoring. Now, multiple companies (Phillips, Acuson/Siemens, General Electric) manufacture advanced TEE-specific probes capable of two- and three-dimensional imaging on top of the original M-mode. Doppler has also been incorporated, providing the examiner the ability to extrapolate vast amounts of information from their patients.

The probes use ultrasound waves generated by the vibration of piezoelectric crystals in the tip of the transducer. These waves have frequencies between 2.5 and 7.5 MHz. The wave's ability to travel through tissues depends on the specific density of the tissues. Differences in impedance cause some of the energy generated by the crystals to be reflected and allow some to continue on to the next tissue plane until all the energy has dissipated. If the impedance is too great, as is the case with bone, all of the energy will be reflected. Images are then generated on the basis of the time from the impulse and the remaining energy found in the waves as they return to the transducer.

The quality of the image depends on a number of factors. The closer structures are to the transducer, the greater is the intensity of the image. Transducers with higher frequencies have less penetration than lower-frequency transducers; thus, if one is trying to visualize structures far away, a lower frequency provides better imaging. Images can also be adjusted with gain, so that unwanted echoes in the near field may be dampened and echoes in the far field enhanced.

Doppler technology uses low-intensity ultrasound reflected from moving columns of blood. The frequency of the returning echo is analyzed and estimations of direction and velocity are made. Accuracy of the estimation depends on the direction of flow relative to the direction of the beam. Parallel orientation provides the most accurate values, and increases in the angle of measurement falsely lower the predicted velocities. Measurements taken at angles greater than 20 degrees have a significant amount of error. Both pulsed-wave Doppler, if one is interested in determining velocity at a specific location, and continuous wave, to identify the highest velocity across an entire line of sight, are available for use during a TEE examination.

A modification of the Bernoulli equation allows an examiner to estimate pressure gradients using the measured velocities. Simplified, the change in pressure between two points is equal to four times the maximum velocity squared (Holen et al., 1977; Hatle et al., 1978). Using this principle, the stenosis of valves,

TABLE 11-4. Guidelines for Multilumen Pulmonary Artery Catheters for Infants and Children

Age (yr)	Catheter Size (F)	CVP to Pulmonary Artery Port Distance (cm)

3 to 8	5	15
8 to 14	7	20
>14	7	30

severity of aortic coarctation, obstruction caused by muscle bundles or membranes, and a multitude of other clinical questions can be answered.

TEE has played a vital role in improving outcomes in pediatric patients with congenital heart disease. Typically, examinations are performed preoperatively to confirm anatomy, and postoperatively to assess repairs and evaluate function. One study looking at 865 consecutive examinations demonstrated alterations to surgical plans based on preoperative TEE examinations in 2% of patients. The same study found that 12% of patients had post-bypass examinations that led to surgical interventions. Many of these interventions saved patients from unnecessary revision operations and their associated morbidity. In addition to surgical interventions, medical management with drugs and fluids was affected in 20% of the examined patients (Bettex et al., 2003).

An earlier report found that pediatric patients leaving the operating room without residual defects seen on the echocardiographic examination had a risk for reoperation of 3%, versus 42% for those who were found to have residual defects (Ungerleider et al., 1989). This ability to detect problems early provides a significantly improved outcome and subsequently reduces costs, as the need for repeat operations is reduced (Randolph et al., 2002).

As evidence supporting the value of TEE in cardiac surgery has increased, recommendations for proper performance of the examination have matured. The American Society of Echocardiographers and the Society of Cardiovascular Anesthesiologists have developed guidelines for adult intraoperative TEE examinations to encourage complete examinations with standardized views and nomenclature so as to improve communication between various care providers (Shanewise et al., 1999). Discussion of the complete examinations is beyond the scope of this chapter, but some of the probe locations and angles are useful for obtaining basic information regarding a patient's condition (Table 11-5). Similar guidelines

TABLE 11-5. Transesophageal Echocardiography Cross Sections

Location	Angle (degrees)	Structures Visualized
Transgastric	0-20	Left and right ventricles, and both atrioventricular valves
	80-100	Two-chamber view of left side
	90-120	Long axis of left side, including left ventricular outflow tract
Midesophageal	0-20	Standard four-chamber view
	30-60	Aortic valve on short axis, coronary arteries
	60-90	Right ventricular inflow and outflow tracts
	80-110 120-160	Bicaval view Long-axis view of aortic valve and left ventricular outflow tract
Upper esophageal	0	Aortic arch on long axis
	90	Aortic arch on short axis

Modified from Shanewise JS, Cheung AT, Aronson S et al: ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination: recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society of Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography, *J Am Soc Echocardiogr* 12:884, 1999.

have also been published to assist clinicians with the pediatric examination (Lai et al., 2006).

Although the benefits have been demonstrated, providers must also be aware of the complications associated with the TEE examination. Problems that may be encountered include damage to the oral cavity, esophagus, or stomach; compromised ventilation; inadvertent extubation; right main stem advancement; vascular compression; and arrhythmias. In light of these serious but rare events, caution should precede placement of the transesophageal probe (Stevenson, 1999). Contraindications to the TEE examination include an unrepaired tracheoesophageal fistula, esophageal web, and recent esophageal or gastric surgery. Failure to ascertain a history of such events may lead to significant damage or even perforation of the esophagus.

Another issue encountered in the pediatric population is the size of the patient. Adult-sized probes are generally appropriate for patients older than 8 years or heavier than 20 kg. Pediatric probes are available for patients less than 20 kg. Most clinicians refrain from placing transesophageal probes in patients weighing less than 3 kg. If echocardiographic images are important to a particular surgery and TEE is contraindicated or impossible, an epicardial probe can be passed to the operative field via a sterile sleeve to obtain necessary imaging.

Temperature

Temperature monitoring is vital during pediatric anesthesia, as children may exhibit hypothermia or hyperthermia, both of which can have profound physiologic consequences (see Chapter 6, Thermoregulation).

Urine Output

Urine output often reflects intravascular volume status and cardiac output. Proper assessment of urine output requires recognition of the physiologic mechanisms that exert an affect on urine flow in children. During the first week of life, the glomerular filtration rate and renal plasma flow are only 25% of normal adult values (Arant, 1978). The neonatal kidney is limited in its ability to concentrate the urine (Simpson and Stephenson, 1993). By the end of the first week of life, the kidneys begin to reach absorption thresholds for sodium and glucose that approach adult levels.

Normal newborns produce between 0.5 and 4 mL urine/kg per hour in the first 3 hours of life (Strauss et al., 1981). Urine flow, which initially ranges from 15 to 60 mL/kg per day, reaches as much as 120 mL/kg per day by the end of the first week of life, with 90% of neonates producing 0.5 to 5 mL/kg per hour (Douglas, 1972; Guignard, 1982). In the neonate who is less than 1 week old, urine flow alone is not a sensitive index of changes in cardiac output or intravascular volume. The limited capacity of the neonatal kidneys to compensate for diminished or excessive intravascular volume demands more precise management of blood and fluid replacement in these infants. Beyond the neonatal period, a urine flow of 0.5 to 1 mL/kg per hour usually indicates adequate renal perfusion and function.

Intraoperative monitoring of urine output is indicated in procedures in which large shifts in fluid, blood, or hemodynamics are anticipated, including blood loss greater than 20% of the EBV, third-space replacement exceeding 50% of the

EBV, CPB, neurosurgery, deliberate hypotension, planned use of diuretics, or planned hemodilution. Silastic Foley catheters are available in sizes small enough (6 F) for full-term neonates. Alternatively, a small feeding tube can be used in premature infants and in those with a small urethra. In infants, urinary bladder catheters should be connected to a urinometer capable of measuring small volumes, or to a vented 10- to 20-mL syringe.

Noninvasive Respiratory Gas Monitoring

Carbon Dioxide

Capnometry is the instantaneous measurement of CO_2 in the breathing circuit; it depicts this information in a continuous graphic display in which both the quality and the quantity of ventilation can be evaluated (Figs. 11-3 to 11-6).

Before 1998, capnography was considered a standard monitor by the ASA for confirming the initial placement and continuous presence of an endotracheal tube. This section of the ASA monitoring standards was updated in 1998 and states that capnography should be used to confirm adequate ventilation during general anesthesia with or without an endotracheal tube (during laryngeal mask airway, face mask, or natural-airway anesthesia). Specifically, these guidelines state, "Continual monitoring for the presence of expired carbon dioxide shall be performed unless invalidated by the nature of the patient, procedure or equipment.... Continual end-tidal carbon dioxide analysis, in use from the time of endotracheal tube/laryngeal mask placement, until extubation/removal or initiating transfer to a

■ **FIGURE 11-4.** Common capnographic diagnoses: poor sampling. *Left:* Poor sampling as evidenced by absence of a plateau phase. This diagnosis could not be made with a capnometer that was incapable of real-time graphics. This is typical of small neonates whose small exhaled volumes are washed out by fresh gas flow. *Right:* The speckled curve projects the full exhaled breath that would be seen if fresh gas flow was diverted. Note that the plateau would be higher than the actual curve by an unpredictable amount. The digital information derived from a curve like the one on the left is useless.

postoperative care location, shall be performed using a quantitative method such as capnography, capnometry or mass spectroscopy" (ASA, 2003).

Most capnometers use the principle of infrared light absorption by sampling circuit gas in either a mainstream or a sidestream fashion. Sidestream analyzers aspirate a sample from the circuit and transport it via a long, narrow-bore tube to a distant analyzing chamber. Advantages include a lightweight airway adapter and the remote location of the delicate components of the analyzing chamber. Disadvantages of sidestream systems include potential occlusion of the sampling tube, distortion or dilution of the exhaled gas wave during aspiration and transport to the analyzing chamber, and the delay necessary to transport

■ **FIGURE 11-3.** Common capnographic diagnoses: rebreathing. *Top:* Normal capnographs. The graph on the right is compressed over a longer time. Note the plateau, suggesting valid end-tidal CO_2 data and the return to baseline between breaths; there is no rebreathing. *Bottom:* Rebreathing, as there is no return to baseline. This can occur with inadequate fresh gas flow or floating unidirectional valves. The small initial deflection before exhalation (the preexhalation hump) can occasionally be seen. It represents the inhalation late in the inspiratory phase of more concentrated exhaled gas from the previous exhalation.

FIGURE 11-5. Common capnographic diagnoses: reduction in end-tidal carbon dioxide tension (P_{ETCO_2}). There are many reasons for sudden reduction in P_{ETCO_2} , some of which result in characteristic capnographic patterns. **A**, Abrupt reduction to zero (or nearly zero) typically indicates mechanical disruption, disconnection, accidental extubation, or plugged sampling line. **B**, Sudden reduction to a lower P_{ETCO_2} while preserving plateau and characteristics of a good trace indicate sudden increase in dead space ventilation as occurs with a pulmonary embolus (either thrombus or air). **C**, Exponential reduction to zero (CO_2 washout curve) is characteristic of no pulmonary blood flow and thus either massive embolus or cardiac arrest.

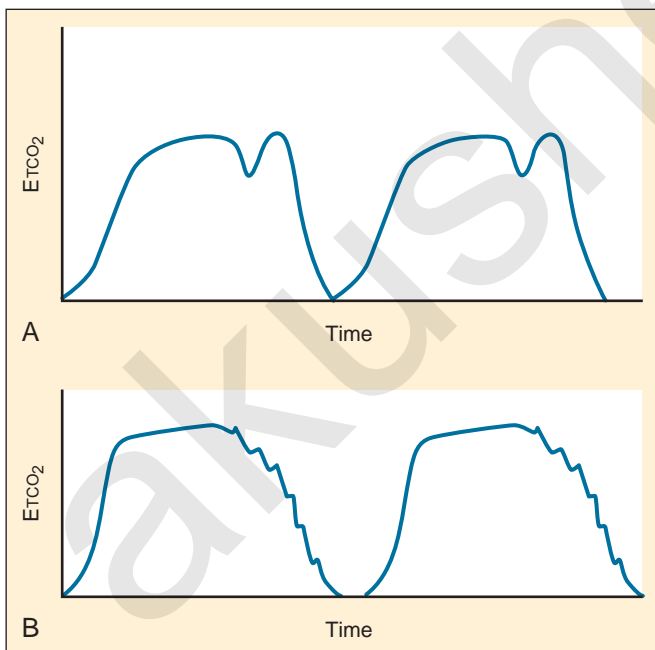

FIGURE 11-6. Common capnographic diagnoses: irregular tracings. Irregularities in the curve are common, especially at the end of exhalation when exhaled gas flow is lowest. **A**, Diaphragmatic activity indicating spontaneous respiratory effort, usually the result of dissipating neuromuscular blockade. **B**, Cardiac oscillations: fluctuations in intrathoracic gas volume as a result of cardiac activity, usually a benign finding.

and analyze the sample. Innovations in capnography technology have allowed a sampling rate as low as 30 mL/min (i.e., microstream technology).

Mainstream analyzers use a sample chamber placed directly into the circuit. They have the advantage of providing virtually instantaneous analysis by avoiding transport of the sample. Such a system necessitates the addition of a delicate and bulky sensor to the proximal airway connection, where it might easily serve as a fixation point to dislodge a small tracheal tube. Solid-state innovations have dramatically reduced the weight of the mainstream sensors, but they remain significantly more hazardous when added to the circuits of neonates and small infants. Although early mainstream sample chambers added as much as 17 mL of dead space to the circuit, currently available models reduce this volume to 2 mL or less.

Capnography in pediatric anesthesia is used to confirm placement of an endotracheal tube in the correct tracheal position and to continuously assess the adequacy of ventilation. Capnography also provides information about the respiratory rate, breathing pattern, endotracheal tube patency, and, indirectly, degree of neuromuscular blockade. Capnography can assist with the diagnosis of metabolic and cardiovascular events and can provide an early warning of a faulty anesthesia delivery system. In pediatric patients, an abnormal increase in end-tidal carbon dioxide tension (P_{ETCO_2}) most commonly signifies hypoventilation, but, rarely, it also indicates the presence of increased CO_2 production, as occurs with temperature elevation or as an early sign of malignant hyperthermia. On the other hand, an abnormally low P_{ETCO_2} may indicate an increase in dead space or suggest a state of low pulmonary perfusion.

Sudden absence of the capnographic tracing indicates a breathing circuit disconnection, and the abnormal presence of inspired CO_2 signifies the presence of a faulty unidirectional valve, an exhausted CO_2 absorber, or, when a semiopen circuit is being used, rebreathing secondary to an insufficient fresh gas flow.

The capnographic tracing of small infants is often characterized by the lack of an apparent alveolar plateau. This is usually a result of a higher respiratory rate, an excessively high sampling flow for the volume of CO_2 produced, excessive dead space in the breathing circuit, or an excessive leak around an uncuffed endotracheal tube.

The degree to which PETCO_2 reflects Paco_2 is subject to many variables, some technical and others physiologic. The technical issues of primary importance in the accurate measurement of mean alveolar CO_2 tension include the volume and flow rate of exhaled gas, the aspirating flow rate (for sidestream analyzers), the fresh gas flow rate, the type of breathing circuit, and the circuit location of the sampling chamber (mainstream analyzers) or lumen of the aspirating tubing (sidestream analyzers). These variables are of particular importance in the small neonate whose small exhaled volumes at low flow rates are often diluted by high fresh gas flows or aspirating gas flows (Badgwell et al., 1987, 1993; Rich et al., 1990; Spahr-Schopfer et al., 1993). Badgwell and others (1987) demonstrated exponential increases in the discrepancy between PETCO_2 and Paco_2 values with progressive reduction in patients who weighed less than 12 kg (Fig. 11-7). The coaxial distal sampling tube that they advocated dramatically improved the correlation.

The physiologic variable that introduces the most significant error in PETCO_2 is dead space ventilation (Swedlow, 1986). Apart from children with severe pulmonary pathology or acute

FIGURE 11-7. Gradient between end-tidal carbon dioxide (ETCO_2) determinations made in the proximal and distal ends of a tracheal tube. Exponential increases in the gradient suggest substantial potential inaccuracy in proximal ETCO_2 determinations for children weighing less than 12 kg. (From Badgwell JM, McLeod ME, Lerman J, et al: End-tidal Pco_2 measurements sampled at the distal and proximal ends of the endotracheal tube in infants and children, *Anesth Analg* 66:959, 1987.)

events such as pulmonary embolus, the most prevalent pediatric population in whom substantial dead space ventilation occurs are those with cyanotic congenital heart disease, particularly right-to-left shunts (Burrows, 1989; Fletcher, 1991).

Other Gases

Measurements of other respiratory and anesthetic gases can provide important information about cardiopulmonary physiology. Confirming the elimination of nitrogen is useful in determining adequate preoxygenation, whereas its presence during anesthesia may reveal a leak in the delivery system or, in combination with a sudden decrease in end-tidal CO_2 , a venous air embolism. The measurement of anesthetic gases and vapors serves to illustrate the uptake and elimination of these agents and to confirm the purity and the accuracy of the tanks and vaporizers used to administer them. The quantity of residual inhaled anesthetic agent has obvious importance in the evaluation of prolonged emergence from anesthesia.

The techniques enabling multigas analysis that have found clinical application are based on properties such as ionized mass separation (mass spectrometry), ultraviolet and infrared light absorption, and absorption into lipophilic substances. A variety of manufacturers produce devices that quantify respiratory and anesthetic gases in the same unit as the capnograph; their complete description is beyond the scope of this chapter.

Monitoring Oxygen and Carbon Dioxide

Because of high oxygen consumption and small functional residual capacity of infants and small children, they are more likely to become hypoxemic during general anesthesia than adults. Careful tracking of arterial oxygenation is vitally important. Noninvasive monitors of oxygenation are ubiquitous in the perioperative setting because of technological advances that have improved their reliability and because of standards that require their application not only in the operating room but also in the PACU and sedation room. These devices are of two basic types: those that measure cutaneous (transcutaneous) oxygen tension, and others that evaluate arterial oxygen saturation (pulse oximeters).

Cutaneous Oxygen Tension

In 1972, a miniature Clark polarographic oxygen electrode, similar to those used in *in vitro* blood gas analysis, became available for application to the skin. When a probe heats the skin to 42° to 44° C, the cutaneous oxygen tension (Pso_2) approaches arterial oxygen tension because the skin blood flow and permeability to oxygen are increased (Barker and Tremper, 1985). The correlation may be better in neonates because their epidermis is less keratinized and their cutaneous capillary bed is denser. In fact, skin heating alters oxygen dissociation and may even result in a Pso_2 value that is higher than the Pao_2 value (Lubbers, 1981). In older children and adults, as the keratinized layer thickens, the diffusion gradient for oxygen becomes more significant. In practice, transcutaneous gas monitors are subject to the effects of these and myriad other nonlinear variables that influence skin perfusion, such as hypotension, hypothermia, and pharmacologic agents. They are the only noninvasive monitors that can provide information regarding significant hyperoxemia

(Monaco et al., 1982; Rafferty et al., 1982; Barker and Tremper, 1985). The correlation, especially outside the physiologic range of P_{aO_2} , is variable and depends on the individual conditions, and the data produced may differ from those provided by the P_{sO_2} by a substantial yet unpredictable amount (American Academy of Pediatrics, 1989). Such results led Barker and Tremper (1985) to propose a more reasonable role for this monitor in determining peripheral tissue oxygen delivery (perfusion) rather than arterial oxygenation.

From a practical standpoint, the monitor is cumbersome. It requires calibration, a warm-up time of 10 to 20 minutes, and meticulous skin preparation and probe placement. It is sensitive to electrosurgical interference and mechanical manipulation. The technical demands of this monitor have limited its current use to special applications, such as detection of hyperoxemia in premature infants. A frequent side effect of transcutaneous monitoring is the occurrence of first- and second-degree burns.

Cutaneous Carbon Dioxide Tension

Cutaneous carbon dioxide tension (P_{sCO_2}) measurement using a variant of the Severinghaus electrode is also available (Nosovitch et al., 2002). Although P_{sCO_2} is always higher than P_{aCO_2} as a result of tissue carbon dioxide production and the increased metabolism caused by a heating sensor, these monitors accurately follow trends in arterial carbon dioxide tension. The predictable gradient from arterial to cutaneous CO_2 tensions enables the monitors to calculate the gradient and display a “corrected” value. These devices are less altered by changes in skin temperature and perfusion than are cutaneous oxygen analyzers. The reasonably good correlation of end-tidal and arterial CO_2 tensions in all but extremely small subjects has limited the interest in cutaneous CO_2 tension monitoring in the operating room to very rare situations.

Pulse Oximetry

Pulse oximetry, invented by Takuo Aoyagi in 1974 and developed as a clinical monitor a decade later, has markedly improved patient safety, especially during the perioperative period (Yelderman and New, 1983; Aoyagi, 2003; Severinghaus, 2007). It provides an estimate of the oxyhemoglobin saturation in arterial blood with a probe on a fingertip (New, 1985). The pulse oximeter uses plethysmography to determine the systolic portion of the cardiac cycle. During systole, there is a greater volume of blood in a pulsatile arterial vascular bed. This vascular bed is positioned between a sensor that contains a two-wavelength (red and infrared, 660 and 940 nm) light-emitting diode and a photodiode receptor (the wavelength varies depending on the manufacturer). Less light is transmitted in systole than in diastole because of the increased volume of the arterial bed. Sophisticated algorithms based on the amount of light absorbed differentiate systole from diastole. Oxygenated and deoxygenated blood absorb different quantities of light, proportional to their concentrations or the percentage of saturation according to the Beer-Lambert law. Once systole is identified through plethysmography, the arterial saturation during this period is determined by using the ratio of light absorption at the two different wavelengths through this vascular bed. The ratio is matched to data acquired over a range of experimentally determined saturations and ratios of light absorption stored in

the instrument’s memory to determine the arterial saturation. Using the ratio of light absorption at two wavelengths makes unnecessary the calibration and zeroing to adjust to the size of the patient or to skin pigment (Aoyagi, 2003). In the 80% to 100% saturation range, arterial saturation values determined by this method correlated well with in vitro measurements (New, 1985). Based on the algorithm used to determine systole and the time-averaging process used over several cardiac cycles, different pulse oximeters have slightly different responses to a variety of clinical situations. Because the device must identify the pulse-added absorption, it may confuse motion of the extremity to which the sensor is attached with pulsating motion and abort the display of saturation data or, worse, display inaccurate data (see later).

Pulse oximetry was introduced into pediatric practice in the United States in the late 1980s (Salzer, 2003). It serves as an early warning signal of impending or actual hypoxemia, often before the onset of cyanosis, frequently reminding anesthesiologists of the alarming rapidity with which infants develop hypoxemia as compared with toddlers and older children (Xue et al., 1996). Continuous-use pulse oximetry is included in the basic monitoring standards of the ASA (2003). Anesthesiologist-blinded studies have demonstrated that the use of pulse oximetry facilitates earlier recognition and fewer episodes of hypoxemia (Coté et al., 1988, 1991). Pulse oximetry has rapidly evolved into a standard monitor during pediatric anesthesia and, as a result, has never been subjected to rigorous outcome studies with a true control group (an anesthetic without a pulse oximeter) (Cohen et al., 1988). There are no outcome studies that demonstrate proven benefit from the use of pulse oximetry (Moller et al., 1993a, 1993b; Pedersen et al., 2001).

A number of well-described limitations of pulse oximetry affect the accuracy of commercially available pulse oximeters. Among other factors, ambient lighting conditions, motion, peripheral circulation to the extremity, body temperature, and abnormal hemoglobins can interfere with accuracy and consistency of pulse oximeter performance (Schramm et al., 1997; Trivedi et al., 1997). Of all these factors, motion artifact is clinically the most common problem, resulting in inaccurate readings, data loss, missed alarms, and false alarms. Patient motion (e.g., shivering and seizures in adults and children, as well as kicking, stretching, and crying in infants) causes movement of venous blood, as well as other normally nonpulsatile body fluid components (e.g., tissue fluid in edematous patients), along with the arterial blood. The pulsatile components of the body fluids other than arterial blood may lead to falsely low saturation readings. If motion is combined with low perfusion at the sensor site, then the venous blood makes a more significant contribution to the pulsatile component and drives the SaO_2 as measured with a pulse oximeter (or SpO_2) even lower. Various algorithm-based motion rejection methods used by manufacturers to minimize the impact of motion artifact and reduce false alarms include averaging saturation data over longer periods of time, freezing values until uncorrupted signals are present, and implementing alarm delays (Pettersen et al., 2007). Other technologies use parallel processing of multiple sophisticated algorithms to isolate the biological signal in the presence of noise. When compared with conventional and other motion-tolerant pulse oximeters, Signal Extraction Technology (Masimo Corp., Irvine, Calif) has been reported to have a better performance in a variety of pediatric clinical settings, including newborn and pediatric intensive care units, the PACU, and the

pediatric sleep lab (Ahlborn et al., 2000; Bohnhorst et al., 2000; Malviya et al., 2000; Barker, 2002; Brouillette et al., 2002; Trang et al., 2004; Workie et al., 2005).

Although the pulse oximeter is a continuous monitor, it does not instantaneously reflect the arterial saturation or the degree of desaturation. Most commercially available pulse oximeters display the average SpO_2 numbers of the most recent 5 to 15 pulses, depending on models and manufacturers, causing a delay in detecting desaturation. When the patient is breathing high concentrations of oxygen and the blood is fully saturated, a substantial decrease in Pao_2 can occur without a change in Sao_2 . Reynolds and associates (1993) detected desaturation in children 30 seconds earlier in probes placed centrally (forehead) than in those placed on a finger. By the time the value indicated by a peripheral sensor had decreased 5%, the value indicated on a central sensor was 30% to 40% lower (Agashe et al., 2006). The precise mechanism for this discrepancy remains unknown, although Severinghaus and Naifeh (1987) postulated that it reflects peripheral blood transit, capillary composition, and oxygen utilization. Centrally placed reflective forehead pulse oximeter sensors are reported to respond faster and to be less likely to be compromised by vasoconstriction than transmittance finger probes (Choi et al., 2010).

Pulse oximeters are designed to warn practitioners when the arterial saturation decreases to below normal, not to serve as quantitative devices in hypoxemic patients. Compared with measured arterial saturation in children with cyanotic congenital heart disease, most pulse oximeters exhibit a progressively positive bias, typically reaching 5% to 15% at an Sao_2 of 60%, in addition to a significant reduction in precision ($\pm 8\%$ to 10%) (Gidding, 1992; Schmitt et al., 1993) (Fig. 11-8). More recently, a pulse oximetry sensor designed specifically for patients who are chronically hypoxemic, such as children with congenital heart disease, has become available. This specialized sensor, called the Blue sensor, has reported precision of less than $\pm 4\%$ between saturations of 60% and 80%. When compared with a standard pulse oximetry sensor on postoperative palliative cardiac surgery patients, the Blue sensor had a bias of 0.21 and

FIGURE 11-8. Accuracy and precision of pulse oximetry (Nellcor N-100) in chronically hypoxemic children with congenital heart malformations. Data comparing pulse oximetry (SpO_2) with CO-Oximetry (Sao_2) reflect a 5.8% mean positive bias for SpO_2 , with wide discrepancies between the two techniques (± 2 SD = -3.8% to $+15.4\%$). (From Schmitt HJ, Schuetz WH, Proeschel PA, et al: Accuracy of pulse oximetry in children with cyanotic congenital heart disease, J Cardiothorac Vasc Anesth 7:61, 1993.)

an accuracy root-mean-square (RMS) error of 3.6% compared with Sao_2 values, whereas the standard sensor had a bias of 0.86 and an accuracy RMS error of 6.4% compared with Sao_2 values (Cannesson et al., 2008c). The Blue sensor demonstrates considerable improvement in the accuracy of pulse oximetry monitoring of cyanotic children.

Interference with the expected spectrophotometric absorption pattern also causes errors in measurement. Low hemoglobin (<5 g/dL) and abnormal hemoglobin species (e.g., methemoglobin, carboxyhemoglobin) cause inaccurate saturation estimates by pulse oximeters, which become progressively inaccurate as Sao_2 decreases (New, 1985; Barker and Tremper, 1987; Barker et al., 1989; Watcha et al., 1989). In contrast, unusual or abnormal hemoglobin molecules, such as fetal hemoglobin and sickle cell hemoglobin, apparently have little effect on the saturation measurement (Jennis and Peabody, 1987; Ortiz et al., 1999). Intravenous dyes such as methylene blue and indocyanine green, affect the expected light absorption and produce spurious information (Ralston et al., 1991). Aberrant radiation (e.g., electromagnetic energy from the electrocautery, infrared heat lamps, operating room lights) and infrared light pulses from lasers and neuronavigation systems also cause incorrect saturation determinations (Brooks et al., 1984; Costarino et al., 1987; Hanowell et al., 1987; Mathes et al., 2008; Zhang et al., 2009).

Multiple-Wavelength Pulse Oximetry

Pulse oximeters that use two wavelengths of light are subject to interference from other hemoglobin species that absorb light across similar spectra. Dyshemoglobins such as carboxyhemoglobin and methemoglobin cannot be detected by pulse oximetry, but their presence in arterial blood can bias the oximeter's estimate of Sao_2 . Multiple-wavelength pulse oximetry (Pulse CO-Oximetry; Masimo Corp., Irvine, CA) has been developed to detect and measure both carboxyhemoglobin and methemoglobin levels noninvasively and continuously, although the accuracy of Sao_2 estimations from these devices is still compromised (Barker et al., 2006). Pulse CO-Oximetry devices that measure carboxyhemoglobin have been shown to be useful in the emergency room for detection of occult carbon monoxide poisoning, and for monitoring and guiding emergency treatment of CO exposure (Suner et al., 2008; Bledsoe et al., 2009; Piatkowski et al., 2009). Methemoglobinemia can be caused by a wide variety of oxidizing drugs and their metabolites and by exposure to industrial chemicals such as aniline dyes, chlorates, and bromates. The clinical usefulness of noninvasive methemoglobin detection and monitoring by Pulse CO-Oximetry has been demonstrated for the diagnosis and treatment of severe methemoglobinemia in the hospital setting (Annabi and Barker, 2009).

Plethysmographic Waveform Analysis

For many years, clinicians have used the shape and amplitude of the plethysmographic waveform from pulse oximetry as a crude and imprecise method to assess blood volume and cardiac output (Partridge, 1987). Respiratory variations in pulse oximetry plethysmographic waveform amplitude can predict fluid responsiveness noninvasively in mechanically ventilated patients, but this method of assessment is technically challenging—neither automated nor continuous, and not available in clinical practice

(Cannesson et al., 2007). An index that provides an automatic and continuous calculation of the respiratory variations in the waveform amplitude is now available with some pulse oximeters. The pleth variability index has been shown to predict fluid responsiveness during cardiac surgery (Cannesson et al., 2008b) and to predict changes in cardiac index with changes in positive end-expiratory pressure after cardiac surgery in mechanically ventilated, sedated patients (Desebbe et al. 2010). This index may allow the optimization of fluid loading noninvasively during and after surgery, but further validation is required before these results can be extrapolated to the general population.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) is another tool available to the anesthesiologist that provides information regarding tissue oxygenation. Its applications range from cerebral oximetry during circulatory arrest, to monitoring for compartment syndrome in the setting of trauma (Tobias and Hoernschemeyer, 2007; Bernal et al., 2010). Although NIRS continues to be studied for its impact on patient outcomes, it is increasing popular as a noninvasive monitor of vital data.

NIRS relies on principles similar to those of pulse oximetry, exploiting the variable absorption of light by color-containing compounds in the body. Infrared light emitted by the device enters the skin and scatters through the tissues beneath, some energy being absorbed and some reflected. The portion of the light that returns to the skin is analyzed and conclusions are drawn about the content of the tissues it passed through (Cohn, 2007).

The basis for analysis of the reflected light is found in the Beer-Lambert law. According to this law, reduction in the intensity of light passing through a substance depends on the absorbance of the substance and its thickness. These principles are used to quantify concentrations of oxygenated hemoglobin, which absorbs light at 805 nm, and deoxygenated hemoglobin, which absorbs at 730 nm, and to determine the regional oxygen saturation ($r\text{So}_2$) of the tissue examined (Tobias, 2006).

Unlike pulse oximetry, NIRS does not require pulsatile flow, because it looks at all the blood in a given tissue including arterial, venous, and capillary blood. This means that NIRS is particularly valuable when pulsatility is lost (e.g., in CPB or circulatory arrest).

NIRS technology is commercially available from only a few companies. The INVOS Cerebral/Somatic Oximeter (Somanetics Corp., Troy, MI), which has been on the market for a long time, provides real-time monitoring capability for the $r\text{So}_2$ of blood in tissues beneath the probe. To target specific tissues such as the brain or kidneys and not the skin and soft tissues between the probe and these organs, the device has been designed to eliminate data from the superficial tissues. The probe incorporates a light-emitting diode and two sensors located at fixed distances from the light. Infrared light passing through the superficial tissue is picked up by the closest sensor, and infrared light passing through the deeper tissues is picked up by the further sensor. Information from the superficial tissues is subtracted from the data returning from deeper tissues to provide accurate estimates of the deep tissue oxygenation (Tobias, 2006).

The Fore-Sight (Cass Medical Systems, Branford, CT) uses laser light at four wavelengths. Based on the same principles as the Somanetics device, it also accounts for the spurious information collected from the superficial tissues to focus

on the deeper areas of interest (Chakravarti et al., 2008). Both devices have approved uses in pediatrics, and probes of different sizes fit this population.

Clinicians presented with data on tissue oxygenation must know how to respond to it, and much has been written about the clinical usefulness of NIRS. Cerebral oximetry has been the most widely studied use of NIRS, and here NIRS has proved to be both a sensitive and specific indicator of cerebral tissue oxygenation (Al-Rawi et al., 2001). Kurth and coworkers (2002) noted thresholds for normal and abnormal values in a piglet model. They found baseline cerebral $r\text{So}_2$ values of 68%, and they found that lactate began rising when the $r\text{So}_2$ dropped to 44%, electroencephalographic changes started at around 42%, and ATP loss occurred at 33%. This information, along with corroborating findings in adult studies, has led to a weak consensus that an $r\text{So}_2$ reduction of 20% from baseline, or an absolute value of 50%, serves as an indication of potential hypoxic injury and warrants intervention.

To establish the value of cerebral oximetry in the pediatric population, Hoffman and colleagues (2008) studied patients treated for hypoplastic left heart syndrome, and they demonstrated improved neurologic scores at age 4 to 5 years in patients who were monitored with cerebral oximetry at the time of their surgery and treated for abnormal values ($r\text{So}_2 < 55\%$). This is encouraging, but most agree that there is still insufficient evidence to support clinical decisions based on NIRS values alone (Hirsch et al., 2009).

NIRS has generated interest in additional applications, including shock, compartment syndrome, plastics, and regional perfusion. Adult literature demonstrates NIRS ability to detect compartment syndrome as well as improvement in tissue oxygenation after fasciotomy (Giannotti et al., 2000). Studies of free flaps found that NIRS identified early evidence of flap failure prior to routine clinical evidence (Holzle et al., 2006).

NIRS provides information regarding tissue oxygenation for a broad spectrum of clinical scenarios. As studies continue, clinicians will better understand how to interpret and respond to the data so as to improve the outcomes of their patients.

Bispectral Index

In 1996, the FDA approved the use of the bispectral index (BIS) monitor (Aspect Medical Systems, Nattick, MA), a device based on electroencephalography (EEG) and used to predict the relative level of hypnosis, or unconsciousness, in anesthetized patients (Rosow and Manberg, 1998). Using a patch affixed to the patient's forehead, the BIS monitor integrates various EEG descriptors into a single, dimensionless, empirically calibrated number ranging from 0 to 100, where 0 represents electrical silence and 100 represents full wakefulness. A state of unconsciousness consistent with BIS values less than 60 usually ensures a lack of intraoperative recall (Glass et al., 1997). In adults, titration of anesthetics to a targeted BIS value between 40 and 60 results in the administration of relatively lower doses of anesthetics and earlier awakening (Gan et al., 1997). Studies in adults suggest that routine BIS monitoring is associated with reduced intraoperative awareness during high-risk surgical procedures (e.g., microlaryngeal surgery, cesarean section, cardiac bypass) (Myles et al., 2003).

In anesthetized children on mechanical ventilation, as well as in those spontaneously breathing through a face mask, BIS

values are inversely proportional to the end-tidal concentration of halothane, sevoflurane, and desflurane (Denman et al., 2000; Davidson et al., 2001; Degoute et al., 2001; Tirel et al., 2006; Kern et al., 2007). Similar relationships between the depth of anesthesia (minimum alveolar concentration [MAC], plasma concentration) and BIS values have been studied during total intravenous anesthesia (TIVA), with or without additional opioids, in children with target-controlled infusion of propofol (Jelezov et al., 2007; Tirel et al., 2008; Rigouzzo et al., 2008; Malherbe et al., 2010). BIS values during sevoflurane anesthesia appear to be proportionately less in children with quadriplegic cerebral palsy and those who are mentally compromised (Choudhry and Brenn, 2002; Valkenburg et al., 2009).

In children, at a given depth of anesthesia (i.e., MAC), there are significant nonlinear inverse correlations between BIS values and age: BIS values are higher in toddlers than in older children in all studies, including TIVA with propofol. Furthermore, in addition to age-related variations in BIS values, interindividual variabilities in BIS index are much higher in infants and children than in adults (Tirel et al., 2006; Kern et al., 2007; Rigouzzo et al., 2008). These characteristics of BIS in children may be associated with age-related differences in brain maturation and synapse formation throughout childhood (Watcha, 2001). The reliability of the BIS index is further diminished in infants younger than 1 year (Tirel et al., 2006; Jelezov et al., 2007; Kern et al., 2007; Rigouzzo et al., 2008).

The clinical benefits of measuring BIS and maintaining appropriate levels of anesthesia, such as reduced risk for intraoperative awareness and improved recovery time, may still be valid in pediatric patients, with the realization of certain characteristics of and differences in children. In adolescents undergoing scoliosis surgery, BIS can predict voluntary patient movement in response to commands during the intraoperative wake-up test (McCann et al., 2002). BIS monitoring was also used successfully for the intraoperative wake-up test in a neonate undergoing neurosurgery for the repair of myelomeningocele (Govindarajan et al., 2006). BIS monitoring in children aged 3 to 18 years who are undergoing tonsillectomy and adenoidectomy is associated with reduced recovery times (Bannister et al., 2001). However, in the same study, BIS monitoring did not affect recovery times in children younger than 3 years who were undergoing hernia repair.

More recently, interest in the efficacy of BIS in monitoring the depth of sedation has increased in other specialties, including critical care, emergency medicine, dentistry, and general pediatrics (Kerssens and Sebel, 2006; Malviya et al., 2006, 2007; Sadhasivam et al., 2006; Froom et al., 2008; Baygin et al., 2010). Also, BIS monitoring has been used in documenting positive sedative effects of regional and spinal blockade with local anesthetics in children, with or without general anesthesia (Davidson et al., 2006; Hermanns et al., 2006). Future studies are expected to further delineate the use of BIS in the pediatric population.

Neurophysiologic Monitoring

It has long been appreciated that the patient's physiologic status is dynamic, and that rapid and life-threatening changes may occur during surgery. The comparative abilities to evaluate the functional status of the nervous system by clinical means and by commonly used physiologic monitoring tools

that are available to anesthesiologists is limited. Routine anesthesia monitoring may reflect stress on the central nervous system (CNS). For example, changes in heart rate related to both brainstem and vagal stimulation provide invaluable information when correlated with surgical activity. However, intraoperative neurophysiologic monitoring (IOM) adds yet another dimension, as well as specificity, to assessment of the status of the patient during surgery and anesthesia.

Neurophysiologic techniques provide important and reliable alternative tools for assessment of function of the pediatric CNS (Sclabassi and Krieger, 1995). These techniques provide objective measures of the functioning of the CNS and can serve to localize, warn of, and document deterioration in neuronal function. Intraoperatively, continuous monitoring of the area of the CNS that is at risk from surgical and anesthetic manipulation provides immediate insight into the effects of these manipulations. Rather than waiting to evaluate the neurologic examination of a child in the postoperative period, continuous IOM provides an immediate view of the integrity of the CNS, permitting changes in operative and anesthetic technique to minimize or correct the deleterious effects of intraoperative manipulations. Advantages of these methods are that the results are objective and quantifiable, the site of the lesion can be identified, and clinically latent and evolving lesions can frequently be demonstrated. These techniques have roles to play both in the diagnostic investigation of pediatric CNS function and in the field of intraoperative assessment of CNS function.

The measures used must be both specific to the neural tissue being manipulated and sensitive to changes in the functioning of the neural tissue produced by the surgical manipulations. Monitoring of the electrical activity dependent on the functioning of the brainstem (brainstem auditory evoked potential [BAEP] and brainstem somatosensory evoked potential [BSEP]), the cortex (EEG, somatosensory evoked potential [SEP], and visual evoked potential [VEP]), the spinal cord (SEP, motor evoked potential [MEP], and electromyogram [EMG]), the various cranial nerves (EMG), and peripheral nerves (compound action potential [CAP] and EMG) provides a multidimensional assessment of the integrity of the neural structures at risk. In addition, many of these measures provide information not only about function itself but also about variables that directly or indirectly affect function, such as blood flow, hypoxia, and hypotension. The goal of IOM is to provide information to the surgeon and anesthesiologist that allows them to modify their operative strategy before inducing additional deficits in the functioning of the CNS.

Perioperative Assessment and Communication

An important aspect of successful IOM is close communication among all members of the surgical team in the planning and execution of surgical procedures. The monitoring team needs to be informed of the nature of the patient's disease process and of the planned operation. Preoperative studies are most useful in defining the effects of the pathology on the neurophysiologic measures to be used during the procedure, and in clarifying the maturational nature of these measures. The neurophysiologists should maintain close communication with members of the surgical team, including surgeons, anesthesiologists, and radiologists, before and during the procedure. This ensures that the monitoring approach is appropriately planned, that appropriate neurophysiologic measures are used during the procedure,

that the anesthesiologist can provide appropriate anesthesia to support the monitoring needed, and that the significance of observed changes is appreciated by all members of the team. The surgeon needs to understand the level of information that the neurophysiologist can provide as the operative procedure is evolving, and the anesthesiologist needs to understand the effects of the pharmacologic manipulations on the monitoring tools available to the neurophysiologist.

Technical Methodology

The recording of high-quality neurophysiologic data depends on the appropriate use of technology—the electrodes, amplifiers, stimulators, and other equipment used to acquire and display the data.

The bioelectrical activity at the scalp and the surface of the body is sensed using metal electrodes, and it is transferred through conducting leads to recording amplifiers. Subdermal needle electrodes are used in the operating room and may be used as stimulating electrodes as well as recording electrodes. The positions of the recording electrodes should be chosen in relation to the expected distribution of the responses to be recorded. Many laboratories place scalp electrodes at sites determined by the international 10-20 system (Jasper, 1958). This system, originally devised for EEG recordings, specifies the position of 21 evenly spaced locations on the scalp. Recording electrodes are placed symmetrically to provide control recordings from the side contralateral to the surgery, even when electrodes may not be positioned in the standard recording sites. Electrodes that are not in the operative field but are on the scalp and not accessible during surgery are either sutured or stapled in place. Electrodes on the face, which are placed to record electromyographic activity, are taped in place. Electrodes in the operative field are placed by the surgeons using sterile technique, usually early in the procedure.

Neurophysiologic signals are amplified using differential amplifiers (Goff, 1974), in which two input channels to the amplifier are differenced. This differencing has the effect of eliminating identical (in-phase) signal components that might be present at each recording electrode (presumably noise), and retaining the signals that are different (out of phase) and presumably produced by physiologic generators. The effectiveness with which a differential amplifier rejects in-phase signals compared with its ability to amplify out-of-phase signals is called the common mode rejection ratio (CMRR). Differential amplifiers typically have CMRRs of greater than 10,000:1 (80 dB). For efficient rejection of in-phase signals, it is extremely important that the impedances of each electrode in a pair be not only as low as possible but as similar as possible, because any inequality in electrode impedance will produce amplitude differences in the in-phase activity that will be amplified along with the desired signal.

In evoked potential recording, the observed neuroelectrical activity, either from the scalp or propagating activity from the cord, is assumed to consist of a signal component representative of underlying activity evoked by the stimulus and random noise consisting of both physiologic signals not relevant to the study and environmental noise generated by ubiquitous sources of electrical signals. Evoked potentials are typically a fraction of the size of the spontaneous brain activity appearing in the background EEG, and about one thousandth the size of the other physiologic and extraneous potentials with which

they are intermixed. The aim of evoked potential recording is to acquire a large, clear response with the least possible noise contamination (i.e., the best signal-to-noise ratio possible); thus, the elimination of unwanted signal components is essential. This elimination is accomplished with analog and digital filtering techniques and signal averaging.

After signal amplification, the most effective method for extracting a signal of interest from background noise is signal averaging. Signal averaging is in effect a cross-correlation between a point-process defined by the occurrence of the stimuli and the recorded evoked activity (i.e., an optimal filter) (Lee, 1960). In averaging, the signal component at each point is coherent and adds directly, whereas the background and noise components tend to be statistically independent and summate in a more or less root-mean-square fashion.

Stimulators

SEP and MEP values are produced by electrical stimulators that produce a shock through the skin with electrodes positioned over a peripheral nerve or transcranially over an area of the cerebral cortex. Electroencephalographic scalp electrodes or electrode plates placed adjacent to the scalp or hard palate can be used to stimulate the cortex. Auditory stimulation is obtained using one of several techniques, depending on, among other things, the surgical procedure involved and whether the auricle is retracted. Options include miniature open-air high-fidelity earphones (commonly used with personal tape players or radios) that rest in the concha of the ear, and a tubal insert earphone. The tubal insert is attractive because it distances the transducer from the recording electrode (producing reduced stimulus artifact) and is easily supported. For stimulation of the visual system, a fiberoptic system, which is positioned directly under the eye but not on the globe, is designed to be mounted on the flash stimulator driven by a photic stimulator. With any of the stimulators, precise synchronization with the monitoring and averaging process must occur.

ANESTHETIC TECHNIQUES

The type of anesthesia as well as the patient's blood pressure, cerebral blood flow, body temperature, hematocrit, and blood gas tensions all affect the functioning of the patient's CNS and thus intraoperatively observed neurophysiologic measures (Grundy et al., 1981; Grundy, 1983; McPherson, 1994; Sloan, 1998). The neurophysiologist must discuss the anesthetic plan with the anesthesiologist before the start of the procedure to ensure that no conflicts exist over the required anesthetic and neurophysiologic monitoring. Both the neurophysiologist and anesthesiologist must understand one another's needs and develop a plan for monitoring and anesthesia that allows both individuals to provide appropriate care for each patient. The halogenated hydrocarbon inhalation agents tend to reduce the amplitude of somatosensory evoked responses (Salzman et al., 1986), and to suppress alpha motor neuron activity that interferes with obtaining MEPs. The best SEPs are often recorded when a narcotic relaxant technique (consisting of an opioid, nitrous oxide (<65%), and a muscle relaxant) is used, whereas the best MEPs are often recorded with TIVA. Thus, when both types of responses are needed, a balancing act with regard to anesthesia is required. Boluses of medications produce more

disruption of signals than constant infusions. Regardless of how medications are delivered, the anesthesiologist must inform the neurophysiologist of medication administration, changes in patient temperature or blood pressure, and any change in the patient's condition.

In many situations, the use of halogenated hydrocarbon inhalation agents is desired to help control blood pressure. Once baseline responses have been obtained and compared with preoperative responses, many children can maintain their responses to an isoflurane level of approximately 0.3 MAC, whereas many adults can maintain their responses to 0.5 MAC or higher. This is highly variable, and it strongly depends on the individual patient's reaction to the inhalation agent. A slow increase in isoflurane until either the blood pressure is controlled or the responses significantly deteriorate usually leads to satisfactory results; however, a small number of patients cannot maintain their SEPs with any inhalation agent on board. Propofol, etomidate, and ketamine also appear to maintain SEPs at anesthetic concentrations and may be particularly useful when signals are expected to be difficult to obtain (Schubert et al., 1990; Kalkman et al., 1991; Taniguchi et al., 1992; McPherson, 1994). Close cooperation between the anesthesiologist and neurophysiologist is important, because some patients, particularly those with immature nervous systems, exhibit sensitivity to anesthetic agents (Sloan, 1998).

Neurophysiologic Measures

Neurophysiologic measures that are routinely used provide a functional map of much of the entire neuroaxis. These include the EEG, an unstimulated measure of cortical function suitable for providing the following information:

1. The degree of cortical activation related either to metabolic process (e.g., hypoxia) or to pharmacologic manipulation (e.g., pentobarbital-induced burst suppression to protect the patient's cortical function) (Niedermeyer and Lopes da Silva, 1993)
2. SEPs and VEPs, which provide additional measures of cortical function specific to certain pathways and vasculature

3. BAEPs and BSEPs, which provide information about the functioning of the brainstem, again specific to certain pathways (Regan, 1989)
4. EMGs, produced either by muscles innervated by the various cranial nerves (providing information about both the cranial nerves themselves and their underlying brainstem nuclei [Kamura, 1983]), or by somatic muscles (providing information about spinal cord or peripheral nerve function)

Maturational Effects

The functional assessment of the pediatric CNS presents difficult and unique problems. The pediatric CNS differs from the adult CNS in that it is maturing over the first several years of life; that is, the neural tissue, the myelin coating of the axonal processes, and the vascular supply to the CNS all show significant changes. These developmental anatomic changes are reflected in maturational functional changes as measured by ascending SEP and by descending MEP activity, VEPs, and BAEPs (Starr et al., 1977; Cracco et al., 1979; Guthkelch et al., 1982). A number of factors contribute to the maturational changes of evoked potentials, and the use of age- and size-matched normal controls is essential. For intraoperative monitoring purposes, infants act as their own controls. Central and peripheral myelination is believed to be completed by 5 years of age, and from then until maturity, the dominant factor affecting SEP latency is height (Yakovlev and Lecours, 1967; Gilmore et al., 1985) (Fig. 11-9).

GENERAL MONITORING PROCEDURES

Neurophysiologic recording during pediatric operations can rapidly become quite complex. It is not unusual to monitor several different neurophysiologic variables simultaneously, such as EEGs, BAEPs, BSEPs, SEPs, MEPs, and EMGs relating to multiple spinal and cranial nerves. This requires a well-organized and theoretically parsimonious approach to monitoring. Baseline responses are obtained before draping the patient and compared with the preoperative evaluation. Significant differences

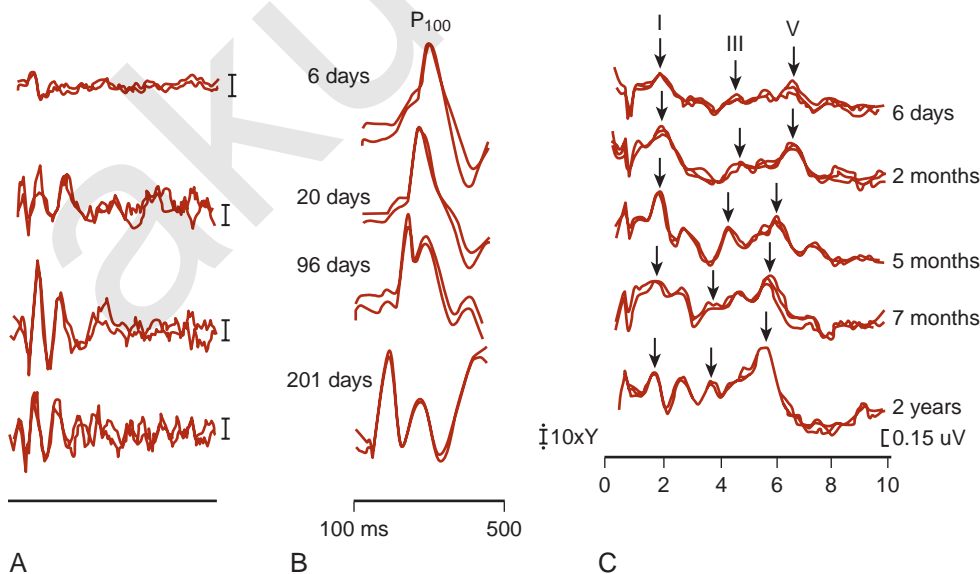

FIGURE 11-9. Maturational changes in cortical somatosensory median nerve evoked potentials (MSPs) (A), flash visual evoked potentials (VEPs) (B), and brainstem auditory evoked potentials (BAEPs) (C), in early infancy. Note the decreasing latency (the time measured from the initiation of the stimulus to the point of maximum amplitude of the evoked potential) and enhancing morphology for the identified waves in all three modalities.

must be accounted for, because signal deterioration caused by the effects of inadequate patient positioning can produce functional deficits even before the start of the operation.

Electroencephalography

The functioning of the cerebral cortex is extremely sensitive to changes in arterial oxygenation and insufficient cerebral blood flow or an inadequate partial pressure of oxygen; this sensitivity is rapidly reflected in the EEG (Meyer and Marx, 1972). Oxidative metabolism supplies the energy for maintenance of the membrane potential of nerve cells, and the EEG depends directly on the transmembrane potentials of neurons, reflecting disturbances of cerebral metabolism such as hypoxia. Some factors that may contribute to ischemic events in surgical patients are decreased oxygen-carrying capacity resulting from hypovolemia, and decreased cerebral perfusion pressure resulting from factors associated with decreased systemic arterial pressure, increased intracranial pressure, and mechanical obstruction of cerebral vessels (Freye, 1990). It is thought that having two channels of continuous EEG monitoring is adequate, because the problems are related more to global or hemispheric effects than to precise focality. The EEG can be observed both as the ongoing unprocessed signal and in a Fourier-transformed representation. The electroencephalographic appearances of any ischemic or hypoxic events are similar, and differentiation between the various putative causative factors is made by being particularly attentive to the clinical situation. For example, blood pressure, ECG, oxygen saturation, administered drugs, and surgical manipulations may all have an observable effect. Other concurrent factors that may alter the EEG are changes in the depth of anesthesia, temperature changes, and changes in CO₂ content. These factors can be recognized by their relatively slow onset, lasting for several minutes, in contrast to the changes of ischemia, which generally occur within seconds. In some situations, the EEG may be acutely depressed on injection of an anesthetic that rapidly passes the blood-brain barrier. Such situations may be found with the use of high-dosage opioid anesthesia, in which fentanyl induces an immediate and marked reduction in fast-frequency activity in the EEG, with an increase in low-frequency, high-amplitude activity in the delta range (Freye, 1990).

A simplified but useful summary of possible changes includes the following:

1. Decreased frequency with increased amplitude (Van der Drift, 1972) implies an ischemic event to the cortex.
2. Widespread frequency slowing and decreased amplitude usually imply brainstem ischemia (Roger et al., 1954).
3. Ischemic events affecting the thalamus and the internal capsule produce unremarkable changes in the EEG (Van der Drift, 1972) but possibly significant changes in the SEPs.

Somatosensory and Motor Evoked Potentials

The neurophysiologic measures of value in assessing the spinal cord consist of SEPs, produced by stimulating various peripheral nerves, and MEPs, which may be observed as either compound muscle or nerve action potentials and which may be produced by either transcranial or spinal cord stimulation. It is advantageous to think of the SEPs as characterizing the ascending activity in the spinal cord and the

MEPs as characterizing the descending activity in the spinal cord. This distinction, although not particularly important with respect to the sensory activity, is potentially extremely important with respect to the descending activity, because important questions remain as to what pathways are being stimulated (Rose, 1994), these distinctions are not as absolute as we would like to think.

Somatosensory Evoked Potentials (Ascending Activity)

SEPs depend on the stimulation of the large afferent fibers of peripheral nerves. After stimulation of peripheral nerves in the arms or the legs, SEPs can be reproducibly recorded over the spine and scalp. In the spinal cord, the SEPs are conducted primarily through the dorsal columns.

SEPs are a sequence of potentials generated in the peripheral nerves, dorsal horn nuclei, dorsal column pathways, and dorsal column nuclei of the spinal cord; the medial lemniscal pathways of the brainstem; and the thalamus and thalamocortical and parietal regions of the brain after the application of a transient electrical stimulus to a peripheral nerve (Sciabassi et al., 1993b). When recorded from electrodes on the surface of the body, the potentials of interest are very small, ranging in size from 2 to 5 mV, and occur in approximately the first 100 msec after the application of a stimulus (often referred to as early and middle latency potentials). Evoked potentials are described in terms of latency and amplitude. Latency is the time measured from the application of a stimulus to the point of maximum amplitude of the evoked potential. Some types of SEP have more than one peak, and the time between peaks is the interpeak latency. The amplitude is the voltage difference between two peaks of opposite polarity, or a reference potential. Measurements of latencies, amplitudes, and interpeak latencies characterize SEP recordings. Changes in these measurements during a surgical procedure may represent injury to the neural tissue between the stimulus generator and the recording electrode.

In all cases, the stimuli are electrical impulses applied transcutaneously, at a rate of 0.7 to 5.3 Hz, depending on the robustness of the response, which is typically a function of the patient's age and pathology. Typically, responses to 128 stimuli are averaged; in many cases, as few as 12 responses may be averaged, providing near real-time updating of the responses.

All types of SEPs are used for intraoperative monitoring, primarily during spinal, cortical, and posterior fossa surgery. Potentials can be recorded after stimulation of the median nerve at the wrist, the common peroneal nerve, the posterior tibial nerve, and the dorsal nerve of the penis and the clitoris. Multiple types of responses from different stimuli and different sources are often simultaneously recorded, allowing the entire neuroaxis to be monitored. Monitoring multiple upper and lower extremity responses simultaneously during spinal surgery allows cord injury to be distinguished from global problems.

Median and Ulnar Nerve Evoked Potentials

The median (MSPs) and ulnar (USPs) nerve evoked potentials are all useful in assessing the brachial plexus, upper spinal cord, brainstem, and telencephalon. One important distinction is that the USPs provide information rostral to T1, whereas the MSPs provide information rostral to C6 (Fig. 11-10). At Erb's

FIGURE 11-10. Median nerve evoked potentials (MSPs) produced by right median nerve stimulation (MD) stimulation. Data are recorded from Erb's point on the right referenced to Erb's point on the left (*bottom trace*); cervical C7, cervical C2 and C3 (left parietal cortex), all referenced to F_z . Note the increase in latency of the large negative wave first identified as N11 at Erb's point, as the activity projects afferently.

point, the response consists of an apparently triphasic (positive-negative-positive) nerve action potential, reflecting the passage of the mixed nerve volley through the brachial plexus. This component is usually labeled N11 for the large negative-going component. At the cervical C7 recording site, the main component is a negative peak occurring at 14-msec latency, N14, with an associated complex structure. It has been postulated that these waves are generated in the dorsal roots, dorsal horn, posterior columns, and structures of the lower brainstem. During spinal fusions, monitoring of the brachial plexus may also alert the surgeon and anesthesiologist to compressive positioning of the arms.

Common Peroneal and Posterior Tibial Nerve Evoked Potentials

In the lower limb, nerves used to elicit cortical SEPs include the tibial, peroneal, and femoral. Spinal potentials are most consistently obtained through stimulation of the tibial nerve at the medial malleolus or peroneal nerve in the popliteal fossa.

SEPs recorded over the spine reflect the afferent volley traversing the dorsal columns. These responses can be recorded from electrodes attached to the skin over the spine, and they progressively increase in latency at more rostral recording locations. Spinal SEPs are relatively easy to obtain in children, with the amplitude and definition of the waves decreasing with increasing age, so that by the mid-teenage years, these responses are more difficult to obtain, as is the case with adults. More rostral recording locations reflect potentials arising in multiple ascending pathways, including the dorsal and dorso-lateral columns, which lie primarily ipsilateral to the side of stimulation.

In our experience, SEPs are extremely sensitive and specific to spinal cord injury, whether it occurs in the dorsal or the ventral pathway. This is confirmed in the literature (Nuwer et al., 1995), where a false-negative rate of 0.063% was found for 51,263 spinal cases in which SEPs were the only potentials monitored. Furthermore, the negative predictive value (i.e., the likelihood of normal spinal cord function in the presence of stable SEPs) was 99.93%. This is a significant improvement over the 0.72% to 1.4% incidence of spinal cord injury reported for unmonitored cases (MacEwen et al., 1975).

Dermatomal Evoked Potentials

A disadvantage of SEPs produced by stimulation of large nerve trunks is that input to the spinal cord usually occurs over more than one level. This problem can be addressed by delivering the stimulus to a small cutaneous nerve that is believed to derive from a single dorsal root, or to the signature area of a particular dermatome. Significant disagreement exists concerning the cutaneous distributions of dermatomes, and care should be taken to stimulate the commonly accepted receptive fields of a root.

Pudendal nerve responses, a special type of dermatomal response, are particularly useful, especially in patients with spina bifida. The pudendal nerve carries sensory fibers from the penis, urethra, anus, and pelvic floor muscles and supplies motor innervation to the bulbocavernosus and pelvic floor muscles, the external urethral sphincter, and the external anal sphincter. Cortical responses to electrical stimulation of the dorsal nerve of the penis, the urethra, and the urinary bladder have all been described (Badr et al., 1982; Haldeman et al., 1982). Pudendal nerve responses are of similar morphology to the tibial nerve SEP (TSP) and are best recorded from the same area of the scalp (Fig. 11-11).

Motor Evoked Potentials (Descending Activity)

Because SEPs reflect function in the dorsal columns of the spinal cord, they do not directly assess the integrity of descending spinal motor tracts. It is possible to have focal damage to the motor areas in the spinal cord in which the SEPs remain normal. Accordingly, misleading results have occasionally been obtained when using SEPs alone for intra-operative monitoring and diagnosis (Lesser et al., 1986), but

FIGURE 11-11. Pudendal nerve responses obtained from a male patient with tethered cord and symptoms referable to the pudendal nerve. All responses are recorded from P_z referenced to F_z . **A**, Responses obtained by stimulating the right branch of the dorsal nerve of the penis. **B**, Responses obtained by stimulating the left branch. Note the significant reduction in amplitude in response to the left-sided stimulation. **C**, Control data recorded during every procedure.

this is rare (Nuwer et al., 1995). MEPs, which may be either evoked EMGs or compound action potentials, can be used to test the integrity of the motor pathways through either electrical or magnetic stimulation (Merton and Morton, 1980; Barker et al., 1985). MEPs can be obtained via stimulation of the motor areas of the brain or spinal cord through the intact skin, direct stimulation of exposed neuronal tissue, or direct root stimulation (e.g., during the release of a tethered cord), and recording of a stimulus-related response either as a compound muscle action potential (CMAP) or as an efferent compound nerve action potential (CNAP) (Fig. 11-12).

Transcranial electrical stimulation may be used to elicit motor responses. There is no general consensus about the location of recording electrodes, outside of specific muscle groups for evoked CMAPs or over the obvious peripheral nerves for evoked CNAPs, nor is there a general consensus concerning which class of these activities is more advantageous to record. CNAPs allow the patient to receive neuromuscular blockade agents. One of the most important stimulation parameters for eliciting reliable MEPs is the interstimulus interval (ISI) of a burst of stimuli (Taylor et al., 1993). It has been found that a burst of stimuli with ISIs between 2 and 5 msec (500 to 200 Hz) produce a maximal response by overcoming the depressed effect of general anesthesia (mentioned earlier) (Kalkman et al., 1995). The significant parameters and morphologic features of

FIGURE 11-12. **A**, Compound muscle action potentials (CMAPs). **B**, Compound nerve action potentials (CNAPs). Both muscle and nerve action potentials were produced by transcranial magnetic stimulation at scalp positions C_4 , P_2 , and C_2 . The CMAPs were recorded from the abductor pollicis brevis muscle, and the CNAPs were recorded from the left median nerve at the wrist.

MEPs are response threshold, onset latency, central conduction time, and response size (Fig. 11-13).

Combined Ascending and Descending Activity

Intraoperative monitoring of MEPS, CNAPs, and posterior TSPs are used to provide a simultaneous measure of the ascending and descending activities in the spinal cord. Through this approach, sequential stimulation is performed of the left tibial nerve, the right tibial nerve, and the spinal cord through the spinous processes. Recording electrodes positioned on the scalp record the bilateral SEPs from the tibial nerve stimuli as well as the afferent activity induced in the spinal area via direct spinal stimulation. Recording electrodes in the popliteal fossa allow the afferent stimulus compound action potentials to be observed, and then the descending compound action potentials produced by the spinal cord stimulation. This combined technique aids in localizing spinal cord dysfunction during surgery by continuously evaluating the adequacy of both the sensory and the motor components of spinal cord neural activity. Many times, both cannot be done because of technical difficulties relating to amplifier saturation and patient movement. In that case, MEPs and SEPs must be obtained separately.

Brainstem Auditory Evoked Potentials

Monitoring of the function of cranial nerve VIII through the use of BAEPs assists in preserving hearing, locating cranial nerve VIII, or determining whether the overall function of the brainstem is altered. BAEPs are also sensitive to retraction on the frontal poles, most likely because of force transmission to the brainstem.

The classic BAEP consists of a minimum of five and a maximum of seven peaks. All occur with 10 msec of a brief click or tone presentation. Wave I is generated in the auditory portion of nerve VIII. Wave II is generated bilaterally at or in the proximity of the cochlear nucleus. Wave III is generated bilaterally

FIGURE 11-13. Motor evoked potentials (MEPs) obtained by transcranial electrical stimulation by needle electrode at C_3 and C_4 during stabilization of a cervical fracture. Channels 7 and 8 (columns 1 and 2) are recorded from the left abductor pollicis brevis and gastrocnemius muscles from stimulation of the right brain (anode at C_4), while channels 9 and 10 (columns 3 and 4) are recorded from the same muscle groups on the right side when the left brain is stimulated (anode at C_3). In many younger infants, both sides of the brain can be stimulated simultaneously. Note the 250-Hz burst of stimulus activity at the beginning of each trace.

from the lower pons near the superior olive and trapezoid body. Waves IV and V are probably generated in the upper pons or lower midbrain, near the lateral lemniscus or possibly near the inferior colliculus.

Waves I through V are relatively resistant to sedative medication and general anesthetics, but this places no constraints on the anesthesiologist. These waves are sensitive to temperature changes, with absolute and interpeak latencies increasing by approximately 0.20 msec. The latency of wave V is the primary concern in intraoperative monitoring of the BAEPs, because this is the most robust and easily identifiable of the waves in this response.

Visual System

VEPs are used to aid in determining the functional integrity of the visual system, primarily in the region of the optic nerves, chiasm, and optic radiations (Albright and Scwabassi, 1985). The recorded activity is generated either at the retina (electroretinogram) or at the cortex.

Stimulation of the visual system using a bright flash is not recommended for diagnostic purposes because of intersubject variability (Ciganek, 1961), except in select situations. In the operating room, this is a very helpful and effective technique (Fig. 11-14).

Electromyography

The EMG is electrical activity produced in muscle fibers below the skin; it has a frequency content ranging from 15 to 150 Hz. Three types of electrodes are used to record the EMGs: fine wire electrodes, which have the highest impedance and the narrowest field of view; subdermal needles, which have an intermediate impedance and a larger field of view; and disk surface electrodes, which have the lowest impedance and the largest field of view (field of view means the integrated level of electrical activity).

FIGURE 11-14. Intraoperative flash visual evoked potentials (VEPs), obtained between midline occipital (O_2) and vertex (C_2) electrodes. Data were from a 10-month-old girl who was operated on for a chiasmal glioma, which was 90% removed. *Top:* Response before resection. *Bottom:* Response after resection. The responses were obtained continuously during the procedure, were abnormal, and were highly variable from response to response, but they were unchanged during the procedure. (From Albright AL, Scwabassi RJ: *Cavitron ultrasonic surgical aspirator and visual evoked potential monitoring for chiasmal gliomas in children*, J Neurosurg 63:138, 1985.)

The recording techniques are essentially the same for all cranial nerves and all muscle groups. Subdermal platinum needle electrodes are used in bipolar recording configurations; that is, all recordings are made between a pair of electrodes inserted into the same muscle group. Bipolar recordings are used to minimize confusion regarding which cranial nerve or branch of a cranial nerve is producing the observed EMG. The electrodes are normally placed before the start of the procedure; occasionally, electrodes are placed in a sterile field by the surgeons.

These signals are listened to continuously for evaluation of nerve function both by the neurophysiologists and by the surgeons. Four categories of EMG activity are observed:

1. No activity, which in an intact nerve is the best situation but which may also be the case in a nerve that has been sharply dissected
2. Irritation activity, which sounds like soft intermittent flutter and is consistent with working near the nerve
3. Injury activity, which sounds like a continuous, nonaccelerating tapping and which can be an indicator of permanent injury to the cranial nerve
4. A “killed-end” response, which sounds like an accelerating firing pattern and is an unequivocal indicator of nerve injury

It is important to note that a sharply cut nerve may produce only a brief burst of activity; monitoring cannot be expected to replace extreme caution when working near the cranial nerves.

EMG is either spontaneous (e.g., anal sphincter activity produced by irritation of S3 to S5 roots during an untethering procedure involving the lower portion of the cauda equina) or evoked, of the type produced in selective rhizotomy for the treatment of spasticity, for placement of pedicle screws, or for ongoing evaluation of the spinal cord. Evoked EMGs have a considerably larger amplitude (>1 mV) than sensory evoked potentials (<0.5 mV) and therefore do not require averaging to extract them from the background noise.

Cranial Nerve Function

Cranial nerve function is monitored continuously during surgery for two reasons: first, to establish the location and orientation of the cranial nerves in the operative field, and second, to preserve functioning in the cranial nerves and their related brainstem nuclei (Sclabassi et al., 1993a). The major observed variables are the EMGs from the appropriate muscle group innervated by the cranial nerves of interest. In general, the cranial nerves ipsilateral to the operative side are monitored; when appropriate, bilateral activity is monitored.

In addition to monitoring the ongoing EMG activity related to the various cranial nerves, these cranial nerves may also be electrically stimulated. This is usually done to determine the location of the nerve in the operative field (because often the nerve is enveloped by tumor and may not be directly observable), or to determine the functional integrity of the nerve (Daube and Harper, 1989). The most common example of this procedure is the direct stimulation of nerve VII. The return path for the stimulating current is provided by a metal electrode inserted into the adjacent muscle mass. In some situations, when very precise localization of the nerve is required, bipolar stimulating electrodes are used. Most of the time, the

question being asked is, Is the nerve there? These techniques are very useful when monitoring during surgery for posterior fossa tumors that extend to the floor of the fourth ventricle.

SUMMARY

The principal goal of intraoperative monitoring is to prevent morbidity, but a more fundamental goal is to provide the operative team with information that allows the operative objective to be accomplished with the best anesthetic and surgical strategy possible, with a clear view of any morbidity being induced along the way. This is particularly important when the degree of difficulty is high and morbidity is likely to be impossible to prevent.

Stringent time constraints exist in the intraoperative monitoring of neurophysiologic function, and damage to the CNS may occur rapidly, over seconds. This constraint has inspired the development of methods for extracting and analyzing evoked potential, EMG, and EEG waveforms rapidly and efficiently. A corollary of the increased sensitivity required to decrease the monitoring time is a higher rate of false-positive results.

False-positive results are also seen in baseline values acquired at the beginning of the procedure and from the preoperative studies. These are usually rapidly identified as such and produce no disruption in the flow of the case. Intraoperative monitoring requires rapid interpretations to be made of complex data, recorded under less-than-optimal conditions. It does no good to inform the surgeon 10 minutes after the fact that a significant change has occurred. Successful intraoperative monitoring of the pediatric CNS requires the acquisition of as many appropriate neurophysiologic variables as possible, and simultaneously. The correct interpretation of these responses is greatly aided by the ability to display the history of all of the acquired data in such a way as to facilitate a comparison of all of the data.

The anesthesiologist caring for infants and children has a wide array of equipment and monitors available. Their configuration depends primarily on the patient's illness, the experience of the anesthesiologist, and the proposed surgery. With the increasing complexity of anesthesia equipment and monitors, the anesthesiologist needs to understand thoroughly the operation and limitations of each device. Last, the anesthesiologist should never rely too heavily on the monitoring equipment and abandon the direct, close, personal surveillance of each patient during anesthesia and surgery.

Airway management is the most important skill of the pediatric anesthesiologist, but what exactly *is* the pediatric airway? Examined through a broad lens, the pediatric airway is a composite of the anatomic development of the head, face, aerodigestive tract, and neck, structures contiguous as well as integral to the airway. It includes the differentiation of the primitive foregut into the trachea and esophagus and the subsequent development and differentiation of the upper and lower airways. It begins where air enters, normally at the nose and mouth, and is continuous through the upper (extrathoracic) and lower (intrathoracic) conducting airways. The dividing line between the upper and lower airways, the thoracic inlet, is bordered by T1 posteriorly, the first pair of ribs laterally, and the superior border of the manubrium anteriorly. Moreover, consideration of the pediatric airway would be incomplete without including its neurophysiology and gas-flow physics. Beyond that, the very practical details of the equipment needed to care for the pediatric airway are critical for the practitioner. In addition, medical conditions with specific airway challenges beget primary as well as secondary effects that must be accounted for as part of the anesthetic plan. Finally, an exit strategy must be established for patients with normal, and in particular, abnormal airways. The anesthesiologist, in collaboration with the surgeon and perioperative physicians and staff, is a critical stakeholder in that plan. Without elaborating on specific procedures covered elsewhere in this text and others, this chapter explores the developmental perspective on the anatomy and physiology of the upper airways and discusses gas-flow characteristics that change with age and abnormal airway conditions.

DEVELOPMENTAL ANATOMY*

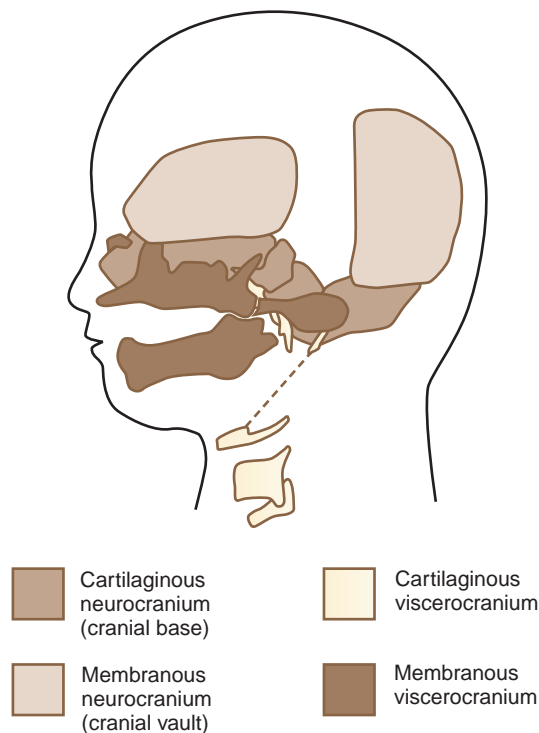

The Upper Airway

Formation of the Cranial Vault and Base

The skull is a critical factor in the development of the face and therefore the upper airway. The skull develops from a membranous and cartilaginous neurocranium (Fig. 12-1). The membranous neurocranium gives rise to the flat bones of the cranial vault, and the cartilaginous neurocranium (chondrocranium) forms the skull base. The flat bones of the neurocranium, which form sutures from edge to edge, also form fontanelles where more than two bones meet. The base of the skull is formed from the cartilaginous neurocranium, which then becomes the base of the occipital bone, the sphenoid, the ethmoid and petrous bones, and portions of the temporal bone.

The cranial base provides a floor for the calvarium and a roof for the face. The shaping of the skull base and contiguous structures is a dynamic process involving reciprocal influences between the cranial base, the pharynx, the face, and the primary and secondary palates. During fetal life and early childhood, neural influences predominate because of the rapid growth of the brain. During postnatal development of the airway, nasal influences play a major role, and because of speech and nutritional requirements, the pharynx also influences the development of the skull base. The anterior portion of the skull base is the roof

*Information in this section is from Holzman, 1998.

■ **FIGURE 12-1.** Development of the skull from neurocranium and viscerocranium contributions at 20 weeks' gestation (lateral view). The skull base, the occipital bone, the body of the sphenoid, and the ethmoid are formed from cartilaginous neurocranium. Cell-signaling as well as geometric influences contribute to further growth of cranial and anterior facial structures.

of the nasomaxillary complex, whereas the posterior portion of the cranial base is the roof of the nasopharynx. During development, the depth of the nasopharynx increases as a result of remodeling of the palate, as well as changes in the angulation of the skull base, providing an enlarged nasal airway for the adult.

Clinical Correlation

The craniosynostoses were thought to occur because of premature fusion of cranial sutures. Coronal synostosis does consistently occur in Apert's syndrome; however, the craniosynostoses are much more complex in their pathoembryology. Current thought strongly suggests that malpositioning of the skull's basal points of dural attachment is the main initiating anomaly in craniosynostosis; this malpositioning theoretically results in the transmission of abnormal tensile forces upward through the dura to produce synostosis of the overlying suture. Growth reciprocity may also play a role; there is some evidence that cranial base malformations are partly caused by calvarial synostosis. Deformity of the skull base is recognizable in almost all patients, as are thinning and irregularity of the calvaria. Additional findings include sphenoid ridge abnormalities, thickening of the bone around the frontozygomatic suture, foreshortened anteroposterior length of the anterior cranial fossa, shallow orbits, anterior and superior displacement of the sphenoid bones, and anterior displacement of the petrous bones. The proptosis typically seen in the craniosynostoses, which can be the result of many factors, may include arrested maxillary growth, a shortened anterior cranial base,

sphenoidal hypoplasia, and forward displacement of the greater wing of the sphenoid bone. Ventricular dilation is consistent as well, although this may not represent hydrocephalus but rather distortion ventriculomegaly. Brain anomalies are also common, and optic nerve atrophy can occur because of the hypoplastic skull base. In addition, hypoplasia of the skull base foramina may result in cranial neuropathies. Hypoplastic, chronically congested sinuses and a challenging mask fit with a hypoplastic midface characterize the airway challenge. The larynx is seldom difficult to visualize with direct laryngoscopy, however, because branchial arch development is usually normal.

Craniovertebral Development

The paraxial mesoderm, a column of tissue on either side of the midline of the embryo, becomes divided into blocks of tissue (somites) at about the fourth week of development. Whereas most of the muscles of the head are derived from mesenchyme of the branchial arches, the cervical somites form the vertebrae of the neck that, under normal circumstances, undergo segmentation (Fig. 12-2). Failure of such segmentation can result in fusion and shortening with severely limited neck movement.

Clinical Correlation

Klippel-Feil syndrome is the result of varying combinations of fusions of the cervical vertebrae, such that the head appears to sit on the shoulders. The normal development of separate cervical vertebrae may be impaired, and fusion of adjacent vertebral bodies may occur. The degree of severity is variable; type I patients have a single-level fusion; type II patients have multiple, noncontiguous fused segments; and type III patients have multiple, contiguous fused segments (Samartzis et al., 2006). Klippel-Feil syndrome can occur with fetal alcohol syndrome, hemifacial microsomia (Goldenhar's syndrome), and anomalies of the extremities. The neck is short, and the hairline is low. In addition, the neck can be webbed. There may be atlanto-occipital fusion. Laryngoscopy and intubation can be extremely difficult, although laryngeal mask airways (LMAs) have been used successfully (Naguib et al., 1986; Nargoziyan, 2004).

The Face

Just as the neurocranium forms the cranial vault and base, the viscerocranium forms the face and is derived mainly from cartilage of the first two branchial arches (Fig. 12-3). Ectodermally-derived neural crest cells of the developing 3- to 4-week-old embryo migrate to branchial arch mesoderm, and the face develops as a result of these massive cell migrations and their interactions. Those cells forming the frontonasal process are derived from the forebrain fold and migrate a relatively short distance as they pass into the nasal region. Those cells that form the mesenchyme of the maxillary and mandibular processes have a considerably longer distance to migrate, because they must move into the branchial arches. At 28 days postconception, the face barely shows its eventual relation to the five primordia from which it is derived: the frontonasal prominence, which is the cranial boundary of the primitive mouth (stomodeum); the paired maxillary prominences (the first branchial arch); and the paired mandibular prominences (also the first branchial arch).

The paranasal sinuses begin developing at approximately 40 weeks of gestational age. The completion of turbinate development

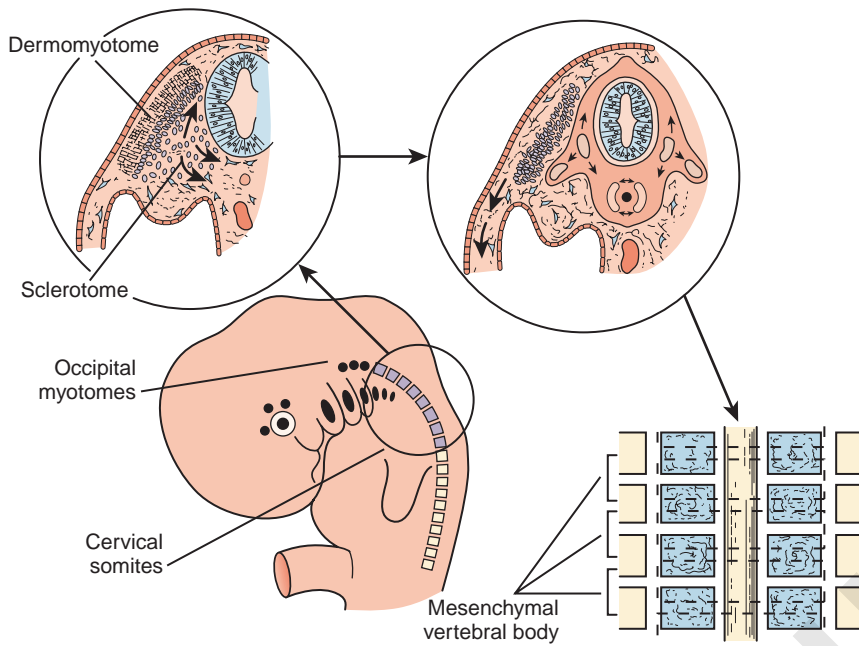

FIGURE 12-2. Craniovertebral development. Three pairs of occipital myotomes advance ventrally to form the muscles of the tongue, along with the hypoglossal nerve, as well as the facial muscles, which are innervated by the facial nerve.

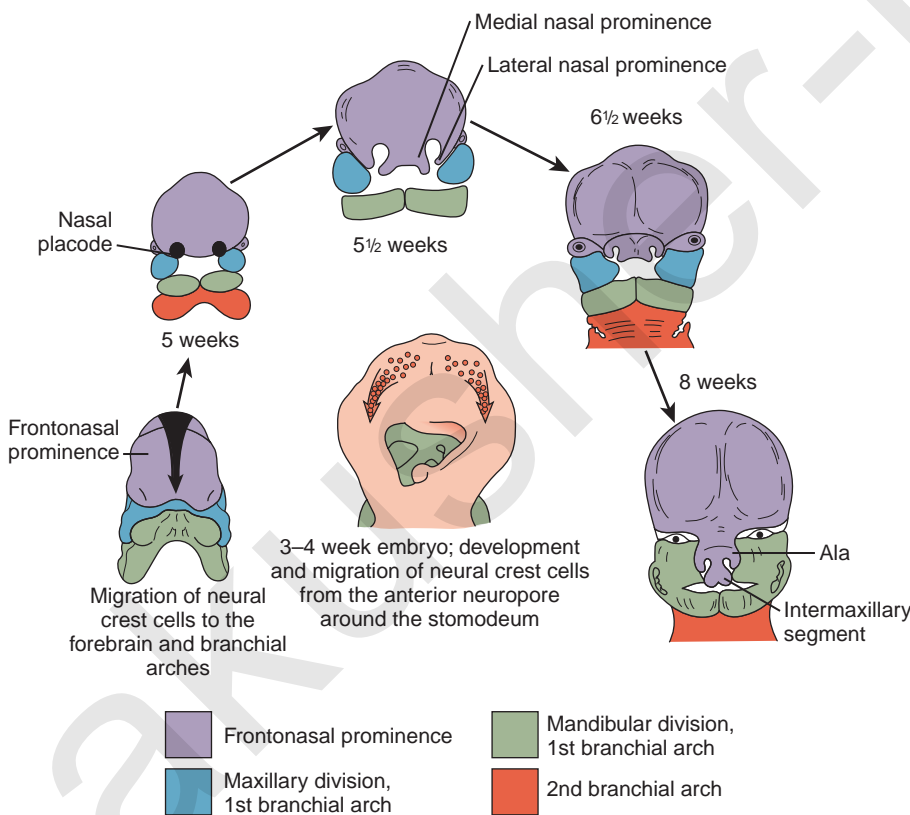

FIGURE 12-3. Development of the face. Neural crest cells form around the anterior neuropore and migrate to give rise to a variety of connective and nervous tissues of the skull, face, and branchial arches. With the frontonasal prominence developing for a shorter distance than the maxillary processes, there is a longer time for clefting of the lip and palate to occur. Severe rhinencephalic malformations may be accompanied by central nervous system abnormalities as well.

signals the beginning of sinus development, which continues until early adult life (Fig. 12-4). Although the exact function of the paranasal sinuses is not well understood, inflammatory, infectious, and neoplastic diseases of the sinuses are of major significance to the anesthesiologist, particularly if there is functional impairment before anesthesia and surgery. Sinus disorders are often comorbidities of asthma, immunoglobulin deficiencies, cystic fibrosis, or Kartagener's syndrome.

The oral cavity—a structure without structures—where much of the anesthesiologist's attention and skills are focused, has a complex developmental heritage. The mouth (stomodeum) appears as a slight depression in the surface ectoderm, separated from the oral cavity by the oropharyngeal membrane. This membrane ruptures at about 24 to 26 days' gestation and the primitive foregut then communicates with the amniotic cavity. The involved germ layers are the endoderm internally and the

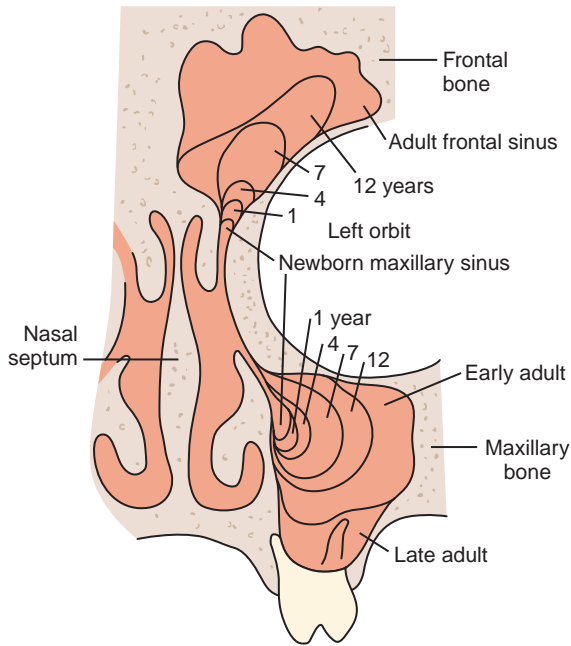

FIGURE 12-4. The paranasal sinuses begin their development at the end of fetal life from the mesenchyme of the lateral wall of the nasal cavity, developing into the turbinates. The completion of turbinate development signals the beginning of sinus development, which continues until early adult life.

ectoderm externally. The tongue surface arises primarily from first arch mesenchyme, with significant contributions from the third and fourth arches, hence its complex innervation by the facial nerve in the anterior two thirds and the hypoglossal nerve in the posterior one third (Fig. 12-5). The muscle bulk of the tongue

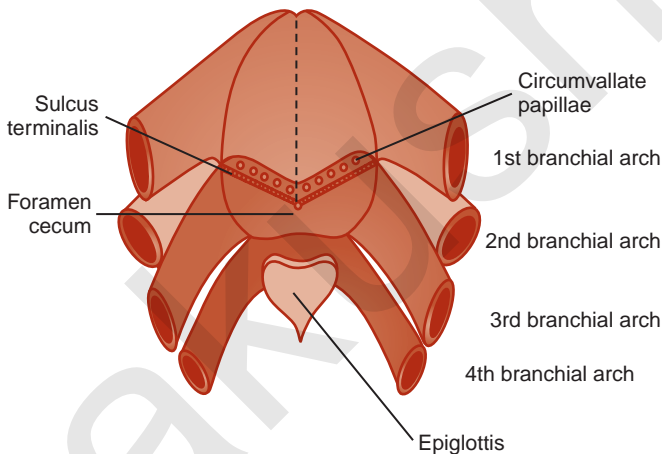

FIGURE 12-5. The tongue is a complex structure, derived as it is from elements of the first four branchial arches. This results in the first branchial arch contributing to the anterior two thirds of the tongue (lingual nerve, a branch of the mandibular division of the fifth cranial nerve), as well as the chorda tympani from the seventh cranial nerve. The third branchial arch contributes to the posterior third of the tongue, resulting in its innervation by the ninth cranial nerve. Tongue muscles, derived from the occipital myotomes in the region of the developing hindbrain, are innervated by the twelfth cranial nerve. The foramen cecum is the pharyngeal floor diverticulum in continuity with the developing thyroid.

arises primarily from occipital somites, explaining the hypoglossal nerve (XII) innervation and its susceptibility to injury from errant placement of dental rolls and pressure injury from overinflated LMA cuffs. The upper lip is formed by the merging of the maxillary prominences with the medial nasal prominences, with the lateral basal prominences forming the alae. The intermaxillary segment in the central portion of the upper lip area consists of a labial component (forming the philtrum), a maxillary component (associated with the four incisor teeth), and a palatal component (which becomes the primary palate).

The palate divides the nasomaxillary complex from the oral cavity (Fig. 12-6). The palatal processes advance in a medial direction from the maxillary processes of the first branchial arch, fusing in the midline in an anterior-to-posterior sequence and uniting with the premaxilla and the developing nasal septum. The soft palate forms from continued growth of the posterior edges of these palatal processes, ending with the formation and fusion of the two halves of the uvula.

Clinical Correlation

Cleft lip and palate are among the most common of congenital anomalies. They may occur alone, as part of a syndrome (there are over 300 syndromes associated with facial clefing), or as a component of a sequence, (e.g., as with Pierre-Robin syndrome). Clefs of the palate may occur by the same mechanism as cleft lip or be secondary to an anatomic obstruction preventing the medial fusion of the maxillary processes. For example, the cleft palate associated with Pierre-Robin syndrome occurs when the tongue, being displaced superiorly and posteriorly as a result of mandibular hypoplasia, interferes with palatal fusion.

Closure of the cleft palate may result in insufficient tissue for development of normal length or function of the soft palate and require a posterior pharyngeal flap. Velopharyngeal insufficiency is the cause of the hypernasal speech, nasal emission, and nasal turbulence (Sidman and Muntz, 2000).

The nose originates in the cranial ectoderm, which subsequently develops into the frontonasal prominence. The superior portion of the nose is formed from the lateral nasal processes, whereas the inferior portion of the nasal cavity is incomplete until the paired maxillary processes of the first branchial arch

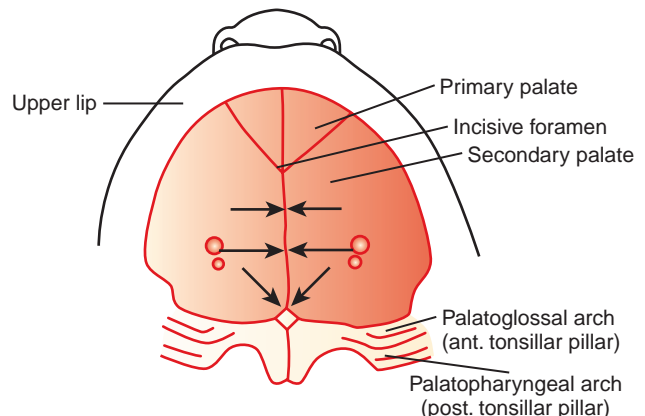

FIGURE 12-6. Formation of the primary and secondary palates, ultimately forming the floor of the nose and the roof of the mouth. The process of midline fusion occurs from posterior to anterior; clefing of the primary or secondary palate may occur in various combinations.

grow anteriorly and medially to fuse with the median nasal processes. The nasal cavities extend posteriorly during development, influenced by the posteriorly directed fusion of the palatal processes, thinning out the membrane that separates them from the oral cavity. By the thirty-eighth day of development, the two-layer membrane consisting of nasal and oral epithelia ruptures and forms the choanae (posterior nares). Failure of such rupture results in choanal atresia, although these choanae are not in the same location as the definitive choanae, which will eventually be located more posteriorly. Because the normal nasomaxillary complex grows both downward and forward, however, it does explain the unexpectedly anterior location in choanal atresia given the eventual normal development of the choanae.

Clinical Correlation

Choanal stenosis is not a blockage but rather a narrowing of less than 6 mm. Choanal atresia is also associated with various syndromes in up to 70% of patients, of which colobomas, heart disease, atresia of the choanae, retarded growth, genital anomalies, ear anomalies (the CHARGE association) is the major one. Repair of this form of choanal atresia may be more complicated, requiring a tracheostomy in infancy as an initial stage and more definitive repair later.

Bilateral choanal atresia is apparent immediately in the neonatal period because infants are obligate nasal breathers. These infants have respiratory distress, paradoxical cyanosis (crying relieves the cyanosis), and failure to thrive. The natural position of the tongue promotes obstruction that is relieved by an oral airway or a McGovern nipple (a standard nipple with an enlarged hole). Unilateral atresia often appears later (2 to 5 years of age) with rhinorrhea and chronic mucoid discharge and is often misdiagnosed. Because the intraoral airway is foreshortened as a result of the abnormally anterior choanal aperture, upper airway obstruction while breathing is common, and visualization of the laryngeal structures may be more difficult. Long-standing choanal atresia may also lead to obstructive sleep apnea.

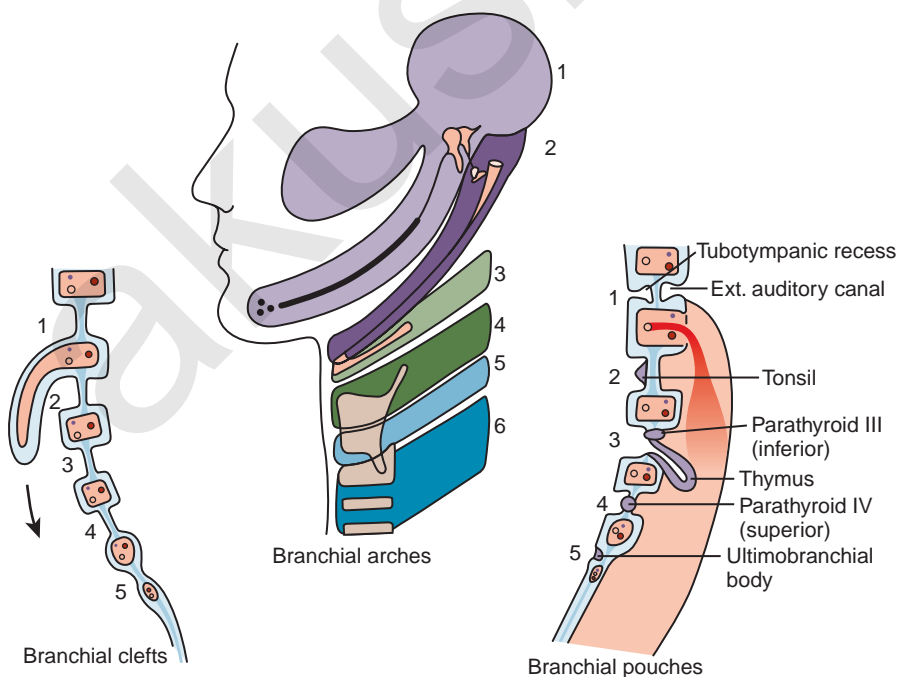

The face, specifically the maxilla and mandible, grows in a dynamic fashion throughout childhood under the influence of bony deposition and resorption, soft-tissue contouring, and hormonal influences. In a reciprocal fashion, the skull base or neurocranium influences midfacial development via the growth of the sinuses, which in turn influence the skull base. Displacement of these structures of the nasomaxillary complex occurs in horizontal, vertical, and anteroposterior axes. These changes ultimately affect the proportions of the face and the morphology of all of the facial structures, including the upper airway.

The Branchial Apparatus

Branchial Arches

The branchial apparatus consists of four branchial arches visible on the surface of the embryo, as well as fifth and sixth arches that cannot be seen on the surface. Branchial pouches and clefts are likewise numbered craniocaudally (Fig. 12-7). The first branchial arch (Meckel's) cartilage is the position of the future mandible, as well as the eventual malleus and incus. The second branchial arch cartilage produces the stapes, the styloid process, the stylohyoid ligament, and the superior portion of the body of the hyoid. The other branchial arch cartilages contribute to the inferior portion of the hyoid as well as the thyroid cartilage.

Striated muscles are also formed in the respective branchial arch mesenchyme. Myoblasts differentiate and migrate to various parts of the head and neck, where they form the muscles of mastication and facial expression, each retaining their original nerve supply. Although muscular actions in the head and neck are thought of as far removed from the origin and course of the cranial nerves, fetal nerves that supply the branchial arch derivatives only have a short distance to travel from the brain. The trigeminal (V) nerve supplies the skin covering the parts of the face derived from the first branchial arch maxillary and

■ **FIGURE 12-7.** The branchial arches, pouches, and clefts. The musculature of each arch is supplied by the (cranial) nerve of its origin; the first arch by the mandibular division of the fifth cranial nerve, as well as the chorda tympani division of the seventh cranial nerve. The seventh cranial nerve supplies the second arch, the ninth cranial nerve the third arch, and the tenth and eleventh cranial nerves the remaining arches. Branchial clefts, when they fail to obliterate during normal development, may result in sinuses or cysts that communicate with the oropharynx through various pathways in the neck.

mandibular divisions (the ophthalmic division does not make a contribution). The facial (VII) nerve supplies the muscles derived from the first arch. The nerve of the third branchial arch is the glossopharyngeal (IX) nerve. Two branches of the vagus (X) nerve supply the remaining branchial arches. The superior laryngeal nerve innervates derivatives of the sixth branchial arch.

Branchial Pouches

The first branchial pouch develops into the tubotympanic recess, becoming the auditory tube and the middle ear cavity (Fig. 12-8). The cavity of the second branchial pouch is largely obliterated as the palatine tonsil develops, but part of it remains as the tonsillar fossa. The endoderm of the second branchial pouch becomes the surface epithelium of the tonsil and the lining of its crypts, with the mesenchyme around the pouch differentiating into lymphoid tissue. The endoderm of the dorsal part of the third branchial pouches differentiates into the inferior parathyroids, and the ventral parts unite to become the thymus. The paired parathyroid glands develop from separate pouches, with one pair derived from the third and the other from the fourth branchial pouch. At the seventh week of development, the parathyroid glands migrate caudally from their respective branchial pouches, with the third pouch parathyroids moving more caudally than the parathyroids of the fourth pouch. Accessory parathyroid tissue may be left along the line of migration. The endoderm of the fourth branchial pouches differentiates into the superior parathyroid glands, and the ventral parts develop into the ultimobranchial bodies, the calcitonin-secreting portion of the thyroid.

Branchial Clefts

Between the first and second arches, the first branchial cleft forms the external ear, which is the only normal structure to arise from a branchial cleft. However, if the second arch does not grow caudally over the third and fourth arches, as it normally should, then the second, third, and fourth clefts can remain as branchial fistulas, in contact with the skin surface between the clavicle and the mandible. Incomplete or arrested development of the branchial clefts may result in residual cysts, sinuses, and fistulas that may eventually become infected and require excision. The clinical significance of the specific embryology is that characteristic locations are of important surgical significance.

FIGURE 12-8. The tympanic cavity develops from the tubotympanic recess, an outgrowth of the first pharyngeal pouch, which extends laterally, contiguous with the external auditory canal having formed from the first pharyngeal cleft.

Clinical Correlation

The second branchial arch may occasionally fail to bury the second, third, and fourth branchial clefts completely, resulting in a cervical sinus communicating with the surface of the skin, and forming a branchial sinus, which may also contain a branchial cyst. These sinuses may be accompanied by a draining infection along the anterior border of the sternocleidomastoid muscle, requiring complete surgical dissection and removal. It is easy to understand embryologically how these tracts can open into the pharynx just posterior to the tonsils and may even pass between the external and internal carotid arteries.

The thyroid begins as a thickening of the endoderm of the floor of the pharynx, in the midline between the first and second pouches, at the foramen cecum. A thin connection, the thyroglossal duct, remains attached to the oral cavity, and its point of attachment marks the origin of the thyroid gland. The thyroid descends along the thyroglossal duct and reaches the level of the first tracheal ring at about the seventh week of gestation (Fig. 12-9). The thyroglossal duct is then normally obliterated. Accessory thyroid tissue may be deposited anywhere along this path; on the other hand, failure of the thyroid to descend may result in a lingual thyroid.

Anomalies associated with abnormal development of the branchial arches are varied, with a range of complexity and airway implications. Whereas too much variation among anomalies exists, an appreciation of the developmental anatomy explains (and helps the anesthesiologist anticipate) the following situations:

1. Unilateral or bilateral hypoplasia of upper airway structures, which may result in a small and hypomobile mandible, choanal stenosis or atresia, and hypoplastic or nonexistent sinuses.
2. Fusions or other abnormalities of various cervical vertebrae.
3. Cleft palate may be the result of failure to fuse, or it may be associated with hypoplastic mandibles and glossoptosis

FIGURE 12-9. Descent of the thyroid along the thyroglossal duct. A lingual thyroid is the most common form of incomplete descent and is found inferior to the foramen cecum, where it may interfere with swallowing as well as breathing, particularly during anesthetic induction in infants.

(Pierre-Robin syndrome) or hemifacial microsomia (Goldenhar's syndrome).

4. Obstructive sleep apnea, which may result from chronic upper airway obstruction as a result of decreased available cross-sectional diameter of the airway with a relatively large volume occupied by the tongue and pharyngeal musculature, as well as an abnormally positioned palate.

The Larynx

Development of the larynx begins at approximately 3 weeks of gestational age with the formation of the laryngotracheal tube from the ventral wall of the foregut. The laryngotracheal tube then grows caudally into the splanchnic mesoderm on the ventral surface of the foregut, dividing into the right and left lung buds. The epiglottis begins to form from the hypobranchial eminence of the third and fourth arches at approximately 30 to 32 days' gestation. The aryepiglottic folds develop from the lateral

boundaries of the fourth arch along a line from the hypobranchial eminence (epiglottis) to the arytenoid eminence of the sixth arch. Incomplete development at this stage may produce varying degrees of persistent laryngeal cleft (Fig. 12-10). A definite larynx may be seen by 41 days' gestation. (Fig. 12-11).

The cricoid and thyroid cartilages begin to develop before the arytenoid cartilages, with chondrification starting at about 7 weeks of gestation. As the thyroid cartilage develops, the glottis deepens, and the true vocal cords align within the thyroid laminae. Failure of the true vocal cords to split to form the primitive glottis at 10 weeks of gestation results in congenital atresia of the larynx or more often, a complete or partial congenital laryngeal web. Although webs may be supraglottic or subglottic, most occur at the level of the glottis. Congenital cysts of the supraglottic region are possibly remnants of the third branchial pouch and lie superior to the derivatives of the fourth arch. By the tenth to eleventh weeks of gestation, the major structures of the larynx have developed and the cartilages are

FIGURE 12-10. Laryngeal cleft, in various grades, results from a persistent communication between the trachea and esophagus, most commonly at the cranial end. Type I lesions are localized to the interarytenoid space superior to the vocal cords; type II lesions involve a partial cricoid cleft. Types III and IV lesions traverse the cricoid completely.

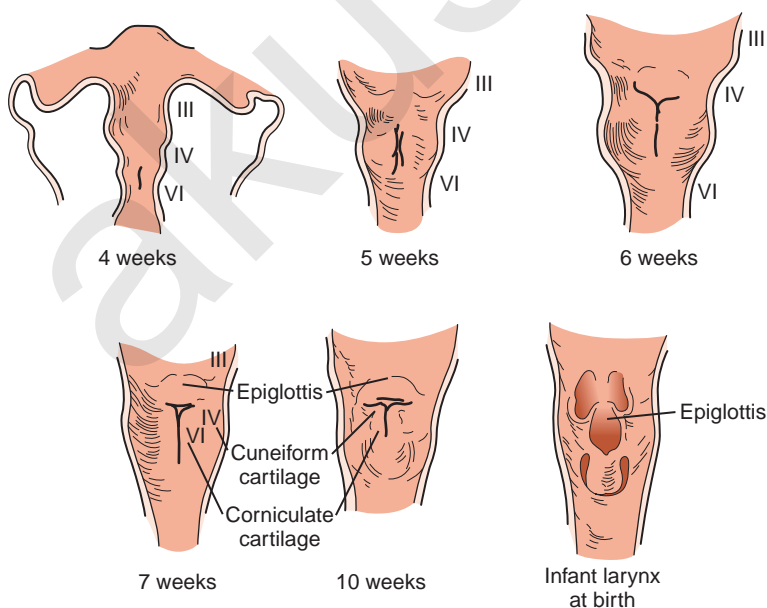

FIGURE 12-11. Development of the larynx. The epiglottis begins to form from elements of the third and fourth branchial arches at approximately 30 to 32 days of gestation, and early arytenoid cartilages can be identified on both sides of the laryngeal slit at this time as well. Incomplete development at this early stage may produce variable degrees of laryngeal cleft.

chondrifying. If the separation of the esophagus and trachea is slightly delayed and the margins of the laryngotracheal groove fail to fuse adequately, the rapidly growing trachea separates the proximal and distal esophagus, resulting in the most common form of proximal esophageal atresia and distal tracheoesophageal fistula.

Eckenhoff's (1951) review of the anatomy of the pediatric larynx has influenced more than a generation of pediatric anesthesiologists with regard to the selection of endotracheal tube size based on the concept of the narrowest (fixed) portion of the upper airway being the level of the cricoid cartilage, or the "funnel-morphing-into-cylinder" concept. Litman et al. (2003) examined laryngeal shape in sedated children undergoing MRI and determined that under sedated conditions with tonic maintenance of laryngeal shape, it is more cylindrical than funnel-shaped, as it is in adults, and that the narrowest portion of the airway is at the level of the vocal cords. Furthermore, they concluded that there is no change in this relationship from childhood to adulthood. This finding has been confirmed by video-bronchoscopic imaging in anesthetized and paralyzed children as well and provides an intriguing challenge to traditional teaching (see Chapter 3, Respiratory Physiology) (Dalal et al., 2008, 2009). The adjudication of these disparate concepts, as well as the confirmation in both reports that the cricoid opening is elliptic rather than circular in shape, with the narrowest transverse diameter, help support the transition over the last 10 to 15 years to the common use of cuffed endotracheal tubes with a smaller diameter rather than tightly (or "appropriately") fitted, uncuffed endotracheal tubes. Moreover, advances in materials and design have allowed the development of thin-walled tubes with shorter, polyurethane cuffs, which provide an equivalent seal at a lower mucosal pressure (Dullenkopf et al., 2005). At this point, the increasingly routine use of cuffed endotracheal tubes, with appropriate care, appears to result in fewer repeated laryngoscopies and reintubations, less postintubation croup and less contamination in the operating room, and lower total fresh-gas flows.

DEVELOPMENTAL PHYSIOLOGY

The Upper Airway

It is almost axiomatic in pediatric training to be told that the infant is an obligate nasal breather, and the reasons are best understood by developmental anatomy. The epiglottis is located in a more cephalad position relative to the other mobile soft-tissue components of the oral cavity, the tongue and soft palate, and their close approximation even during normal respiration may impair transoral breathing. Nasal resistance may provide up to 50% of total airway resistance and varies depending on alar orientation, the pyriform aperture, the nasal cavity, and the choanae. This is of practical importance to the pediatric anesthesiologist particularly when anatomic or even therapeutic (e.g., nasogastric tube) obstructions are present, because airway resistance is significantly increased and therefore respiration may be compromised.

The tongue, palate, pharynx, epiglottis, and larynx all have to work together to accomplish feeding and breathing. With postnatal growth, the mandible enlarges, descends, and protrudes, and the oral cavity enlarges vertically. The tongue occupies a more anterior position as the oral cavity and pharynx grow, and

the larynx descends from its C2 position in the neck to C4 after one year of age. The clinical usefulness of the high-lying larynx is that it places the epiglottis into contact with the soft palate, allowing the infant to be a nasal breather while sucking and swallowing. With the growth of the oral cavity and the rearrangement of intraoral architecture during the first few months of life, infants convert from obligate nasal breathing to nasal and oral breathing.

Isono (2006) has reviewed the physiology of airway maintenance at the pharyngeal level and described the pharynx as a collapsible air-filled tube surrounded by soft tissues enclosed in a rigid box of bony structures, the mandible and vertebrae, with the lumen of the tube determined by the balance of the soft-tissue mass and the size of the surrounding rigid box. This simple approach explains the success of routine clinical airway maneuvers—continuous positive airway pressure (CPAP) serving as a pneumatic stent for the collapsed air-filled tube and surrounding soft tissue, and anterior displacement of the jaw serving to enlarge the rigid box. An oral airway displaces the base of the tongue anteriorly, thereby increasing the transpharyngeal luminal space and moving the base of the tongue away from the prevertebral bodies. Anesthetics, of course, depress the integrity of pharyngeal muscle tone through a variety of mechanisms, including the attenuation of neural input caused by the loss of consciousness and the decrease in tone of the diaphragm and intercostal musculature. The tongue and its muscular attachments such as the genioglossus, geniohyoid, sternohyoid, sternothyroid, and thyrohyoid are affected as well. All of this conspires to narrow the pharyngeal airway, more so in infants and small children than adults, especially during the first year of life (Isono et al., 2000). Adults are more equipped than children to defend against these effects, because they possess a more competent negative pressure reflex serving to augment pharyngeal tone, although the negative pressure reflex has been shown in infants younger than 1 year old as well (Thach et al., 1989; Horner et al., 1991). In addition, the progressive increase in pharyngeal cross-sectional area during the first year of life is positively influenced by the growth of the mandible and maxilla.

Pharyngeal airway obstruction has long been recognized as a significant component of the clinical entity called *laryngospasm*, and the application of CPAP, whether applied transnasally or transorally, depresses pharyngeal muscle tension and provides a mechanical pneumatic stent for the upper airway (Fink, 1956; Alex et al., 1987). This is a subtle component of the routine technique used by experienced pediatric anesthesiologists in applying gentle amounts of positive pressure during the induction phase, especially with infants and small children.

The fetus is an experienced swallower, well practiced from the age of 10 to 11 weeks' gestation, with suckling following at 18 to 24 weeks' gestation. This is fortunate, because coordination of this highly complex task is dependent on practice in utero and learning in pre- and postnatal life. However, breathing, even in utero, is a relatively late event, occurring at about 32 to 37 weeks' gestational age, and premature infants show their lack of experience with significant discoordination between swallowing and breathing, as do children who are neurologically impaired (Goldson, 1987; Arvedson et al., 1994).

Protective airway reflexes are initiated via adduction of the true and false vocal cords, closing the laryngeal vestibule. The epiglottis deflects posteriorly to cover the laryngeal inlet, diverting food into the pyriform sinuses. Finally, the larynx elevates

through the effort of the suprahyoid musculature, contracting prior to the entrance of the food bolus into the hypopharynx, which aids in opening the cricopharyngeal sphincter. Moreover, activation of sensory receptors in the pharynx and anterior tonsillar pillars inhibits respiration during swallowing. Finally, the esophageal phase, from the upper esophageal sphincter to the lower esophageal sphincter (LES), is mediated by contractions that occur throughout the length of the esophagus via a coordinated peristaltic wave. The cricopharyngeal sphincter returns to a tonic state (+5 mm Hg) from its relaxed state (−15 mm Hg), as do the diaphragmatic crura, the angle of the gastroesophageal junction, and the diaphragm, thereby preventing reflux into the hypopharynx. Reflex protection of the airway occurs via two pathways: anterograde protection accomplished during normal swallowing, and retrograde protection accomplished by antireflux mechanisms. Laryngeal and nasopharyngeal closure occur via the influence of the superior laryngeal nerve on laryngeal secretions manifest themselves as reflex closure of the larynx and sustained apnea (Perkett and Vaughan, 1982; Bartlett, 1985). With maturity, coughing replaces apnea as a protective mechanism (Miller et al., 1952; Leith, 1985). As far as gastrointestinal reflux is concerned, increasing attention has been devoted to its contribution to recurrent pneumonia, reactive airways disease, apnea, and respiratory failure. The upper and lower esophageal sphincters maintain a resting tone of 10 to 30 mm Hg over intragastric pressure, and in combination with crural support and the acute gastroesophageal angle, act to prevent regurgitation of stomach contents. However, premature infants have a lower LES pressure and a less acute gastroesophageal angle; central nervous system (CNS) immaturity is related to abnormalities of the LES relaxation pattern (Hillemeier, 1996).

DEVELOPMENTAL AIRWAY PHYSICS

Because of the variable diameter and length of the trachea, as well as the common (mainly in toddlers) problems of foreign body aspiration and anatomic or functional airway obstruction, understanding the physics of gas flow is even more crucial in pediatric anesthesia than in any other anesthesiology subspecialty. Noisy breathing is often an ominous sign in infants and small children. Stridor is noisy breathing coupled with increased inspiratory efforts, such as nasal and rib-cage flaring and suprasternal and sternal retraction. Severe airway obstruction may result in cyanosis, respiratory distress and fatigue, pneumothorax, pneumomediastinum, and death. Purely inspiratory stridor usually indicates lesions in the upper part of the airway. Lesions distal to the vocal cords usually produce expiratory stridor. Biphasic stridor is most characteristic of obstruction at the level of the subglottic space. Physical laws not only help explain the basis of these signs but provide guidance about effective clinical intervention (see Chapter 3, Respiratory Physiology in Infants and Children).

Laminar and Turbulent Flow

Laminar flow of a fluid (whether the fluid is a liquid or a relatively slowly-moving gas) through a tube is proportional to the pressure gradient (total pressure drop/length of tube), the fourth power of the radius of the tube and inversely proportional

to the viscosity of the fluid. This relationship is expressed mathematically in the Hagen-Poiseuille Law:

$$\dot{V} = \frac{P\pi r^4}{8\eta l}$$

where \dot{V} equals the flow of the gas, P equals the total pressure drop, r equals the radius of the tube, η equals viscosity, and l equals length.

The most important implication of the Hagen-Poiseuille Law is that halving the radius, for example, decreases flow rate by the fourth power, or 16-fold. Likewise, doubling the radius increases the flow rate 16-fold; this is critically important, especially for infants and small children, and it explains the improvement in respiratory distress with appropriate treatment for conditions such as croup. In normal lungs, laminar flow occurs only in the periphery of the lung (small peripheral bronchi and bronchioli) where the flow is relatively slow in relation to the diameter of the airways. For the rest of the airway system, the flow pattern is predominantly turbulent because of uneven airway diameters and an average of 24 (19 to 27) airway branchings.

For turbulent conditions, the change in the expression from flow rate to the square of the flow rate illustrates that a much greater driving pressure is required to maintain gas flow. Fanning's equation expresses this relationship mathematically, where the radius of the tube to the fifth power now determines that flow.

$$\dot{V}^2 = \frac{P4\pi^2 r^5}{l\mu f}$$

where \dot{V} equals the flow of the gas, P equals the total pressure drop, r equals the radius of the tube, μ equals density, l equals length, and f equals Fanning's friction factor.

Upper and lower conducting-airway air flow is turbulent, whereas the peripheral airways are characterized by laminar air flow, enhancing alveolar ventilation. The conducting airways bifurcate progressively (but not symmetrically). Cartilaginous support is characteristic of the main, lobar, and segmental bronchi, and more distal conducting airways have bronchial muscle forming a geodesic network. The total cross-sectional area of the respiratory tract is minimal at the third generation (Fig. 12-12). Small bronchi extend through about seven generations, and the total cross-sectional area increases by about sevenfold by generation 11. After the eleventh generation, cartilage

■ **FIGURE 12-12.** Cross-sectional area of the respiratory tract in relation to airway generations. With growth of the airways, compliance increases and resistance to gas flow falls according to the Hagen-Poiseuille Law, where resistance falls according to the fourth power of the radius. (From Weibel ER: Morphometry of the human lung, New York, 1963, Academic Press.)

disappears from the airway wall. With these noncartilaginous walls embedded within the lung parenchyma, contiguous elastic tissue serves to hold the airways open, and therefore lung volume plays a substantial role in the maintenance of conducting airway patency. In the terminal bronchioles, the total cross-sectional area is about 30 times the area at the level of the large bronchi. Flow resistance in these small airways is about 10% of lower airway resistance (Macklem and Mead, 1967).

Flow in laminar profiles enhances diffusivity, because flow at the center of the shear increases the rate of spread in that direction (Fig. 12-13). Fluids or gas molecules moving through a tube under constant pressure separate into a gradient of velocity profiles, with the fastest component in the center and the slowest components near the wall. When the cross-sectional area is reduced, the velocity must increase (and the pressure decrease) in order to maintain the same volume flow rate; resulting gas flow is much more turbulent. With abrupt narrowing, complete separation of the stream profiles occurs, the center stream constricts to a minimum value, and laminar flow may not be able to resume because of the turbulence. Pragmatically, when difficulty with positive pressure ventilation occurs, the natural response of the anesthesiologist is to apply more pressure to the rebreathing bag. For the patient whose airway is compromised, this results in more turbulence in the upper airways and less effective air flow downstream. Passive exhalation may also be impaired, and air trapping may result. However, if the pressure gradient (ΔP) across the obstruction is reduced (e.g., changing to spontaneous breathing from controlled ventilation in order to reduce the high pressure proximal to the obstruction), then air flow may be enhanced distally. This applies to airway narrowing, regardless of intrinsic or extrinsic causes.

Clinical Correlation

Causes of stridor include congenital, inflammatory, traumatic, and foreign bodies; a congenital cause is found in 85% of children younger than 2.5 years of age (Holzman, 2000). Severe airway obstruction may result in cyanosis, respiratory distress and fatigue, pneumothorax, pneumomediastinum, and death.

■ **FIGURE 12-13.** Taylor dispersion: fluids (or gases) moving through a tube under constant pressure separate into a gradient of velocity profiles with the fastest component in the center and the slowest components near the wall. With a reduction in cross-sectional area, the velocity must increase (and the pressure decrease) in order to maintain the same volume-flow rate. Turbulence results. Clinically, when resistance to air flow occurs, the natural response is to apply more pressure to the breathing bag; this will result in more turbulence in the upper airways and less effective air flow downstream.

Bubble Stability and Breathing: Laplace's Law

The pressure inside a vessel is always higher than the surrounding gas pressure, because the surface of the vessel is in a state of tension. In this respect, alveoli resemble bubbles, or spherical vessels. Laplace's Law describes the relationship between the radius of a vessel and the wall tension required to withstand a given internal fluid pressure. This is different for cylinders and spheres; a sphere has half the wall tension of a cylinder. Wall tension increases as the sphere becomes larger, and the radius of curvature decreases in order to balance the downward component of tension. A rough analogy is hanging heavy clothing on a clothesline; in order for the clothesline to sag less, its tension must be increased. The exact amount of pressure inside the sphere depends on the surface tension of the liquid and the radius of curvature. Laplace's equation expresses this mathematically:

$$P = 2T/R$$

where P equals pressure within the sphere, T equals surface tension of the liquid, and R equals the radius of the sphere. In addition to the amazing ability of pulmonary surfactant to dramatically reduce the surface tension at the alveolar surface (gas-liquid interface), the surfactant stabilizes the airspace by its ability to change the surface tension as the surface expands and contracts during the respiratory cycle; it decreases surface tension as the surface expands and increases the surface tension as the surface contracts, affecting Laplace's Law so as to maintain and stabilize air space pressure during the respiratory cycle and prevent alveolar collapse (see Chapter 3, Respiratory Physiology in Infants and Children).

Understanding this relationship also helps explain the improvement in ventilation/perfusion matching with spontaneous breathing when there are two functional lung units of unequal compliance and resistance; an unusually high surface tension, along with interstitial fluid accumulation (edema) and fibrosis, would decrease compliance of the segment. Two functional units (e.g., lungs) of equal compliance and resistance increase their volumes equally when mouth pressure is increased to a constant level; the time course of wash-in is identical for both units. If the compliances of the two units are identical but the resistance of one is twice that of the other, however, the time constant is also twice normal and the unit with the higher resistance fills more slowly, although the volume increase in both units is the same if inflation is prolonged indefinitely. If inspiration ceases after 2 seconds, the pressure is higher in the unit with the lower resistance. Although it is true that paralysis and artificial ventilation do not greatly alter gas exchange ventilation/perfusion (V/Q) matching, dead space to tidal volume ratio (V_D/V_T), and shunt in young, healthy patients in comparison with spontaneous ventilation. This is not true for patients with inequalities in the distribution of ventilation because of asymmetric resistances between lung units (Fig. 12-14). Slow or sustained inflation permits increased distribution of gas to slow alveoli and so tends to distribute gas in accordance with the compliance of the different functional units. Such a situation is the principle underlying frequency-dependent compliance.

Clinical Correlation

Infantile (or idiopathic) respiratory distress syndrome (IRDS), or hyaline membrane disease, is a major cause of respiratory distress in preterm infants because of surfactant deficiency, as

■ **FIGURE 12-14.** **A**, An idealized state showing the reciprocal relationship between resistance and compliance; gas flow is preferentially delivered to the most compliant regions, regardless of the rate of inflation. Static and dynamic compliance are equal. **B**, A typical state of respiratory disease, where alveoli exist in fast and slow groups. The relationship between compliance and resistance results in preferential delivery of inspired gas to the stiff alveoli if the rate of inflation is rapid; an end-inspiratory pause serves to redistribute gas from the fast alveoli to the slow alveoli.

well as ongoing respiratory embarrassment in bronchopulmonary dysplasia. Surfactant is a complex mixture of lipids and proteins secreted in type II respiratory epithelial cells that lowers alveolar surface tension and therefore decreases the pressure needed to keep alveoli open and inflated. Surfactant deficiency and the consequent alteration in the ability of alveoli to remain optimally inflated results in reduced compliance, reduced functional residual capacity, unevenly increased airway resistance, and decreased alveolar ventilation. These anatomic changes therefore result in an increased physiologic dead space, ventilation/perfusion imbalance, hypoxemia, hypercarbia, and mixed respiratory and metabolic acidosis. In addition, for children with peripheral airways obstruction who require assisted ventilation, the work of breathing during spontaneous breaths is decreased by the application of positive end-expiratory pressure (Graham et al., 2007).

Bernoulli's Principle and Venturi's Effect

In 1738, Bernoulli demonstrated that the pressure of a fluid is least where its speed is greatest. This decrease in pressure when a fluid passes through a region of constriction is the basis of Venturi's effect, demonstrated almost 60 years later when Venturi showed that as a liquid passes beyond a constriction to a wider part of a tube, its speed gradually decreases, accompanied by a gradual increase in pressure. Furthermore, Venturi showed that in order for a streaming fluid to regain a pressure much higher than that at the constriction, the tube immediately distal to the constriction has to open out very gradually, usually not more than a cone angle of about 15 degrees. This is really a conservation of energy principle; in a steady flow the sum of all forms of mechanical energy is the same at all points (i.e., the sum of the kinetic and potential energies are constant).

Clinical Correlation

In Venturi jet ventilation, actually based on Bernoulli's principle and initially described by Sanders in 1967 for clinical use, a jet replaces the constriction of a tube and the oropharynx or trachea acts as the diffuser. An activating toggle switch attached to an oxygen source at 50 psig via a variable pressure-reducing valve controls the stream of gas aimed at the trachea. This technique is often used for laser surgery of the vocal cords. Because the pressure is subatmospheric at the distal end of the jet, air is entrained to swell the stream of gas. This principle is also used during supplemental oxygen therapy (the "Venturi" mask with a variable-orifice air-entrainment port); it is also the principle behind the function of an atomizer.

AIRWAY EQUIPMENT

Routine Pediatric Airway Equipment

Face Masks

Because the cushion-seal face masks used for anesthetizing children have dead spaces from 50 to 80 mL, they add substantially to rebreathing. For this reason, Rendell-Baker and Soucek (1962) introduced a molded, low-dead-space face mask specifically for use with spontaneously breathing infants and children at a time when the administration of halothane anesthesia by mask was popular. However, it is easier to seal to the patient's face with a cushioned face mask than a Rendell-Baker model, and a good mask seal is particularly useful for the application of CPAP during the induction or emergence from general anesthesia.

The use of the proper technique by a clinician when employing a face mask is more important than the type of mask selected.

The clinician's fingers must not depress the submental soft tissues of small children, because the tongue will be forced against the hard and soft palates and an upper airway obstruction may result. Children who have craniofacial anomalies may present a special challenge when attempting to obtain a good mask seal. This includes children with midfacial dysmorphism such as occurs in Apert's syndrome, Crouzon's disease, choanal atresia, or more severe forms of frontonasal dysplasia. Obtaining an adequate mask fit in patients with craniofacial anomalies may be considerably more difficult than the laryngoscopy or tracheal intubation. A useful technique for the ventilation of the lungs of children with midface hypoplasia is to support their cheeks with dental rolls that are placed between the gingiva and buccal mucosa; this often results in a better mask fit.

Airway Adjuncts

Oropharyngeal airway devices should be available in the full range of sizes at each anesthetizing location. The required airway size can be estimated by a careful external examination of the child and by measuring the distance from the teeth to the base of the tongue. An oropharyngeal airway device that is too small can displace the base of the patient's tongue inferiorly toward the pharynx, thereby increasing the degree of obstruction, which may worsen with the application of CPAP in an effort to improve the airway obstruction. An airway that is too large may reach the laryngeal inlet and result in trauma or laryngeal hyperactivity and laryngospasm. It is common practice by some clinicians to insert an oropharyngeal airway device upside down, or convex to the natural curvature of the tongue and then to rotate the airway 180 degrees. However, this maneuver may abrade the hard palate and it is therefore not recommended. A less traumatic technique for the insertion of an oropharyngeal airway device is to use a tongue depressor to displace the tongue to the floor of the mouth and to insert the device concave to the tongue's surface.

Oropharyngeal airway devices are often used as "bite blocks" after a patient's trachea has been intubated, in order to prevent the clenching of the teeth on the endotracheal tube. This maneuver may, however, be hazardous in children between 5 and 10 years of age with loose deciduous teeth. Oropharyngeal airway devices are responsible for up to 55% of anesthesia-related dental complications (Clokier et al., 1989). Furthermore, when an oropharyngeal airway device is used as a bite block during long cases, it may cause necrosis of the tongue, uvular edema, or lip damage (Moore and Rauscher, 1977; Shulman, 1981). A gauze pad that has been rolled up and placed between the patient's upper and lower molar teeth is a better method of preventing the teeth from clenching on an endotracheal tube and minimizing dental trauma. Caution must be exercised, however, that the roll not slip and place undue pressure on the lateral aspect of the tongue (paraglossal sulcus), where the hypoglossal nerve runs.

Nasopharyngeal airway devices are generally constructed from red rubber or polyvinyl chloride and are available in various sizes. A nasal airway should be lubricated and gently inserted transnasally. Nasopharyngeal airway devices may traumatize the turbinates or adenoids of young children. Moreover, care must be exercised when using a nasopharyngeal airway device in children who have a bleeding diathesis or a congenital abnormality of the midface such as choanal atresia or frontonasal dysplasia. The proper length for the nasopharyngeal

airway may be estimated by measuring the distance between the patient's auditory meatus and the tip of the nose. The insertion of a nasopharyngeal airway device that is too long may cause laryngospasm. Furthermore, if the airway is too short, the upper airway obstruction may not be relieved.

The LMA is used successfully for routine pediatric anesthetics and even for adenotonsillectomies (Webster et al., 1993; Williams and Bailey, 1993). LMAs are currently manufactured in several sizes, for patients ranging from neonates to large adults. With minimal inflation of the mask's cushion and thorough lubrication of the nonlaryngeal surface, an LMA should be seated at the laryngeal inlet and cause minimal discomfort to the patient postoperatively. Following its blind passage through the oral cavity, the proper seating of an LMA is generally heralded by a slight rise of the device when the mask's cushion is inflated with air. Care should be taken to use the minimal effective inflation pressure for the cuff, typically up to 60 cm H₂O. The routine use of a manometer is advocated. In some patients, the cushion of the LMA overrides the proximal portion of the esophagus, thereby exposing the patient to the risk of the aspiration of gastric contents, with the LMA serving as a conduit to the lungs (Nanji and Maltby, 1992). Nevertheless, although ideal positioning of an LMA appears to be achieved in only 50% of cases, the vast majority of patients fare very well (Rowbottom et al., 1991; Goudsouzian et al., 1992; Mizushima et al., 1992).

Although it was originally thought that pediatric-sized LMAs might not function adequately because of differences in airway anatomy, this fear proved to be unfounded. The #1 LMA, a miniature version of the adult LMA, was designed to fit infants who weigh less than 6.5 kg. It has worked satisfactorily even in premature infants as small as 1 kg, in newborn resuscitation, and in airway maintenance for infants with upper-airway congenital anomalies (e.g., Pierre-Robin, Goldenhar's, Treacher-Collins, and Schwartz-Jampel syndromes). In difficult intubating conditions, it has been used throughout the whole procedure or as a conduit for endotracheal intubation. The endotracheal tube can often be easily directed through an LMA without fiberoptic laryngoscopy.

Flexible LMAs in sizes 2, 2.5, and 3 are also available for pediatric use. The cuff is similar to a standard LMA, but the airway tube is wire-reinforced, longer, and more flexible, allowing it to be positioned away from the surgical field. Although the flexibility of the tube is advantageous for positioning, it is more difficult to insert, it may dislodge more easily, and biting can occlude it. Moreover, the flexibility of this LMA does not allow the rotation technique for insertion. Adenoidectomy or even tonsillectomy can be performed with the flexible LMA, because the cuff prevents soiling of the glottis and the trachea by blood and secretions from the surgical site. If tracheal intubation is planned via LMA, a standard LMA is a more logical choice in children, because it is shorter and has a larger diameter; in adolescents or adults, the intubating LMA (Fastrach) can be used.

The more cephalad and anterior position of the larynx of a child as compared with an adult has prompted the use of an alternate insertion technique in children. In this case, the LMA is inserted with its cushion placed against the hard palate. The device is then rotated through 180 degrees until the cushion is seated at the laryngeal inlet (McNicol, 1991). This method for the insertion of an LMA appears to be especially useful in preschool and young school-age children.

Endotracheal Tubes

The most definitive method for airway management in children remains intubation of the trachea. Polyvinylchloride is still the most popular material employed for the production of endotracheal tubes, although other materials continue to be used and newer technologies are evolving. For example, Weiss and Dullenkof (2007) have reexamined design requirements of pediatric endotracheal tubes, including cuff placement below the cricoid cartilage, which requires a smaller, more distally placed cuff. Among other features, with polyurethane replacing the polyvinylchloride cuff, the sealing pressures for children are in the range of 6 to 14 cm H₂O (Weiss and Dullenkof, 2007). Recommended performance specifications, as well as detailed standards, for endotracheal tubes have been published (Carroll et al., 1973; Shupak and Deas, 1981).

Table 12-1 lists estimated values for the appropriate endotracheal tube sizes and lengths as well as those for pediatric LMAs (Cole, 1957; Penlington, 1974; Morgan and Steward, 1982; Steven and Cohen, 1990). In general, the size of the tube is more related to the age rather than size of the patient. When selecting an endotracheal tube for a child, it is important to remember that the presence of a deflated cuff adds about 0.5 mm to the tube's external diameter. However, the external diameters of endotracheal tubes differ widely among the manufacturers of the tubes. Cuffs also differ in their shapes and positions along the endotracheal tube. In addition, because nitrous oxide diffuses into the closed airspace of an endotracheal tube's cuff when the inflation valve is closed, this valve should be rendered incompetent during long procedures. Otherwise, the intracuff pressure should be monitored and maintained at a level below 25 cm H₂O (18.4 mm Hg). A variety of endotracheal tubes are available for special needs, including preformed oral or nasotracheal tubes (Ring-Adair-Elwyn [RAE] tubes) for oral or dental surgery and wire-reinforced (anode) endotracheal tubes for head and neck surgery or laryngotracheal reconstruction, when the tube may be inserted through the tracheal stoma and

sutured to the anterior chest wall. The special precautions that must be taken with endotracheal tubes during laser surgery of the aerodigestive tract have been described (Sosis 1989, 1992; Sosis and Dillon, 1990, 1991, 1993). The majority of laser airway surgery in pediatrics is for the treatment of juvenile laryngeal papillomatosis or other laryngeal anomalies, and these are cases that lend themselves well to Venturi jet ventilation of the lungs. However, wrapped endotracheal tubes may be required for pediatric laser airway surgery when the laryngeal inlet is too narrow to permit a sufficient entrainment of pharyngeal gas for the Venturi technique (Holzman, 1991, 1992).

Since the seminal report by Koka et al. (1977), an air leak around an endotracheal tube has been strongly advocated for the prevention of postintubation croup in infants and children younger than 10 years of age. Surprisingly, a great deal of variability exists in the ability of a clinician to recognize an air leak around an uncuffed endotracheal tube (Schwartz et al., 1993). However, cuffed endotracheal tubes are advantageous for certain abdominal or thoracic procedures. Also, patients with pulmonary pathologic conditions with poor lung compliance may require high peak inspiratory pressures to assure adequate ventilation of the lungs, and a cuffed endotracheal tube may be necessary for these cases. Because of an increasingly sophisticated understanding of developing laryngeal anatomy and vastly improved materials science in the manufacture of endotracheal tubes, there is a currently a greatly expanded use of cuffed endotracheal tubes in all ages (see *The Larynx*, p. 350). Accordingly, the use of a cuffed endotracheal tube should be individualized (Table 12-2). Likewise, children who are susceptible to croup during a viral illness of the respiratory tract may benefit from tracheal intubation with a smaller endotracheal tube than is normally used, with or without a cuff, as long as the lungs can be ventilated adequately. A throat pack may help make a seal when an uncuffed endotracheal tube is employed.

Endotracheal tubes are available with or without a special opening known as a *Murphy eye* in the wall opposite the tube's distal bevel. Endotracheal tubes fabricated without the Murphy

TABLE 12-2. Advantages of Cuffed vs. Uncuffed Endotracheal Tubes

	Cuffed	Uncuffed
Advantages	Not important for subglottic stenosis	Larger tube, therefore less resistance for spontaneous breathing and mechanical ventilation
	Fewer repeat laryngoscopies and reintubations	Lower risk of occlusion
	Less contamination	No cuff = no ridges
	Lower fresh-gas flow	No concern about tip-to-cuff border distance
	Better protection against aspiration	No requirement for pressure monitoring
Indications	High risk of aspiration	Minus the concerns on the left, most likely does not matter much
	Preexisting or impending impaired pulmonary compliance	
	Patient with poor lung compliance	
	undergoing minimally invasive abdominal or chest surgery	
	Cardiopulmonary bypass	
	Requirement for precisely controlled mechanical ventilation	

eye are known as *Magill tubes*, whereas those that have this opening are called *Murphy tubes*. The Murphy eye was designed to provide an alternate pathway for the flow of ventilatory gases if the distal opening of the endotracheal tube was occluded—a common situation, especially in infants (Murphy, 1941). However, there are potential disadvantages to the presence of a Murphy eye on an endotracheal tube, including a tendency for accumulation of secretions and the possibility that a stylet, catheter, or bronchoscope may get stuck, requiring the removal of the entire assembly. Cuffed endotracheal tubes manufactured without a Murphy eye can have the cuff located closer to the tube's tip. Nevertheless, pediatric anesthesiologists generally favor the use of an endotracheal tube that is equipped with a Murphy eye because of the obstruction risk. Recently, Weiss and Dullenkoff (2007) have reexamined the design requirements of a more anatomically suitable pediatric endotracheal tube, including cuff placement below the cricoid cartilage, thus requiring a smaller, more distally placed cuff and removal of the Murphy eye. Among other features, with a polyurethane as opposed to a polyvinylchloride cuff, the sealing pressures for children are in the range of 6 to 14 cm H₂O, well under the 20 to 25 cm H₂O for the leak test.

Stylets are often inserted into endotracheal tubes used for children to provide rigidity and bend the tube to a desired shape. However, the increased rigidity provided by a stylet can result in greater trauma. Moreover, because of metal fatigue, old wire stylets may break during their removal from an endotracheal tube, placing the patient at risk for the aspiration of a foreign body. Stylets should be of the proper size for the endotracheal tube, and they should be well lubricated so they can be removed easily. The tip of the stylet should be

properly recessed (1 to 2 cm) from the tip of the endotracheal tube to avoid its extrusion from the tube and direct trauma to the mucosa. Each stylet should be carefully inspected for any potential weak points.

The concerns about anatomic differences between children and adults were typically partisan enough that while an emerging acceptance of endotracheal intubation was obvious beginning in the 1950s and 1960s, it remained a relatively rare technique in pediatric anesthesia. Clinicians were warned about the narrowest part of the pediatric airway located at the cricoid cartilage. Outcome studies began to suggest the safety and efficacy of endotracheal intubation in infants and children, and pediatric anesthesia clinicians were becoming more vocal in defense of this emerging technique. See related video online at www.expertconsult.com.

Laryngoscopes

The ability to use standard straight and curved laryngoscope blades is mandatory in pediatric anesthesia. The laryngeal structures of infants are encountered at a more cephalad and anterior position, approximately the level of C2 to C3, depending on age, until the child reaches school age, when the laryngeal structures descend to a level opposite the body of C4. It is common practice to use a straight laryngoscope blade such as the Miller 0 or 1, or the Wis-Hippel 1.5, to intubate the trachea of an infant or a child up to school age. A curved laryngoscope blade with a wider spatula, such as the Macintosh blade may be advantageous to control the tongue of an older child. Whether to use the straight or the curved laryngoscope blades can be determined according to this approximate age distribution; however, the individual preferences of the clinician may vary, as can individual circumstances. The larger tongue of a patient with Down's syndrome, at any age, for example, may be easier to manipulate with the wider spatula of a Macintosh blade. A short laryngoscope handle is most useful for the intubation of the trachea of an infant, a small child, or an obese patient.

Equipment for the Management of a Difficult Airway in a Child

Line-of-sight devices have been the mainstay of direct laryngoscopy techniques, yet difficulties with laryngoscopy and intubation are not rare. Although it is typically acknowledged as a rare event, there is emerging literature that difficulty with laryngoscopy may be encountered in 5% to 20% of adult patients; although this may be substantially less of an issue in children and it may be age dependent (0.57% in newborns and toddlers, 0.12% in preschool, and 0.05% in school-age patients) (Rose and Cohen, 1994, 1996; Ezri et al., 2003; Schmidt and Koch, 2008).

Anterior commissure laryngoscopes, because of their tubular construction, are particularly useful with a difficult-to-visualize "anterior" (cephalad) larynx in the patient with a small oral cavity. They require a fiberoptic external light source. In addition, long bronchoscopy forceps must be available. The 15-mm connector is removed from the endotracheal tube, and the laryngoscope is inserted. With the epiglottis lifted directly from the laryngeal surface, the tip of the laryngoscope should be placed at the glottic opening. The endotracheal tube is inserted through the tubular laryngoscope blade. Although direct visualization of the glottis is usually lost at this point, correct positioning

FIGURE 12-15. Use of an anterior commissure laryngoscope for endotracheal intubation; when an endotracheal tube with its 15-mm connector removed is inserted through the tubular blade after the epiglottis is lifted from the laryngeal surface and the tip of the blade is placed at the glottic opening, the bronchoscopy forceps can grasp the proximal end of the tube while the laryngoscope is removed over the tube and forceps.

and the tubular structure of the blade guide the tube into the trachea. Using the forceps, the tube is held in place while the laryngoscope is removed over the tube and forceps (Fig. 12-15). The endotracheal tube connector is then replaced, and the tube position is verified.

Newer technologies, such as fiberoptic bronchoscopy and the availability of video machines, are making it much easier to develop ways of viewing the larynx that are not directly line-of-sight dependent. The skills required for effective use of these devices are different, and although pediatric anesthesiologists must keep abreast of new technologic skills, conventional rigid laryngoscopy is used the majority of the time.

With fiberoptic and video modifications, flexible, malleable, and rigid devices have been developed that have added to the laryngoscopy tool shed in recent years. Optical stylets may be rigid, flexible, or malleable; resemble a conventional laryngoscope; or be more like a flexible fiberoptic bronchoscope (Liem et al., 2003). The basic design consists of a fiberoptic rod with an eyepiece at the user end that allows the anesthesiologist to view the advancement of the endotracheal tube, which is threaded over the device. Examples of these devices include the Bonfils Retromolar Intubation Fiberscope (Karl Storz Endoscopy; Culver City, California), the Shikani Optic Stylet (Clarus Medical LLC; Minneapolis, Minnesota), the StyletScope (Nihon Kohden Corp.; Tokyo, Japan), the Video Optical Intubation Stylet (VOIS, Acutronic Medical Systems, AG; Baar, Switzerland), and the Levitan FPS Scope (Clarus Medical LLC; Minneapolis, Minnesota) (see Chapter 10, Equipment, Fig. 10-24). The Bonfils laryngoscope is a nonmalleable scope, whereas the Shikani laryngoscope has a distally malleable stylet. It can accommodate a size 2.5 endotracheal tube in its pediatric version. All of these stylets can be used alone or in conjunction with rigid direct laryngoscopy. In the absence of direct laryngoscopy, a jaw lift or jaw thrust should be used to increase the anteroposterior distance of the hypopharyngeal space and move the base of the tongue away from the laryngeal inlet.

Rigid fiberoptic laryngoscopes have a fiberoptic bundle encased in a closed structure. They serve the same function as conventional rigid laryngoscopes, in that they are intended for viewing the larynx and confirming the insertion of the endotracheal tube. They cannot view the subglottic space or be inserted by any route other than transorally. Examples include the Bullard laryngoscope, UpsherScope, and WuScope. Only the Bullard laryngoscope is available in pediatric versions (see Chapter 10, Equipment, Fig. 10-30). The Acutronic Video Intubating laryngoscope (Acutronic Medical Systems, AG; Baar, Switzerland) was developed by Weiss and resembles a conventional laryngoscope and blade with a fiberoptic bundle that can be coupled to a video camera.

Rigid video laryngoscopes allow the image to be displayed to an eyepiece or a video screen. The video camera may be located within the handle, mounted on the handle, or displayed remotely. Other rigid video laryngoscopes include the Glidescope (Verathon, Inc.; Bothell, Washington) (see Chapter 10, Equipment, Fig. 10-31; see related video online at www.expertconsult.com). It is available in pediatric and neonatal versions. Because the larynx is not in the line of sight, the Glidescope should be used with a stylet. Exposure of the vocal cords on the image does not necessarily occur from exposure of the larynx. Antifogging solutions are not required, because a charge-coupled video chip covered by a heated glass window is incorporated into the blade, making it fog resistant.

The flexible fiberoptic laryngoscopes that are used for children are generally smaller than adult scopes, and not all small fiberscopes are designed with a channel for suctioning or oxygen insufflation. Also, pediatric fiberscopes may be limited in the extent of their tip excursion in comparison with larger fiberoptic laryngoscopes. A pediatric fiberoptic laryngoscope is often used to intubate the trachea of a child who is breathing spontaneously with a volatile anesthetic. In such cases, an airway intubation (Frei) mask or one with a similar design, which incorporates a grommet through which a fiberscope may be passed, is very useful (Frei, 1995) (see related video online at www.expertconsult.com).

It may seem counterintuitive to advocate blind intubation techniques amidst these advances in technology; however, in skilled and thoughtful hands, these methods are worthy of consideration because they have stood the test of time, and simply put, they work! Devices for blind intubation include the gum elastic bougie (e.g., Eschmann Stylet, Portex Limited; Hythe, United Kingdom) and the light wand (e.g., Trachlight, Laerdal Medical; Wappingers Falls, New York). In one study, children whose tracheas were found to be extremely difficult to intubate by conventional means were intubated without difficulty with the use of a light wand (Holzman et al., 1988). Finally, tactile intubation can be accomplished by using the index and middle fingers of the non-dominant hand intraorally to palpate the epiglottis while the endotracheal tube or stylet is advanced along the palmar surface of the index finger to the larynx, laryngeal inlet, and intratracheally.

It is important to emphasize that these newer and developing technologies, as well as the older ones, require familiarization on the part of the anesthesiologist; no one can be expected to use these devices or techniques in the heat of battle with a difficult airway. Preparation and practice under controlled circumstances are the best preparation for emergency situations, and as always, chance favors the prepared mind. A well-stocked cart for use with difficult airways should be immediately available in every operating room suite.

Breathing Systems

The valved-circle anesthesia system or variations of Ayre's valveless T piece are the most common breathing circuits for pediatric patients (Mapleson, 1954). For years, the T piece was recommended for children weighing less than 10 kg because of the decreased resistance to spontaneous breathing, the better "feel" of the rebreathing bag in the hand of the anesthetist, and the faster anesthesia induction and emergence times using higher nonrebreathing fresh-gas flows. Improvements in machine components have resulted in low-resistance valves, reduced dead space at connections, improved CO₂-absorbent canister design, and the availability of capnography, as well as changes in philosophy that favor controlled pulmonary ventilation in small children; such improvements have rendered these arguments less durable. Likewise, modern, less-soluble inhalation agents make the influence of the breathing circuit less of an issue.

The compression volume of the breathing circuit is an important influence on alveolar ventilation in children, because their tidal volumes are so much smaller. Breathing circuits with large compression volumes can be "ventilated" far in excess of the volume delivered to the patient. Many circle systems modified for pediatric use are not only shorter, but they also have a smaller radius of curvature of the tubing, which according to Laplace's Law renders them less distensible and thus further decreases compression volume. Compliance of the tubing can also be decreased with fine wire or reinforced plastic.

Another important consideration for small children is the dead space of the breathing system. Dead space only exists when fresh and exhaled gases are mixed (i.e., at the Y piece); dead space no longer exists when fresh and exhaled gases are completely separated. Accordingly, the dead space of the Y piece in a circle system can be decreased by the addition of a median septum. Similarly, the dead space of an elbow in a Mapleson D system can be decreased by the addition of a fresh gas delivery port within the elbow (the Norman elbow).

CLINICAL AIRWAY CARE

Expert airway care is the most important skill in pediatric anesthesiology, and skill in understanding and controlling anesthetic depth is arguably the most important aspect of providing safe and expert airway care. It is critical to the success of spontaneous breathing techniques for diagnostic examination of the native airway, dynamic changes such as extrinsic compression or tracheomalacia, and for interventions such as the removal of a foreign body from the airway (see videoclip of infant bronchoscopy online at www.expertconsult.com). Aside from the assessment of heart rate, blood pressure, and patient movement, depth of anesthesia can also be evaluated by continuous monitoring of the heart sounds, the "classic" eye signs, and repeated examination of muscle tone. The arms and legs should feel completely relaxed, and the abdominal muscles should be soft and easily compressible, like bread dough, distinct from the boardlike rigidity of the excitement phase or the mild to moderate muscle tone of the awake or sedated state. Disconjugate gaze and pupillary dilation shortly after inhalation induction support the assessment of light anesthesia, whereas midsize pupils in midposition, along with other physical findings of acceptable anesthetic depth, add to the clinician's assessment. All signs together should be used to form a composite, so that

ideally the anesthesiologist should be able to ensure lack of patient movement in response to stimulation. Facility in determining anesthetic depth is also important for successful "deep" extubations—that is, the removal of the endotracheal tube while the patient is deeply anesthetized and breathing spontaneously. The presumption is that the patient will have less coughing, bucking, and airway irritability during the emergence process because of the lack of an endotracheal tube. In experienced hands, this technique is at least as safe as the more typical "awake" extubation (Patel et al., 1991; Pounder et al., 1991; Karam et al., 1995).

Profound surface analgesia of the oropharynx and laryngeal apparatus can be achieved by a combination of topical anesthesia of the tongue and posterior pharyngeal wall, glossopharyngeal nerve block, and superior laryngeal nerve block, as well as a transtracheal injection of local anesthetic (Cooper and Watson, 1975). Because most children will not tolerate this strategy well when they are awake, it is usually accomplished with sedation.

- Nebulized or gargled lidocaine can be used in older (i.e., school age) children to obtain surface analgesia of the tongue and pharyngeal surfaces.
- Local spray anesthesia can be used regardless of age by using age-appropriate concentrations of lidocaine (1% for infants, 2% for young school-age children, and up to 4% for older children and adolescents). Cooperative patients can gargle and swallow the accumulated spray; spray and suctioning sequences may have to be used for more deeply sedated patients.
- The internal branch of the superior laryngeal nerves can be blocked bilaterally as they pierce the thyrohyoid membrane just superior to the greater cornua of the thyroid cartilage (Fig. 12-16). Only a small amount of local

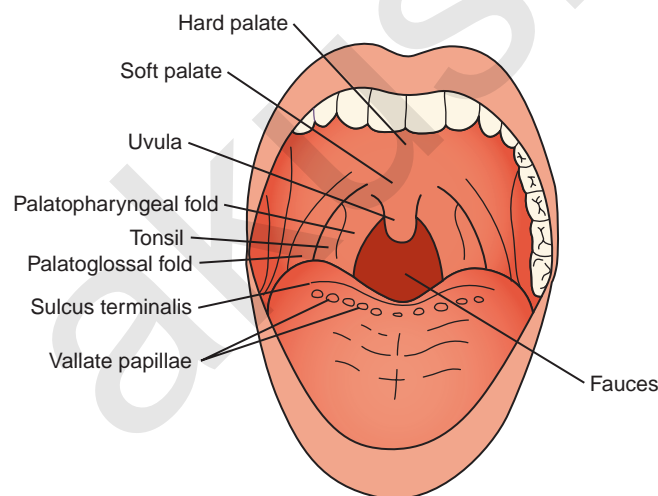

■ **FIGURE 12-16.** The internal branch of the superior laryngeal nerve pierces the thyrohyoid membrane at a vertical midpoint between the thyroid and hyoid cartilage, just superior to the greater cornua of the thyroid. It is here that the nerve can be percutaneously accessed to block sensation to the mucous membranes of the pharynx and supraglottic larynx.

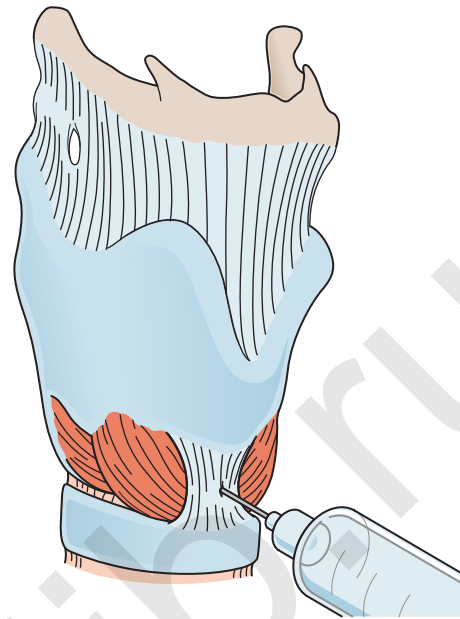

anesthetic (e.g., lidocaine 1%) is required; after a sterile preparation of the skin, a fine needle is entered perpendicular to the skin at a point above the greater cornua of the thyroid cartilage, midway vertically between the thyroid and hyoid cartilages; the thyrohyoid membrane is pierced, and local anesthetic is deposited after careful aspiration just below. Then the needle is withdrawn slightly, just above the membrane. The onset of this block takes a few minutes, so it should be done before the glossopharyngeal nerve block.

- The glossopharyngeal nerves can be blocked bilaterally throughout their submucosal course in the posterior tonsillar (palatopharyngeal) pillar with the use of a tonsil block needle (Fig. 12-17). Only a small amount of local anesthetic volume of lidocaine 1% is required; careful aspiration before injection is a must. Typical injection locations are at the 2-, 4-, 8-, and 10-o'clock positions as the anesthesiologist faces the patient directly. The block is established quickly.
- A transtracheal block to anesthetize the recurrent laryngeal nerve can be accomplished with the use of a fine needle or small IV catheter piercing the cricothyroid membrane after the above blocks, using an age-appropriate concentration of lidocaine 1% to 4%. Accurate intratracheal location of the needle or catheter is confirmed by aspiration of air before injection, which is often accompanied by vigorous coughing; therefore, the needle or catheter should be withdrawn as soon as possible (Fig. 12-18).

Laryngospasm occurs more often in conjunction with airway-related procedures, and multiple strategies for the prevention and treatment of laryngospasm have been sought. CPAP is routinely used in preventing or treating laryngospasm and soft tissue upper airway obstruction. Usually, pressure at 5 to 10 cm H₂O as measured on the breathing circuit pressure gauge is effective; higher pressures are occasionally required. Care should be exercised, because opening pressure of the lower esophageal sphincter may be as low as 10 to 12 cm H₂O, and

■ **FIGURE 12-17.** Intraoral approach to the glossopharyngeal nerve as it runs submucosally posterior to the posterior tonsillar pillar (palatopharyngeal fold). Blocking the nerve as it courses through the palatopharyngeal fold provides sensory analgesia to the mucosa over the palatine tonsil, the adjacent soft palate, the pharynx, and the posterior third of the tongue.

■ **FIGURE 12-18.** Transtracheal approach to the subglottic space, providing sensory blockade to the mucosa of the infraglottic trachea via the recurrent laryngeal nerve.

therefore the risk of gastric insufflation exists. Also, while CPAP is effective for soft-tissue obstruction, it is not necessarily effective for tumors of the airway or scar tissue.

CARE OF THE CHILD WITH A DIFFICULT AIRWAY

General Issues

The care of a child with a difficult airway must begin with an assessment of resources; the most important part of that assessment is a self-assessment. Questions to ask include:

1. Do I routinely take care of children? If not, then the pediatric airway may, for me, be relatively unique.
2. Do I routinely take care of children younger than 2 years of age? This population has consistently different anatomic and physiologic characteristics from those of older children, such as a much higher oxygen consumption and CO₂ production, a smaller functional residual capacity, and a greater reduction in intrathoracic volume when supine, anesthetized, and relaxed; therefore, this age range has substantially less oxygen reserve during airway misadventures.
3. Do I routinely take care of the subset of children with difficult airways? If not, then the pediatric difficult airway is definitely a special instance.

There is some evidence that the toll of providing care for children, especially resuscitation, may occasionally impose a substantially larger psychological burden on the pediatric specialist. For this reason, a color-coded resuscitation aid such as the Broselow-Luten system may decrease practitioner anxiety and afford more time for critical thinking during crises (Luten and Broselow, 1999, Luten et al., 2002). Although the evaluation of difficult airway anatomy in a child is, in principle, very similar to that of an adult, children often do not cooperate. With

regard to the difficult airway, patients with a difficult airway as a “syndrome” are not usually the challenge; they have been previously identified, are often well categorized, and may even have a tracheostomy; the challenge is the patient who may look somewhat challenging to the less experienced evaluator but indeed has a difficult airway.

Specific Issues Unique to Children with Difficult Airways

Traditional clinical teaching is that the sniffing position is the optimal position for aligning the axes of the trachea, pharynx, and oral cavity. Because the anteroposterior dimension of the head in children is so much larger than that of the chest, a pillow or ring under the head may not be necessary to achieve this sniffing position; it may simply involve placing the patient on the flat mattress pad of the operating-room table, or even placing a small roll under the shoulders. This presumes normal mobility of adjacent structures of the larynx. With poor mobility of laryngeal structures, such as in the anteriorly placed larynx, direct laryngoscopy in the extended head position actually swings the larynx anteriorly as the anesthesiologist lifts the laryngoscope blade, making visualization more difficult. It is often better to flex the head onto the chest, as the glottic aperture then moves posteriorly and may be visualized directly. Indirect visualization may now be accomplished with many available devices, as described above. In order to develop comfort and expertise and retain familiarity, these devices must be used routinely.

Decision algorithms about the difficult airway are available, and most of the issues that are specific to the anticipated difficult pediatric airway are not that different from those for adults, including a broad range of appropriate equipment, occasional imaging studies, and preparation with sedation and topical local-anesthetic techniques (Fig. 12-19). If a spontaneous-breathing anesthetic technique is chosen, pediatric anesthesiologists are already comfortable with the assessment of anesthetic depth in children. Patient cooperation is a key crucial difference in the recognized difficult airway and in children is influenced by the chronologic, developmental, emotional, and intellectual components of the preoperative assessment. Surgical airway access, whether by needle cricothyroidotomy, open cricothyrotomy, or tracheostomy, is hazardous, especially in inexperienced hands, yet it may be the only option available. If this is a possible part of the airway plan, collaboration with a surgeon is essential.

The unexpected difficult pediatric airway patient is a different matter. Wheeler proposed a very reasonable modification to the well-accepted adult difficult airway algorithm (Fig. 12-20) (Wheeler, 1998). The key to this, or any other, algorithm is that it presents a reasoned and organized approach to a high-risk situation.

Care of the Patient with a Surgical or Reconstructed Airway

Tracheostomy

The need for pediatric tracheostomy is divided between the relief of airway obstruction (approximately 40%) and the need for prolonged ventilation of the lungs and pulmonary

toilet (approximately 50%). Most patients remain with the basic underlying problem that resulted in the tracheostomy—typically severe subglottic stenosis—and a prolonged need for mechanical ventilation because of underlying lung disease or difficulty with maintaining an adequate translaryngeal airway caused by poor secretion control. Accidental decannulation and a tracheostomy tube plug are common perioperative events. Because a tracheostomy bypasses the natural sphincteric and glottic closure mechanisms responsible for warming and humidifying air and maintaining a functional residual capacity, children with a tracheostomy require airway humidification. Suctioning is usually required to clear accumulated secretions. The underlying disorders for which tracheostomy is performed are often chronic but potentially life threatening, especially after any surgical intervention; therefore, apnea with cardiac and respiratory monitoring including pulse oximetry, are routine whether the patient is in the intensive care unit (ICU) or another unit. Follow-up examinations for evaluating residual granulomas and evaluation for decannulation are common. Often, patients have mask aversion and post-traumatic stress disorder because of prolonged ICU care and life-threatening illness.

Pharyngeal Flap Surgery

Following cleft-palate repair, pharyngeal flap and oronasal fistula repair may be needed for velopharyngeal insufficiency. Different types of palatoplasties are performed to alleviate the hypernasality, depending on the cause and dynamics of the insufficiency. The length and width of the flap are tailored to the degree of velopharyngeal incompetence, and it is important for the anesthesiologist to know which kind of repair was done, especially if for subsequent surgery a nasal endotracheal tube or nasogastric tube will be placed, both of which are more problematic if a patient has had a superiorly based flap (Fig. 12-21). Direct vision with a fiberoptic laryngoscope is often the best technique to minimize trauma to the reconstructed area.

External Distraction Devices

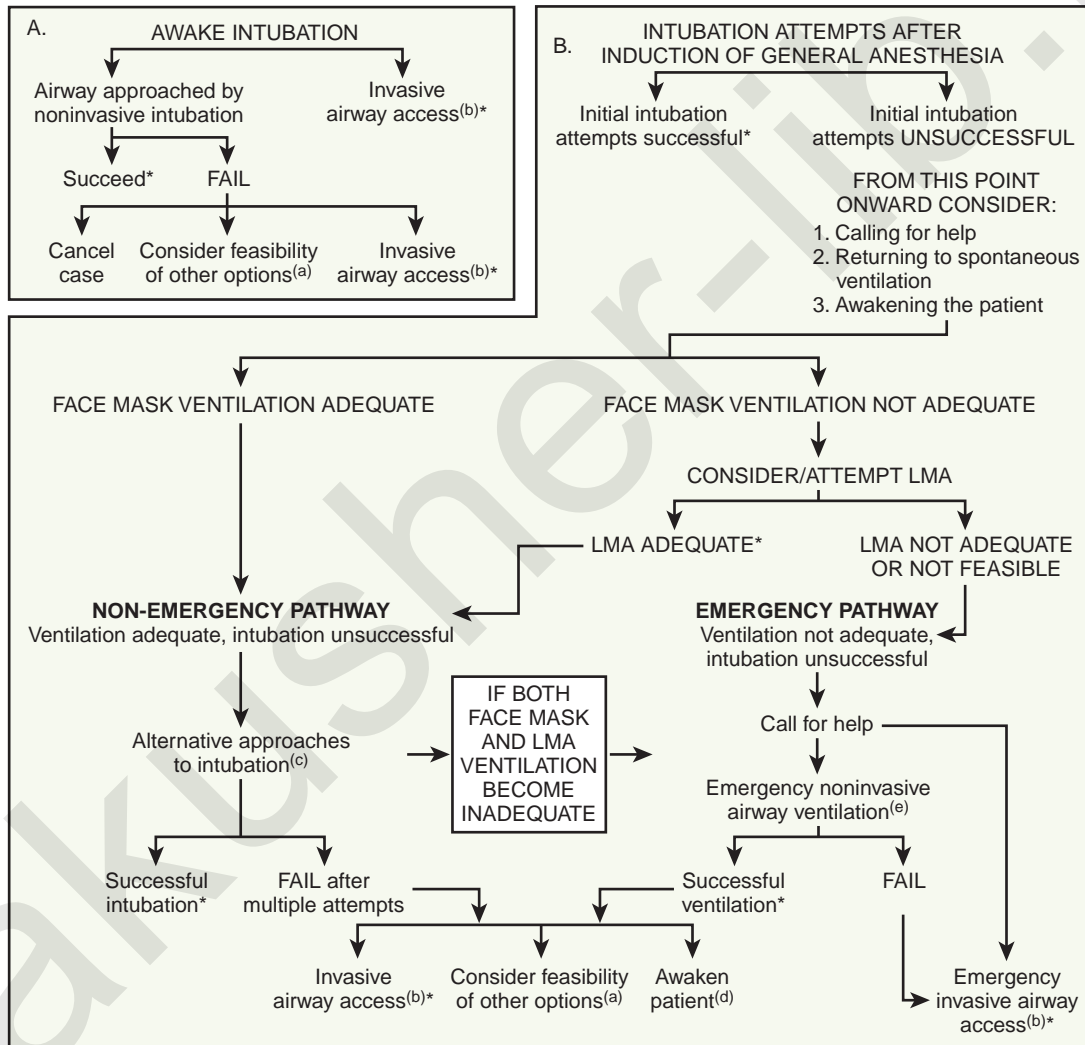

Distraction osteogenesis for unilateral or bilateral advancement of maxillary or mandibular structures has become the major technique in craniofacial surgery. The use of distraction allows the surgeon better control in positioning the bony segments after the osteotomy, enables the segments to be moved a greater distance, and eliminates the need for bone grafts. However, the device may contribute to trismus and also decrease jaw opening. Its presence may interfere with routine airway techniques, and therefore advanced airway-management skills may be needed (Fig. 12-22). Midface advancement using a halo distractor or rigid external distraction (RED) device is favored by some surgeons, whereas others may use an internal midface distractor. Both types have drawbacks. For the anesthesiologist, the initial placement is not as much of a problem as the subsequent procedures to remove them. Limited ability to open the mouth may occur once the distraction is finished. This may be the result of the new position of the maxilla in relation to the mandible, or it may be caused from pain and swelling of the muscles through which the devices pass. The anesthesiologist must therefore be prepared for a more difficult intubation after the initial procedure.

DIFFICULT AIRWAY ALGORITHM

1. Assess the likelihood and clinical impact of basic management problems:
 - A. Difficult ventilation
 - B. Difficult intubation
 - C. Difficulty with patient cooperation or consent
 - D. Difficult tracheostomy
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management
3. Consider the relative merits and feasibility of basic management choices:

4. Develop primary and alternative strategies:

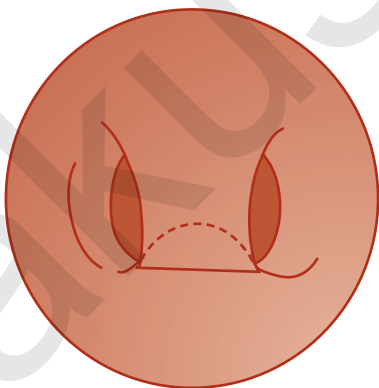

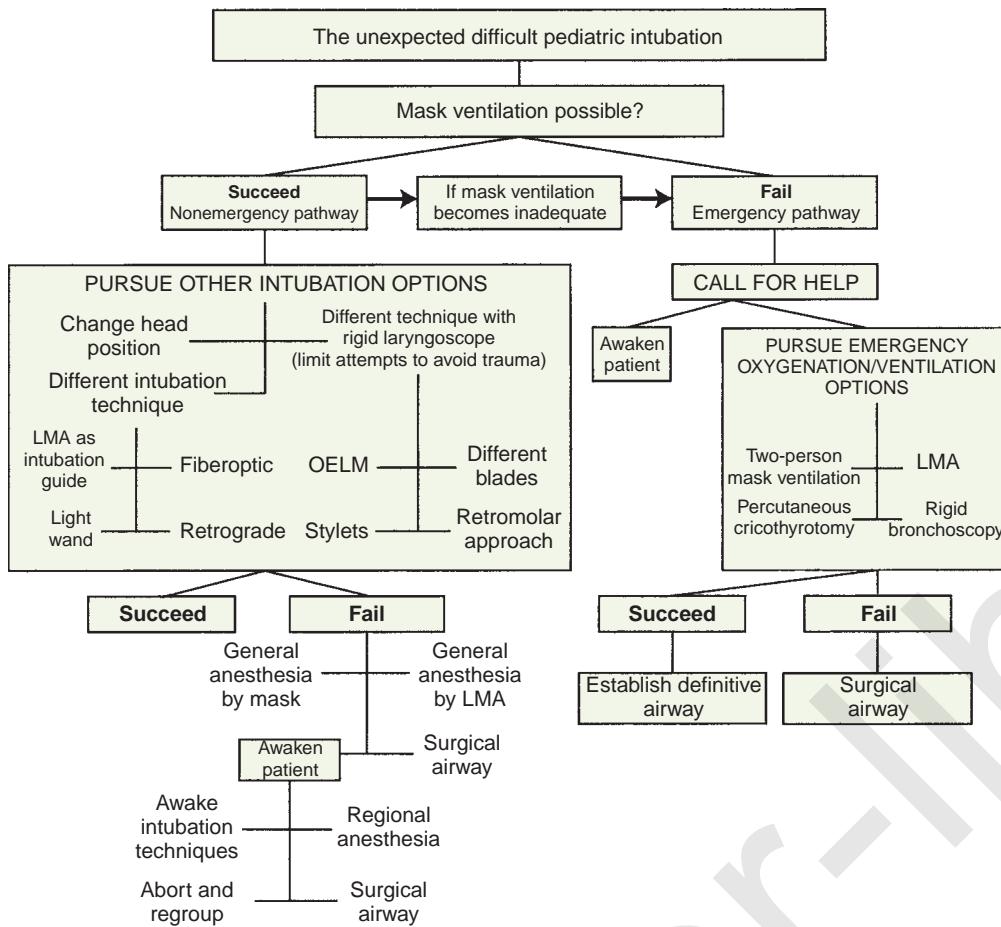

* Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO₂

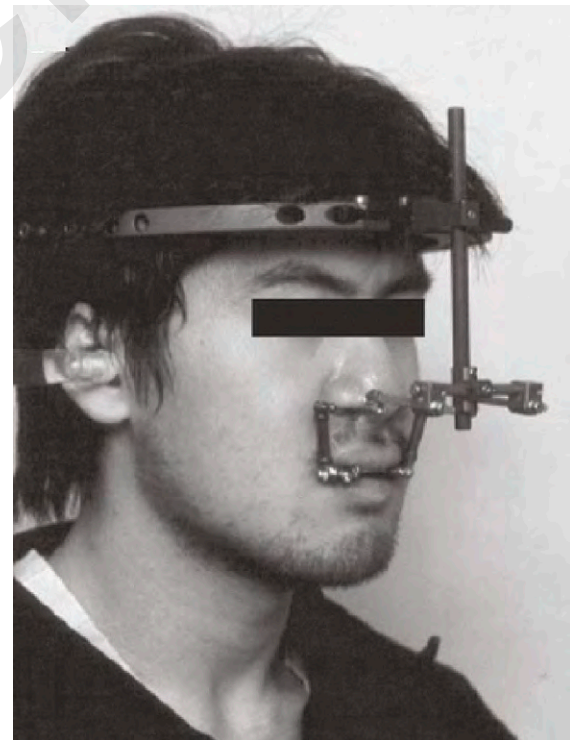

- a. Other options include (but are not limited to): surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the emergency pathway.
- b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.
- c. Alternative non-invasive approaches to difficult intubation include (but are not limited to): use of different laryngoscope blades. LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.
- d. Consider re-preparation of the patient for awake intubation or canceling surgery.
- e. Options for emergency non-invasive airway ventilation include (but are not limited to): rigid bronchoscope, esophageal-tracheal combitube ventilation, or transtracheal jet ventilation.

■ FIGURE 12-19. Difficult airway algorithm. (Courtesy of the American Society of Anesthesiologists.)

■ **FIGURE 12-20.** A decision pathway for the difficult pediatric airway.

■ **FIGURE 12-21.** Superiorly-based pharyngeal flap for velopharyngeal insufficiency. Pharyngeal flaps may be superiorly or inferiorly based, but the superiorly based repair has fewer complications. There are sphincter pharyngoplasty approaches as well. By decreasing the cross-sectional area of the airway, a previously adequate airway may be changed to a partially or totally obstructed airway; returning to the operating room to take down the flap may be lifesaving.

■ **FIGURE 12-22.** External maxillary distraction device. Distraction osteogenesis is a major technique in craniofacial surgery, and its use allows improved bone positioning after osteotomy, greater segmental movement, and elimination of bone grafts. The challenge for the anesthesiologist is the limitation in mouth movement, airway access, and planning for repeat procedures.

Restoring the Natural Airway

Airway Device Removal

The literature does not provide an extubation strategy for the difficult airway; however, it should probably be closely related to the intubation strategy. Awake extubation vs. extubation before the return of consciousness is a principal consideration, as are general clinical factors that may produce an adverse impact on ventilation after the patient has been extubated. Backup plans for airway management if the patient is not able to maintain adequate ventilation after extubation are a must, as is availability of a device that can serve as a guide for expedited reintubation such as a bougie or exchange catheter (Mort, 2007). Occasionally, a difficult extubation because of patient anxiety is facilitated by a sedation strategy (Arpino et al., 2008).

Decannulation of Tracheostomies

Decannulation should not usually be considered until the underlying disease that necessitated the tracheostomy has been resolved. A careful evaluation must be made of the effectiveness of the patient's own ventilatory efforts, efficiency of oxygenation, and ability to handle secretions. Decannulation evaluation is typically accomplished by endoscopic examination, with particular attention to edema, stenosis, or granuloma formation, with a sequencing of tracheal tube downsizing and capping, and followed by removal and closure of the tracheal stoma. Downsizing may be a more difficult strategy in

smaller patients, for whom tracheostomy-tube removal and observation may be a better choice given their smaller airways and therefore greater relative resistance to breathing during the downsizing process. Finally, the anesthetic technique for decannulation is a matter of preference and experience; some prefer sedation, whereas many prefer a general anesthetic with a small endotracheal tube after the endoscopic examination.

SUMMARY

The airway is a composite of the anatomic development of the head, face, aerodigestive tract, and neck—structures contiguous as well as integral to the airway. This chapter considers the developmental anatomy, physiology, and air flow physics crucial to an informed plan for managing the pediatric airway. Airway equipment for routine and difficult airway applications is then considered, and a discussion of clinical care in these circumstances is included. Finally, restoration of the natural airway is addressed.

Anesthetic induction, maintenance, and recovery pose unique challenges and considerations in infants and children. The anesthetic plan should be designed as a continuous process that cares for the patient from admission to discharge, anticipating the patient's preoperative anxiety, intraoperative requirements, and postoperative recovery. Each step in the continuum is interrelated and interdependent. All factors, including the patient's age, medical history, surgical procedure, and discharge disposition must be considered in selecting drugs and techniques to ensure safe induction, a stable intraoperative course, and a comfortable, rapid recovery.

The induction of general anesthesia in infants and children requires sensitivity, flexibility, and finesse, as well as specialized knowledge and skills. Eliciting concerns, perceiving fears, and predicting the degree of cooperation from patients and their families, in addition to obtaining the history of medical conditions, previous anesthetics, medication use, allergies, familial disorders, recent illnesses, loose teeth, and *nil per os* (NPO) status during the preoperative interview are all essential in formulating a plan for the anesthetic induction. The pediatric anesthesiologist must determine whether preinduction medications, topical anesthetics, or parental presence are indicated and whether an inhalation or intravenous technique is to be used. The setting, monitoring, and method of obtaining intravenous access and securing the airway also need to be determined in advance to ensure the smoothest course possible.

Once anesthesia is induced, the anesthesiologist is responsible for maintaining a state of analgesia, amnesia, adequate muscle relaxation, and autonomic nervous system stability while providing optimum surgical conditions. To achieve this goal, the anesthesiologist should choose appropriate anesthetic and adjuvant medications and continuously monitor anesthetic depth, oxygenation, ventilation, cardiovascular function, fluid balance, body temperature, and if indicated, glucose and electrolyte levels. For critically ill patients or for patients undergoing major or prolonged procedures, more extensive and invasive monitoring may be required. The pediatric anesthesiologist must ensure appropriate positioning and protective measures to avoid soft tissue injury in this at-risk population. Management of all factors, from the choice of pharmacologic agents, to the use of regional anesthetic adjuncts, to the adjustment of ambient temperature, is the role of the pediatric anesthesiologist.

Postoperatively, the pediatric anesthesiologist should plan a relatively swift awakening to ensure adequate airway maintenance, protective reflexes, and hemodynamic stability while avoiding pain, emergence agitation, nausea, and vomiting. A rapid return to the preoperative level of consciousness, although ideal for ambulatory and short-stay patients, may be frightening and disorienting to a child who is not prepared to awaken in a new and unfamiliar environment among strangers. Pain, however slight, magnifies these responses dramatically. Nonambulatory and critically ill patients may

not need a rapid emergence and can benefit from an extended period of sedation and analgesia. If they are being transferred directly to an intensive care unit (ICU), continuous monitoring is indicated. Once the patient is in the postanesthesia care unit (PACU) or ICU, the anesthesiologist must assess airway patency, cardiovascular status, body temperature, and level of discomfort. Pain, nausea, and vomiting should be evaluated and treated appropriately.

INDUCTION OF GENERAL ANESTHESIA

The induction of general anesthesia can be the most critical yet rewarding interaction that a pediatric anesthesiologist has with young patients and their families. Minimizing anxiety, psychological trauma, and crying during induction has many advantages, including reduced occurrence of airway complications, emergence agitation, postoperative pain, short- and long-term behavioral changes, patient and family dissatisfaction, and difficult inductions with subsequent anesthetics (Laycock and McNicol, 1988; Kotiniemi et al., 1997; Kain et al., 1999; Przybylo et al., 2005; Kain et al., 2006). With the increased focus on family-centered care, including parents' concerns and priorities in the decision-making process being the norm, it is essential that all parties are prepared as well as possible regarding information, preferences, and expectations. If premedications or topical anesthetics are indicated, adequate time should be allotted to ensure maximal benefit. Smooth separation of child and family, be it before or after induction, should be facilitated by clearly stated instructions and participation of perioperative personnel.

Psychological Considerations

During the preoperative period, it is extremely important to identify the children and families who are likely to develop pronounced fear and anxiety before and during the induction of anesthesia. Because the level of stress and underlying temperament that predispose individuals to extreme anxiety may not be overtly apparent, it is essential that the pediatric anesthesiologist carefully evaluate each patient. Indicative behaviors, beyond the obvious crying and uncooperative child, include the absence of social interaction, vocalization, emotional expression, and age-appropriate independence from parents (Kain et al., 1997). It is also helpful to assess family members' levels of anxiety and coping styles. Premedication with anxiolytics has been shown to be the most consistently effective intervention for facilitating induction and reducing postoperative complications in anxious patients (Bergendahl et al., 2004; Almenrader et al., 2007; Schmidt et al., 2007).

Medical Considerations

Most children and infants scheduled for elective surgical procedures are in good health, but common disorders such as upper respiratory tract infection (URI), reactive airways disease, gastroesophageal reflux, obesity, and hemodynamically stable congenital heart lesions can pose diagnostic and management challenges for the pediatric anesthesiologist.

Patients with known medical problems should be carefully interviewed and examined, and if general anesthesia is to be induced, appropriate precautions and interventions should be taken. These issues are explored in detail elsewhere in this text (see Chapters 9, Preoperative Preparation, and 36, Systemic Disorders). An overview of some basic considerations is discussed below.

Upper Respiratory Tract Infections

URI is by far the most common problem the pediatric anesthesiologist encounters, especially in the ambulatory surgery setting. URI and the accompanying inflammation increase upper and lower airway irritability and secretions, and they may increase the incidence of laryngospasm, bronchospasm, and perioperative hypoxemia (see Chapter 36, Systemic Disorders) (DeSoto et al., 1988; Cohen and Cameron, 1991; Coté, 2001; Bordet et al., 2002; Elwood et al., 2003). Risk factors for associated complications include nasal congestion, copious secretions, reactive airways disease, history of prematurity, passive smoking, airway surgery, endotracheal intubation, and laryngeal mask airway insertion (Tait et al., 2001; von Ungern-Sternberg et al., 2007). Even in patients without a history of asthma, airway reactivity can develop with URI or lower respiratory tract infection and last as long as 6 to 8 weeks (Empey et al., 1976; de Kluijver et al., 2002). The decision to postpone the procedure depends on the urgency of the surgery, the severity of symptoms, and the need to instrument the airway (Tait and Malviya, 2005). In these patients, prophylactic bronchodilator treatment should be considered before the induction of anesthesia and before the emergence from anesthesia and extubation.

Reactive Airways Disease

In children with reactive airways disease (RAD), a detailed past medical history must be obtained to determine the severity of the disease and the effectiveness of current medical treatment. Recurrent emergency visits and hospital admissions, especially those to critical care units and/or involving the use of steroids, are red flags for poor control of symptoms. Mild asthma that is poorly controlled may improve with more aggressive treatment, whereas well-controlled severe RAD may require sustained optimized therapy. In a patient with active or recent bronchospasms, elective surgery should be postponed for 4 to 6 weeks. If surgery is required, preinduction treatment with a β_2 -agonist is recommended to minimize respiratory complications (Scalfaro et al., 2001). Recent steroid use may require perioperative stress-dose steroid coverage (see Chapter 36, Systemic Disorders).

Congenital Heart Disease

Children with congenital heart disease (CHD) may require antibiotic prophylaxis preoperatively for the prevention of bacterial endocarditis. Recommendations by the American Heart Association (AHA) were updated by Wilson et al. in 2007. The recommendations can also be downloaded from the AHA website at <http://www.americanheart.org>. The guidelines for the AHA subacute bacterial endocarditis (SBE) prophylaxis, which were formulated by an AHA writing group with input from national and international experts, have been significantly

modified. CHD conditions associated with the highest risk for SBE are listed as follows:

1. Unrepaired cyanotic lesions,
2. Repaired CHD with prosthetic material within 6 months of the procedure, and
3. Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization).

Prophylaxis is only recommended for “dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa” and “invasive procedure of the respiratory tract that involves incision or biopsy of the respiratory mucosa, such as tonsillectomy and adenoidectomy” (Wilson et al., 2007). Standard antibiotic recommendations include amoxicillin PO or ampicillin IV 50 mg/kg (maximum dose 2 g) 30 to 60 minutes before the procedure. Alternative antibiotics for those patients allergic to penicillin or ampicillin include clindamycin, cefazolin, ceftriaxone, azithromycin, or clarithromycin.

Animal studies indicate that if the preoperative SBE dose is missed, the effective prophylaxis can be given within 2 hours (but not after 4 hours) after the procedure (Berney and Francioli, 1990; Dajani et al., 1997).

Preoperative Fasting

Preoperative fasting times allow for gastric emptying and reduction of aspiration risk. Evidence of rapid gastric emptying in infants and children and efforts to improve the perioperative experience of young patients and their families have resulted in liberalization of pediatric fasting guidelines. Based on clinical observation and studies of residual gastric volumes, international recommendations for NPO times before anesthetic induction in healthy children are 2 hours for clear liquids, 3 to 4 hours for breast milk, 4 hours for infant formula (in infants younger than 3 months), 6 hours for infant formula (in infants older than 6 months), 6 hours for light meals, and 8 hours for heavy meals (Schreiner et al., 1990; Litman et al., 1994; Cook-Sather et al., 2003; Søreide et al., 2005; Murat and Dubois, 2008). This growing consensus has given rise to the 2-4-6 rule. Although these fasting times do not apply to children with gastrointestinal or systemic disorders that may interfere with or slow gastric emptying, Cook-Sather and colleagues (2009) have reported that even in overweight and obese children undergoing elective surgery, the 2-hour minimum preoperative clear-liquid fasting guideline is adequate.

Allowing infants and children to have oral intake closer to the time of surgery can help reduce patient irritability, parental stress, and risk of dehydration. Conversely, the short and multiple fasting times can lead to confusion and NPO violations. It is extremely important that those giving and receiving instruction on preoperative food and fluid intake clearly understand the terminology (i.e., what constitutes a clear liquid), timing, and need for adherence to the guidelines (Schoenfelder et al., 2006). A clear liquid is a solution (as opposed to a suspension) that contains no particulate matter. Examples of clear liquids include water, Pedialyte, carbonated beverages, clear tea, plain gelatin, and fruit juices without pulp (American Society of Anesthesiologists, 1999; Ferrari et al., 1999).

Preanesthetic Preparations

The preoperative interview, which is essential for obtaining pertinent positive and negative findings in the patient’s history and physical condition, may be the only opportunity for the anesthesiologist to assess child-family anxiety and establish a relationship of trust and confidence. Successful interaction with children requires skill and experience, but more importantly it requires honesty and playfulness. Most centers have presurgical tours and/or short movies to prepare children and families for the perioperative experience. Children are typically encouraged to bring a familiar object or favorite toy, and most pediatric waiting areas are designed as playrooms that are supplied with everything from busy boxes to video games. The anesthesiologist should take advantage of these preoperative tools during the preoperative interview. They should sit at the child’s eye level and initiate communication based on the child’s present activity. If the child offers an opening, such as asking to see their stethoscope, they should follow their lead. The anesthesiologist should express genuine interest or play with the child. This may help gain the child’s confidence and divert or reduce fear and anxiety. Tone of voice and facial expression should be calm and friendly for all age groups. Infants can be engaged with varying facial expressions and games of “peek-a-boo.” Good humor and empathy will go a long way in alleviating patient and family stress and anxiety.

Most children can be well managed in this friendly environment. An anesthesia mask may be given to the child to play with in the waiting area before induction (Fig. 13-1). Allowing children to choose a flavor (e.g., bubble gum, cherry, or grape) can provide them with a sense of control. The additional support of pacifiers, toys, and music boxes is often helpful.

■ **FIGURE 13-1.** An anesthesia mask may be given to the child to play with in the waiting area before induction.

Children should keep the objects brought from home, particularly security blankets or other transitional objects, during the induction of anesthesia. Clowns have also been used for the prevention of preoperative anxiety in children (Vagnoli et al., 2005; Golan et al., 2009).

Family responses, questions, and interactions with the child are important to note. It is essential for the pediatric anesthesiologist to include patients and families in decisions regarding anesthetic induction and care. Together they should agree on the needs for premedication, parental presence, and the type of induction technique (inhalation vs. intravenous) to ensure the smoothest and safest induction possible. Unfortunately, even the best of plans can fail, and back-up measures such as another premedicant, induction room, or means of induction, must be readily at hand. For older, combative children scheduled for elective procedure, postponing the procedure until the child is properly prepared should be considered. Inhalation induction by force should be a measure of last resort.

Premedication

As stated above, the use of premedication is the most reliably effective intervention for reducing preinduction anxiety and stress for young patients and their parents. Preoperative medications are described in detail in Chapter 9, Preoperative Preparation, and are discussed only briefly here. Historically, premedication referred to long-acting sedatives and anticholinergic agents that were often given intramuscularly (IM) or rectally (PR) to prepare children in inpatients' units for their trip to the operating room. Contemporary administration of sedatives, typically by mouth, is administered just before induction to facilitate child-parent separation, anesthetic mask acceptance, and/or patient cooperation. IM administration is almost now solely reserved for extremely agitated, uncontrollable children.

Benzodiazepines

Midazolam, a water-soluble benzodiazepine, is the most commonly used preinduction medication (Kain et al., 1997). Given orally at 0.5 mg/kg mixed with fruit-flavored syrup, midazolam will create a calm, euphoric, or drowsy state in most children within 15 to 30 minutes. To potentiate its effect, children should be kept in a nonstimulating environment, and ambulatory children who may become unsteady should be held carefully on the parent's lap or placed in bed. Coté et al. (2002) showed that a wider range of doses can be effective, adjusting for time of onset, and that respiratory compromise does not occur in otherwise healthy, unmedicated children. Paradoxical reactions, including restlessness, agitation, and disinhibition, occur in approximately 1% to 3% of patients (McMillan et al., 1992; Golparvar et al., 2004). The bitter taste of midazolam, which is difficult to conceal, may reduce acceptance. Midazolam can also be administered via nasal mucosal delivery at 0.2 mg/kg with a more rapid onset but has the disadvantage of an unpleasant burning sensation (Zedie et al., 1996). Prolonged recovery times are not seen with the use of midazolam premedication (Davis et al., 1995b; Bevan et al., 1997). Acetaminophen (20 mg/kg), in fruit-flavored syrup, can also be mixed with midazolam as part of premedication for postoperative analgesia, especially for short ear cases, such as myringotomies (Watcha et al., 1992).

Opioids

The use of opioids for premedication is uncommon in healthy children who are undergoing elective procedures. Even with noninvasive delivery systems such as oral transmucosal fentanyl citrate (OTFC), the advantage of relatively rapid onset is offset by the disadvantages of dysphoria, pruritus, nausea, and vomiting (Goldstein-Dressner, 1991; Ashburn et al., 1993; Epstein et al., 1996). Opioid premedication is best reserved for children experiencing pain, in which analgesia and sedation can be synergistic. The risk of respiratory depression, especially in infants younger than 6 months of age, should always be taken into account.

Ketamine

Ketamine can be given via the oral, nasal, rectal, or IM route (Stewart et al., 1990; Gutstein et al., 1992; Weksler et al., 1993; Tanaka et al., 2000). Ketamine is an effective sedative, but it can also cause increased secretions, nausea, vomiting, psychological disturbances, and prolonged recovery. IM injection of ketamine, 2 to 3 mg/kg (undiluted) may be useful in uncooperative, combative children as the last resort to avoid inhalation induction by force, which increases the risk of physical and psychological trauma to patients (Hannallah and Patel, 1989).

Alpha 2-Adrenergic Receptor Agonists

Oral (4 mcg/kg) and rectal (5 mcg/kg) clonidine can produce excellent perioperative sedation and anxiolysis while reducing the anesthetic requirement, emergence agitation, and postoperative pain, shivering, nausea, and vomiting (Bergendahl et al., 2004; Schmidt et al., 2007; Tazeroualti et al., 2007). The prolonged postoperative sedation seen with clonidine premedication may be advantageous after major surgical procedures but can delay discharge for same-day surgery patients. Similar findings have been described with transmucosal dexmedetomidine 0.5 to 1 mcg/kg (Schmidt et al., 2007; Yuen et al., 2008).

Topical Anesthesia

For children who require or prefer an intravenous (IV) induction, there are multiple approaches to achieving topical anesthesia. Local anesthetics can be delivered without needles through the skin's protective stratum corneum into the innervated dermal layers via eutectic (EMLA) and liposomal (EL-MAX) creams or driven by mechanisms such as heat, iontophoresis, laser-assistance, or pressurized helium (Hung et al., 1997; Baron et al., 2003; Zempsky et al., 2004; 2008; Sawyer et al., 2009). These techniques, each with limitations, are capable of providing analgesia within 1 to 60 minutes of application. Reported satisfactory anesthesia varies with technique and patient age. Children younger than 6 or 7 years of age tend to report pain, secondary to fear and anticipation of needlesticks, even with apparent anesthesia (Arts et al., 1994; Kleiber et al., 2002).

Parental Presence During Induction

Parental presence during induction of anesthesia (PPIA), in the operating room or a separate area such as an induction room, has increased significantly in the United States over the last decade

(Kain et al., 2004). Although the practice avoids separating children from their parents, it has not been shown to decrease patient anxiety or increase cooperation during induction (Kain et al., 1998; Arai et al., 2007). One benefit, which is important in terms of family-centered care, is an increase in parental satisfaction scores. Kain and colleagues, in 2006, confirmed the previous findings of Bevan et al. from 1990 that PPIA had a measurable benefit when a calm parent accompanied an anxious child, and a worsening effect when an anxious parent accompanied a calm child. There was no measurable benefit when both parent and child were calm. Subsequently, they have determined that parental preparation to reduce anxiety (e.g., learning distraction techniques, and avoiding reassuring behavior) can significantly improve the outcome of PPIA (Kain et al., 2007).

The logistical disadvantages of PPIA in the operating room include limited space, noise, unfamiliar equipment, and the need for parents to wear gowns and masks. Induction rooms can help anesthesiologists avoid some of these problems, but in both settings the parents must be prepared for the changes that can occur during induction, especially rapid loss of consciousness, uncoordinated movements, increased respiratory rate, and signs of upper airway obstruction. The anesthesiologist should be prepared to reassure the parent and respond quickly, especially if something goes wrong during induction. Parents need to be escorted to the waiting room as soon as their child loses consciousness.

Preparation for Induction

In the operating room or an induction room, anesthetic and monitoring equipment and supplies must be complete, confirmed, and readily available. The preinduction checklist for equipment should include a checked anesthesia machine, the gas pressures of accessory oxygen and nitrous oxide cylinders, an air-tight breathing circuit, the availability of a self-inflating bag, working suction, size-appropriate airway supplies (larger, smaller, and predicted, and including face masks, oral and nasal airways, laryngoscope blades and endotracheal tubes), and medications for induction and maintenance of anesthesia, as well as emergency medications. With the exception of patients suffering from malignant hyperthermia, emergency drugs for all pediatric inductions are atropine and succinylcholine, which should always be drawn into syringes of an appropriate size for the patient's age and weight and clearly labeled in case of severe laryngospasm. Supplies for starting and securing IV access should be prepared. Additional ancillary equipment such as tongue depressors, adhesive tape, and soft suction catheters should also be at hand. If laryngeal mask airway (LMA) use is planned, appropriate size LMAs should be included in the set up. Monitoring devices, such as an in-flow oxygen analyzer, a pulse oximeter, a capnograph, an electrocardiograph (ECG), and an automated blood pressure cuff, should all be checked and ready. The temperature of the operating room should be properly adjusted and warming devices (e.g., Bair Hugger and other warming blanket or a radiant heat lamp) should be used.

Monitoring During Induction

At a minimum, monitoring during induction should include pulse oximetry and capnography. The precordial stethoscope, once the *sine qua non* of pediatric anesthesia, has apparently

been displaced by more accurate and adaptable monitors (Watson and Visram, 2001). However, the precordial stethoscope is still an essential and more sensitive and continuous monitor for changes in breath sounds and the quality of heart beat, especially in infants and young children. Vital signs can vary markedly during the induction of anesthesia and should be observed continuously with a precordial stethoscope and in accordance with the ASA standards for patient safety (1986). If the child is anxious, it is probably best to place additional monitors like ECG pads and a blood pressure cuff after induction instead of losing the opportunity for a calm induction. However, medical condition and early infancy may necessitate full monitoring before and during induction. If this is the case, the baseline measurements should be obtained before the patient is exposed to any anesthetic agent.

Methods of Induction

There are many approaches for safely inducing general anesthesia in children. The particular technique chosen depends on the patient's age; surgical procedure; underlying illness; discharge disposition; and in part, the preference of the anesthesiologist, the patient, and their family. The induction methods include: inhalational, IV, IM, and various combinations of these techniques.

Inhalation Induction

Whether sedated or awake, accompanied or alone, lying down or sitting up, a child breathing sevoflurane with or without nitrous oxide through a mask and circuit will become anesthetized. It is this simple fact that has made inhalation induction the most commonly used technique in pediatric anesthesia in the United States. In this manner, the induction of anesthesia is achieved with relative ease, speed, and safety, while avoiding the fear and pain of intravenous catheter insertion. Successfully selecting the approach, guiding the child and family through the process, and smoothly adapting to their needs is the challenge and reward of pediatric anesthesia induction.

When transitioning a child from the preoperative area to the site of induction, it is paramount that the well-sedated or asleep child is minimally stimulated or disturbed and that the awake or lightly sedated child is kept occupied and distracted by an anesthesiologist or family member. One person, either the anesthesiologist or a family member, should do all the talking, which should be reassuring and continuous. Giving patients and families the choice to have the child carried, walked, or wheeled to the induction location is another way to encourage participation and give them a sense of control. Perioperative staff need to remain quiet immediately before and during the induction, or they should be asked to step away. Regardless of location, age of the patient, or intended procedure, induction of anesthesia should be completely focused on the child and uninterrupted by other activities or last-minute preparations.

Once in the operating or induction room, the child may be given the choice to lie down or sit up. If sitting is elected and parents are present, the child can be offered the option to sit in a parent's lap or next to them (Fig. 13-2). The anesthetic mask, either one introduced in the waiting area or one detached from

FIGURE 13-2. Sitting up during induction of anesthesia is an option. If parents are present, the child can sit in a parent's lap or next to a parent.

the anesthesia circuit, should be shown (again) to the child. Putting artificial fruit or candy flavors in the mask may help disguise the odor of the anesthetic. One should never place the mask on the child's face without warning. Even with preparation, some children, especially those with previous experience with inhalation inductions, may strongly reject the anesthesia mask (Przybylo et al., 2005). The mask may become more acceptable if a family or staff member initially tries it on, or if the anesthesiologist applies it to one of the child's toys or random body parts before placing it near his or her face. Other methods to introduce the mask include having the child watch the insufflation of the anesthetic bag or hold the mask him or herself as he or she begins to breathe into the circuit. Making a game out of this activity is far better than getting into battle of wills. Distraction techniques such as storytelling, singing, counting, or just talking nonsense are strongly encouraged. If the child still emphatically objects to the mask, other approaches such as supplemental sedation or an IV induction should be considered.

One way to initiate inhalation induction and avoid a negative reaction to the smell of the inhalation agent is to begin with a high flow of nitrous oxide and oxygen at a 2:1 ratio. The mask should be loosely applied to the child's face until sedation is evident. The full sedative effect of nitrous oxide will occur within 2 minutes and be observable as the respiratory rate slows. Sevoflurane can then be added and increased rapidly to 6% to 8%. Except in young infants, short exposure to high concentrations of sevoflurane does not cause significant hemodynamic changes. Timing of the introduction of sevoflurane, the rapidity of increase, and the distraction techniques employed should vary with the child and family's mood, level of anxiety, and degree of cooperation. Hyperventilation should be discouraged to avoid apnea

during the induction. If the child objects to the smell of the inhaled anesthetic, breathing through the mouth to reduce the smell can be suggested.

DuBois et al. (1999) compared three induction techniques of conventional tidal-volume breathing of sevoflurane: incremental increasing concentrations (2% to 6% to 8%) in 100% oxygen, 8% in 100% oxygen, and 8% in a 1:1 mixture of nitrous oxide and oxygen. There were minimal differences among the three approaches. Lejus and colleagues (2006) compared the two different breathing techniques of conventional tidal volume and single-breath vital capacity of 7% sevoflurane in children older than 5 years of age. Eyelash-reflex loss was more rapid in the vital-capacity group compared with the tidal-volume group, but the time to deep anesthesia, bispectral index values 60 and 40, and the incidences of side effects were similar in both groups. Of note, the vital-capacity technique was preferred over the tidal-volume technique by the children. The authors propose that the decreased exposure to the smell of sevoflurane and decreased awareness of losing consciousness explained the higher preference scores in the vital-capacity group.

If a child has fallen asleep or is well sedated in a parent's arms or on a stretcher, anesthesia can be induced by the "steal technique," as originally described by Guedel in 1921 (Calverley, 1986). While avoiding moving or awakening the child, 70% nitrous oxide at high flows via an anesthesia mask is held closely over the child's face. At first the mask should not touch the skin, but as sedation deepens it is placed gently on the face while incrementally increasing the concentration of sevoflurane. Monitoring devices should be attached as soon as possible. Once adequately anesthetized, the child can be transferred to a stretcher or operating-room bed if needed.

Once the patient has accepted the mask and is breathing the inhalation agent, it is extremely important to closely follow the progress of induction. The first sign is usually nystagmus, especially if nitrous oxide is being used. The eyes then usually close; the limbs and head may relax; and respiration becomes slower, regular, and deeper—then shallower and more rapid. Often children will have uncoordinated movements during the hyperreflexic phase of anesthesia and develop "snoring" or noisy breathing as the anesthetic depth deepens and as the patient develops partial upper airway obstruction. Although prepared for this preoperatively, parents should be reminded and reassured that this is normal during the induction of anesthesia. Until the eyelash reflex is gone, nothing should be done to move or stimulate the patient, unless airway obstruction or a similar need arises. Nurses and surgeons should not touch the patient without getting permission from the anesthesiologist. As soon as anesthesia is induced and the patient can tolerate moderately painful stimuli, an IV catheter can be started.

Unless excessive fluid or blood loss is anticipated, a 20-gauge catheter for children and a 22- or 24-gauge catheter for infants and small children fulfill the need for routine elective procedures. It is an error to use small-gauge catheters in infants and children merely because of their size. If adequate percutaneous sites are not available, use of a central venous catheter or surgical cut-downs may be indicated. Conversely, in children undergoing relatively minor procedures where major fluid shifts or blood loss are not anticipated, it is much better to have a working 22-gauge IV rather than a nonfunctioning 20-gauge catheter or multiple infiltrated IVs in an attempt to get larger venous

access. If a scalp vein is used, caution is advised. Inadvertent subcutaneous injection of certain drugs, such as calcium, can cause tissue destruction and sloughing of the scalp.

Maintenance of the Upper-Airway Patency

Upper airway obstruction can arise during induction of anesthesia (even in healthy infants and children) for several reasons, including tongue displacement, excess soft tissue, velopharyngeal collapse, and laryngospasm. Applying pressure to the soft tissue between the rami of the mandible when holding a mask on a patient's face can push the tongue against the hard and soft palate or displace it posteriorly, leading to occlusion of the oral pharynx or its outlet, respectively. Even minimal relaxation of the pharyngeal and laryngeal muscles during induction can significantly reduce oral and nasal passages already compromised by enlarged or increased amounts of lymphoid tissue. Relaxation of the pharyngeal and laryngeal muscles, accompanied by a marked increase in respiratory effort and excessive generation of negative pressure, which can occur in response to pain and other stimulation, may result in collapse of the velopharynx. To prevent upper airway obstruction from these causes, the pediatric anesthesiologist must learn to hold the anesthesia mask snugly to the patient's face and perform the triple airway maneuver—neck extension, jaw thrust, and mouth opening—without applying pressure to the soft tissue or causing pain (Fig. 13-3). In addition, a moderate amount of continuous positive airway pressure (CPAP; 10 to 15 cm H₂O) can counteract the collapsing force on the relaxed upper airway (Motoyama, 1997; Hammer et al., 2001). Careful and

continuous monitoring of breath sounds via a precordial stethoscope is essential to guide and maximize the effectiveness of upper-airway maintenance by hand.

When the patient is sufficiently anesthetized, an oropharyngeal airway may be inserted to further aid in maintaining a patent airway. Insertion of an oral airway in an inadequately anesthetized patient risks triggering laryngospasm. The proper length of an oral airway, with the tip behind the base of the tongue, can be estimated by holding the airway over the side of the child's face extending from the ear to the angle of the mandible. A preferred method for inserting an oral airway is to slide it gently forward and downward over the tongue while the tongue is pulled outward by a tongue depressor. The technique of inserting the airway upside down and then correcting the orientation in the posterior pharynx should be avoided in children. It tends to push the tongue posteriorly and obstruct the oral pharynx, particularly in infants (Smith, 1980). A nasopharyngeal airway is better tolerated when the anesthesia is too light for insertion of an oropharyngeal airway. This type of airway should be well lubricated and inserted very gently to prevent mucosal injury and bleeding.

If the obstruction is not relieved by airway maneuvers, the patient may have laryngospasm, which can result from laryngeal mucosal irritation and is often initiated by the aspiration of saliva. Vigorous positive pressure ventilation may push the secretions down into the larynx, which intensifies the spasm and further inflates the stomach, compromising pulmonary gas exchange. The risk of regurgitation and aspiration of gastric contents also increases. A healthy child can tolerate a few moments of laryngospasm. A more successful approach is to maintain moderate continuous positive pressure and synchronous ventilation with the "expiratory" phase of laryngospasm, which is when the vocal cords momentarily relax. By using 100% oxygen and intermittent positive pressure, one can ventilate enough gas through the glottis to avoid serious hypoxemia. If rapid oxygen desaturation and bradycardia ensue, IV succinylcholine (2 mg/kg) and atropine (0.02 mg/kg) or 5 mg/kg of IM succinylcholine should be administered without delay (Liu et al., 1981; Hannallah et al., 1986). Airway patency needs to be reestablished with or without tracheal intubation.

Intravenous Induction

In children and adults, induction via the IV route has the advantage of speed and avoids the unpleasant odors and sensations of an inhalation induction. The major disadvantage involves the difficulty and fear associated with venipuncture in young children. Topical anesthetic, as discussed previously, can significantly reduce pain associated with catheter insertion if it is used appropriately and enough time is allowed. Children younger than 6 or 7 years of age have shown less overall benefit from the use of topical anesthetics than older children, probably because the fact that young children, although numb, continue to associate needles with pain. Children who are 8 to 10 years of age and older may prefer an IV induction to a mask, often because they have unpleasant memories from a previous experience. Dorsal hand, radial, and if needed, antecubital veins are typically most visible, accessible, and acceptable sites for IV catheter insertion. Wrist, foot, and saphenous veins are other possibilities, but they are difficult to access unless the extremity is immobilized and the skin is anesthetized.

FIGURE 13-3. To maintain upper airway patency, the pediatric anesthesiologist holds the anesthesia mask snugly to the patient's face and performs the triple airway maneuver—neck extension, jaw thrust, and mouth opening—without applying pressure to the soft tissue or causing pain.

The anesthesiologist should always be honest with children, explaining each step of the procedure without frightening them. Using distraction techniques during the placement of the catheter is superior for reducing pain and agitation, compared with using encouragement and complements on good behavior or courage. Before the delivery of any medications, the anesthesiologist should ensure that the IV catheter is easily flushed to avoid inadvertent subcutaneous infusions. Securing the IV insertion site is particularly important in children, because they often emerge in an uncooperative and agitated state. The extremity in which the catheter is inserted should be taped to a cushioned board with a loop of IV tubing to prevent accidental pull and removal of the catheter.

Propofol

An induction dose of propofol is 2.5 to 3.0 mg/kg in healthy unmedicated children between the ages of 3 and 12 years (Manschot et al., 1992). In induction studies, children younger than 2 years of age required a significantly larger dose (2.6 to 3.4 mg/kg), whereas older children needed less (Aun et al., 1992; Manschot et al., 1992). Induction with propofol in children can cause significant decreases in blood pressure and inotropy, similar to those observed after thiopental (Mirakhor, 1988; Hannallah et al., 1991; Manschot et al., 1992).

A major drawback to propofol is the pain it causes on injection. In a quantitative systematic review, Picard and Tramèr (2000) determined that the only approach that had a reliably low number of needed-to-be-treated (NNT) patients was the lidocaine-tourniquet technique (similar to a Bier block; see Chapter 16, Regional Anesthesia) and that preinjection of local lidocaine and analgesics, temperature of medication, speed of infusion, and vein size had no significant effect. Yew et al. (2005) and Rochette et al. (2008) have shown that the addition of medium-chain triglyceride to propofol preparation also decreases pain on injection. Propofol offers the advantage of having antiemetic properties (Borgeat et al., 1990).

Thiopental

The induction dose of thiopental in healthy children is 5 to 6 mg/kg (Coté et al., 1981). In infants between 1 and 6 months of age, the median effective dose (ED₅₀) is reported to be 6.8 mg/kg; in infants younger than 2 weeks of age, it is 3.4 mg/kg (Jonmarker et al., 1987). The dose for induction in infants younger than 5 months was almost twice that for older children (see Chapter 7, Pharmacology of Pediatric Anesthesia, Fig. 7-18). Like propofol, thiopental is a cardiac depressant and vasodilator, and it should be used with care in patients suspected to have hypovolemia or decreased cardiac function.

Etomidate

The induction dose of etomidate in healthy children is 0.3 mg/kg, and it is often recommended in patients who have limited hemodynamic reserve. Sarkar and colleagues (2005) confirmed that in children there are no significant changes in right atrial, aortic, or pulmonary artery pressure, or systemic or pulmonary vascular resistance after bolus dosing. Side effects include pain on injection and myoclonic movements.

Ketamine

Ketamine is a dissociative anesthetic, and a dose of 2 mg/kg produces a catatonic-like state in children within 1 to 2 minutes. Its ability to stimulate the release of endogenous catecholamine and subsequently elevate heart rate and blood pressure and dilate bronchial airways supports its use in patients who may benefit from these properties. Ketamine increases oral and airway secretions and is associated with psychological and behavioral sequelae in children. To minimize these side effects, antisialagogues (glycopyrrolate, 0.1 mg/kg) and benzodiazepines (0.5 mg/kg) are recommended, respectively.

MAINTENANCE OF ANESTHESIA

After induction, the anesthesiologist is responsible for maintaining patient analgesia, amnesia, and immobility, as well as maintaining autonomic and hemodynamic stability to allow for optimum working conditions for surgical procedures. Today, a balanced anesthetic technique that is tailored toward each patient and accounts for his or her medical conditions, as well as the surgical procedure and planned postoperative management, is preferred. To do this, the anesthesiologist has several options with respect to anesthetic drugs, including inhalational versus intravenous agents. Adjuvant drugs for pain control, muscle relaxation, and prevention of postoperative nausea and vomiting are also used. Furthermore, in certain patients, regional anesthesia allows for improved pain control with a reduction in the use of opioids that can have significant side effects.

During the maintenance phase, the anesthesiologist must always be vigilant, with careful and continual monitoring of anesthetic depth, oxygenation, ventilation, cardiovascular function, fluid balance, body temperature, and glucose and electrolyte levels. In more critically ill patients, the anesthesiologist may need to place more invasive monitors for more accurate observation of the patient's status. Ultimately, the anesthesiologist is the patient's advocate in the operating room, communicating with the surgeons and allowing for a safe, comfortable, and successful outcome in the perioperative period.

Pharmacologic Agents

Inhaled Anesthetics

Inhaled anesthetics are the most commonly used agents in the administration of general anesthesia in pediatric patients. Although halothane was a staple in pediatric anesthesia for years, the development of newer agents with better safety profiles has made halothane nearly obsolete (Lerman, 2004). With discontinuation of the production of halothane in the United States, sevoflurane, desflurane, and isoflurane are now the most commonly used inhalation agents. Nitrous oxide is also commonly used as an adjunct, although there remains some controversy regarding its use.

Introduced in 1995, sevoflurane became the agent of choice for inhalation inductions. In addition to its rapid and smooth induction of anesthesia, sevoflurane causes few arrhythmias, less cardiovascular depression, and minimal renal or hepatic toxicities, all of which are improvements over halothane

TABLE 13-1. Characteristics of Volatile Anesthetics

	Molecular Weight (Da)	Boiling Point (°C)	Vapor Pressure at 20° C (mm Hg)	Blood Gas Partition Coefficient	MAC (%)	
					Infant (1-6 mo)	Child (3-10 yr)
Isoflurane	184.5	48.5	239	1.4	1.7	1.6
Desflurane	168.0	23.5	664	0.4	9.4	8.0
Sevoflurane	200.1	58.5	160	0.6	3.3	2.5

(Lerman, 2004). Isoflurane and desflurane also have more stable cardiovascular profiles and less associated toxicity compared with halothane. However, each agent has limitations that warrant consideration in certain patients and clinical situations. Table 13-1 summarizes the characteristics of the commonly used volatile anesthetics.

Nitrous Oxide

Nitrous oxide is the oldest and has been the most widely used anesthetic in both adults and children. It has an inoffensive odor and a very low solubility (blood-gas partition coefficient of 0.47) that results in rapid uptake and distribution. Because it has a minimum alveolar concentration of 104% for general anesthesia, nitrous oxide cannot be used as a sole anesthetic at normal atmospheric pressures. Therefore, it is generally used as an adjunct to reduce the minimum alveolar concentration of a primary inhalation agent, increasing the rate of induction of general anesthesia, as well as providing or augmenting the analgesic aspect of general anesthesia (Emmanouil and Quock, 2007).

Nitrous oxide has mechanisms of action that continue to be discovered. It appears that the anesthetic effect occurs through inhibition of *N*-methyl-d-aspartate (NMDA) glutamate receptors in the central nervous system. Analgesia occurs through release of endogenous opioids that then stimulate opioid receptors and spinal level γ -aminobutyric acid (GABA) receptors. Anxiolysis occurs through activation of GABA_A, although this pathway is still being investigated (Emmanouil and Quock, 2007).

Although nitrous oxide is widely used, there are certain patients and clinical situations in which its use is not recommended and even contraindicated. In adults with pulmonary hypertension, nitrous oxide increases pulmonary artery and pulmonary wedge pressures (Schulte-Sasse et al., 1982). However, in healthy infants, Hickey and colleagues (1986) observed mild decreases in heart rate, blood pressure, and cardiac index with no increase in pulmonary artery pressure or vascular resistance.

Nitrous oxide accumulates in closed, gas-containing spaces and should be avoided in patients at risk of toxicity caused by this expansion. This includes patients with obstructed loops of bowel, pneumothorax, pneumocephalus, and middle-ear surgery. Nitrous oxide also has been shown to increase middle cerebral-artery blood-flow velocity and may increase intracranial pressure (ICP), making its use in children with increased ICP contraindicated (Wilson-Smith et al., 2003). Furthermore, in situations in which maximal oxygen delivery is needed, such as shock, massive blood loss, severe anemia, and compromised cerebrospinal blood flow, nitrous oxide should be avoided. Children with abnormal vitamin B₁₂ and B₁₂-related metabo-

lism may also be at risk of neurologic injury after exposure to nitrous oxide during a routine anesthetic procedure (Sanders et al., 2008).

The role of nitrous oxide in postoperative nausea and vomiting (PONV) has been examined extensively. Although the incidence was increased when used with propofol, no difference was seen in the incidence of PONV with or without nitrous oxide when used with sevoflurane or desflurane in children (Watcha et al., 1991; Kuhn et al., 1999; Bortone et al., 2002). Nitrous oxide supports combustion. Thus, its use in patients undergoing oral or facial procedures should be reevaluated with regard to the possibility of an airway fire.

Sevoflurane

Since its introduction in the mid 1990s, sevoflurane has replaced halothane as the agent of choice for inhalation inductions in pediatric patients. It is a fluorinated methyl isopropyl ether with a blood-gas partition coefficient of 0.68, allowing for rapid induction and recovery. With a nonpungent odor and minimal airway irritation, up to 8% sevoflurane can be delivered without significant breath holding, coughing, or laryngospasm. The minimum alveolar concentration (MAC) of sevoflurane decreases from 3.3% in neonates and infants younger than 6 months old to 2.5% in children between 6 months and 5 years old and to 2.0% in adults (Hatch, 1999). Lerman and colleagues (1994) found that the MAC-sparing effect of nitrous oxide was significantly less for sevoflurane.

Sevoflurane causes minimal cardiovascular side effects in children. Compared with desflurane, sevoflurane produces less hypotension. There is also less tachycardia than isoflurane and less myocardial depression than halothane (Frink et al., 1992b; Holzman et al., 1996). Using echocardiography, Wodey et al. (1997) found that sevoflurane did not affect heart rate, cardiac index, or myocardial contractility. Furthermore, it does not sensitize the myocardium to epinephrine (Hayashi et al., 1987). Arrhythmias are uncommon with sevoflurane compared with other agents (Hatch, 1999).

Sevoflurane affects respiratory function, with some studies suggesting it does so to a greater extent than other agents (Doi et al., 1994; Yamakage et al., 1994). Brown and colleagues (1998) found that compared with halothane, minute ventilation and respiratory frequency were lower in infants on 1 MAC of sevoflurane, but that there were only moderately increased end-tidal carbon dioxide (CO₂) levels. Sevoflurane is, however, an effective bronchodilator (May et al., 1996). Neurologically, sevoflurane has been associated with cortical epileptiform electroencephalograms, although no lasting clinical sequelae (such as seizures) have been attributed to sevoflurane alone. Further

studies are necessary to determine which patients are at risk and what can be done to decrease the incidence of these EEG changes (Constant et al., 2005).

As much as 5% of sevoflurane is metabolized, with defluorination producing an inorganic fluoride that is then excreted in the urine. Peak fluoride concentrations, although higher in sevoflurane than in isoflurane, are still well below the accepted nephrotoxic level of 50 mmol/L. There is rapid elimination, and these levels remain below toxic levels even with prolonged anesthetics (Levine et al., 1996; Hatch, 1999). In addition, the metabolism of sevoflurane by the $P_{450}E_1$ system is mostly in the liver and not the kidneys. Thus, the concern of nephrogenic diabetes insipidus (DI) by elevated fluoride levels does not appear to be an issue.

Sevoflurane reacts with soda lime in the anesthesia circuit, resulting in the production of compound A. Compound A increases more when Baralyme brand (Allied Healthcare Products Inc., St. Louis, Mo) is used, when dry rather than wet absorbents are used, and when lower fresh gas flows (0.5 to 1 L) are used, resulting in increased canister temperatures (Frink et al., 1992a). Ebert and colleagues did not find evidence of renal injury after sevoflurane was administered in high concentrations (3% end-tidal) for 8 hours (1998). Kharasch and colleagues (1997) also found no significant renal dysfunction in patients with low-flow sevoflurane (1 L/min) when compound A was detected. Other studies have also documented no worsening of renal function after sevoflurane, even in patients with preexisting renal impairment (Conzen et al., 1995). New generation CO_2 absorbers, including DragerSorb Free and Amsorb Plus, have been shown to provide adequate CO_2 absorption while reducing the production of compound A, even at fresh gas flows as low as 500 mL/min (Marini et al., 2007).

Spontaneous ignition, fire, and explosion resulting from an exothermic reaction of sevoflurane with desiccated CO_2 absorbers have also been reported (Castro et al., 2004; Wu et al., 2004). With high fresh gas flow, the increasing dryness of the absorbent increases degradation of sevoflurane. Dunning et al. (2007) demonstrated that up to 3 mol of hydrogen were produced in the reaction of sevoflurane with heated, desiccated absorbent. The authors postulate that this hydrogen is the most likely fuel in anesthesia machine fires. Special attention should be paid to situations in which absorbent desiccation may be greater, such as in seldom-used anesthesia machines and in operating rooms where high fresh-gas flows relative to body size are used (Wu et al., 2004). The use of newer absorbents or Mapleson D circuits can also help avoid this problem (Woehlck, 2004).

While the question of sevoflurane-related hepatitis has been raised in case reports, metabolism of sevoflurane does not result in the trifluoroacetylated liver proteins that trigger the immune-mediated hepatitis seen with halothane, and immune-based hepatitis after sevoflurane has not been reported (Kharasch, 1995; 2008). Malignant hyperthermia has been reported with sevoflurane use (Otsuka et al., 1991).

Both postanesthetic emergence time and the time when discharge criteria are met are significantly lower in patients given sevoflurane compared with those receiving halothane; however, patients receiving sevoflurane had significantly higher pain scores that required analgesics to be administered earlier (Naito et al., 1991; Sarner et al., 1995). In a meta-analysis of randomized controlled trials, Kuratani and Oi (2008) demonstrated that sevoflurane had a higher probability of emergence

agitation compared with halothane (Fig. 13-4). Treatment or pretreatment with either dexmedetomidine, fentanyl, or propofol can mitigate emergence agitation after sevoflurane anesthesia.

Desflurane

Desflurane is a fluorinated methyl ethyl ether with a blood:gas solubility coefficient of 0.42, which is close to nitrous oxide and lower than any other agent. With lower potency, the MAC in newborns is 9.2%, in infants it is 8% to 9.9%, and in older children and adults it is 6% (Hatch, 1999). Because of its lower boiling point (22.8° C), desflurane requires a heated pressurized vaporizer. It is also resistant to degradation and biotransformation.

Desflurane is highly irritating to the upper airway. Zwass and colleagues (1992) found that it caused moderate to severe laryngospasm in 49% of unpremedicated patients and moderate to severe coughing in 58%. These parameters did not improve with premedication. The authors concluded that desflurane, although safe for maintenance of anesthesia, was limited in its use for inhalation inductions. Recent changes in the package insert suggest that desflurane is not recommended for use in patients undergoing bag-and-mask ventilation or in patients with an LMA in place.

Studies in both adults and children have demonstrated a dose-related effect of desflurane on ventilation, with a decrease in tidal volume, minute ventilation, and the ventilatory response to CO_2 . Respiratory rate was shown to increase (Lockhart et al., 1991; Behforouz et al., 1998). At 1 MAC, desflurane exhibits bronchodilator effects. However, with increasing concentration to 2 MAC, desflurane increased airway resistance as opposed to other inhalation agents that continued to produce bronchodilation (Dikmen et al., 2003). In children with known airway susceptibility, desflurane caused significant elevations in airway resistance and increased airway narrowing (von Ungern-Sternberg et al., 2008).

Desflurane has been shown to provide cardiovascular stability. Systemic vascular resistance decreases, which results in a decrease in systemic blood pressure without changes in cardiac output. Taylor and Lerman (1992) showed a mean percentage decrease in systolic arterial pressure of $29 \pm 13\%$ from pre-anesthetic values in children, with the incidence of hypotension greatest in infants and least in children 5 to 12 years of age. These pressure differences, however, did not require intervention. Heart rate increases in a dose-dependent manner, and arrhythmias are uncommon. Sympathetic tone increases, but there does not appear to be increased sensitization of the myocardium to epinephrine as is seen with halothane (Hatch, 1999).

Because of its low blood:gas partition coefficient, desflurane allows for rapid emergence and recovery, which has been demonstrated in several studies of children (Taylor and Lerman, 1992; Welborn et al., 1996; Wolf et al., 1996). However, Welborn et al. (1996) found that recovery from desflurane was associated with a significantly greater incidence of agitation and excitement, and that there was no difference in the time to meet discharge criteria as compared with other inhaled anesthetics. Wolf and colleagues (1996) found that desflurane, unlike isoflurane, was not associated with postoperative apnea and suggested that it may be useful in ex-premature infants. More recently, however, Sale et al. (2006) showed that although there was a faster time to awakening with desflurane, apnea did occur with desflurane and there was no difference between desflurane and sevoflurane

SEVOFLURANE AND EMERGENCE AGITATION

FIGURE 13-4. Meta-analysis of emergence agitation caused by sevoflurane (*Sevo*) versus halothane (*Halo*). The center of each purple diamond is the odds ratio (OR) for individual trials, and the corresponding horizontal line is the 95% confidence interval (CI). The open diamond is the pooled result. (From Kuratani N, Oi Y: Greater incidence of emergence agitation in children after sevoflurane anesthesia as compared with halothane: a meta-analysis of randomized controlled trials, *Anesthesiology* 109:229, 2008.)

in the incidence of postoperative apnea in the ex-premature infant undergoing hernia repair (Kuratani et al., 2008).

Isoflurane

Isoflurane is a stable liquid that has a blood:gas partition coefficient of 1.4, which is much higher than both sevoflurane and desflurane. Like the other inhalation agents, the MAC of isoflurane is age-dependent, ranging from 1.3% in preterm infants to 1.7% in infants 6 to 12 months of age and decreasing to 1.6% in children 1 to 5 years old, compared with 1.2% in adults (Cameron et al., 1984; LeDez and Lerman, 1987). Because of its pungent odor, isoflurane causes coughing and laryngospasm, which precludes its use for inhalation inductions. Isoflurane is resistant to biodegradation, making the incidence of hepatotoxicity and nephrotoxicity minimal (Eger, 1984). The emergence profile is similar to that of halothane.

Like the other inhalation agents, isoflurane produces a dose-dependent respiratory depression, with an increase in respiratory rate and smaller tidal volumes that produce an increase in arterial CO_2 pressure. Isoflurane depresses ventilation to a greater extent than halothane, and isoflurane anesthesia requires mechanical ventilation (Eger, 1984). It is also a bronchodilator, with continued effects at higher concentrations (Dikmen et al., 2003).

Isoflurane, in a dose-dependent manner, decreases systemic vascular resistance, resulting in a subsequent drop in the systemic arterial pressure and increase in heart rate, all while maintaining cardiac output (Wolf et al., 1986). Tachycardia is particularly seen in younger patients (Eger, 1984). However, there is no reported increase in the incidence of arrhythmia, and it does not appear to sensitize the myocardium to epinephrine.

Isoflurane produces muscle relaxation and potentiates the intensity and duration of action of pancuronium and to a lesser extent vecuronium and atracurium. This results in the need to adjust dosing of these neuromuscular blockers accordingly.

Intravenous Agents

With more information available about IV agents and their pharmacokinetic and pharmacodynamic profiles in infants and children, their use has increased in these populations. Hypnotic and sedative agents, as well as the short-acting opioids, have been found to be both safe and effective in the pediatric population. In certain populations, including children who are susceptible to malignant hyperthermia, the use of total intravenous anesthesia (TIVA) has become essential.

The use of TIVA has both advantages and disadvantages. While TIVA allows for rapid recovery and does not require the sophisticated equipment needed to administer inhaled anesthetics, it can be associated with increased intraoperative awareness, prolonged recovery after long infusions, and the need for supplemental analgesia. In addition to this, newborns and young infants with immature hepatic enzyme systems and renal clearance can have significant accumulation of certain intravenous drugs. In the pediatric population, an inhalation induction for placement of an intravenous catheter often is done and negates some of the advantages of TIVA. All of these factors need to be considered when determining if TIVA is the ideal anesthetic for a particular patient.

Propofol

Propofol is a short-acting intravenous agent that is used for both induction and maintenance of anesthesia. With its fast onset, smooth maintenance, clear headed emergence, and decreased incidence of nausea and vomiting, it has many properties that make it ideal for TIVA. It is commonly used for procedures and sedation outside of the operating room, often as the sole agent in locations such as magnetic resonance imaging (MRI) and the endoscopy suite. Although propofol has no direct analgesic properties, patients receiving it seem to have lower analgesic requirements. At lower doses, it may not produce amnesia (Marik, 2004).

Propofol is highly lipid-soluble and rapidly cleared and redistributed into the peripheral tissues, with a short, context-sensitive half time (see Chapter 7, Pharmacology of Pediatric Anesthesia, Fig. 7-16). Relative to adults, children have a larger central compartment, and they have a higher clearance that can be twice that of adults, resulting in higher dosing requirements. Hannallah and colleagues (1994) showed that with a background of 60% nitrous oxide, pediatric patients required a dose of 250 to 300 mcg/kg per minute to prevent movement with surgical stimulation. A dose of 150 to 200 mcg/kg per minute stabilized the hemodynamic indices of those who received muscle relaxants. Moderate hypotension and bradycardia are associated with propofol administration, with a decrease in mean arterial pressure (MAP) of approximately 10% on induction and another 10% during the early maintenance phase. The arterial pressure subsequently returns to baseline (Passenbacher et al., 2002). The use of adjuncts such as opioids can accentuate these responses, while coadministration of ketamine has been shown to preserve hemodynamic stability, albeit with more postoperative agitation (Aouad et al., 2008).

Pain during injection is an issue with propofol. However, preadministering or mixing it with lidocaine appears to attenuate this somewhat. Often, an inhalation induction followed by the administration of propofol for maintenance also avoids this issue in children. Propofol is associated with a shorter recovery time and a shorter time until discharge. It is also associated with significantly decreased incidence of postoperative nausea and vomiting when compared with halothane (Marsh et al., 1991; Watcha et al., 1991; Hannallah et al., 1994). Cohen et al. (2004) found in patients aged 2 to 36 months that propofol at 200 mcg/kg with analgesic supplementation had the same hemodynamic, recovery, and antiemetic profile as sevoflurane. Emergence delirium does not appear to be an issue with propofol.

Although many properties of propofol make it ideal for sedation, it has been associated with several adverse effects in children and adults undergoing prolonged infusions (greater than 48 hours) at high doses of greater than 4 mg/kg per hour (Vasile et al., 2003). This propofol infusion syndrome (PRIS) is characterized by bradycardia, hypotension, lipemic plasma, fatty liver enlargement, significant lactic acidosis, rhabdomyolysis, and myoglobinuria. Usually, PRIS leads to fatal renal, cardiac, and circulatory failure (Fudickar and Bein, 2009).

PRIS is caused by propofol's impairment of oxygen utilization and inhibition of mitochondrial electron transport, leading to cytolysis of both skeletal and cardiac muscle cells (Kam and Cardone, 2007). Children appear to be more prone to PRIS because of low glycogen storage and high dependence on fat metabolism (Fudickar and Bein, 2009). Current therapy involves immediate stoppage of the propofol infusion, cardiorespiratory support, and hemodialysis or hemofiltration to eliminate the propofol and its toxic metabolites. Carbohydrate supplementation is also recommended (Fudickar and Bein, 2009).

Dexmedetomidine

Dexmedetomidine is a highly selective α_2 -adrenoreceptor agonist with both sedative and analgesic properties. Its elimination half-life is 2 hours, with a rapid distribution half-life of only 6 minutes (Dyck and Shafer, 1993), making it ideal for IV infusion. U.S. Food and Drug Administration (USFDA)-approved for sedation in the intensive care unit in adult patients who are mechanically ventilated, dexmedetomidine has now been used in the pediatric ICU setting, as well as for sedation in noninvasive and invasive procedures (Chrysostomou et al., 2006; 2009). It has minimal effects on respiration, which may be beneficial in pediatric patients with upper airway obstruction, and it allows for agitation-free emergence (Mahmoud et al., 2010).

Several studies have reported efficacy of dexmedetomidine for sedation in noninvasive radiologic imaging. Compared with midazolam, dexmedetomidine provided better quality of sedation and less need for rescue sedation (Koroglu et al., 2005). In another study by Koroglu and colleagues (2006), patients randomly received either dexmedetomidine or propofol. Both agents demonstrated equally effective sedation, but propofol had shorter induction, recovery, and discharge times; however, hypotension and oxygen desaturation were more common with propofol. Mason and colleagues (2006) found that the effective mean loading dose of dexmedetomidine for children during radiologic imaging was 2.2 mcg/kg, followed by a continuous infusion of 1 mcg/kg per hour. There was no change in end-tidal CO_2 and no oxygen desaturation while these children were breathing room air.

For invasive procedures, use of dexmedetomidine as the sole agent for sedation has produced mixed results. For cardiac catheterization, Munro et al. (2007) used an average maintenance infusion rate of 1.15 ± 0.29 mcg/kg per hour with a range of 0.6 to 2 mcg/kg per hour. Hammer and colleagues (2008) noted that dexmedetomidine significantly depressed sinus and AV nodal function with sinus cycle length and sinus node recovery time increasing. Sixty percent of patients needed a propofol bolus for movement, for an increasing bispectral index (BIS) number, or in anticipation of stimulus. Because of dexmedetomidine's limited analgesic effects, use of ketamine or inhalational agents as an adjunct to dexmedetomidine has been shown to be effective in several studies (Ard et al., 2003; Tosun et al., 2006).

In adults, hypotension and bradycardia are reported, especially when propofol is given as a large and rapid bolus dose or with other agents that are negative chronotropes. There appears to be a biphasic response, with an initial increase in systolic blood pressure and a reflex decrease in heart rate, followed by stabilization of both parameters below baseline values (Bloor et al., 1992). In pediatric patients, Hammer and colleagues (2008) demonstrated an increase in MAP and a decrease in heart rate from baseline values after a 10-minute loading dose of dexmedetomidine 1 mcg/kg. These effects did not continue once an infusion of 0.7 mcg/kg per hour was administered. Respiratory rate and end-tidal CO₂ did not change. It also appears that concurrent use of medications that affect cardiac conduction, such as digoxin, enhance the risk of bradycardia. Mukhtar et al. (2006) demonstrated a sympatholytic effect of dexmedetomidine in pediatric patients undergoing cardiopulmonary bypass. Dexmedetomidine, through its centrally acting α_2 -adrenergic agonist effect, also can reduce the shivering threshold in children and be used to reduce postoperative shivering (Blaine et al., 2007).

Adjuvant Agents

Today, there are numerous adjuvant agents available for use during the maintenance phase of anesthesia that allow for better intraoperative and postoperative management. Improved pain control, smoother emergence, and a more comfortable immediate postoperative period are all goals that are hopefully achieved through a balanced anesthetic technique. Furthermore, by decreasing the amount of the more noxious agents used, one reduces the undesirable side effects that can be associated with them. Opioids, nonsteroidal antiinflammatory drugs, hypnotics, antiemetics, and muscle relaxants all are commonly used in the pediatric population to improve quality of perioperative care.

Opioids
