Opioids and their synthetic analogs are widely used in infants and children as adjuncts during maintenance of anesthesia, as well as to provide for better postoperative pain management. Whereas morphine and fentanyl have historically been the opioids of choice, newer agents such as remifentanyl have become an important part of pediatric anesthesia. The agent chosen, as well as the dosage used, depends on the overall goal and the plan for postoperative management (spontaneous vs. mechanical ventilation). Opioids and other analgesics are discussed in greater detail in Chapter 7, Pharmacology of Pediatric Anesthesia. The intravenous dosages of opioids for children are listed in Table 13-2.

Morphine is a long-acting hydrophilic analgesic that is commonly used for management of both intraoperative and postoperative pain. There is a prolonged duration of action in very young infants because of its lower clearance and longer elimination half-life, which requires lower doses and a longer dosing interval in the newborn period (Lynn and Slattery, 1987). However, total body morphine clearance is 80% that of adults by 6 months of age (Bouwmeester et al., 2004). There does not appear to be an age-related difference in the respiratory depression that occurs (Lynn et al., 1993). Morphine can cause hypotension as a result of histamine release, and urticaria and bronchospasm can be seen. Postoperative nausea and vomiting can also occur.

Hydromorphone is a hydrogenated ketone derivative of morphine that is 7 to 10 times more potent. When compared with morphine, hydromorphone is more lipophilic and has a shorter time to onset and duration of action. It produces less sedation, nausea, and vomiting, but it can still produce significant respiratory depression. Both morphine and hydromorphone are widely used in patient-controlled and epidural analgesia.

Fentanyl is a lipophilic synthetic opioid that is approximately 100 times as potent as morphine but has a relatively short duration of action of 1 to 2 hours. Fentanyl is safely used as a primary anesthetic agent and as a supplemental analgesic during an inhalational anesthetic. Pharmacokinetic studies in neonates, infants, and children have demonstrated a highly variable volume of distribution, rate of clearance, and half-life (Koehtop et al. 1986; Singleton et al. 1987). Because the effect is less predictable in neonates and premature infants, postoperative ventilatory support should be considered.

In addition to the known side effects of the other opioid analgesics, fentanyl can cause chest wall rigidity and bradycardia. Chest wall rigidity may compromise the ability to bag-mask ventilate a patient and can necessitate the use of muscle relaxants to improve ventilation. Bradycardia, although beneficial in adults, can compromise cardiac output in small infants and may require treatment with vagolytic agents or muscle relaxants that cause tachycardia.

Fentanyl is ideal for patients who need short-term anesthesia and analgesia in which a quick return to baseline respiratory function is desired. It is widely used in outpatient procedures as well as in neurosurgical cases. In cardiac surgery patients, higher doses (upward of 50 mcg/kg) have been found to provide patients with hemodynamic stability. For longer procedures, it can also be administered as a continuous infusion. However, its context sensitive half-time profile changes dramatically after 2 hours of the infusion (see Chapter 7, Pharmacology of Pediatric Anesthesia, Fig. 7-15).

TABLE 13-2. Intravenous Dosages of Opioids in Children

Drug	As Major Anesthetic	As Adjunct	As Postoperative Analgesic
Morphine	0.2-2 mg/kg	0.05-0.1 mg/kg/hr	0.05-0.1 mg/kg
Fentanyl	50-100 mcg/kg	1-3 mcg/kg/hr	1-2 mcg/kg
Sufentanil	10-15 mcg/kg	0.1-0.3 mcg/kg/hr	—
Alfentanil	150-200 mcg/kg	1-3 mcg/kg/min	—
Remifentanyl	0.2-1 mcg/kg/min	0.1-0.4 mcg/kg/min	—
Hydromorphone	5-10 mcg/kg	3-5 mcg/kg/hour	3-5 mcg/kg

Sufentanil is approximately 1000 times as potent as morphine, with an elimination half-life about half that of fentanyl but a similar neonatal pharmacokinetic profile (Davis et al., 1987a, 1987b). It is often administered as a continuous infusion.

Alfentanil is approximately 25 to 100 times as potent as morphine. It has a small volume of distribution and an elimination half-life one third that of fentanyl. In neonates, it has a prolonged elimination time and increased volume of distribution (Davis et al. 1989). It also has great patient-to-patient variability, making its effects more difficult to predict. Like other opioids, alfentanil has a high incidence of PONV.

Remifentanil is an ultrashort-acting opioid with potency similar to fentanyl. It undergoes esterase cleavage to inactive metabolites, making its clearance independent of hepatic or renal clearance. Ross et al. (2001) found a consistent pharmacokinetic profile, with neonates and infants younger than 2 years of age having the largest volume of distribution and most rapid clearance. It has a constant context-sensitive half-life of 3.4 to 5.7 minutes in all age groups despite the duration of administration and the dose infused. With a mean rate of 0.55 mcg/kg per minute, Davis et al. (2001) demonstrated that remifentanil was safe and provided stable intraoperative and postoperative conditions in premature and full-term infants undergoing pyloromyotomy. It allowed for rapid emergence without postoperative apnea. For tonsillectomy and adenoidectomy, remifentanil provided faster extubation times compared with fentanyl. However, these patients had higher pain discomfort scores postoperatively, indicating that supplemental analgesia for the postoperative period is necessary (Davis et al., 2000).

Methadone is a long-acting synthetic opioid with an elimination half-life of about 35 hours. It is equally as potent as morphine when administered intravenously. It is administered when protracted postoperative pain relief is anticipated.

Meperidine is one tenth as potent as morphine and does not have the increased narcotic effect in the newborn. In older infants and children, it offers the same advantages as morphine. Histamine release is associated with its use. Doses of meperidine that are less than 0.5 mg/kg reliably treat postanesthetic shivering (Macintyre et al., 1987).

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) are often used intraoperatively to help decrease postoperative pain. Ketorolac has been shown to improve postoperative analgesia with a decrease in nausea and vomiting (Watcha et al., 1992; Cohen et al., 1993). There is continued controversy, however, as to whether the effects on platelet function should limit its use in the perioperative setting. Splinter and colleagues (1996) found that ketorolac increased bleeding in tonsillectomy patients. However, other studies have shown that ketorolac improved postoperative analgesia without increasing the incidence of bleeding after tonsillectomy and cardiac surgery (Romsing et al., 1998; Moffett et al., 2006). It has also been shown to be effective and safe in neonates and premature infants, and its kinetics have been described in children 6 to 18 months of age (Papacci et al., 2004; Lynn et al., 2007). It should be avoided in patients with compromised renal and hepatic function.

Acetaminophen is often given per rectum intraoperatively to supplement opioid analgesia. Korpela et al. (1999) found that there was a dose-related reduction in the number of

children requiring a postoperative rescue opioid when given acetaminophen 40 or 60 mg/kg rectally after induction of anesthesia. There was also a decrease in PONV. Doses higher than 40 mg/kg, however, are at or near toxic levels, and higher dosing warrants further safety studies. Subsequent doses should be modified.

Intravenous acetaminophen provides effective analgesia, with 100% bioavailability, a rapid onset of action within 5 minutes of administration, and peak analgesic efficacy at 1 hour after administration (Wilson-Smith and Morton, 2009). Prins and colleagues (2008) compared IV with rectal acetaminophen in children younger than 2 years old who were undergoing craniofacial surgery. They found that the IV form was more effective, producing analgesia more rapidly and with less interpatient variability compared with the rectal administration. In the United States, ongoing studies are looking at the efficacy and safety of IV acetaminophen in the pediatric population for future approval by the Food and Drug Administration.

Hypnotics and Sedatives

Benzodiazepines, although most commonly used for premedication, can be used intraoperatively to ensure amnesia as part of a balanced anesthetic and to prevent emergence delirium. The shorter half-life of midazolam makes it well-suited for intraoperative use. In a meta-analysis, midazolam premedication was not found to cause a significant delay in either time to emergence or time to discharge from the PACU (Cox et al., 2006).

Ketamine

Ketamine, an NMDA-receptor antagonist, has long been used in pediatric anesthesia because of its analgesic properties and its ability to produce a dissociative state. Blood pressure is well maintained with spontaneous ventilation and preservation of laryngeal reflexes. However, it can produce psychodysmorphic symptoms that require supplementation with a benzodiazepine. To produce satisfactory conditions for diagnostic or therapeutic procedures, ketamine can be administered as intermittent bolus doses of 0.2 to 1 mg/kg along with glycopyrrolate to reduce oral secretions, or as an infusion of 1 to 2 mg/kg per hour after a loading dose (Morton, 1998). Ketamine at subanesthetic infusion doses of 0.1 to 0.25 mg/kg per hour has been shown to improve pain control and have an opioid-sparing effect (Finkel et al., 2007). Further studies to determine ketamine's antihyperalgesic properties in the pediatric population are needed.

The question of whether ketamine affects central nervous system development in newborns has been raised. In humans, organogenesis of the central nervous system begins in utero and continues for several years after birth. Ketamine is associated with neuronal apoptosis in animal models during organogenesis. However, no long-term learning or behavioral disturbance has ever been noted in children after ketamine administration for anesthesia (Lois and De Kock, 2008).

Antiemetics

Prevention of PONV is an important aspect of any anesthetic. Prophylactic use of serotonin receptor (5-HT₃) antagonists such as ondansetron and granisetron has decreased the incidence of PONV with minimal side effects and a decreased length of stay when compared with droperidol (Davis et al., 1995a; Fujii

et al., 1996; Patel et al., 1997; Khalil et al., 2005). The half-life of ondansetron in infants and children younger than 2 years of age is 50% greater than in adults, making repeat dosing in the PACU unnecessary.

Metoclopramide (0.15 mg/kg) has antiemetic effects via antagonism of central dopaminergic receptors, as well as prokinetic effects caused by increased gastric emptying. Other agents with demonstrated effectiveness include dimenhydrinate at 0.5 mg/kg and perphenazine at 70 mcg/kg (Splinter and Rhine, 1998; Kranke et al., 2003).

Dexamethasone has been shown to be effective in reducing the incidence of PONV in children after tonsillectomy and after strabismus surgery (Splinter and Roberts, 1996; Madan et al., 2005). Kim et al. (2007) have shown no dose escalation response to dexamethasone in children having tonsillectomy or adenoidectomy. A dose of 0.0625 mcg/kg was as effective as 1.0 mcg/kg. There is also improved pain control in tonsillectomy patients (Elhakim et al., 2003). Several studies have shown that the best available treatment for patients at increased risk of PONV was a combination of a 5-HT₃ antagonist and dexamethasone (Henzi et al., 2000; Gombar et al., 2007).

Muscle Relaxants

Muscle relaxants are discussed in greater detail in Chapter 7, Pharmacology. The following overview briefly discusses the advantages and disadvantages of the different agents currently available.

Succinylcholine is a depolarizing muscle relaxant with a fast onset (able to produce intubating conditions within 1 minute) and short duration of action. It can be given IV (2 mg/kg in infants and small children or 1 mg/kg in older children) or IM (3 to 4 mg/kg with an onset of 3 to 4 minutes) (Liu et al., 1981). Because of the incidence of bradycardia and possible asystole, atropine (0.02 mg/kg) is administered before succinylcholine. Although its use in children is warranted in emergency situations, caution should be used because of the serious complications that can be associated with it. Succinylcholine can cause significant hyperkalemia in patients with neuromuscular disorders and burns, dysrhythmias, muscle rigidity, masseter spasm, and postoperative myalgias. In susceptible individuals, it can also trigger malignant hyperthermia.

Vecuronium is an intermediate-acting steroidal nondepolarizing muscle relaxant. Vecuronium does not produce the vagolytic response that one sees with pancuronium. In children, it has a higher ED₉₅ than in infants and adults (Meretoja et al., 1988). The duration of its effect is more prolonged in infants (73 minutes) compared with children (35 minutes) and adults (53 minutes) (Meretoja, 1988).

Rocuronium is an intermediate-acting steroidal nondepolarizing neuromuscular blocker that is similar in structure to vecuronium but one tenth as potent. It produces the most rapid onset of paralysis of the nondepolarizing agents and is used for rapid sequence inductions as an alternative to succinylcholine. At a dose of 0.6 mg/kg, the onset of maximal block is 1.3 + 2 minutes in children between 1 and 5 years old, and the time to recovery is 26.7 + 1.9 minutes (Woelfel et al., 1992). It can produce tachycardia and causes pain on injection in lightly anesthetized patients. Interaction of rocuronium with volatile anesthetic agents augments the intensity of neuromuscular blockade without effects on duration of or recovery from the block (Wulf et al., 1998).

Cisatracurium is an intermediate nondepolarizing agent that is a 1R-isomer of atracurium. At a dose of 0.15 mg/kg, the onset of maximal block is 2 + 0.8 minutes in infants and 3 + 1.2 minutes in children. Time to recovery was longer in infants (43.3 + 6.2 minutes) than in older children (36 + 5.4 minutes) (Taivainen et al., 2000). Cisatracurium undergoes hydrolysis at body temperature and physiologic pH (Hoffman elimination). It maintains hemodynamic stability and does not cause the release of histamine.

Pancuronium is a long-acting steroidal nondepolarizing muscle relaxant. It causes tachycardia by blocking vagal activity at the ganglionic level and through the release of norepinephrine. This tachycardia can be beneficial in young infants that depend on increased heart rate to improve cardiac output. Partially metabolized in the liver, the rest is then excreted by the kidneys, making its action prolonged in patients with hepatic or renal failure.

Regional Anesthesia

Regional anesthesia has become an important part of the anesthetic management of pediatric patients in the perioperative period. Regional techniques can decrease the intraoperative requirement of inhaled and intravenous agents and allow for a more rapid emergence with effective postoperative analgesia and minimal sedation (Markakis, 2000). Although caudal anesthesia remains the most popular regional technique in this population, epidural anesthesia, field blocks, ultrasound-guided peripheral nerve blocks, and neuroaxial opioids have also been used to a greater extent. The various regional analgesia techniques, as well as the choices and dosages of local anesthetics and opioids for regional analgesia are detailed in Chapter 16, Regional Anesthesia.

Caudal Anesthesia

Caudal blocks continue to be the most commonly used regional technique in infants and children. As an adjunct to general anesthesia, caudal blockade provides both intraoperative and postoperative analgesia for procedures in the lower abdomen, pelvis, or lower extremities. This block is easily performed with few associated complications, such as dural puncture and intravascular injection (Dalens and Hasnaoui, 1989). Anatomic features that contribute to these occurrences are the caudal position of the dural sac in infants at S3, the increased vascularity of the area, and the development of the sacral fat pad in school-aged children. Awareness of these factors should decrease the risk of complications.

Because infants and children do not cooperate and remain still while they are awake, caudal blocks are typically performed under general anesthesia. Once the airway is secured, the patient is placed in the lateral decubitus position and the sacral hiatus is identified and cleaned. Although several needle types and sizes have been investigated, short, beveled (22-gauge) needles have a lower incidence of intravascular injection compared with standard needles (Dalens and Hasnaoui, 1989). The needle is inserted through the sacrococcygeal ligament and advanced into the caudal space. Aspiration to confirm that there is no blood or cerebrospinal fluid (CSF), which would indicate inadvertent intravascular or intrathecal puncture, is performed before injection of the drug. Because the patient is under

general anesthesia, the response to a standard test dose of epinephrine may be masked with minimal heart rate or blood pressure change seen. However, an increase of 25% or more in the T-wave amplitude appears to be a more reliable positive predictor of intravascular injection and was seen consistently with an epinephrine dose of 0.25 to 0.5 mcg/kg (Tanaka and Nishikawa, 1999; Kozek-Langenecker et al., 2000).

Bupivacaine is a local anesthetic that has long been used due to its relative safety and longer duration of action. It has a maximal safe dose of 2.5 mg/kg. Yaster and Maxwell (1989) recommend caudal dosing of bupivacaine 0.25% at 1 mL/kg, which should block approximately 10 spinal segments, with a maximal volume of 20 mL. For procedures longer than 3 hours, the caudal procedure can be repeated with a more dilute concentration of 0.125% or 0.175% to minimize the risk of toxicity as well as motor blockade. Levo-bupivacaine is the (S)-(-)-enantiomer of racemic bupivacaine, with similar local-anesthetic properties and potency. However, it is less toxic to the central nervous system and is less likely to cause myocardial depression and fatal arrhythmias than racemic bupivacaine (Tsui and Berde, 2005). Levo-bupivacaine 0.25% at a dose of 0.8 mL/kg provides adequate analgesia for penile or groin surgery (Taylor et al., 2003).

Ropivacaine is an S-enantiomer of bupivacaine with less cardiovascular and central nervous system toxicity than racemic bupivacaine. It produces significantly less motor blockade and stronger vasoconstriction at low concentrations (Zink and Graf, 2004). Several studies have shown comparable analgesic efficacy between ropivacaine, levo-bupivacaine, and bupivacaine (Ivani et al., 2002; Breschan et al., 2005; Locatelli et al., 2005). With lower systemic absorption and lower toxicity, ropivacaine is the drug of choice for prolonged use in neonates or patients with abnormal metabolism (Hansen et al., 2001). Hong and colleagues have shown that a high volume–low concentration of ropivacaine provides a higher level of block and longer duration of analgesia than a high concentration–low volume of ropivacaine (Hong et al., 2009), where the total drug amount is the same.

Other medications with analgesic properties, injected into the caudal space with and without local anesthetics, have been shown to be efficacious. Opioids, clonidine, and ketamine have been used with varying success and are discussed in greater detail in Chapter 16, Regional Anesthesia.

Contraindications to caudal anesthesia include active sepsis, local infection of the skin at the injection site, coagulopathy, sacral anomalies (including previous meningomyelocele), and uncorrected hypovolemia (Markakis, 2000). After caudal blockade, urinary retention occurs in approximately 10% of patients but is usually short-lived (Yaster and Maxwell, 1989).

Epidural Anesthesia

Placement of an epidural catheter through the caudal, lumbar, or thoracic route allows for continuous epidural delivery of local anesthesia both intraoperatively and postoperatively at the appropriate segmental level. Many have found success with catheters that were introduced caudally then threaded to the lumbar or thoracic level (Bosenberg et al., 1988). However, in 2002, Valairucha and colleagues found only 67% of catheter tips were in optimal position when threaded from below, and Blanco et al. (1996) could only advance 22% of catheters threaded from between L4 and L5 to predicted thoracic levels.

Direct placement at the lumbar and thoracic levels can be technically more challenging and present an increased risk of complications. However, weighing risks and benefits, anesthesiologists with experience in their placement and use have found that they provide successful analgesia for upper abdominal and thoracic procedures when specifically indicated. Rapp et al. (2005) demonstrated that ultrasound guidance allows for identification of the epidural space, ligamentum flavum, and dural structures, as well as the depth at which loss of resistance occurs. Willschke et al. (2006c) had a faster catheter placement, less bone contact, and direct visualization of epidural local anesthetic spread when ultrasound guidance was used instead of the standard loss-of-resistance technique. Further studies to evaluate whether there is a reduction in the complication rate in pediatric epidural anesthesia when using ultrasound for placement are ongoing.

Epidural analgesia can be provided through bolus dosing or continuous infusion of local anesthetics. Bupivacaine (0.125% to 0.25%) or ropivacaine (0.2%) can both be used. A continuous infusion through a lumbar catheter at a rate of 0.3 mL/kg per hour maintains an analgesic level between T10 and L1.

Epidural opioids can also provide effective analgesia without sympathetic, sensory, or motor blockade (Shapiro et al., 1984; Rosen and Rosen, 1989). Respiratory depression is a major complication that requires careful dosing and observation. Pruritus, nausea, vomiting, and urinary retention can also occur but can be minimized with smaller doses of opioids or a small dose of naloxone (0.5 to 1 mcg/kg). Preservative-free morphine (30 to 70 mcg/kg caudally or 50 mcg/kg epidurally) is hydrophilic, which allows for a delayed onset, decreased systemic uptake, and prolonged duration of action (15 to 20 hours) (Attia et al., 1986; Rash et al., 1990). Fentanyl and hydromorphone are lipophilic, with a more rapid onset, greater systemic absorption, and shorter duration of action, making them more appropriate as adjuncts for continuous infusions (Dalens et al., 1986).

Subarachnoid Opioids

Subarachnoid injection of morphine has been found to have a similar efficacy and side effect profile to epidurally placed morphine. The recommended dose is 10 to 20 mcg/kg (Krechel and Helikson, 1993). Delayed respiratory depression may occur and is typically more severe than when given in the epidural space (Nichols et al., 1993). Careful monitoring and delayed further dosing of opioids are necessary.

Peripheral Nerve Blocks and Field Blocks

With advances in technology, peripheral nerve blocks are increasingly being used in the pediatric population as adjuncts to general anesthesia and to manage postoperative pain. These blocks can supply analgesia for the upper and lower extremities and allow for one-sided blockade as opposed to the central regional techniques. Axillary, interscalene, sciatic, and femoral nerve blocks have all been described. The more recent use of ultrasound allows for real-time imaging of the anatomy and direct visualization of the needle in anesthetized patients who cannot indicate discomfort or pain caused by direct nerve injection. As a result, ultrasonography is gaining in popularity over landmark-based techniques and neurostimulation (Marhofer and Frickey, 2006; Roberts, 2006). It also decreases the volume

of local anesthetic per block by 30% to 50%, which allows the anesthesiologist to stay within maximum dosing guidelines and still achieve success (Ecoffey, 2007). Toxicity can further be avoided by using diluted solutions and solutions that contain epinephrine (Berde, 1989). Disposable pumps that can deliver continuous peripheral nerve block infusions of local anesthesia can be used for continued postoperative pain control at the patient's home (Ganesh et al., 2007). Ludot and colleagues (2008) demonstrated successful analgesia and overall satisfaction with this technique in children who had a suitable family environment and proper parental instruction on the catheter's management.

Field blocks are also an important aspect of pediatric anesthesia and allow for improved postoperative pain control while decreasing the incidence of side effects associated with opioids. Compared with caudal anesthesia, ilioinguinal-iliohypogastric nerve block, wound infiltration, local anesthesia "splash," dorsal-penile nerve block, and subcutaneous ring block have all been shown to be effective for the chosen surgical procedure (Cross and Barrett, 1987; Hannallah et al., 1987; Fell et al., 1988; Casey et al., 1990). The use of ultrasound has also caused a revision in the technique of these blocks. The unpredictable depth of the posterior rectus sheath in children is more defined with ultrasound, allowing for improved analgesia. Furthermore, use of ultrasound for ilioinguinal-iliohypogastric nerve blocks reduced the volume of local anesthetic used to 0.075 mL/kg (Willschke et al., 2006a).

Monitoring

In children, meticulous attention to the patient through both clinical observation and the use of monitors during the maintenance phase of anesthesia is of the utmost importance. Physiologic changes can be subtle and occur without warning, requiring a constant vigilance on the part of the anesthesiologist. Monitoring devices alone are not adequate to care for these patients. Through careful observation of changes in chest movement, breath sounds, and heart tones with a precordial stethoscope; skin color; and capillary refill, variations in children's ventilation and circulation can be found by the anesthesiologist long before a monitor indicates them.

In addition to observation, standard monitoring devices include a pulse oximeter, capnography, ECG, an automated blood pressure measuring device, a temperature probe, and a precordial stethoscope (Fig. 13-5). For longer surgical procedures or when there are anticipated fluid shifts, a Foley catheter to monitor urinary output as an indication of IV volume is also recommended. Invasive monitoring of arterial blood pressure or central venous pressure is also indicated in certain clinical situations.

Standards of Intraoperative Monitoring

In the tradition of safety that has been a hallmark of anesthesia care and practice, standards for basic anesthetic monitoring were initially proposed in 1986 by the Harvard University teaching hospitals (Eichhorn et al., 1986). These were then adopted and amended by the American Society of Anesthesiologists (ASA), with the last iteration approved in 2005. As stated in the document, these standards apply to all general anesthetics, regional anesthetics, and monitored anesthesia care. Although some rare

FIGURE 13-5. In addition to observation, standard monitoring devices in the operating room include a pulse oximeter, capnograph device, ECG machine, automated blood pressure measuring device, temperature probe, and precordial stethoscope.

clinical situations may preclude use of all of the recommended monitors, it is expected that these standards are technologically attainable and should be used by all practitioners.

Standard I states that "qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthetics, regional anesthetics, and monitored anesthesia care" (ASA, 2005). It stipulates that this continuous care is "without any interruption at any time" because of the rapidly changing status of patients under anesthesia. Standard II stipulates that oxygenation, ventilation, circulation, and temperature be continually evaluated. "Continually" is defined as "repeated regularly and frequently in steady rapid succession" (ASA, 2005). For each component, specific objectives and methods are outlined. A combination of clinical observation and technical methods is recommended. Whereas there are no mandates for specific instrumentation, quantitative measurements are "strongly encouraged" over qualitative measures alone. Standard monitoring and supplemental measures recommended in pediatric anesthesia are shown in Box 13-1.

Pulse oximetry, introduced in the 1980s, has become a mandatory instrument in the perioperative care of pediatric patients. The pulse oximeter accurately reflects saturation in all age groups with various hematocrit values, including premature infants with fetal hemoglobin over the range of 60% to 100% SaO_2 (Deckardt and Steward, 1984). Recent advances in pulse oximetry include newer designs that claim to improve performance during low-perfusion states and patient motion, often a consideration in newborns and infants. Signal extraction technology (SET) uses algorithms that filter out interference, resulting in a 90% lower false-alarm rate (Miyasaka, 2002). Other devices provide continuous noninvasive measurement of total hemoglobin concentration and allow for differentiation between different hemoglobin types (Noiri et al.,

Box 13-1 Standard Monitors and Supplementary Measurements in Pediatric Anesthesia

STANDARD MONITORS

Physiology

Clinical observation by qualified anesthesiologist
 Oxygenation: Pulse oximeter
 Ventilation: Stethoscope, capnograph, gas flow meter
 Circulation: Stethoscope, blood pressure cuff
 ECG
 Temperature probe: Rectal, esophageal, or axillary
 Anesthetic depth: BIS monitor

Safety

Oxygen analyzer with low concentration alarm
 Ventilator with low pressure and disconnect alarm

SUPPLEMENTAL MEASUREMENTS

Continual

Fluids given
 Urine output (catheterization and urinometer)
 Blood loss
 Direct arterial pressure
 Central venous pressure
 Pulmonary arterial pressure and wedge pressure
 Cardiac output (noninvasive or invasive)
 EEG
 Somatosensory-evoked potentials

Intermittent

Train-of-four twitch response on nerve stimulator
 Arterial blood gas tensions, pH, hematocrit
 Serum levels of Na⁺, K⁺, Ca²⁺, glucose
 Colloid oncotic pressure
 Coagulation profile

2005; McMorrow and Mythen, 2006). The reliability of these new technologies continues to be investigated. Further information on monitoring devices, their mechanisms of action and clinical uses is presented in Chapter 11, Monitoring.

In addition to the information obtained through standard monitors, continuous clinical observation is imperative in the care of pediatric patients. It is often the first indication of an impending change in a patient's respiratory status. Through both visual observation and the use of a regular or precordial stethoscope, the anesthesiologist can determine the rate and depth of ventilation, as well as determine whether an endotracheal tube is one sided or if a patient is hypoxic. Stridor is indicative of extrathoracic airway narrowing and obstruction. Furthermore, periodic manual ventilation of the patient, with the anesthesiologist's hand on the bag, allows the anesthesiologist to detect changes in the patient's dynamic compliance and respiratory resistance that may be caused by air leaks in the anesthesia circuit, airway obstruction, or movement of the diaphragm.

Normal cardiovascular function is indicated by suitable heart tone and rate, rhythm, pulse volume, capillary refill, and skin color. Blood loss can be quantified by visual estimation of bleeding in the surgical field, pulse rate and volume, counting and

weighing of blood-soaked sponges, and measuring the volume of blood in suction bottles. Temperature, although monitored directly, can also be sensed by touch to confirm readings and avoid initiation of treatment for false hypothermia or hyperthermia. Through clinical observation, the anesthesiologist obtains a significant amount of information beyond that which monitors alone can offer.

Invasive Monitoring

Invasive arterial and central venous monitoring is technically more difficult in infants and children and not without risk. Even though there are definite indications for each, the anesthesiologist must weigh the risks and benefits to determine whether their use is appropriate.

Indications for direct arterial pressure monitoring are beat-to-beat monitoring of blood pressure when hemodynamic fluctuations are expected or pharmacologic manipulation can occur; an inability to measure blood pressure noninvasively; the need to frequently measure arterial blood gas samples; or other laboratory analyses to aid in management of the patient (Barbeito and Mark, 2006). Arterial catheters are typically placed percutaneously in the wrist (radial or ulnar), groin (femoral), or foot (posterior tibial or pedal). They should not be placed anywhere where there is evidence of vascular compromise or lack of collateral circulation. A noninvasive blood pressure monitor should always be available to verify the readings of the direct monitor.

Indications for a central venous catheter in the perioperative period include the need to measure central venous pressure to help quantify fluid balance; the need to infuse intravenous drugs for which peripheral access is inappropriate (i.e., vasoactive drugs, phlebitis-causing agents, hypertonic solutions); frequent blood draws; the need for prolonged access; difficult or impossible peripheral access; and the need for larger access for fluid administration than is achievable through peripheral catheter.

The risks of central catheter placement include vascular injury, unintentional arterial puncture, and pneumothorax, just to name a few. However, Verghese and colleagues (1999) showed that real-time ultrasound guidance for placement of an internal jugular catheter was superior to the landmark technique, with a high success rate and fewer carotid punctures. Another study demonstrated advantages of this technique in children older than 1 year of age or heavier than 10 kg (Leyvi et al., 2005).

Bispectral Index

The bispectral algorithm uses a statistical process to analyze EEG signals and compute a number between 0 and 100 that represents the degree of awareness. The variables analyzed include the frequency and power spectrum of the EEG, the amount of burst suppression, and the degree of synchronization of the EEG (Bowdle, 2006). In infants and children, studies have validated the bispectral index (BIS) and demonstrated that more accurate titration of general anesthesia is achieved with its use, resulting in shorter recovery times (Denman et al., 2000; Bannister et al., 2001; McCann et al., 2002; Powers et al., 2005). However, several studies have demonstrated low BIS values in young infants (younger than 1 year old) before awakening and poor correlations between

anesthetic concentration and BIS (Davidson et al., 2005; Klockars et al., 2006; Malviya et al., 2007). Newer indices to measure anesthesia depth continue to be developed, including the Narcotrend index, the A-line ARX index, and the cerebral-state index. All of these are currently being studied for validation in children and with regard to BIS.

Anesthesia Record

The anesthesia record is extremely important as a data sheet during anesthesia, as a source of information for later anesthetics, and as a legal document. It should contain all of the pertinent preoperative information, including the patient's medical history, significant laboratory values, time of last food or liquid intake, vital signs, and a record of a focused physical examination. It should be signed by the trainee as well as the attending anesthesiologist, who is the legally responsible party.

After induction, a brief description of induction and intubation should be recorded, noting the drugs given, the size of the endotracheal tube, whether it is cuffed or uncuffed, and verification of proper air leak around the tube. Gas flow rates, maintenance concentrations, doses of anesthetic and adjuvant drugs, blood pressure, pulse, respiratory rate, temperature, oxygen saturation readings, and end-tidal CO₂ should be entered at regular intervals.

With advances in technology, automated anesthetic record systems have become more widely used (Egger Halbeis et al., 2008). Sanborn et al. (1996) found that electronic scanning recorded a higher incidence of intraoperative incidents than those reported voluntarily. Others have reported improvements in patient safety and care with automated systems (Junger et al., 2001; Merry et al., 2001). As automated records become more user friendly, affordable, and integrated with the care process, they eventually could be the standard method of recording information in the operating room.

Fluids and Electrolytes

Fluid therapy in the perioperative period needs to account for several different fluid requirements: fluid deficits, maintenance fluid, and the volume of fluid necessary to maintain adequate tissue perfusion. Fluid deficits come from numerous sources, including preoperative fasting, gastrointestinal and renal losses, hemorrhage and third space losses (see Chapter 5, Regulation of Fluids and Electrolytes).

Historically, maintenance fluid requirements were based on the recommendations of Holliday and Segar (1957), which state that the basal caloric needs of infants and children dictate their fluid requirements. They proposed that an infant needs 100 mL of water per 100 kcal of caloric expenditure. On the basis of 1 mL of fluid per 1 kcal of caloric requirement, the fluid requirements in infants and children were approximated by the following formulas:

0 to 10 kg: 4 mL/kg per hr

10 to 20 kg: 40 mL + 2 mL/kg per hr above 10 kg

>20 kg: 60 mL + 1 mL/kg per hr above 20 kg

For every 100 calories of energy expenditure or 100 mL of water, a child needs 3 mmol of sodium, 2 mmol of potassium,

5 mmol of chloride, and 5 g of dextrose. While 5% dextrose in 0.2% or 0.45% NaCl meets these requirements for maintenance fluids, several recent articles describing clinically significant hyponatremia caused by perioperative fluids have raised some concerns (Arieff, 1998; Halberthal et al., 2001). Practitioners are tending to reduce the average fluid maintenance volume to half or two thirds of the classic recommendations proposed by Holliday and Segar (1957) based on these findings or are using isotonic saline solutions (Paut and Lacroix, 2006; Bailey et al., 2010). Further studies are necessary to evaluate what the most appropriate maintenance fluids are; however, one must individualize fluid therapy and monitor blood sodium levels in patients who are receiving prolonged infusions.

Pediatric patients are typically kept fasting for 2 hours from clear fluids and 4 to 8 hours (sometimes longer) from breast milk and solid food before induction for elective surgery. To determine the fasting deficit, one multiplies the hourly maintenance fluid requirement by the number of hours of restriction. Half of the fluid deficit plus the hourly maintenance fluid requirement should be given during the first hour of anesthesia. One quarter of the fluid deficit plus the hourly maintenance fluid is infused during the second and third hours, along with the replacement of any third-space fluid loss (Furman et al., 1975). These deficits should be replaced with a balanced salt solution such as normal saline or Lactated Ringer's solution that does not contain glucose.

Glucose requirements in pediatric patients need to account for the hazards of both hyperglycemia and hypoglycemia. Hyperglycemia produces an osmotic diuresis that leads to dehydration and electrolyte abnormalities. It also appears to worsen neurologic outcome in cerebral ischemia and should be avoided (Lanier et al., 1987). On the other hand, hypoglycemia is known to cause cerebral ischemia and brain damage, especially in newborns. Infants and some children who have fasted for a prolonged period without glucose supplementation can become hypoglycemic during anesthesia yet show no overt clinical symptoms (Welborn et al., 1986). Intraoperative monitoring of blood glucose levels in these patients is recommended. However, preoperative hypoglycemia occurs rarely in normal, healthy infants and children (1% to 2%), making it less likely that the majority of patients need glucose administered in the perioperative period (Murat and Dubois, 2008).

Recommendations on the appropriate glucose-containing solution to administer, if IV glucose is to be given, have changed over the years (Bailey et al., 2010). Whereas a 5% dextrose solution consistently causes hyperglycemia, 2.5% dextrose in Lactated Ringer's solution maintains normal blood glucose levels (Welborn et al., 1987). Dubois et al. (1992) also investigated the use of lower dextrose solutions (1 or 0.9%) and found normal blood glucose concentrations without hypoglycemia.

A urethral catheter allows continual monitoring of urine output and the state of hydration and blood volume during major surgical procedures or when there is significant loss of blood and fluids. Urethral catheterization is recommended in surgeries lasting for 4 hours or longer. Urine output of more than 0.5 mg/kg per hour should be maintained to avoid damage to the renal tubules.

Ventilation

To maintain alveolar ventilation in infants and small children under general anesthesia, partial rebreathing or nonrebreathing Mapleson D- or F-type circuits (such as the Bain or Jackson-Reese) are commonly used. With their light weight and low flow resistance, they have desirable qualities for the pediatric population, although the lack of scavenging is a drawback. Today, adult circle systems with smaller pediatric circuits are safely used in children. However, in small infants, one must account for the potential for increased airway resistance and increased circuit compliance that diminishes the accuracy of measured tidal volume. For a more detailed discussion of pediatric anesthesia circuits and ventilators, refer to Chapter 10, Equipment.

For controlled ventilation in infants and children without major respiratory dysfunction, the ventilator can be set initially at a tidal volume of 10 mL/kg or peak pressure of 16 to 18 cm H₂O. Respiratory rates between 20/min for infants and 12/min for older children are sufficient, although higher respiratory rates are recommended for young infants (Peters et al., 1998). A positive end-expiratory pressure (PEEP) of at least 5 cm H₂O prevents airway closure and atelectasis in anesthetized infants and young children (Motoyama, 1996). Once the steady state of ventilation is established, tidal volume and respiratory rate can be adjusted to maintain an end-tidal CO₂ between 35 and 40 mm Hg (see Chapter 3, Respiratory Physiology in Infants and Children).

Temperature Maintenance

Infants and small children are at particular risk of hypothermia because of their relative lack of adipose tissue and their increased body surface area relative to their body weight, which increases the difference between heat loss and heat production. Under general anesthesia, core temperature control is impaired and regulatory defenses, including nonshivering thermogenesis, are not triggered (Sessler, 2008). Furthermore, vasodilation, exposure to the cold operating room environment, insensible heat loss, and infusion of cold intravenous fluids all contribute to the development of hypothermia. The mechanisms of thermoregulation are further discussed in Chapter 6, Thermoregulation: Physiology and Perioperative Disturbances.

Accurate monitoring of body temperature is imperative to maintaining normothermia as well as detecting malignant hyperthermia. Core temperature monitoring is the best indicator of thermal status and can be easily measured with an esophageal probe (Sessler, 2008). Because this is not always a possibility, near-core sites including the mouth, axillae, bladder, rectum, and skin surface are other possibilities, although they each have limitations. The safe range for a child's core temperature is between 35.5° and 37.5° C. To prevent complications caused by hypothermia, anesthesiologists need to be proactive and begin warming the patient as soon as or before the temperature deviates from this range.

There are several means by which body temperature can be maintained. Forced-air warmers preserve intraoperative normothermia better than circulating-water mattresses (Kurz et al., 1993). Humidifiers in the anesthesia circuit also help prevent evaporative heat loss, damage to the ciliated airway epithelia, and

postoperative pulmonary complications (Chalon et al., 1979). Additionally, increasing room temperature, using radiant warming lamps, wrapping the child's head and other exposed areas with plastic, and using warmed intravenous fluids help to conserve heat. Careful monitoring, however, is necessary to prevent hyperthermia that can sometimes occur when all of these measures are combined.

Blood Loss and Blood Component Therapy

Accurate and continuous monitoring of blood loss and its timely replacement are critical in pediatric patients. Relatively small losses in infants can produce significant changes in hemoglobin concentration and hemodynamic stability, making careful determination of acceptable blood loss mandatory. Estimated blood loss needs to account for the contents of suction bottles as well as a visual estimate of blood lost on the surgical drapes and the weight of blood-soaked sponges. Allowable blood loss is determined by the patient's estimated blood volume, preoperative and intraoperative hematocrit values, cardiopulmonary and general medical conditions to provide adequate oxygen transport, and risk versus benefit of the transfusion. Estimated blood volumes in pediatric patients are age dependent and are listed in Table 13-3.

Once the estimated blood volume (EBV) is known, one can determine the maximum allowable blood loss (MABL). This should be done for each patient before the induction of anesthesia and is achieved with the use of a simple mathematical calculation as follows (Barcelona et al., 2005):

$$\text{MABL} = \frac{\text{EBV} \times (\text{Starting HcT} - \text{Target HcT})}{\text{Starting HcT}}$$

For example, an 11-month-old infant weighing 10 kg with an initial hematocrit value of 35 would have an EBV of 750 mL (75 mL/kg). Assuming the minimum acceptable or target hematocrit value of 25, the MABL would be:

$$\text{MABL} = \frac{750 \times (35 - 25)}{35} = 214 \text{ mL}$$

The use of a trigger value alone to determine the need for transfusion is no longer recommended in most guidelines, because hemoglobin and hematocrit values may not accurately reflect blood volume or oxygen carrying capacity (Weldon, 2005). In actively bleeding patients without volume replacement, hematocrit values alone can be misleading (Hume and Limoges, 2002). However, the hematocrit value along with good clinical judgment can serve as a guideline for

TABLE 13-3. Estimates of Circulating Blood Volume

Age of Patient	Blood Volume (mL/kg)
Premature newborn	90-100
Full-term newborn	80-90
3 mo-1 yr	75-80
3-6 yr	70-75
>6 yr	65-70

when to consider transfusion (National Institutes of Health Consensus Conference, 1988).

Debate continues as to whether a crystalloid or colloid solution should be used to replace blood volume as the hematocrit is allowed to decrease (Bailey et al., 2010). The SAFE Study (2004) randomized adult ICU patients to receive either 4% albumin or normal saline for fluid resuscitation with the primary outcome being death from any cause. In 6997 patients, they found no difference in death rate or in number of days in either the ICU or the hospital between the groups. This was in contrast to a meta-analysis by the Cochrane Injuries Group Albumin Reviewers (1998), which suggested that the administration of albumin resulted in a 6% increase in the absolute risk of death when compared with the administration of crystalloid. If a colloid solution (e.g., albumen, hetastarch) is used, blood loss is replaced milliliter for milliliter. If a crystalloid solution is used, 2 to 3 times the volume of the blood loss is replaced. Although colloid may be more physiologic, it is more expensive and has not been shown definitively to be superior to crystalloid replacement. In otherwise healthy patients, the use of crystalloid is safe and effective to replace the MABL.

The minimum recommended hemoglobin concentration allowable has changed over the years. With the exception of patients who are in the early neonatal period (with high oxygen affinity of fetal hemoglobin and decreased oxygen unloading at tissue levels) and those with cyanotic cardiopulmonary disease, the previously recommended 10 g/dL is no longer a prerequisite hemoglobin concentration. Several studies have demonstrated cardiovascular stability with significant anemia (hemoglobin of 6 to 7 g/dL) in both animals and children who underwent acute normovolemic hemodilution (Stehling and Zauder, 1991; Fontana et al., 1995). Lacroix and colleagues (2007) found no difference in outcomes in children randomized to either a restrictive-strategy group (transfusion threshold of 7 g/dL) or a liberal-strategy group (transfusion threshold of 9.5 g/dL). However, a randomized, controlled trial comparing two hemodilution protocols (to a hematocrit value of 21.5% versus 27.8%) in children during hypothermic cardiopulmonary bypass found that a lower hematocrit value was associated with a poorer performance on psychomotor development tests at 1 year of age (Jonas et al., 2003).

The best recommendations to date appear to be those of the National Institutes of Health Consensus Conference on Perioperative Red Cell Transfusion (1988): healthy patients with hemoglobin values of 10 g/dL or greater rarely require transfusion, whereas those with values less than 7 g/dL often require transfusion. Thus, to keep operative hemorrhage and blood volume under control in a situation of continued blood loss, hemoglobin may be decreased temporarily to as low as (but not below) 7 g/dL (hematocrit 20%), with proper monitoring of blood pressure, arterial and mixed venous P_{O_2} . The hemoglobin level should be increased postoperatively (i.e., to 8 g/dL with a hematocrit of >25%) when the patient needs more oxygen uptake for increased metabolic needs.

Once the MABL is exceeded, transfusion is necessary, usually in the form of packed red blood cells (PRBCs). The hematocrit of PRBCs varies between 60% and 80% and can be adjusted according to the need of the physician administering the blood. The volume of PRBCs needed to replace the blood loss beyond MABL can be calculated as follows:

$$\text{PRBCs (mL)} = \frac{\text{Blood loss MABL} \times \text{Desired HcT}}{\text{HcT of PRBCs}}$$

Once the blood loss exceeds one blood volume (massive blood loss), a coagulopathy can develop because of both a reduction in platelets (dilutional thrombocytopenia) and a reduction in labile clotting factors. In patients with clinical signs of nonsurgical bleeding, the administration of other blood components, including platelets, fresh frozen plasma, and cryoprecipitate becomes necessary. The management of blood component therapy and massive blood loss is detailed in Chapter 14, Blood Conservation.

EMERGENCE AND EXTUBATION

Emergence

Prompt and safe emergence from general anesthesia begins with predicting the conclusion of surgery and assessment of the patient. The tapering or discontinuing of anesthetic agents must take into account the diverse pharmacokinetics and pharmacodynamics of inhaled anesthetics, intravenous anesthetics, muscle relaxants, and/or regional nerve blocks. The patient's age and medical condition must also be considered. For example, in infants the longer elimination half-lives for many agents may require earlier termination of agents than in children or adults. The patient's response to the pain, disorientation, or sudden awareness needs to be anticipated to ensure a gentle awakening. Judicious use of opioids for analgesia and hypnotics for sedation can help reduce agitation on emergence. With careful and appropriate planning, all anesthetized patients should emerge smoothly and on time.

As the anesthetics are curtailed, the respiratory rate and pattern should be observed. A rapid respiratory rate may be seen in cases of inadequate analgesia or stage 2 of anesthesia. Titrating subtherapeutic doses of an opioid can reduce pain experience on emergence. Increasing the fresh gas flow and moderately increasing the rate of controlled or assisted ventilation can facilitate the elimination of residual inhaled anesthetic. The criteria for adequate emergence from stage 2 of general anesthesia in pre- or nonverbal children include:

- Grimacing, using eyebrows and/or forehead,
- Spontaneous eye opening, and
- Purposeful movement, such as reaching for the endotracheal tube.

Paradoxical movement of the thorax and abdomen may indicate incomplete recovery from general anesthesia, residual paralysis, or upper airway obstruction, and they each need to be investigated and their causes addressed.

If neuromuscular blockers were used, recovery should be monitored using peripheral nerve stimulation and clinical assessment. Kopman et al. (1997) observed that recovery of a train-of-four (TOF) ratio over 0.90 is needed to assure adequate neuromuscular function, especially in the ambulatory setting. Neuromuscular blockade is reversed with intravenous atropine (0.02 mg/kg) followed by neostigmine (0.06 mg/kg). In infants, a higher dose of atropine (0.03 mg/kg) is recommended. Glycopyrrolate (0.01 mg/kg) is as effective as atropine and may produce a more stable heart rate (Warran et al., 1981).

Sugammadex, a new rapid-acting reversal agent, which has been approved for use in Europe, Australia, and New Zealand, encapsulates rocuronium and vecuronium, preventing binding to neuromuscular junction receptors. Studies in adults have shown recovery from weak blockade to a train-of-four ratio of 0.9 occurs in approximately 2 minutes with doses of 2 mg/kg or higher (Sorgenfrei et al., 2006; Suy et al., 2007; Vanacker et al., 2007). Plaud and colleagues (2009) demonstrated that in recovery from neuromuscular blockade from 0.6 mg/kg rocuronium, a train-of-four of 0.9 was attained in 0.6, 1.2, and 1.1 minutes in infants, children, and adolescents, respectively, with 2 mg/kg of sugammadex.

The clinical criteria for adequate recovery from nondepolarizing neuromuscular blockade in preverbal and uncooperative children include:

- Maintaining adequate, nonparadoxical breathing;
- Generating a negative inspiratory pressure greater than 30 cm H₂O;
- Sustaining tetanic contraction at 50 Hz;
- Sustaining hip flexion with leg elevation for 10 seconds; and,
- Lifting the head and/or coughing forcefully.

At the conclusion of surgery, while the child is still under general anesthesia, a lubricated suction catheter should be gently passed into the stomach to remove any gastric contents and gases that may have accumulated. This practice reduces the risk of vomiting and aspiration during emergence and decreases intra-abdominal pressure, allowing for greater expansion of the lungs. Gastric suctioning is especially important in patients thought to have a full stomach or an increased risk for gastroesophageal reflux. For all patients, mucosal injury and bleeding from suctioning should be avoided.

Extubation of the Trachea

The endotracheal tube can be removed from a patient who is well anesthetized (deep extubation) or from one who has successfully emerged from general anesthesia (awake extubation). Deep extubations should be performed in patients whose airway was well maintained by mask ventilation during induction of anesthesia and who are still receiving intravenous or inhalation agents at levels that will prevent coughing and laryngospasm. Before extubation, an oropharyngeal airway should be placed to avoid upper airway obstruction. Depth of anesthesia should be confirmed by the absence of any response to suctioning of the oral pharynx and deflation of the endotracheal tube cuff, if one is present. If airway patency was satisfactory before intubation, the return to spontaneous breathing is not a prerequisite for extubation. Deep extubation can be performed safely when using sevoflurane or desflurane to allow expedient awakening after extubation (Valley et al., 2003). This technique is especially useful for patients with a history of reactive airways disease.

Awake extubations, with protective laryngeal reflexes intact, should be performed in the child with difficult airways and full stomach risks. Before an awake extubation, infants and young children may respond to laryngeal stimulation by breath holding, bronchospasm, chest-wall rigidity, marked cyanosis, and oxygen desaturation. This phenomenon is impressive and may resemble the cyanotic spells seen in infants with tetralogy of Fallot. Fortunately, these episodes are self-limited, provided

that alveolar ventilation is maintained. Older children show less of a tendency toward sudden desaturation, but they are at a greater risk of forceful coughing against the endotracheal tube (bucking) when extubation is delayed. This may lead to a greater incidence of postintubation croup (Koka et al., 1977). Thus, older children should be extubated as soon as protective reflexes return.

Until recently, it was a widely accepted practice to ventilate the patient with high flows of 100% oxygen for several minutes before extubation in order to wash out residual anesthetics and replace them with pure oxygen. Recent studies, however, have demonstrated that this practice of “preoxygenation” should be modified and that patients should be ventilated with a mixture of oxygen and air (1:1 to 2:1 ratios of oxygen and air provide about 60% to 70% oxygen), instead of 100% oxygen, to minimize airway closure and atelectasis, which almost always develop during general anesthesia, especially in infants and children (see Chapter 3, Respiratory Physiology). To eliminate atelectasis, before extubation the lungs must be reinflated with several “vital capacity maneuvers” (sustained positive airway pressure of 35 to 40 cm H₂O for several seconds) with air-oxygen mixtures and then maintain PEEP/CPAP (5 to 7 cm H₂O) (Benoit et al., 2002; Lindahl and Mure, 2002; Tusman et al., 2003).

Technique of Extubation

The removal of the endotracheal tube should be performed with as much attention to detail as when it was inserted. Placement of an oral airway or a bite block before awakening can greatly reduce the risk of complete occlusion by the teeth on the endotracheal tube and compromise of the airways. Severe or complete occlusion of the tube or the upper airways associated with marked inspiratory effort, and intrathoracic negative pressure can result in postobstructive pulmonary edema (Galvis et al., 1980; Sofer et al., 1984). Oropharyngeal airways are preferred in patients whose airway patency was less than satisfactory during anesthetic induction. Soft bite blocks made of rolled gauze and tape can reduce the incidence of soft-tissue damage to the gums, palate, and lips associated with plastic airways. After reinflation of the lungs with high pressures to eliminate atelectasis, the lungs are inflated again with oxygen-air mixture synchronously with the child's inspiration by gently squeezing the anesthesia bag. The bag is then held momentarily at end-inspiration with a positive pressure of 15 to 20 cm H₂O to maintain a high lung volume as the endotracheal tube is gently pulled out. This last maneuver serves the following three functions:

1. It inflates the lungs with an oxygen-rich gas mixture, providing an increased oxygen reservoir that may be needed if breath holding or laryngospasm occurs (Motoyama et al., 1987).
2. Positive pressure (or stretching the airway walls) decreases the incidence and intensity of laryngospasm (Suzuki and Sasaki, 1977; Sasaki, 1979).
3. The patient's first response after extubation will be a cough-like forceful exhalation or coughing, expelling any secretions trapped between the ET tube and the laryngeal wall, thus minimizing the laryngeal reflex to secretions and laryngospasm.

The initial moments after extubation are critical; oxygen saturation, heart rate, and heart rhythm must be continuously monitored with a pulse oximeter, precordial stethoscope,

and ECG. The oral pharynx is suctioned quickly to remove any secretions, and a face mask is applied to reestablish the breathing circuit and application of CPAP. The patency of the airway is maintained by lifting the mandible forward into the jaw-thrust position. If spontaneous ventilation does not resume laryngospasm, often the results of secretions triggering laryngeal reflexes should be considered. Under these circumstances the pharynx and larynx must be cleared of secretions swiftly, even during laryngospasm, to prevent further irritation of the airway.

Once alveolar ventilation is reestablished, the patient is carefully examined for gastric distention and for signs of aspiration and pneumothorax. Even if the stomach was suctioned previously, the child may still retch and vomit. If vomiting occurs, it is often sufficient to turn the child's head to the side to allow secretions to fall into the cheek for removal or to roll the child on to the side.

Transport to the Postanesthetic Care Unit

When breathing is satisfactory, the patient is transported to the PACU in the lateral position with supplemental oxygen via a mask, keeping the airway clear of the tongue and secretions and protecting against aspiration (Smith, 1959; Isono et al., 2002). By holding the chin up and extending the neck, the anesthesiologist can further ensure a patent airway and feel the warm breaths, indicating gas exchange. During transport to the PACU, the guardrails should be up and the safety straps should be securely fastened to prevent injury. Patients should be covered with warmed blankets to reduce heat loss during transport. Monitoring during transport should include clinical observation of chest movement, color, and gas exchange in awake and active patients and heart and breath sounds with a precordial stethoscope in sleeping patients.

More extensive monitoring, including continuous pulse oximetry, electrocardiography, and invasive blood pressure measurements, should be maintained for compromised or critically ill patients. These patients, whether intubated or not, must have a self-inflating resuscitation bag or a Mapleson D circuit connected to an oxygen cylinder with a flow rate set to maintain adequate alveolar ventilation and oxygenation. Appropriately sized endotracheal tubes, a laryngoscope, and medications for intubation and resuscitation should be available in the PACU.

POSTANESTHETIC RECOVERY

The postanesthetic recovery period is a time of high risk for pediatric patients. A large percentage of otherwise healthy infants and children (20% to 40%) develop oxygen desaturation ($SpO_2 = 94\%$) during transport and on arrival at the PACU (Patel et al., 1988). Oxygen desaturation occurs sooner, is more pronounced, and has a longer duration in infants than in children and a longer duration in children than in adults (Xue et al., 1996). Postoperative hypoxemia is most likely caused by atelectasis, but upper airway problems such as obstruction, croup, and laryngospasm, are more likely in children (4% to 5%) than adults (Cohen et al., 1990). All children, therefore, should be administered oxygen supplementation during their transport from the operating room and on arrival at the PACU, until they can maintain satisfactory oxygen saturation in room air or at their baseline F_{iO_2} . Nausea,

vomiting, temperature instability, and postoperative pain also require prompt and effective treatment to ensure patient comfort and efficient discharge timing.

Recovery in the Postanesthetic Care Unit

The PACU should be situated adjacent to the operating rooms to facilitate rapid and safe patient transport and to allow the anesthesiologist ready access in case of an emergency. Each bed space should have an oxygen supply with humidification, a self-inflating resuscitation bag, a suction apparatus, a pulse oximeter, an ECG monitor, and an automated blood pressure apparatus. Other supplies and commonly used medications should be readily available. In addition, the PACU should be equipped to handle any emergency that may arise when caring for infants and children. Additional features needed for the PACU are an isolation room for either infectious or immunosuppressed patients and the ability to function as a critical care unit with additional mechanical ventilatory and invasive monitoring capabilities.

Initial Care

On arrival at the PACU, the anesthesiologist confirms the patency of the patient's airway, assesses the adequacy of ventilation, and ensures the supply of humidified oxygen. The anesthesiologist records the heart rate, respiratory rate, blood pressure, SpO_2 , and temperature, which are reported to the nurse. The anesthesiologist then gives a report to the nurse concerning the child's condition, special problems related to any underlying illnesses, the events of the surgery, the anesthetic technique used, and medications given. The anesthesiologist should remain at the bedside until the child is reasonably stable and well attended. PACU staff must be competent in recognizing and initiating the treatment of commonly encountered problems, including inadequate ventilation, agitation, pain, vomiting, temperature instability, and delayed awakening. Before leaving the PACU, the anesthesiologist writes a summary note and postoperative orders.

Awakening Responses

With most currently used general anesthetic techniques, awakening occurs within a few minutes of the conclusion of surgery. Unfortunately, no one technique guarantees a smooth emergence, and agitation may occur in the early recovery period. Agitation may be caused by numerous factors, including emergence delirium caused by anesthetic agents, pain, metabolic disturbances (e.g., hypothermia, hyperthermia, hypoglycemia, hyponatremia), neurologic disturbances, a behavioral response to sudden awakening in a strange environment; separation anxiety, airway obstruction with resultant hypoventilation and hypoxia, and combinations of these factors. As discussed at the beginning of this chapter, a pediatric anesthesiologist should plan the general anesthetic approach to minimize or avoid many of these factors. The incidence of emergence delirium can be reduced with an opioid or hypnotic. Pain can be prevented in these patients by judicious use of analgesics or regional techniques intraoperatively. Any metabolic disturbances should be quickly recognized and treated swiftly and appropriately.

FIGURE 13-6. As pediatric patients awaken from anesthesia, they often need reassurance or the comfort of being touched or held to alleviate anxiety.

Measures other than the use of pharmacologic agents can often be effective in calming the awakening pediatric patient. Some patients simply need reassurance or the comfort of being touched or held to alleviate anxiety (Fig. 13-6). Parental presence has been shown to reduce the incidence of fear, crying, anger, and clinging during hospitalization (Fiorentini, 1993; Fina et al., 1997; Kamerling et al., 2008). Both parents and PACU staff have reported beneficial results from parental involvement. Once the infant or child has documented stable vital signs, a parent should be present.

Last but not least, the importance of detecting airway obstruction, inadequate ventilation, hypercarbia, and/or hypoxemia as causes of agitation cannot be overemphasized. Misdiagnosis can lead to inappropriate use of opioids and sedatives. Delayed and erroneous treatment of these problems can have serious consequences, including respiratory and cardiac arrests.

Common Problems in the Postanesthetic Care Unit

Apnea of Prematurity

Apnea may be central (no respiratory effort), obstructive (respiratory effort without gas flow), or mixed (both central and obstructive). Apnea is defined as cessation of breathing for longer than 15 seconds or for less than 15 seconds associated with bradycardia, cyanosis, or pallor (Nelson et al., 1978; Thatch, 1985). Repetitive pauses of breathing, lasting 5 to 10 seconds and not associated with other changes in infants, are termed periodic breathing. These abnormal respiratory patterns, which are observed commonly in neonates and preterm infants, can

appear or worsen in preterm infants after exposure to anesthetic agents (Rigatto, 1986). This is particularly true for prematurely born infants with a previous history of apnea (Liu et al., 1983).

In a combined analysis of eight studies from the halothane era, Coté et al. (1995) found that postoperative apnea was:

- Strongly and inversely correlated to both gestational age and postconceptual age (PCA)
- Associated with a previous history of apnea
- Not associated with being small-for-gestational age
- Associated with anemia (hematocrit <30) regardless of gestational age or PCA

They concluded that the risk of apnea in infants without a history of apnea or anemia is greater than 5% (95% CI) until PCA of 48 weeks with a gestational age of 35 weeks, and the risk remains greater than 1% until PCA of 54 to 56 weeks with gestational age of 32 weeks. They further concluded that older infants with apnea in the PACU and those with anemia should be admitted and monitored overnight. Because of these findings, it is generally recommended that preterm infants of fewer than 44 to 46 weeks PCA be admitted for monitoring after general anesthesia (Gregory et al., 1983; Coté et al., 1995). Regional anesthesia and subarachnoid blocks without sedation have been shown to decrease the risk of postoperative apnea (Williams et al., 2001). Sale et al. (2006) in a prospective comparison study, found no increase in respiratory events with the use of sevoflurane and desflurane. Welborn et al. (1998) found caffeine (10 mg/kg) to be effective in treating apnea in premature infants undergoing elective surgery. These patients, however, are still routinely admitted for observation and treatment.

Airway Obstruction

Although patients should be able to maintain airway patency before leaving the operating room, it is not uncommon for an infant or a child to have an obstruction after the stimulation of extubation and transportation has subsided. The anesthesiologist must be acutely aware of any changes in the breathing pattern at this time, because hypoventilation can lead to a reaccumulation of volatile agents in the alveoli that can further blunt the respiratory drive. Hypercarbia may result in dysrhythmias and hypertension, and hypoxemia in infants may lead to further suppression of breathing (Knill and Clement, 1984; Motoyama and Glazener, 1986). Neck extension, mouth opening, and jaw thrust alone or together may be enough to correct the problem. Nasopharyngeal airways, if necessary, are better tolerated than oropharyngeal airways in this setting. If obstruction continues, reassessment of anesthetic and neuromuscular blockade reversal should be conducted and possible reintubation may be considered.

Other causes of respiratory distress may be present in a way similar to upper airway obstruction. Pneumothorax, silent aspiration, and pulmonary edema should be considered and investigated if the patient continues to exhibit respiratory compromise.

Obstructive Sleep Apnea

Patients with obstructive sleep apnea syndrome (OSA) are predisposed to postoperative apnea (see Chapter 24, Anesthesia for Pediatric Otorhinolaryngologic Surgery). OSA is characterized by prolonged partial and/or intermittent complete upper airway obstruction that disrupts normal breathing and sleeping

patterns (American Thoracic Society, 1996). Although OSA in adults is commonly associated with obesity, in children it more often arises from enlarged tonsils and adenoids (Young et al., 1993). Surgical removal of enlarged adenoids and tonsils often markedly improves upper airway patency (Schechter et al., 2002). OSA also occurs in infants and young children with a narrowing of upper airways secondary to craniofacial abnormalities, neuromuscular disorders, and Trisomy 21, which may worsen during the postoperative period (Marcus, 2001; Au and Li, 2009). Children with OSA have an increased sensitivity to opioids (Brown et al., 2004) (Fig. 13-7).

Postobstructive Pulmonary Edema

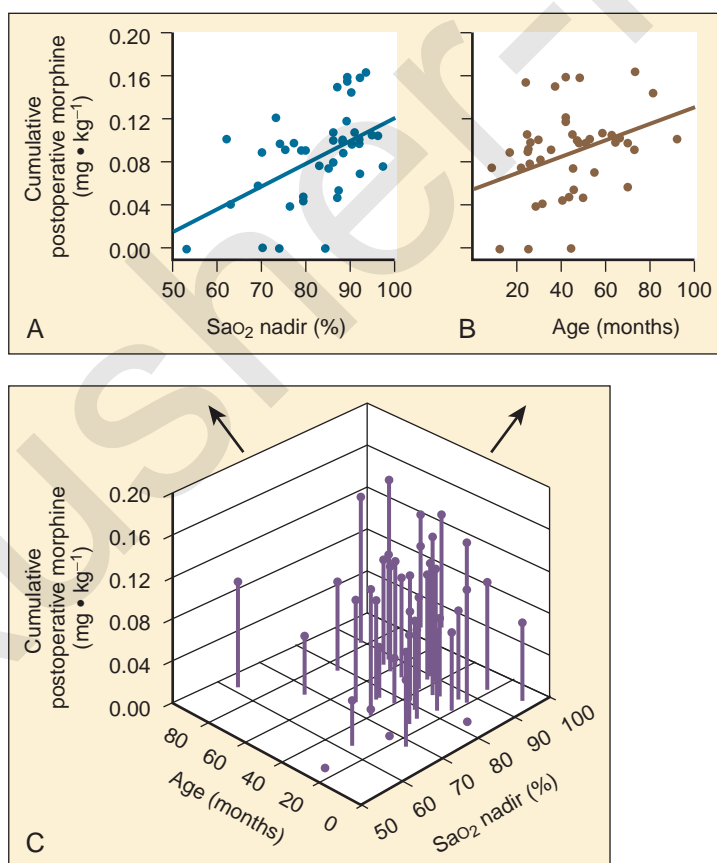

Pulmonary edema developing shortly after the relief of upper airway obstruction is known as postobstructive pulmonary edema (POPE) and negative pressure pulmonary edema (NPPE). It was first noted after difficult intubation in children and subsequently described after relief of laryngospasm both in infants and children (Travis et al., 1977; Galvis et al., 1980; Sofer et al., 1984). The first signs, which include rales, wheezing, desaturation, and copious production of pink, frothy respiratory secretions, may occur immediately after the relief of the obstruction. The cause of this type of pulmonary edema is

attributed to the marked negative intrathoracic pressure generated by forced inspiration against a closed glottis (Mueller's maneuver), which leads to increased interstitial negative pressure, increased right-side cardiac preload, increased pulmonary vascular resistance, acute hypoxia, and increased capillary permeability (Thiagarajan and Laussen, 2007).

A high index of suspicion, as well as early recognition and intervention are essential to preventing complications secondary to postobstructive pulmonary edema. Once upper airway obstruction is relieved, patients should receive CPAP by mask (5 to 10 cm H₂O) with a high concentration of oxygen. Diuretics, along with intravenous fluid restriction, should be considered. If hypoxemia (SpO₂ <95%) persists, the patient may require endotracheal intubation and ventilation with a moderate PEEP (10 cm H₂O) until pulmonary edema is dissolved. Most cases are self-limited and usually resolve within 24 to 48 hours, but life-threatening complications are not unusual.

Postintubation Croup

The incidence of postintubation croup was reported to be about 1% (Koka et al., 1977). The most common cause is a tight-fitting endotracheal tube without an air leak at 30 to 40 cm H₂O with positive airway pressure (Koka et al.,

■ **FIGURE 13-7.** Age (in months) and preoperative arterial oxygen saturation (Sao₂) nadir (%) are significantly correlated with the cumulative postoperative morphine dose (mg/kg) required for analgesia after adenotonsillectomy. The correlation of each variable with the cumulative postoperative morphine dose is shown in the two-dimensional plots (A and B), and the correlation of the combined variables with the cumulative postoperative morphine dose is shown in a three-dimensional scatter plot (C). Estimates for each child are depicted with a filled circle. The magnitude of the cumulative postoperative morphine dose in the three-dimensional scatter plot is depicted by the height of the stem supporting each circle. (From Brown KA, Laferriere A, Moss IR: Recurrent hypoxemia in young children with obstructive sleep apnea is associated with reduced opioid requirement for analgesia, *Anesthesiology* 100:806–810, 2004.)

1977). Other factors associated with postintubation croup may include traumatic or repeated intubation, “bucking” or coughing with the ET tube in place, changing the head position, the duration of surgery, and neck surgery. The incidence of postintubation croup seems to have decreased since this initial report. This may be secondary to the better quality of implant-tested sterile endotracheal tubes and the increased use of smaller-sized cuffed endotracheal tubes and corticosteroids.

The croup scoring system by Downs and Raphaely (1975) objectively quantifies the severity of the condition and its use can be helpful in treatment decisions (Table 13-4). Cool, humidified mist administered after extubation may be helpful in mild cases of croup. Racemic epinephrine (0.5 mL of 2.25% solution), diluted in 3 to 5 mL of normal saline solution and administered by nebulizer for 5 to 10 minutes, assists patients with progressively worsening symptoms and stridor by producing mucosal vasoconstriction, resulting in a shrinking of swollen airway mucosa. The “rebound effect” and recurrence of symptoms are well described and necessitate observing the patient for up to 4 hours after treatment. Anene et al. (1996), in a prospective, double-blind, placebo-controlled study, found that dexamethasone is effective in reducing the incidence of postintubation croup in children who have been intubated for longer than 48 hours.

Cardiovascular Instability

Cardiac rhythm disturbances and blood pressure fluctuations are rare in infants and children recovering from general anesthesia in comparison with adults (Hines et al., 1992; Murat et al., 2004). Bradycardia is typically a response to medications such as neuromuscular-blockade reversing agents or fentanyl, or it can be a normal variant that should be treated only if it is associated with hypotension. Hypoxia is also an important cause of bradycardia, especially in neonates and young infants. Tachycardia may be secondary to hypovolemia, inadequately treated pain, or anticholinergic medications. Careful assessment and appropriate therapy should be instituted to correct volume deficit or the need for analgesia. Hypertension may also reflect inadequate analgesia, an anticholinergic effect, or excessive hydration, or it may be an artifact caused by the use of an inappropriately small blood-pressure cuff. Hypotension is more unusual and is most often caused by hypovolemia secondary to inadequate fluid replacement or ongoing blood loss. Appropriate fluid resuscitation should be instituted.

Nausea and Vomiting

Postoperative vomiting (POV) is the most common complication of anesthesia in infants and children and a major cause of delayed PACU discharge and unscheduled admission for ambulatory patients (Patel and Hannallah, 1988; Murat et al., 2004). Nausea, also a common postoperative complication, is rarely included in pediatric studies because of the challenges of accurate assessment in infants and young children. Factors that increase the risk of POV include surgeries such as strabismus repair, adenotonsillectomy, and orchiopexy; age; gender; history of motion sickness; and intraoperative opioids. Eberhart noted four independent predictors of pediatric POV, including a duration of surgery equal to 30 minutes, an age of 3 years, strabismus surgery, and a positive history of POV in the patient's parent or sibling. When present, these risk factors increased the likelihood of POV (Fig. 13-8) (Gan et al., 2007). Early ambulation and clear liquids, in an attempt to meet the discharge criteria in the short-stay surgery settings, may precipitate vomiting, particularly in susceptible patients (Schreiner et al., 1992). Although rarely life threatening in the PACU, vomiting has the potential for causing aspiration, hypovolemia, and/or hyponatremia.

■ **FIGURE 13-8.** Simplified risk score from Eberhart and colleagues to predict the risk for POV in children. When 0, 1, 2, 3, or 4 of the depicted independent predictors are present, the corresponding risk for PONV is approximately 10%, 10%, 30%, 55%, or 70%, respectively. (From Eberhart LH, Geldner G, Kranke P, et al.: *The development and validation of a risk score to predict the probability of postoperative vomiting in pediatric patients*, *Anesth Analg* 99:1630, 2004.)

TABLE 13-4. Clinical Croup Score

Criteria	Score		
	0	1	2
Inspiratory breathing sounds	Normal	Harsh with rhonchi	Delayed
Stridor	None	Inspiratory	Inspiratory and expiratory
Cough	None	Hoarse cry	Bark
Retraction and flaring	None	Suprasternal, (+) flaring	Suprasternal, subcostal, intercostal, (+) flaring
Cyanosis (sat <90%)	None	In room air	In 40% oxygen

From Downes JJ, Raphaely RC: Pediatric intensive care, *Anesthesiology* 43:238-250, 1975.

For prophylaxis against POV, intravenous serotonin (5-HT₃) receptor antagonists, such as ondansetron (0.1 to 0.15 mg/kg) and granisetron (0.04 mg/kg) given intraoperatively, have been shown to be highly effective with rare side effects (Patel et al., 1997; Fujii et al., 2002). Dexamethasone (0.2 to 0.5 mg/kg) given intraoperatively is effective in decreasing the incidence of both nausea and vomiting (Aouad et al., 2001). In combination these medications are synergistic (Davis et al., 2008). Gan and colleagues (2003) published guidelines for preventing and treating POV and recommended prophylaxis only in patients with moderate to high risk. In pretreated patients who develop POV in the PACU, a dose of an alternative 5-HT₃ blocker or an antiemetic from another family of medications (antihistamine, antidopaminergic) should be considered.

Temperature Instability

Even with the most careful attention to maintaining normothermia, patients often arrive in the PACU with lowered body temperature. Usually covering the patient with warmed blankets is sufficient, but radiant warming lamps and conductive warming blankets should be used in extreme cases. Hyperthermia that develops in the PACU may indicate the onset of an infectious process and should be watched closely. Malignant hyperthermia may be seen initially during the postanesthetic period. If malignant hyperthermia is suspected, appropriate investigation and therapy should be instituted without delay.

Emergence Delirium

Emergence delirium (ED) is a significant problem for children (Vlajkovic and Sindjelic, 2007). ED in children appears to be a dissociated state of consciousness characterized by inconsolability, thrashing, and incoherence (Fig. 13-9). Having all but disappeared with the discontinued use of older anesthetic agents, ED reemerged as a problem in children with the introduction of desflurane and sevoflurane (Davis et al., 1994; Aono et al., 1997; Grundmann et al., 1998). Theoretic explanations for this occurrence include rapid awakening in a strange environment, variable recovery of central nervous system function,

■ **FIGURE 13-9.** Emergence delirium in children appears to be a dissociated state of consciousness characterized by inconsolability, thrashing, and incoherence.

precipitous withdrawal from GABA receptors, and a yet-to-be-defined psychomotor side effect. Inadequately treated pain has also been proposed as a major contributor to this phenomenon, but studies have demonstrated a high incidence of ED in pain-free patients (Wells et al., 1999; Uezono et al., 2000). Risk factors include an age younger than 5 years old, otolaryngologic and ophthalmologic procedures, use of isoflurane, rapid emergence, the need for intraoperative opioids, anxious parents, poor socialization, and low adaptability scores (Voepel-Lewis et al., 2003; Kain et al., 2006). In this state, children pose a danger to themselves and care providers with complications arising in the forms of increased bleeding, pain, medication use, and need for staff. Other complications include patients pulling at surgical drains, loss of intravenous catheters and tubing, and longer PACU stays.

Several instruments and therapies have been proposed and studied to evaluate and prevent ED. The Pediatric Anesthesia Emergence Delirium Scale (PAEDS), using five criteria (eye contact, purposeful movement, awareness of environment, restlessness, inconsolability), has been demonstrated to be valid and reliable (Box 13-2) (Sikich and Lerman, 2004). A single intravenous prophylactic treatment of fentanyl 2.5 mcg/kg, clonidine 2 mcg/kg, ketamine 0.25 mg/kg, nalbuphine 0.1 mg/kg, or dexmedetomidine 0.15 mcg/kg has been shown to decrease incidence of ED (Cohen et al., 2001; Kulka et al., 2002; Dalens et al., 2006; Ibacache et al., 2004). Other routes of administration such as intranasal fentanyl 1 mcg/kg and oral clonidine 4 mg/kg are also effective (Finkel et al., 2001; Tazeroualti et al., 2007). Aouad and colleagues (2007) found that 1 mg/kg propofol after discontinuation of sevoflurane at the end of surgery decreases the incidence of ED without prolonging recovery.

Pain and Discomfort

All pediatric patients, including neonates and premature infants, experience pain if it is untreated. Differentiating between pain, anxiety, and other causes of stress in this age group is an ongoing challenge. Each age group and each patient has a different behavioral manifestation and communication ability regarding pain. The selection of the appropriate pain-assessment tool,

Box 13-2 The Pediatric Anesthesia Emergence Delirium Scale (PAEDS)

1. The child makes eye contact with the caregiver.
2. The child's actions are purposeful.
3. The child is aware of his or her surroundings.
4. The child is restless.
5. The child is inconsolable.

Items 1, 2, and 3 are scored on a scale of 0-4 as follows: 4 = not at all; 3 = just a little; 2 = quite a bit; 1 = very much; 0 = extremely. Items 4 and 5 are scored in reverse, as follows: 0 = not at all; 1 = just a little; 2 = quite a bit; 3 = very much; 4 = extremely. The scores of each item are added to obtain a total PAEDS score. The degree of emergence delirium increases directly with the total score.

(From Sikich N, Lerman J: Development and psychometric evaluation of the pediatric anesthesia emergence delirium scale, *Anesthesiology* 100(5):1142, 2004.)

from the multitude available, is crucial. Many of these tools are not designed for patients recovering from surgery and general anesthesia. Disorientation, fear, and regression may alter communication and behavior and cause misinterpretation. Some pain scales have a limited application in the clinical setting. As with pain assessment, selection of a pain management technique must be individualized for the patient, the surgical procedure, and the hospital setting. Selection must also be made with a good understanding of each technique's advantages and shortcomings. For these techniques to be successful, conscientious postoperative care must be given.

Pain Measurement and Assessment

Most techniques measure the intensity of pain by assigning incremental values. The most common technique, self-reporting, depends on verbal, cognitive, and developmental skills. Adapting adult patient surveying tools such as the McGill Pain Questionnaire, researchers have developed scales using verbal description and graphic rating (Melzack, 1975). Such tools are modified for age, culture, and cognitive ability (McGrath et al., 1985; Varni et al., 1987). Word lists and questioning techniques have been developed (Abu-Saad et al., 1990; Wilkie et al., 1990). Graphic or symbolic representations of pain intensity also require modification. The visual analog pain scale, initially developed for adult pain measurement, is typically a 10-cm horizontal line defined by "no pain" on the left end and "severe pain" on the right. In older children and adolescents, this instrument has been used with success (Abu-Saad, 1984; McGrath et al., 1985). In younger children, replacing the definers with different words, such as "no hurt" and "most hurt," numbers, or happy and sad faces has also been tested (Broadman et al., 1988; Savedra and Tesler, 1989). For younger children with preoperational reasoning, less abstract quantitative measurements, including counting poker chips, selecting color scales, and marking graduated thermometers, are more easily understood and used (Eland and Anderson, 1977; Hester, 1979; Jeans and Johnston, 1985). A further variation involves a progression of happy to crying faces; the faces are either illustrated, as in McGrath's Facial Affective Scale and the Wong-Baker FACES Pain Rating Scale, or photographed, as in Beyer's Oucher Scale (McGrath et al., 1985; Beyer and Aradine, 1988; Wong and Baker, 1988). Numeric values are assigned in each of these methods for progressive levels of pain intensity.

In infants and nonverbal children, observational pain scales must be implemented. For the evaluation of postoperative pain, the Children's Hospital of Eastern Ontario Pain Scale (CHEOPS) and the Objective Pain Scale grade behavioral manifestations of pain (McGrath et al., 1985; Hannallah et al., 1987). The CHEOPS assesses six categories—cry, facial expression, verbal response, torso position, leg activity, and arm movement—in relationship to the surgical wound. The Objective Pain Scale contains physiologic and behavioral changes associated with pain. These scales were designed for research purposes and are specific for age. The Facial Expression-Leg Movement-Activity-Cry-Consolability (FLACC) Scale has been shown to be valid and reliable in children who were preverbal, cognitively impaired, recovering from surgery, or undergoing painful procedures (Merkel et al., 1997; Voepel-Lewis et al., 2002; Manworren and Hynan, 2003; Nilsson et al., 2008). The Multidimensional Assessment of Pain Scale (MAP) has also shown promise of wide

applicability (Ramelet et al., 2007). Neonatal and premature infant pain scales have been created and verified; these include the Neonatal Infant Pain Scale (NIPS), the Crying-Requires Oxygen-Increased Vital Signs-Expression-Sleep (CRIES) Scale, and the Premature Infant Pain Profile.

Observational pain assessment techniques are also fraught with variability. Studies have demonstrated that scoring by parents, nurses, and physicians can be unreliable when assessing pain by cry, behavior, and constructed pain scales (Wasz-Hockett et al., 1985; Beyer et al., 1990; Favaloro and Touzel, 1990; Watt-Watson et al., 1990). As with older children, previous experience, emotional and medical status, and clinician interaction can affect the response.

Because no single technique or approach is ideal, medical personnel assessing pain in children must be well versed and flexible. Verbal, graphic, behavioral, and physiologic measures have been examined and tested, but further work on psychology and emotional interplay is needed. Although cognitive development is well understood, a hospitalized child often regresses, and expected and previously observed abilities may be lost. Much progress has been made in acknowledging that infants and children experience pain, but a great deal of work is still needed to fully reveal the degree and manner of their experience.

Pain Management

The intraoperative use of opioids and regional anesthesia for preventing postoperative pain has been discussed. Even with the best planning, patients may still experience pain in the PACU. Although most pain and discomfort originate from surgical incision and tissue irritation, other causes, including tight bandages or casts, distended bladders, and corneal abrasions, should not be overlooked. Each of these problems requires immediate attention from the appropriate medical personnel. Foley catheters and nasogastric tubes may also be causes for distress. Preoperatively, patients should be prepared to expect these catheters, which will reduce anxiety during recovery. Treatment of pain in the PACU depends on the patient's medical condition, the surgical procedure, and discharge disposition. Oral acetaminophen (10 to 15 mg/kg) is useful in patients without intravenous access who have had minor surgical procedures. Rectal acetaminophen (30 to 40 mg/kg) may take up to 2 hours to achieve a therapeutic level and so is not effective for treating acute pain in the PACU. NSAIDs can play an important role in pain management for patients with compromised airways and respiratory function and can serve as adjuncts to opioid techniques, including neuroaxial and patient controlled analgesia use. Ketorolac should be avoided in patients with an increased risk for bleeding and those who underwent bone-grafting procedures.

Morphine (0.025 to 0.05 mg/kg) or fentanyl (0.5 to 1.0 mcg/kg), given in incremental doses, can be used to achieve an analgesic state in patients recovering from a general anesthetic. If hospital admission overnight or longer is planned, then morphine use is preferable because of its longer duration of action. For patients undergoing extensive surgical procedures with moderate to severe pain anticipated, continuous infusion of an opioid should be considered. Hendrickson et al. (1990) demonstrated better analgesia and greater patient satisfaction with continuous infusion compared with intermittent dosing. Continuous infusion can create consistent analgesic blood levels of morphine and remove the need for children to communicate their pain

(Berde, 1989; Esmail et al., 1999). Patient-controlled analgesia allows the patient to self-administer small incremental doses of a local anesthetic and an opioid. Patient-controlled analgesia has been extensively studied in children, and studies support its efficacy and safety (Gaukroger et al., 1989; Lawrie et al., 1990; Tyler, 1990; Berde et al., 1991). In younger children and infants, nurse-assisted patient-controlled analgesia is a useful alternative (Monitto et al., 2000; Angheliescu et al., 2005). However, there are risks associated with its use (Voepel-Lewis et al., 2008). It is most effective if patients are selected, evaluated, and instructed before surgery. Side effects of opioid use, including nausea, vomiting, pruritus, and urinary retention, should be anticipated and treated when they occur. Placement of indwelling catheters in the epidural space, body cavities, and nerve sheaths allows for continued use of local anesthetics and opioids for several days after surgery. In older children, patient-controlled epidural anesthesia (PCEA) has been shown to be safe and effective (Birmingham et al., 2003). Careful dosing and monitoring for side effects, including oversedation, respiratory arrest, and toxicity of local anesthetics, are essential. The advantages, limitations, and possible dangers of these techniques are discussed in Chapter 15, Pain Management.

Discharge from the Postanesthetic Care Unit

With more rapid recovery from general anesthesia and a greater variety of surgical cases being scheduled on an outpatient basis, strict time criteria for discharge from the PACU are becoming less useful. The Modified Aldrete Score examines the criteria of motor activity, respiration, blood pressure, consciousness, and color (Table 13-5). The Simplified Postanesthetic Recovery Score assesses consciousness, airway, and movement (Steward, 1975). Both scores can be helpful as guidelines in determining when a patient is ready for discharge. Inclusion of oxygen saturation by pulse oximetry is indicated. Before a child can be safely discharged from the PACU, a careful examination should

TABLE 13-5. Modified Aldrete Score

Criteria	Characteristics	Points
Activity	Voluntary movement of all limbs to command	2
		1
	Voluntary movement of two extremities to command	0
Respiration	Unable to move	
	Breathe deeply and cough	2
	Dyspnea, hypoventilation	1
	Apneic	0
Circulation	BP +/- 20 mm Hg of preanesthesia level	2
	BP >20-50 mm Hg of preanesthesia level	1
	BP >50 mm Hg of preanesthesia level	0
Consciousness	Fully awake	2
	Arousable	1
	Unresponsive	0

	Cyanotic	0

From Aldrete JA: The postanesthesia recovery score revisited, *J Clin Anesth* 7:89-91, 1995.

Box 13-3 PACU Discharge

1. The child is fully awake or easily aroused when called.
2. The airway is maintained and protective reflexes are present.
3. Oxygen saturation is maintained above 95% on room air or stable at the preoperative level with or without oxygen.
4. Hypothermia is absent, and hyperthermia is controlled.
5. Pain and nausea and vomiting are controlled.
6. There is no active bleeding.
7. Vital signs are stable.

be conducted to ensure safety on the patient floor, with its reduced nursing care and observation (Box 13-3).

From the PACU, patients can be admitted to a short-stay recovery unit or to a hospital ward. Regardless of the patient's disposition, the anesthesiologist is responsible for the follow-up, to ensure that no anesthetic complications occur, and to continue treatment for those patients receiving special pain management techniques. For ambulatory patients, a single visit is usually all that is needed. For patients with complicated medical conditions and/or extensive surgery, visits should continue until the patient is stable. Postanesthetic notes should be written in the patient's chart to communicate any findings or suggestions that may assist in the patient's recovery.

Short-Stay Recovery Unit

Patients undergoing outpatient procedures continue to recover in an ambulatory or a short-stay recovery unit (SSRU). Complications seen in the PACU can also occur here. The most common causes for unplanned hospital admission from the SSRU are vomiting, croup, fever, and family request (Patel and Hannallah, 1988). Criteria for discharge have been established (Box 13-4).

When discharged to home, the patient's family should be instructed concerning fluid intake, pain control, nausea and vomiting, and any special directives concerning the surgical procedure. In addition, a telephone number where someone will be available 24 hours a day should be supplied.

Box 13-4 Criteria for Discharge to Home

1. Vital signs are stable.
2. Intact gag reflex, swallowing, and cough, allowing for oral intake.
3. Ambulation or movements are appropriate for developmental level. (Patients who received regional analgesia must demonstrate returning motor function.)
4. Nausea and vomiting should be minimal, allowing for retention of ingested fluids.
5. No signs of respiratory distress, such as stridor retractions, nasal flaring, "barking" cough, wheezing, cyanosis, or dyspnea.
6. Patient is oriented to person, place, and time as appropriate for age.

Voiding is not necessary, but if present, it is helpful to assess fluid status and residual regional anesthesia.

(From Patel RI, Rice LJ: Special considerations in the recovery room of children from anesthesia, *Int Anesthesiol Clin* 29:55, 1991.)

SUMMARY

Maintenance of anesthesia, emergence, and postoperative care are parts of the continuous perioperative care of a patient. With improved technology in intraoperative monitoring under the guidelines for standards of monitoring and vigilance, anesthetic management of infants and children has become much safer in recent years. Yet the understanding of the young patient's special needs in terms of equipment, fluid requirement, airway management, and altered pharmacokinetics is essential. Newer anesthetic agents and adjuvant drugs, together with progress in regional analgesic techniques in infants and children, allow pediatric anesthesiologists to combine conduction analgesia

with various general anesthetics for prompt and smooth emergence with appropriate postoperative analgesia. The great variety in patient age, size, and physiology necessitates planning and execution of postoperative management to be patient specific.

Summary	417

The year 1492 is often recalled as the year in which “Columbus sailed the ocean blue.” Few recall that in that same year the first recorded attempt at therapeutic transfusion occurred in Rome. After having an apoplectic stroke, Pope Innocent VIII lapsed into a coma. His physician ordered that the blood of three of the Pope’s young sons (he is said to have had many) be transfused in an attempt to revive him. Not surprisingly, the attempt failed, because the route of transfusion was *per os*, and led to the death of the Pope and to the deaths of his three sons, each of whom had been promised a ducat as payment.

Jean-Baptiste Denis is thought to be the first to attempt an intravenous transfusion of whole blood. He was a Parisian physician and astrologer who, in 1667, gave a teenage boy the blood of either a lamb or a dog in an attempt to restore him after he had been bled multiple times for fever. Denis was later tried for murder when another of his patients died. He was exonerated, but transfusion was subsequently banned throughout Europe for more than 100 years (Moore, 2003).

More than 300 years after the death of Pope Innocent VIII, the first successful human transfusion was performed in Philadelphia and credited to the University of Edinburgh-trained

“Father of American Surgery,” Philip Syng Physick (Fig. 14-1). He did not publish any writings about his accomplishment and few details exist of the circumstances or outcome (Jepson, 1974).

The deaths of the Pope’s three children are a reminder that the blood of a child is precious and should be conserved whenever possible. This chapter describes the techniques available to the pediatric anesthesiologist for conserving the blood of pediatric patients and provides insight into hemoglobin function, anemia, blood banking, and transfusion practices.

HEMOGLOBIN STRUCTURE AND FUNCTION IN THE NEONATE, INFANT, AND CHILD

Hemoglobin, the primary oxygen-carrying pigment, is a large complex tetrameric protein consisting of iron-containing heme groups (protoporphyrin IX ring with attached ferrous iron atom) and the globin protein moiety (Fig. 14-2). The paired arrangement of polypeptide globin chains each interacting with an attached heme group provides the complex reversible interactions that allow for the transport of oxygen.

■ **FIGURE 14-1.** Philip Syng Physick. This portrait is by Robert Reynolds (circa 1840), who copied an earlier portrait (circa 1836) by Henry Inman (1801-1846). (Adapted from Rutkow IM: *Moments in surgical history: Philip Syng Physick [1768-1837]*, Arch Surg 136[8]:968, 2001.)

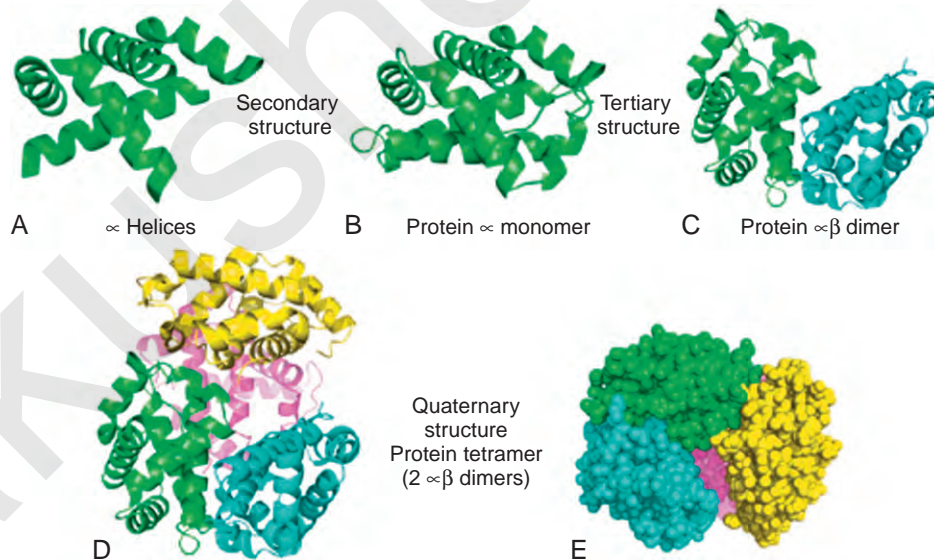

Because each heme moiety has the capacity to bind a single oxygen molecule, a molecule of hemoglobin can transport as many as four oxygen molecules; remarkably, this process is accomplished without the input of energy.

In the healthy child and adult the tetrameric structure of hemoglobin consists of two polypeptide alpha (α) chains and two beta (β) chains and is designated *hemoglobin A*. The

chains differ in the number and sequence of amino acids and in the chromosomes on which their structure is coded. The gene for the α chain is located on chromosome 16, whereas the genes for the β chain and for the embryonic and fetal chains (gamma [γ], epsilon [ϵ], and zeta [ζ]) are closely linked on chromosome 11.

Hemoglobin structure during the embryologic period is characterized by three hemoglobin species, which include Gower-1 ($\zeta_2\epsilon_2$), Gower-2 ($\alpha_2\epsilon_2$), and Portland ($\zeta_2\gamma_2$) (Fig. 14-3). By the tenth week of gestation, these embryonic hemoglobin species are nearly completely replaced by fetal hemoglobin ($\alpha_2\gamma_2$), which is also called *hemoglobin F*. At 10 to 12 weeks of gestation, the distribution of hemoglobin is about 80% to 90% fetal hemoglobin and 10% hemoglobin A. Synthesis of fetal hemoglobin ceases at approximately 38 weeks of gestation; at birth, the percentage of fetal hemoglobin has decreased to about 70% to 80% and, under normal circumstances, continues to decrease thereafter. By 6 months of age, fetal hemoglobin levels typically have decreased to less than 5% and by 1 year of age, to 2%, which is a level similar to that in adults.

The primary physiologic function of hemoglobin is to carry oxygen acquired in the capillary beds of the pulmonary alveoli (or, in fetal life, the chorionic villi of the maternal placenta) and release it in the reduced-oxygen environment of the tissues. Hemoglobin also is important as a biological buffer and in the transport of both carbon dioxide (the Bohr effect) and nitric oxide (Fig. 14-4). In its primary role as an oxygen carrier, hemoglobin functions by altering its affinity for oxygen through changes in the quaternary structure of the protein moiety. This relationship can be usefully illustrated by examining the appearance of the oxyhemoglobin dissociation curve

■ **FIGURE 14-2.** Hemoglobin. The structure of hemoglobin, made up of two α -globin chains and two β -globin chains, is used to illustrate the hierarchical nature of protein folding. **A**, Globin chains are composed almost entirely of α helices. **B**, The organization of secondary structural elements within a domain or protein defines the fold or tertiary structure, as is illustrated for the α helices (green ribbon) of an α -globin chain of deoxyhemoglobin. The spatial relationship of subunits in the assembled protein defines the protein's quaternary structure. **C**, To form a hemoglobin molecule, an α -globin chain and a β -globin chain (green and blue, respectively) assemble to form a dimer. **D**, Two $\alpha\beta$ dimers assemble to form the hemoglobin tetramer (α chains, green and magenta; β chains, blue and yellow). **E**, A space-filling model of the hemoglobin tetramer in which the atoms are represented by spheres with radii proportional to their van der Waals radii is shown for the hemoglobin tetramer, colored as described. (Modified from Rigby AC, Furie B, Furie BC: *Protein architecture: relationship of form and function*. In Hoffman R et al., editors: *Hematology: basic principles and practice*, ed 5, Philadelphia, 2009, Churchill Livingstone Elsevier.)

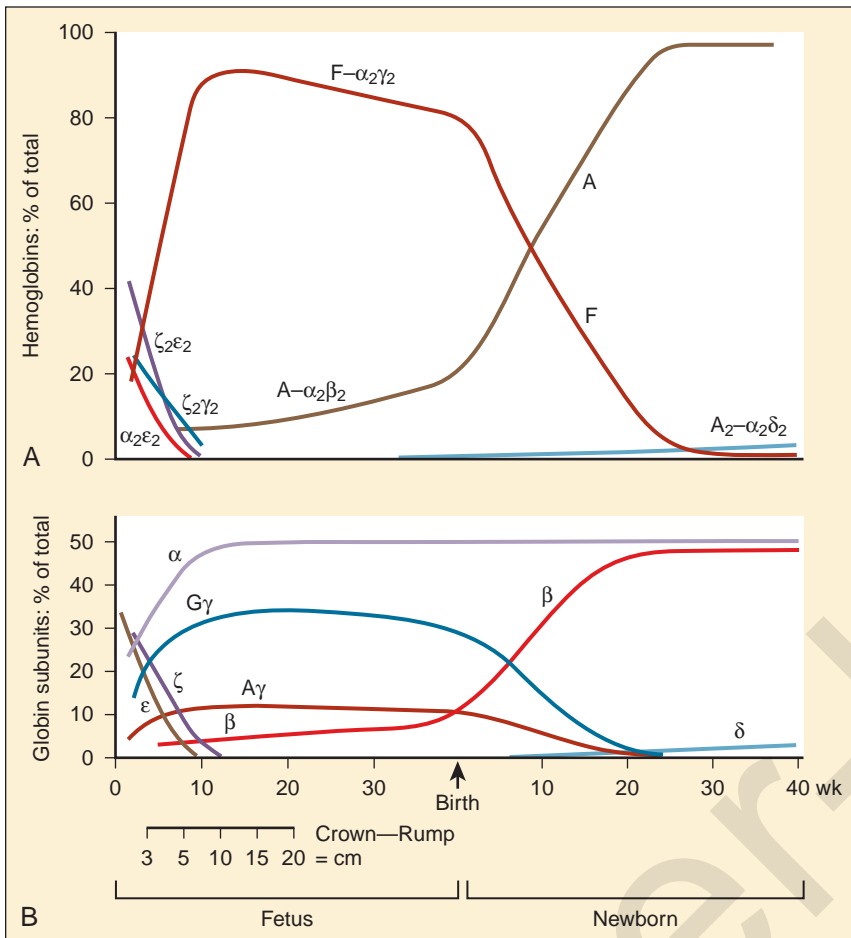

FIGURE 14-3. Hemoglobin structure during human development from embryo to early infancy. **A**, Hemoglobin tetramers. **B**, Globin subunits. A and A $_2$, Adult hemoglobin; F, fetal hemoglobin. (Modified from Polin RA, Fox WW: Fetal and neonatal physiology, ed 2, Philadelphia, 1998, Saunders.)

(Fig. 14-5). The sigmoidal shape of the curve, which describes the relationship of hemoglobin saturation at various levels of oxygen tension, results from the four globin chains individually interacting with oxygen and collectively affecting the affinity of the other chains for oxygen. This complex interaction results in an affinity curve that demonstrates hemoglobin's low affinity (flat portion of the lower curve) for oxygen in hypoxic environments and a rapidly increasing affinity (steep portion) as oxygenation of each heme group occurs until the molecule becomes saturated (flat portion of upper curve). The classic shape of the curve is described for hemoglobin A and reflects the physiologic requirement to load and unload oxygen within a narrow range of oxygen tensions. Other hemoglobin species and mixtures of species have different affinities for oxygen and therefore produce different dissociation curves that in turn reflect embryonic or fetal needs.

The dissociation curve for fetal hemoglobin reflects its function as an acceptor of oxygen carried by maternal hemoglobin A. Therefore, fetal hemoglobin must have a greater affinity for oxygen than maternal hemoglobin (hemoglobin A) to accept oxygen carried to the uterine villi. The increased affinity of fetal hemoglobin for oxygen can be traced to its lower capacity to interact with 2,3-diphosphoglycerate (2,3-DPG), because the binding site for 2,3-DPG is on the β chain, which is absent in fetal hemoglobin (Jepson, 1974). Although one would expect that the increased affinity for oxygen characteristic of fetal hemoglobin would be essential for adequate oxygen delivery in the fetus, that appears not to be the case, as illustrated by the

lack of deleterious effects on the fetus when hemoglobin A is transfused in utero (Mathers et al., 1970). Furthermore, infants born to mothers with hemoglobinopathies characterized by an increased affinity for oxygen show no apparent effects (Moore et al., 1967). By extension, it can be presumed that in the neonate, transfusion with blood containing hemoglobin A is not harmful and may in fact have clear advantages, especially in critical illness (Oski, 1973).

As previously discussed, the characteristic sigmoidal shape of the oxyhemoglobin dissociation curve of hemoglobin A is a reflection of its structure, whereas its position with respect to oxygen saturation and oxygen tension is a function of various factors. Under normal circumstances, the oxygen tension at which hemoglobin A is 50% saturated (P_{50}) is 27 mm Hg. Temperature, pH, P_{CO_2} , and 2,3-DPG levels all have profound effects on oxygen affinity and therefore on P_{50} , resulting in a leftward or rightward shift in the position of the curve. Because the appearance of the oxyhemoglobin dissociation curve for the neonate is identical to that of the adult at a pH of 7.6, environmental differences are potentially more important to hemoglobin's functional affinity than are fundamental differences in the hemoglobin molecule itself (Nelson et al., 1964). Under normal circumstances, the P_{50} increases from about 19 mm Hg at 1 day of age to the adult level of 27 mm Hg at age 4 to 6 months (Fig. 14-6). At the end of the first year, the P_{50} actually exceeds that of the adult at a level slightly greater than 30 mm Hg (Oski, 1973). For further reading, see Chapter 3, Respiratory Physiology in Infants and Children.

FIGURE 14-4. The Bohr effect. Carbon dioxide (CO_2) generated in peripheral tissues combines with water (H_2O) to form carbonic acid (H_2CO_3), which dissociates into protons (H^+) and bicarbonate ions (HCO_3^-). Deoxyhemoglobin acts as a buffer by binding protons and delivering them to the lungs. In the lungs, the uptake of oxygen (O_2) by hemoglobin (Hb) releases protons that combine with bicarbonate ion, forming carbonic acid, which, when dehydrated by carbonic anhydrase, becomes CO_2 , which then is exhaled. (Modified from Polin RA, Fox WW: Fetal and neonatal physiology, ed 2, Philadelphia, 1998, Saunders.)

The red blood cell (RBC) is of great importance to the function of hemoglobin. Loss of nuclear constituents during normal erythropoiesis imposes on the RBC a finite existence in the circulation. The absence of a nucleus allows it to function more effectively in oxygen transport but limits its ability to repair defects in the cell membrane, because it lacks the ability to synthesize the necessary proteins. The mature RBC maintains approximately 40 enzymes capable of various functions, such as electrolyte homeostasis, energy metabolism through anaerobic glycolysis, maintenance of cell membrane shape and integrity, maintenance of heme iron in the ferrous state, and maintenance of appropriate levels of 2,3-DPG. Free hemoglobin is rapidly removed and cannibalized, whereas hemoglobin maintained within the RBC membrane has a life span of up to 120 days. Fetal RBCs have a life span of only 60 to 90 days. With increasing prematurity, the life span of the RBC is progressively shorter, contributing to the frequency of transfusions required among the most premature patients. RBC senescence results from the loss of enzyme function necessary for maintenance of the membrane integrity. Ultimately, progressive loss of membrane results in the loss of the characteristic biconcave shape of the RBC, a shape that is less deformable and more fragile, and in sequestration and destruction of the RBC in the sluggish circulation of the spleen.

FIGURE 14-5. Oxyhemoglobin dissociation curve. Curve B is from a normal adult at $38^{\circ}C$, pH 7.40, and P_{CO_2} 35.0 mm Hg. Curves A (newborn) and C illustrate the effect on the affinity for oxygen of variations in temperature ($^{\circ}C$), pH , P_{CO_2} , 2,3-diphosphoglycerate (DPG), adenosine triphosphate (ATP), methemoglobin (Met Hb), and carboxyhemoglobin (CO Hb). *Hb*, Hemoglobin; *S*, Saturation. (Modified from Duc G: Assessment of hypoxia in the newborn: suggestions for a practical approach, Pediatrics 48[3]:469, 1971.)

PHYSIOLOGIC ANEMIA AND THE ANEMIA OF PREMATURITY

At term, the neonate has a hemoglobin concentration of approximately 17 g/dL. As hemoglobin F is replaced with hemoglobin A over the ensuing months, the hemoglobin level decreases to a low of 10 g/dL, and the oxyhemoglobin dissociation curve shifts rightward. This shift is the result of the combination of increasing levels of hemoglobin A and increased levels of 2,3-DPG as described by Oski (1973). An increase in the levels of either one alone is insufficient. The importance of this is apparent in infants who have respiratory distress syndrome with abnormally low levels of 2,3-DPG and who show improved oxygen unloading at the tissue level after transfusion with fresh adult blood. The transition from a P_{50} of 19 mm Hg in the term neonate to 27 mm Hg (as in the adult) typically occurs over 4 to 6 months. However, in the premature patient this transition may be delayed to as late as age 12 months.

As the conversion from hemoglobin F to hemoglobin A occurs, the hemoglobin concentration decreases from 17 to 18 g/dL at birth to a nadir of 10 to 11 g/dL at 8 to 12 weeks of age. This is termed the *physiologic anemia of infancy*, a condition that persists until the hemoglobin concentration increases to levels typical of the older child and adult over the second half of the first year. The anemia in the healthy

■ **FIGURE 14-6.** Oxygen equilibrium curve of blood at different postnatal ages. The mean \pm SD oxygen tension at which hemoglobin A is 50% saturated shifts from 19.4 ± 1.8 mm Hg on the first day of life to 30.3 ± 0.7 mm Hg at age 11 months (normal in adults is 27.0 ± 1.1 mm Hg). HbO_2 , Oxyhemoglobin. (Modified from Oski FA: *The unique fetal red cell and its function: E. Mead Johnson Award address, Pediatrics* 51[3]:494, 1973.)

neonate is asymptomatic and is therefore not a true anemia; thus, *physiologic* is used to differentiate the normal decrease in hemoglobin in the full-term neonate from that in the premature neonate. In the premature infant, this anemia occurs earlier, persists longer, and is symptomatic, with hemoglobin levels often decreasing to as low as 8.0 g/dL as early as the fourth week after birth.

The origin of physiologic anemia (and to a lesser extent, the anemia of prematurity) can be traced to a dramatic decrease in levels of erythropoietin. Erythropoietin, a glycoprotein of 34,000 Da, is synthesized in the fetal liver and thereafter in the kidneys and is the primary growth factor for erythroid progenitors. Its activity is primarily regulated by oxygen tension; as oxygen tension decreases, expression of the erythropoietin gene increases. In the fetus, erythropoietin gene expression is high, because oxygen tensions are low. The leftward position of the oxyhemoglobin dissociation curve necessitates that hemoglobin concentration be maintained at levels that will deliver sufficient oxygen to fetal tissues despite the high oxygen affinity of fetal hemoglobin.

At birth, oxygen tensions increase quickly, effectively halting erythropoietin synthesis, and consequently, erythropoiesis. In the full-term neonate, erythropoietin and, consequently, hemoglobin levels begin increasing around the age of 4 months, resulting in the correction of physiologic anemia, which is often called the *physiologic nadir* to emphasize the physiologic or nonpathologic nature of the decrease in hemoglobin. In premature infants, the phenomenon is more complex

and is complicated by the need for repeated blood sampling in hospitalized premature infants. Often, the blood sampling requirements equal or exceed half of the total blood volume in infants weighing less than 1 kg (Stockman, 1986). The need for phlebotomy results in a need for the transfusion of adult banked blood—blood containing hemoglobin A with its characteristic lower affinity for oxygen. The resulting increase in tissue-oxygen tension further decreases erythropoietin synthesis and prolongs the duration of anemia for a period that is dependent on factors such as weight, gestational age, and the ongoing need for transfusion.

The *anemia of prematurity* is a true anemia that produces clinical signs and symptoms such as tachycardia, bradycardia, apnea, delayed growth, and poor weight gain. Treatment is directed at these consequences and consists of either transfusion, or more recently, the use of recombinant erythropoietin. Studies examining the potential benefit of booster transfusions targeted to keep hemoglobin levels greater than 10 g/dL in premature infants have been mixed; some have shown improvements in weight gain, and others have failed to demonstrate benefit (Blank et al., 1984; Stockman et al., 1984; Keyes et al., 1989).

The use of recombinant erythropoietin has also been studied extensively in the treatment of anemia of prematurity. A Cochrane Review described the results of 23 studies involving 2074 infants (Fig. 14-7) (Ohlsson and Aher, 2006). The end point of the majority of the studies was a reduction in the need for transfusion and donor exposure after enrollment. In the majority of studies, the need for transfusion was reduced; however, the reduction is of limited clinical significance. Several studies also found an increased incidence of retinopathy of prematurity among those treated with erythropoietin. The lack of clinically relevant benefit and the potential to increase the occurrence of retinopathy of prematurity prompted the recommendation against the use of erythropoietin as a means of reducing the need for transfusion in premature infants. Transfusion practices and indications in this group are discussed later in this chapter.

PERIOPERATIVE STRATEGIES FOR BLOOD CONSERVATION

This section discusses the following techniques and drugs that have been studied to limit allogenic blood transfusion in the pediatric population: erythropoietin, iron supplementation, hemostatic drugs, preoperative autologous blood donation, preoperative hemodilution, and deliberate hypotension. Not all these methods of blood conservation are ideal for every patient or surgical procedure, but each method has a place in the perioperative management of blood conservation in the pediatric patient.

Erythropoietin

As discussed in the previous section, erythropoietin is an inducible glycoprotein produced in the kidneys and extrarenal tissues. It regulates erythropoiesis in response to tissue hypoxia. Acute anemia is associated with exponential increases in erythropoietin in the plasma. However, in the critically ill, erythropoietin induction is blunted, as has also been observed

Analysis 01.03. Comparison 01 Erythropoietin vs. placebo or no treatment, Outcome 03, Use of one or more red blood cell transfusions (low dose EPO)

Review: Early erythropoietin for preventing red blood cell transfusion in preterm and/or low-birth-weight infants
Comparison: 01 erythropoietin vs. placebo or no treatment
Outcome: 03 use of one or more RBC transfusions (low dose EPO)

FIGURE 14-7. Erythropoietin and the need for transfusion among preterm and low-birth-weight infants: erythropoietin versus placebo or no treatment. Although the various outcomes of studies using erythropoietin (EPO) to decrease the need for transfusion among premature infants tend to favor its use, the effect sizes are small and may not be clinically relevant. CI, Confidence interval. (Modified from Ohlsson A, Aher SM: Early erythropoietin for preventing red blood cell transfusion in preterm and/or low birth weight infants, Cochrane Database Syst Rev, 19[3]:CD004863, 2006.)

in various chronic illnesses in childhood. The exact mechanism of the inhibition observed in both critical illness and chronic illness has not been described (Krafte-Jacobs et al., 1994). Regardless of the mechanism, both situations often lead to the need for blood transfusion. The use of recombinant erythropoietin has been investigated as a means of reducing the need for transfusion or the frequency of transfusion in chronic or critical illness.

Adult studies have shown mixed results in the efficacy of recombinant human erythropoietin to avoid or limit blood transfusion. Several randomized controlled studies, including a study reported by Silver et al. (2006), have shown that at least 1 unit of blood was saved in patients in an adult intensive care unit (Corwin et al., 2002). More recently, however, Corwin and colleagues (2007) reported that in a large, prospective, randomized controlled trial involving more than 1400 adult patients, the group receiving erythropoietin had a 10% decrease in the need for transfusion compared with the control group. However, that study and others found an increase in the instances of thrombotic events among patients receiving erythropoietin.

A benefit, albeit small, was found in studies that examined the use of perioperative erythropoietin for reducing the need for transfusion during and after procedures in which transfusion is normally required. Laupacis and Fergusson (1998), in a meta-analysis involving adults undergoing either orthopedic or cardiac surgery, found a significant reduction in allogenic RBC transfusion in both groups of patients (Fig. 14-8). In a study of children undergoing craniofacial repair, Helfaer et al. (1998) found that

children receiving preoperative erythropoietin required transfusion significantly less often than controls (64% vs. 100%). Other small studies (183) and case reports have concluded that erythropoietin is efficacious in reducing the need for RBC transfusion in children, but in the absence of data from large, well-designed prospective trials, its use cannot be recommended.

Iron Supplementation

The main cause of iron-deficiency anemia in the developed world is blood loss, primarily from gastrointestinal tract bleeding, menstruation, numerous blood draws, or surgical blood loss. The development of iron deficiency is dependent on the individual's iron reserve, which in turn is dependent on the age, sex, rate of growth, and rate of absorption of iron.

The incidence of iron deficiency anemia is approximately 9% among children 1 to 2 years old in the United States (Looker et al., 1997). For adult patients with normal iron storage, there is conflicting evidence as to whether iron supplementation perioperatively improves the hemoglobin level. Several randomized control trials have failed to show that oral iron supplementation increases hemoglobin levels perioperatively (Crosby et al., 1994; Sutton et al., 2004; Mundy et al., 2005). However, two clinical trials (one randomized and one nonrandomized) with colorectal surgical patients have shown that treatment with oral iron supplementation for two weeks significantly increased hemoglobin levels and decreased blood transfusion rates (Okuyama et al.,

FIGURE 14-8. Proportion of patients receiving transfusions in studies of erythropoietin. *Admin*, Route of administration; *CI*, confidence interval; *I*, intravenous; *O*, open label control; *OR*, odds ratio; *P*, placebo; *S*, subcutaneous. (Modified from Laupacis A, Fergusson D: *Erythropoietin to minimize perioperative blood transfusion: a systematic review of randomized trials*, *Transfus Med* 8[4]:309, 1998.)

2005; Lidder et al., 2007). The conclusion of a review by Beris et al. (2008) for the Network for Advancement of Transfusion Alternatives was that there is insufficient evidence to recommend the use of intravenous iron as a means of reducing the need for perioperative transfusion in adults. As with the use of erythropoietin, few data for children are available.

Hemostatic Drugs

Three currently available hemostatic drugs have been well investigated and extensively used to limit blood loss perioperatively. Two of the drugs, aminocaproic acid (EACA) and tranexamic acid (TA), are lysine amino-acid synthetic derivatives; the third, aprotinin, is a naturally occurring antifibrinolytic and proteinase inhibitor (Fig. 14-9). These drugs have been extensively used in adults and, more recently, in children.

Fibrinolysis, the lysis of formed fibrin clot, results from the enzymatic conversion of the proenzyme plasminogen to plasmin, a process that is mediated by tissue plasminogen activator, urokinase, factors XIa and XIIa, and kallikrein. Fibrinolysis results in the cleavage of polymerized fibrin strands at multiple sites and releases fibrin degradation products such as D dimer (Kolev and Machovich, 2003). EACA and TA exert their antifibrinolytic activity by reversibly blocking the lysine binding site on plasminogen, preventing binding to fibrin and conversion to active plasmin. As an inhibitor of fibrinolysis, TA is 10 times more potent than EACA. TA may also improve hemostasis by preventing plasmin-induced platelet activation, and both EACA and TA have antiinflammatory properties, but they are less than those of aprotinin (Eaton, 2008).

Antifibrinolytics have been used in children primarily for spine surgery and cardiac surgery, although they have been used for other procedures, including craniofacial reconstruction and repair of congenital diaphragmatic hernia during extracorporeal membrane oxygenation (ECMO). Sethna et al. (2005) reported on a randomized study of 44 pediatric patients undergoing elective spine surgery who received either TA (100 mg/kg loading dose followed by 10 mg/kg per hour) or saline placebo during the procedure; the treatment group had a 41% reduction in blood loss (Fig. 14-10). In a subsequent study involving children with Duchenne's muscular dystrophy, the same authors found a similar reduction in the transfusion requirement (Shapiro et al., 2007).

For adult cardiac surgery, the use of antifibrinolytics is well established. For children, although the efficacy data are less available and of lower quality, they support the use of TA and EACA primarily in children undergoing repair of cyanotic congenital heart disease. Bulutcu et al. (2005), in a series of studies involving 750 cyanotic patients, found that both TA and EACA were beneficial in reducing transfusion requirements by up to 50%, reducing blood loss by 44%, and significantly reducing times for sternal closure and rate of reexploration.

Few complications have been associated with the use of TA and EACA, although concerns have been related to thrombosis in patients, such as those undergoing ECMO or a Fontan procedure requiring the use of a baffle fenestration. Although case reports suggest the potential for concern, studies involving 71 patients undergoing a Fontan procedure and 431 patients undergoing ECMO have failed to demonstrate an increased risk of thrombosis (Hocker and Saving, 1995; Gruber et al., 2000; Downard et al., 2003).

FIGURE 14-9. Molecular structures of three hemostatic drugs. Aminocaproic acid (upper center) and tranexamic acid (upper right) are synthetic derivatives of lysine (upper left). Aprotinin (lower) is a proteinase inhibitor. Term, Terminal. (Modified from Eaton MP: Antifibrinolytic therapy in surgery for congenital heart disease, *Anesth Analg* 106[4]:1087, 2008.)

FIGURE 14-10. Mean intraoperative total blood loss in patients undergoing spinal surgery for scoliosis. Patients received either tranexamic acid or placebo. Blood loss was less in the tranexamic acid group among patients with secondary scoliosis (P less than .01) and for all patients (P less than .01). Asterisks, Statistical significance; error bars, standard deviation; N.S., not significant. (Modified from Sethna NF, Zurakowski D, Brustowicz RM, et al.: *Tranexamic acid reduces intraoperative blood loss in pediatric patients undergoing scoliosis surgery*, *Anesthesiology* 102[4]:727, 2005.)

Aprotinin is a nonspecific serine protease inhibitor derived from bovine lung that inhibits proteases with active serine residues, especially plasmin. The resulting effects are an attenuation of inflammatory responses and antifibrinolysis. Aprotinin and the lysine analogues have very different modes and scopes of action, but ultimately both function by inhibiting fibrinolysis through the inhibition of plasmin. Additionally, aprotinin is thought to restore the adhesive properties of platelets independently of its effect on the inhibition of fibrinolysis (Bradfield and Bode, 2003). The efficacy of aprotinin is somewhat less clear than that of either EACA or TA. Eaton (2008), in a comprehensive review published in 2008, described in detail the available data on the efficacy of aprotinin use in pediatric cardiac surgery, in which it is most often used. Of the 14 randomized controlled trials, 11 showed a reduction in at least one parameter of blood loss or replacement. Three studies by Boldt et al. (1994, 1993a, 1993b) showed no benefit, whereas the majority of observational studies described in Eaton's review did show benefit. The difficulty in evaluating the extensive literature on the use of aprotinin in pediatric cardiac surgery lies in the differences in end points (e.g., transfusion requirement, or chest tube output), dosing regimens (i.e., high dose vs. low dose), surgical procedures (e.g., Fontan procedure or ventricular septal defect), cardiopulmonary bypass management, and patients (e.g., infants, neonates, or reoperation). The relatively small numbers evaluated within each study and the virtually endless potential permutations of the resulting data make drawing conclusions about efficacy

difficult, although the weight of the existing evidence in adults and children suggests a benefit similar to that obtained with the lysine derivatives TA and EACA.

The use of aprotinin has raised concerns about the potential for complications, including thrombosis, anaphylaxis, and, most importantly, renal failure. In 2006 the Multicenter Study of Perioperative Ischemia Research Group reported on the largest observational prospective study of antifibrinolytic therapy (Mangano et al., 2006). The study tracked 4374 patients undergoing coronary artery bypass grafting and compared the use of aprotinin (1295 patients), EACA (883 patients), and TA (822 patients) with placebo (1374 patients). Aprotinin was associated with higher risks of death, cardiovascular event, cerebrovascular event, and renal failure. EACA and TA were not associated with increases in renal, cardiac, or neurologic complications. All three agents decreased blood loss to essentially the same degree.

In 1993, the Food and Drug Administration (FDA) approved aprotinin for patients at high risk of bleeding who were undergoing coronary artery bypass grafting with cardiopulmonary bypass (Ray and Stein, 2008). After the publication of the Blood Conservation Using Antifibrinolytics in a Randomized Trial (BART) study (Fergusson et al., 2008), Bayer Pharmaceuticals notified the FDA of its intent to withdraw aprotinin from the market. In that study of 2331 high-risk adult cardiac surgery patients, the investigators sought to determine whether aprotinin was superior to either TA or EACA in decreasing significant postoperative bleeding. The trial was terminated early because of an excess of deaths in the aprotinin group (6%) compared with the TA group (3.9%) and the EACA group (4.0%) (Fig. 14-11).

Preoperative Autologous Blood Donation

Since the 1980s, preoperative autologous donation (PAD) of blood 2 to 3 weeks before the operation has been used for adult cardiac and noncardiac surgical procedures in which blood loss and the need for blood transfusion are expected. The primary goal is to decrease the amount of allogenic blood transfused (Nath and Pogrel, 2005; Schved, 2005; Ferraris et al., 2007).

Numerous studies have documented the safety and benefit of this practice for adults in various settings. The main benefit is that it decreases the exposure to allogenic blood. A concern, though, is the amount of blood transfused (both allogenic and autologous) in patients who undergo PAD (Henry et al., 2002). The increased rate of transfusion is thought to lead to an increased risk of administrative errors with the increased number of units transfused (Schved, 2005). Vega et al. (2008) reported statistically higher complication rates among patients having reconstructive breast surgery who had PAD compared with patients in a control group who did not preoperatively donate their own blood.

Published studies of children and PAD are limited mostly to patients undergoing orthopedic or cardiac surgery. No large pediatric randomized controlled trials of this technique have been performed. Many of the case series involve a combination of PAD and other techniques, such as acute normovolemic hemodilution, erythropoietin, and controlled hypotension, making the evaluation of PAD alone difficult.

Masuda et al. (2000) studied children weighing less than 20 kg. The children were not given erythropoietin, and each child predonated a mean (with standard deviation indicated as SD) of 48 (SD = 17) mL/kg of blood over an average of 50 (SD = 16) days. No child in the study group received allogenic blood transfusion, but 80% of children in the control group did. Sonzogni et al. (2001) pretreated children in a PAD group with subcutaneous erythropoietin 3 times a week for 3 weeks preceding cardiac surgery and once intravenously on the day of the operation. The controls were 39 consecutive age-matched patients from the previous year. Children predonated 9 mL/kg of blood on two separate occasions if the hematocrit was greater than 33%. Three of the 39 children in the study group required transfusion with allogenic blood, compared with 24 of the 39 in the control group.

Most studies of PAD in orthopedics involve scoliosis surgery. Murray et al. (1997) studied 243 consecutive pediatric patients undergoing spinal fusion and found that 90% of the children who predonated did not require allogenic blood during surgery. Moran et al. (1995) reported similar results in their study of children undergoing spinal fusion. In that study, the proportion of patients who needed allogenic blood (11%) was nearly identical to that found by Murray and colleagues. In both studies, at

FIGURE 14-11. Kaplan-Meier curves showing survival at 30 days. Among the 2328 patients who were included in the analysis of death at 30 days after surgery, patients in the aprotinin group had a reduced rate of survival as compared with those in the tranexamic acid group ($P = 0.05$) and the aminocaproic acid group ($P = 0.06$). (Modified from Fergusson DA, Hebert PC, Mazer CD, et al.: A comparison of aprotinin and lysine analogues in high-risk cardiac surgery, *N Engl J Med* 358[22]:2319, 2008.)

least 70% of the children were able to complete the donation process. Concern about the ability of children, especially young children, to complete the donation program is often cited as an obstacle to PAD. However, in both of these studies, children younger than 10 years successfully completed the donation process. Clearly, the ability of infants, toddlers, and young school-aged children to tolerate the donation process is uncertain at best. The use of sedation or general anesthesia to facilitate this process would seem to be somewhat unreasonable and excessive, although it has been reported (Velardi et al., 1998). A contraindication for PAD includes predonation anemia.

Compared with acute normovolemic hemodilution (ANH), PAD has important disadvantages. The risk of transfusion errors (e.g., wrong unit or wrong patient) is not less with PAD than with the use of allogenic blood; the cost of obtaining, storing, and processing the predonated blood is not less with PAD; and the likelihood of contamination of the unit is not less with PAD. It is often unclear from the existing literature how the collection process occurs. For example, it is not clear whether these children require sedation before blood collection. Each of the problems is eliminated or nearly eliminated with ANH. ANH also has the advantage of returning fresh whole blood to the patient in contrast to PAD, which provides only the RBC component. Therefore, PAD should be reserved for older children, and the indications for the use of the predonated blood should be identical to those for allogenic units.

Acute Normovolemic Hemodilution

ANH is a technique designed to decrease the need for allogenic blood transfusion by the preoperative withdrawal of the patient's own blood to be reinfused as needed during the subsequent procedure. The withdrawn blood is collected in standard blood-collection bags containing anticoagulant. The circulating volume is restored with either colloid (1:1) or crystalloid (3:1), thereby reducing the hematocrit and the potential for loss of RBC mass as bleeding occurs during the procedure (Helm et al., 1996; Ferraris et al., 2007). Children weighing less than 35 kg typically do not fill an entire collection bag. As bags typically contain approximately 63 mL citrate-phosphate-dextrose (CPD) and hold 450 mL blood, the volume of the anticoagulant needs to be reduced if the volume of collected blood is less than 450 mL. Studies of adults have examined the potential benefits of various replacement fluids, including hetastarch, albumin, and Lactated Ringer's solution. All appear to be acceptable in adults, but few data exist to guide practice in children. Given that phlebotomy takes place just before the procedure and the withdrawn blood never leaves the patient's operating room, the potential for error in transfusing the wrong blood to the wrong patient is greatly reduced. The withdrawn fresh whole blood, which contains the non-RBC components not found in banked blood, is reinfused at the end of the procedure.

The volume of blood to be removed can be calculated with the following formula:

$$V = EBV \times (H_i - H_f) / H_{av}$$

where V is volume to be removed; EBV is estimated blood volume; H_i is initial or starting hematocrit value; H_f is the final or desired hematocrit value; and H_{av} is the average hematocrit value. The final or desired hematocrit is unclear and is dependent on various factors, including age, procedure, coexisting disease, and expected blood loss. Some have suggested that young

infants are not appropriate candidates for ANH, because they have a limited capacity to increase cardiac output in response to anemia and the presence of fetal hemoglobin may limit oxygen unloading (Weldon, 2005). Supporting data, however, are lacking. In studies of older children and adolescents, hematocrit values have been allowed to decrease to as low as 9% without the development of lactic acidosis or other evidence of hypoperfusion (Fontana et al., 1995). The lowest appropriate or safe level of the desired hematocrit value is a function of the *critical hemoglobin*, which is the hemoglobin or hematocrit value below which oxygen consumption becomes delivery dependent and the ability to increase cardiac output is exceeded as lactic acidosis develops, reflecting insufficient oxygen delivery to the tissues. The critical hemoglobin concentration for humans is unknown, although studies in young healthy volunteers have failed to produce evidence of insufficient oxygen delivery at hemoglobin concentrations as low as 4.8 g/dL despite pharmacologic maneuvers that limited oxygen delivery to 7.3 mL/kg per minute (Lieberman et al., 2000). With the absence of cardiovascular disease in children, the ability to tolerate hematocrits of this level can be reasonably assumed; however, no large body of data exists to support the safety of the practice in children. Safety concerns must be balanced against the evidence for benefit usually determined by a reduction in total allogenic blood transfused or the reduction in exposure to units of allogenic blood. Linderkamp et al. (1992) calculated the following minimally acceptable hemoglobin concentrations: 6 g/dL for children and adults, 12 g/dL for preterm infants at birth, and 11 g/dL for full-term neonates at birth. These critical values were determined from oxygen transport parameters and oxygen consumptions (Linderkamp et al., 1992). Of course, the size of the preterm infant and the full-term neonate would preclude them from ANH; sufficient blood could not be drawn without risking a suboptimal hemoglobin concentration.

Several prospective randomized studies in adults show a modest decrease in the need for allogenic blood transfusion in both cardiac and noncardiac surgery (Goodnough et al., 1994; Moran et al., 1995; Kumar et al., 2002). In a 1998 meta-analysis, Bryson et al. did not demonstrate clear benefit with regard to a reduction in exposure to allogenic blood. According to the Society of Thoracic Surgeons Practice Guidelines, in the adult population the usefulness of ANH is not well established but may have benefit when used in conjunction with other blood conservation strategies (Masuda et al., 2000; Ferraris et al., 2007). A small series of adult patients of the Jehovah's Witness faith who underwent live donor hepatic transplants demonstrated a clear benefit when their results were compared with those of historical controls (Jabbour et al., 2005). The patients in this series not only underwent ANH but also were treated preoperatively with erythropoietin to increase the preoperative level of hemoglobin. The potential benefits of ANH or a combined approach to blood conservation remain unclear and can be addressed only by well-designed studies of sufficient size to provide clinicians with reassurance that the benefit outweighs any potential risk.

Deliberate Hypotension

Controlled, deliberate, or induced hypotension is a method of blood-conservation strategy first described by Cushing in 1917. Since then, the technique has been applied to numerous procedures in various settings, with a multitude of different

pharmacologic agents, and with patients of all ages. In a literature review, Tobias (2002) specifically looked at agents and techniques that can be used in infants and children.

Deliberate hypotension is defined as mean arterial pressure of 50 to 65 mm Hg, or 30% below baseline, which decreases bleeding in the surgical field and may be indicated for any procedure in which a relatively bloodless operating field is needed or whenever blood loss can be expected to require transfusion (Degoute, 2007). The ideal pharmacologic agent to induce controlled hypotension has the following characteristics: short onset, easily reversible and titratable, minimal toxic metabolites, minimal effects on vital organs, and predictable dose-dependent effect (Degoute, 2007). Numerous agents have been used successfully in both adults and children. A comprehensive review of agents useful in pediatrics was prepared by Degoute (2007). A summary of drugs is shown in Table 14-1.

The efficacy of deliberate hypotension to reduce the need for transfusion and improve the quality of the surgical field has been studied extensively for more than 30 years, although no

large well-designed study or meta-analysis has demonstrated its efficacy in children. Still, the technique is widely accepted and used in children and infants. Most recent studies have focused on techniques and agents that may be used to achieve hypotension rather than on safety or efficacy. Shear and Tobias (2005), however, published a small study of cerebral oxygenation during controlled hypotension to 55 to 65 mm Hg using near infrared spectroscopy. They found that even with mean pressures of less than 54 mm Hg, oximetry values never decreased to less than 20% below baseline. They concluded that deliberate hypotension within the limits of 55 to 65 mm Hg was safe with regard to cerebral oxygenation.

Techniques for achieving deliberate hypotension are primarily pharmacologic, although positioning and regional techniques are occasionally used. The pharmacologic agents are derived from several different classes, including ganglionic blockers (e.g., trimethaphan), vasodilators (e.g., nitroglycerin and nitroprusside), β -blocking agents (e.g., esmolol), calcium channel blockers (most often nicardipine), and the volatile

TABLE 14-1. Drugs Used in Controlled Hypotension During Surgery

Drug	Site of Action	Predominant Action	Major Inconvenience
Anesthetics			
Bupivacaine (spinal anesthesia), ropivacaine (epidural anesthesia)	Medulla	Blockade of the sympathetic nervous system	On/off; need vasoconstrictor (ephedrine)
Inhalation anesthetics: Isoflurane, sevoflurane	Vessels: Vasodilation	Blockade of α -adrenoceptors	Resistance; need high concentrations or adjuvants
Opioids: Remifentanyl	Heart: Bradycardia	Blockade of the sympathetic nervous system	None
Vasodilators			
Sodium nitroprusside	Resistance/capacitance vessels: Vasodilation	Direct acting	Cyanide toxicity; heavy monitoring
Nitroglycerin	Capacitance vessels: Vasodilation	Direct acting	Resistance; adequate monitoring
Adenosine	Resistance vessels: Vasodilation	Direct acting	Cost; histamine release
Alprostadil	Resistance vessels: Vasodilation Heart: \downarrow Chronotropic effect	Direct acting	Cost
Calcium channel antagonists: Nicardipine, diltiazem	Resistance vessels: Vasodilation Heart: \downarrow Inotropic effect	Direct acting	None
Fenoldopam	Resistance vessels: Vasodilation	Dopamine DA ₁ -receptor agonist	None; cost?
Autonomic Nervous System Inhibitors			
Trimethaphan	Vessels: Vasodilation heart: \downarrow Contractility	Blockade of the ganglia of the autonomic nervous system	Histamine release; resistance
Clonidine	CNS	Presynaptic α -adrenoceptor agonist	Unpredictable effect
Urapidil, phentolamine	Vessels: Vasodilation	Postsynaptic α -adrenoceptor antagonist	Unpredictable effect
Labetalol	Heart: \downarrow Contractility vessels: Vasodilation	α/β -Adrenoceptor antagonist	Slow-onset cardiac failure if used to treat profound arterial vasoconstriction
Esmolol	Heart: Bradycardia, \downarrow contractility	β -Adrenoceptor antagonist	Resistance; cardiac failure
ACE Inhibitors			
Captopril, enalapril	Vessels: Vasodilation	Angiotensin II inhibitors	Long duration of action

Modified from Degoute Controlled hypotension: a guide to drug choice, *Drugs* 67(7):1053, 2007.
ACE, Angiotensin-converting enzyme; CNS, central nervous system; \downarrow , decrease.

agents (presumably sevoflurane, with its greater titratability). The review by Tobias (2002) provides an extensive discussion of various agents. Often a combination of agents is required to provide adequate control of blood pressure, especially in young, healthy adolescents. The use of vasodilators such as nitroprusside or a volatile agent often results in reflex tachycardia that limits hypotension. Most practitioners find that satisfactory hypotension can be achieved only when heart rate is controlled, typically with a β -blocker (e.g., esmolol) or with a combination agent that blocks both α and β receptors (e.g., labetalol). Other agents that may be helpful in controlling heart rate, include clonidine (an α -receptor agonist) or a narcotic (especially remifentanyl), as was shown in endoscopic sinus surgery and middle ear procedures (Degoute et al., 2003; Eberhart et al., 2003).

Dexmedetomidine has gained acceptance in various settings, but its use in this setting would appear to be limited. Nonetheless, it has been compared with remifentanyl in two studies (one adult and one pediatric). In neither study was dexmedetomidine found to be superior (Tobias, 2002; Richa et al., 2008). A third article described only one patient for whom dexmedetomidine was used successfully to induce hypotension for spine instrumentation (Tobias and Berkenbosch, 2002). In the absence of additional data from larger prospective studies, the use of dexmedetomidine for controlled hypotension cannot be recommended.

Although the use of deliberate hypotension is widely accepted, the practitioner must be attentive to safety concerns, primarily those related to focal ischemia to such vital areas as the retina, spinal cord, and brain. Deliberate hypotension is contraindicated in patients with compromised circulation involving any critical vascular bed, elevated intracranial pressure, profound anemia or polycythemia, or sensitivity to any of the proposed hypotensive agents. The hematocrit concentration should be maintained at an adequate level. Despite the suggestion by some that deliberate hypotension and extreme ANH may be safely combined, deliberate hypotension should never be combined with ANH because of the risk of end organ ischemia (Schaller et al., 1983). The anesthesiologist must have experience with the technique and with the agents used to achieve hypotension. Adequate monitoring is essential, including invasive arterial blood pressure in all cases and central venous pressure monitoring in many or most cases. Patients placed in the reverse Trendelenburg position or in any position in which the

head is higher than the heart must have the arterial pressure monitored and zeroed to reflect cerebral perfusion pressure. Arterial blood gases should be monitored frequently to ensure that a metabolic acidosis is not present, suggesting poor tissue perfusion or cyanide toxicity, when using sodium nitroprusside. Owing to its potential for toxicity, sodium nitroprusside deserves additional mention.

Sodium nitroprusside is 44% cyanide by weight. It interacts with oxyhemoglobin and spontaneously dissociates into methemoglobin, cyanide, and nitric oxide (Fig. 14-12). Its vasodilatory action is mediated principally through the action of nitric oxide. Although it is a highly efficacious vasodilator, when used in high doses for protracted periods, sodium nitroprusside may produce intoxication with its by-product, cyanide. Free cyanide radicals generated by the metabolism or breakdown of sodium nitroprusside are metabolized by one of the following four potential mechanisms:

1. Cyanide may bind and inactivate mitochondrial cytochrome oxidase and prevent oxidative phosphorylation, leaving anaerobic metabolism as the only path to energy production, leading to lactic acidosis.
2. Cyanide may be converted to thiocyanate by the enzyme rhodanase. Treatment with thiosulfate promotes metabolism of cyanide to thiocyanate, which may be excreted by the kidney.
3. Vitamin B₁₂ converts cyanide to cyanocobalamin (this is a relatively minor pathway).
4. Free cyanide may be consumed by reversibly combining with methemoglobin into cyanomethemoglobin, a non-toxic compound.

The primary deleterious effect of cyanide intoxication is the poisoning of aerobic metabolism at the level of the mitochondria. Cyanide directly inhibits the functioning of the electron transport chain through its effects on cytochrome oxidase. When sodium nitroprusside infusion exceeds the capacity of thiocyanate to eliminate it, signs and symptoms become manifest. In addition, methemoglobinemia may develop if sodium nitroprusside is infused at doses exceeding 10 mcg/kg per minute for more than 10 to 12 hours.

Signs and symptoms of thiocyanate toxicity include nausea, disorientation, confusion, psychosis, weakness, muscle spasm, hyperreflexia, and convulsions. Cyanide toxicity has been known to result in "unexplained cardiac arrest," coma, encephalopathy,

FIGURE 14-12. Primary pathways of sodium nitroprusside metabolism. CN, Cyanide; CO, cytochrome oxidase; CYANOHGB, cyanomethemoglobin; METHGB, methemoglobin; NO, nitric oxide; OXYHGB, oxyhemoglobin; SNP, sodium nitroprusside. (Modified from Friederich JA, Butterworth JF: Sodium nitroprusside: twenty years and counting, *Anesth Analg* 81[1]:152, 1995.)

convulsions, and irreversible focal neurologic abnormalities. Regardless of the amount infused, any patient who receives sodium nitroprusside and who subsequently has neurologic abnormalities, cardiovascular instability, and increasing metabolic acidosis should be assessed for cyanide toxicity. The current method of monitoring for cyanide toxicity, particularly under general anesthesia, is insensitive. The value of measuring blood levels of cyanide is limited by the delay in obtaining results, which may not be available for several hours or days. Blood levels of cyanide exceeding 40 $\mu\text{mol/dL}$ are typically associated with toxicity; levels exceeding 70 to 80 $\mu\text{mol/dL}$ are potentially lethal. In otherwise healthy patients (such as those undergoing spinal fusion and a hypotensive technique), the presence and severity of metabolic acidosis correlates well with cyanide toxicity. However, among critically ill patients, ascertainment of cyanide toxicity may be confounded if the patient has acidosis from another cause. In children, the need for rapidly increasing doses or excessively large doses (greater than 10 mcg/kg per minute) of sodium nitroprusside within the first 60 minutes of initiation to maintain the desired clinical effect should alert the clinician of the potential for impending cyanide intoxication.

Prevention of cyanide toxicity can best be accomplished by limiting the dose and duration of the infusion and by close monitoring for signs and symptoms consistent with intoxication, especially metabolic acidosis. Infusions greater than 5 mcg/kg per minute should be avoided, and evidence for resistance or tachyphylaxis should be sought, especially early in the infusion. Patients with reduced renal function are at particular risk for the accumulation of thiocyanate and consequent intoxication.

Treatment, when required, usually consists of immediate discontinuation of the infusion, administration of oxygen, and correction of acidosis followed by the initiation of a thiosulfate infusion (at a dose of 60 mg/kg per hour after an initial bolus of 30 mg/kg infused over 20 to 30 minutes). Alternatively, dialysis may be beneficial to remove thiocyanate; hydroxocobalamin (50 mg/kg bolus followed by 100 mg/kg per hour) may assist by binding with cyanide to form nontoxic cyanocobalamin; or sodium thiosulfate (150 to 200 mg/kg slowly) with sodium nitrite (4 to 6 mg/kg, slowly) assists in converting hemoglobin to methemoglobin, which competes with cytochrome oxidase for cyanide (Friederich and Butterworth, 1995). Deliberate hypotension has become a useful and widely accepted technique in adults and children as experience has accumulated with its use over more than a generation. Still, the clinician must weigh the potential benefits against the risks associated with hypotensive anesthetic techniques.

Miscellaneous Techniques for Reducing Intraoperative Blood Loss

Vasoconstriction, positioning, and tourniquets are used to reduce operative blood loss and to optimize the surgical field. Tissue infiltration with epinephrine 1:200,000 as a vasoconstrictor for blood conservation has had positive outcomes in adult breast surgeries, but there are no reports from the pediatric population (Brantner and Peterson, 1985; Courtiss, 1987). Animal studies suggest that blood loss is limited for the duration of the epinephrine's effect, but delayed bleeding may occur (Rey et al., 1996). Karl et al. (1983) evaluated the safety of subcutaneous epinephrine infiltration under halothane anesthesia and reported that epinephrine, 10 mcg/kg, was safe in the pediatric population and that children tolerate a higher dose than adults.

The reverse Trendelenburg position, or head-up tilt position, is often used in head and neck surgery to minimize blood loss and to ensure a dry surgical field. Orthostatic stress experiments on healthy, awake, adult subjects have shown a decrease in cardiac output of up to 25% while maintaining mean arterial blood pressure. However, blood pressure is maintained by a baroreceptor reflex, and volatile anesthetics decrease the sensitivity of this reflex (Muzi and Ebert, 1995; Cooper and Hainsworth, 2001). Quantitative data are not available for the graded change in circulatory responses to various degrees of the reverse Trendelenburg position and the loss of compensatory baroreceptor reflex during general anesthesia in adults or children.

The use of pneumatic tourniquets after exsanguination of the upper or lower extremities significantly improves the operative conditions, particularly for cementing of bone (Abdel-Salam and Eyres, 1995; Wakankar et al., 1999). However, although tourniquet use as a blood conservation strategy is widely accepted in adults and children, there are potential risks, including nerve injury, increased infection, vascular injury, and cardiac and pulmonary injury (Estebe and Malledant, 1996; Kaabachi et al., 2005). In pediatric orthopedic surgery, the use of a tourniquet was identified by Kaabachi et al. (2005) as a risk factor for postoperative wound infection. The use of wide contour cuffs may reduce the likelihood of injury by decreasing mean tourniquet cuff pressure without compromising the quality of the surgical field (Reilly et al., 2009). In children with sickle cell disease (SCD) who require an extremity procedure, tourniquets have been used safely, provided that moderate hyperventilation with pH 7.40 to 7.45 and excellent oxygenation are maintained throughout the procedure (Adu-Gyamfi et al., 1993).

TRANSFUSION TRIGGERS

In 2005, approximately 29 million units of RBC and non-RBC blood components were transfused. Specific data are not available for the pediatric population, but at least one study indicates that approximately 1% of transfusions are administered to patients younger than 18 years (Sullivan et al., 2002). Although the present blood supply is safer than ever in terms of preventing transfusion-mediated infection, complications from blood component transfusions are not uncommon. Therefore, decisions about transfusion for any patient should weigh the potential benefits of transfusion against the risks, the occurrence of which may be unknown. Expert guidelines published for adult and pediatric patients all call for clinical judgments by the practitioner. As a result, transfusion practices vary considerably (Blanchette et al., 1991; Stehling et al., 1994; American Society of Anesthesiologists Task Force on Blood Component Therapy, 1996; Roseff et al., 2002; Desmet and Lacroix, 2004). The following sections summarize the existing guidelines and literature related to pediatric patients.

Transfusion of Fresh Whole Blood or Reconstituted Whole Blood

The transfusion of fresh whole blood (less than 5 days old) would appear to be the obvious choice for resuscitation of a bleeding child, because it replaces all the lost components. However, the storage of whole blood is problematic. In particular, factors

V and VIII are especially labile and tend to be rapidly depleted (Brecher, 2002). Also, refrigerated platelets lose their discoid shape, resulting in decreased survival (Murphy and Gardner, 1969). These factors, combined with the desire to optimize the number of usable components from only one donor and to treat patient-specific needs, have led to special requests for fresh whole blood, if available, in most centers (Roseff et al., 2002).

If fresh whole blood is not available but desired, stored RBCs can be reconstituted with fresh frozen plasma (FFP) (Roseff et al., 2002). This method of administering whole blood, however, provides no platelets and exposes the patient to twice as many donors. Few clinical scenarios require whole blood (Box 14-1). For massive transfusion, it can probably be used without further justification (Blanchette et al., 1991). However, for acute but controllable blood loss, particularly in the larger child, replacement with RBCs, crystalloid fluids, and colloid fluids are probably sufficient unless the clotting factors become excessively diluted (greater than 1 blood volume of replacement in adults). If that happens, plasma or platelets (or both) may be administered as needed.

TRANSFUSION OF RED BLOOD CELLS

There are only two accepted indications for the transfusion of RBCs: to increase oxygen-carrying capacity or avoid an impending inadequate oxygen-carrying state; and to suppress the production or dilute the amount of endogenous hemoglobin in selected patients with thalassemia or sickle cell disease (Hume and Limoges, 2002). Because neonates, particularly premature low-birth-weight patients, differ from infants and older children in terms of blood volume and physiology, they are discussed separately.

Transfusion in Patients Younger than 4 Months

Beside having a smaller absolute blood volume than older patients, children younger than 4 months have different physiologic processes than older patients. Examples include the premature infant's limited erythropoietin response to decreased oxygen delivery, as previously discussed, and the newborn's inefficient humoral system that precludes formation of antibodies to allogenic RBCs (Stockman et al., 1984; DePalma and Luban, 1990).

Box 14-1 Guidelines for Transfusion of Whole Blood

Exchange transfusion for the following:

- Hemolytic disease of the newborn
- Hyperbilirubinemia with risk of kernicterus

After cardiopulmonary bypass

Extracorporeal membrane oxygenation

Massive transfusion (i.e., transfusion of >1 blood volume in 24 hours)

Modified from Roseff SD, Luban NL, Manno CS.: Guidelines for assessing appropriateness of pediatric transfusion, *Transfusion* 42(11):1398-1413, 2002.

These young patients perhaps receive the most transfusions of all patient groups; infants receiving multiple transfusions are exposed to blood from approximately 10 different donors (Sacher et al., 1989; Strauss, 1991). Recent work has focused both on delineating guidelines for transfusion and on limiting the number of donors needed for these young patients.

Replacement of iatrogenic blood losses caused by blood draws for laboratory testing has historically accounted for approximately 90% of the transfusions in neonates (Kaabachi et al., 2005). Older guidelines and expert opinions have advocated replacing blood losses resulting from phlebotomy when losses exceed 5% to 10% of the total blood volume (Blanchette et al., 1991; Wakankar et al., 1999). These guidelines note that the decision to transfuse should not be made solely on the amount of blood lost but should include factors such as the clinical status of the patient, the patient's hemoglobin level, and the length of time over which the losses occurred (Blanchette et al., 1991). Currently transfusion simply to replace phlebotomy losses is much less common (Ramasethu, 1999; Simon et al., 1998; Shannon et al., 1995).

Maintenance of hematocrit levels greater than 35% (hemoglobin greater than 13 g/dL) for neonates with severe respiratory disease continues to be common practice without the support of evidence (Roseff et al., 2002). In a study of 10 oxygen-dependent infants with bronchopulmonary dysplasia, small-volume transfusions increased oxygen transport and decreased oxygen extraction. However, hemoglobin levels alone were not predictive of which children would benefit from transfusion (Alverson et al., 1988).

Transfusion in Patients Older than 4 Months

The transfusion practice guidelines of the American Society of Anesthesiologists Task Force on Blood Component Therapy (1996) are largely applicable to pediatric patients without cardiopulmonary disease. The points about RBC transfusions are summarized as follows:

1. Transfusion is rarely indicated when the hemoglobin concentration is greater than 10 g/dL.
2. Transfusion is almost always indicated when the hemoglobin concentration is less than 6 g/dL, especially if the anemia is acute.
3. The determination of whether intermediate hemoglobin concentrations (6.0 to 10 g/dL) justify transfusion should be based on the patient's risk of complications from inadequate oxygenation.
4. The use of a single hemoglobin trigger for all patients is not recommended.

Other guidelines have also been published specifically for pediatric patients older than 4 months (Roseff et al., 2002; Stehling et al., 1994) (Box 14-2).

Although numerous studies have been performed to delineate optimal hemoglobin levels in critically ill adults, few studies have been performed involving children. Traditionally, a hemoglobin level greater than 10 g/dL has been advocated for critically ill patients. In a landmark article by Hebert et al. (1999), a trial randomly assigned patients to receive RBC transfusions according to a liberal strategy (transfusion for hemoglobin less than 10 g/dL) or a restrictive strategy (transfusion for hemoglobin less than 7 g/dL). Although there was a higher

Box 14-2 Guidelines for Transfusion of Red Blood Cells in Patients Older Than 4 Months

Emergency surgical procedure in patient with clinically significant preoperative anemia

Preoperative anemia when other corrective therapy is not available

Intraoperative blood loss $\geq 15\%$ of total blood volume

Hematocrit $< 24\%$

In perioperative period, with signs and symptoms of anemia

While receiving chemotherapy or radiotherapy

With chronic congenital or acquired symptomatic anemia

Acute blood loss with hypovolemia not responsive to other therapy

Hematocrit $< 40\%$

With severe pulmonary disease

With extracorporeal membrane oxygenation

Sickle cell disease and any of the following:

Cerebrovascular accident

Acute chest syndrome

Splenic sequestration

Recurrent priapism

Preoperatively when general anesthesia is planned, to increase hemoglobin to 10 g/dL

Chronic transfusion programs for disorders of RBC production (such as thalassemia major and Diamond-Blackfan syndrome unresponsive to therapy)

Modified from Roseff SD, Luban NL, Manno CS: Guidelines for assessing appropriateness of pediatric transfusion, *Transfusion* 42(11):1398-1413, 2002.

in-hospital mortality rate in the liberally transfused group, there was no difference between the groups in the 30-day mortality rate. The liberal strategy group also tended to have higher estimates of severity of multiple organ dysfunction and nosocomial infections.

The Hebert article spawned an interest in performing a similar study in children. The Transfusion Requirements in the Pediatric Intensive Care Unit (TRIPICU) trial was published in 2007 (Lacroix et al., 2007). In this trial, 637 infants and children in the intensive care unit were randomly assigned to a liberal strategy (transfusion for hemoglobin less than 9.5 g/dL) or a restrictive strategy (transfusion for hemoglobin less than 7 g/dL). There was no difference between the groups in the percentage of patients with new or progressive multiple organ dysfunction syndrome (the primary outcome) or death. However, patients in the restrictive strategy group received 44% fewer transfusions than did those in the liberal strategy group. This study suggests that in stable, critically ill children, a transfusion threshold of 7 g/dL decreases transfusion requirements without increasing adverse outcomes.

Clinicians should remember that the goal of RBC transfusion is to ensure adequate oxygen delivery to the tissues. The clinical

picture of the patient is at least as important as the hemoglobin level in determining whether RBC transfusion is required or justified. At the minimum, findings of tachycardia or tachypnea, decreased urine output, or cool vasoconstricted extremities may indicate the need for increased oxygen-carrying capacity. Alternatively, acid-base balance or blood lactate levels can be monitored. More recently, central venous catheters that continually report mixed venous oxygen saturation have been developed in sizes appropriate for children. In addition, noninvasive cerebral oximetry measurements correlate well with measured mixed venous oxygenation in some patients (Cua et al., 2004; Tortoriello et al., 2005). In the future, these and other monitors under development may allow clinicians to better individualize treatment and predict which patients will benefit from RBC transfusion.

When the decision has been made to transfuse RBCs into a child, the appropriate volume must then be determined. Babies in the intensive care unit often receive “top-up” transfusions for slowly progressive anemia caused by phlebotomy. Typically, the dose is 10 to 15 mL/kg administered over 2 to 3 hours. For the larger child in the operating room, an estimate of allowable blood losses may be calculated before any procedure during which blood loss is expected. This can be accomplished with the patient’s estimated blood volume (EBV), weight, initial hematocrit (Hi), and lowest allowable hematocrit (Hp) (Table 14-2). For example, the maximal allowable blood loss in a 5-kg infant with an Hi of 40% and in whom a hematocrit value of 24% is determined safe would be calculated as follows:

$$\text{EBV} = 5 \text{ kg} \times 80 \text{ mL/kg} = 400 \text{ mL blood}$$

$$\text{At hematocrit of } 40\%, \text{ estimated RBC mass} = 400 \text{ mL blood} \times 40\% = 160 \text{ mL of RBCs}$$

$$\text{At hematocrit of } 24\%, \text{ estimated RBC mass} = 400 \text{ mL blood} \times 24\% = 96 \text{ mL of RBCs}$$

$$\text{At hematocrit of } 24\%, \text{ RBC loss} = 160 \text{ mL} - 96 \text{ mL} = 64 \text{ mL}$$

$$\text{Allowable blood loss} = 3 \times 64 \text{ mL} = 192 \text{ mL (where 3 is a conversion factor for Hgb to HCT)}$$

A simpler method of calculating allowable blood loss uses the Hi, the Hp, and the average of the two hematocrits (Hav) as follows (Desmet and Lacroix, 2004):

$$\text{Allowable blood loss} = \text{EBV} \times (\text{Hi} - \text{Hp}) / \text{Hav}$$

$$\text{Allowable blood loss} = 400 \text{ mL} \times (40 - 24) / 32 = 200 \text{ mL}$$

Because blood loss is difficult to calculate in the operating suite, particularly with small patients and small wounds,

TABLE 14-2. Estimated Blood Volume

Age Group	Estimated Blood Volume (mL/kg)
Premature infants	90-100
Term newborns	80-90
Infants younger than 1 yr	75-80
Older children	70-75

these calculations should serve only as estimates and should be accompanied by laboratory measurements whenever possible before the decision to transfuse is made.

The effect that a volume of transfused RBCs will have on a child's hemoglobin level can also be estimated. In general, 10 mL/kg of RBCs will increase the hemoglobin by 1 to 2 g/dL. However, after a child has been exposed to a unit of blood, the child may be given as much of the unit as tolerated (avoiding polycythemia or volume overload) to avoid exposure to blood from other donors owing to ongoing postoperative blood loss or phlebotomy.

RBC Transfusion for Uncorrected Cyanotic Congenital Heart Disease

Children with uncorrected cyanotic congenital heart disease deserve special mention. Intuitively, cyanotic patients require a higher oxygen-carrying capacity to maintain adequate oxygen delivery in the presence of mixing lesions. Indeed, in the absence of phlebotomy in these children, polycythemia develops because of increased erythropoietin in response to poor tissue-oxygen tension. The usual recommendation for these children is to use transfusion to maintain hemoglobin concentrations of 13 to 18 g/dL, although support for this practice is lacking (Meliones et al., 1995; Stehling et al., 1994; Paridon, 1998; Lacroix et al., 2007). Anecdotal evidence from patients of the Jehovah's Witness faith who underwent operations to repair congenital heart disease suggests that lower hemoglobin levels may be tolerated in cyanotic patients (Kawaguchi et al., 1984; Henling et al., 1985).

Transfusion in patients with cyanotic heart disease may have effects beyond increasing oxygen-carrying capacity. Beekman and Tuuri (1985) studied seven children with right-to-left shunts in the catheterization laboratory. Partial exchange transfusions were used to increase the mean (shown with SD) baseline hemoglobin of 13.7 (0.5) g/dL to 16.4 (0.4) g/dL. This intervention not only increased the arterial oxygen saturation; it also decreased the degree of shunting by 59%. Presumably the decrease in shunting resulted from an increase in systemic vascular resistance as a result of an increase in blood viscosity.

RBC Transfusion for Sickle Cell Disease

Patients with SCD often have perioperative complications or a crisis. Early reports cited perioperative mortality rates of 10% and an incidence of postoperative complications of up to 50% (Vichinsky et al., 1995). The two indications for RBC transfusion in a patient with SCD are correction of a preexisting anemia and dilution of hemoglobin S concentration. Some experts advise a preoperative dilution of hemoglobin S levels to less than 30% (Bhattacharyya et al., 1993). However, this practice has never been shown to be of clear benefit.

To more completely address this controversy, Vichinsky and colleagues (1995) performed a multicenter, randomized trial that compared a conservative transfusion strategy (transfusion to increase the hemoglobin level to 10 g/dL) with an aggressive transfusion strategy (transfusion to decrease hemoglobin S to less than 30%). The patients underwent a total of 604 operations. The groups were well matched, and

the mean preoperative hemoglobin levels were 10.6 g/dL in the conservative group and 11.0 g/dL in the aggressive group. When transfusion-associated complications were excluded, there was no difference in the incidence of major complications (e.g., acute chest syndrome, painful crisis, neurologic event, or death) even though the conservatively treated group had a higher concentration of hemoglobin S (59% vs. 31%). However, the incidence of transfusion-related complications was twice as high in the aggressively treated group (14% vs. 7%). These authors concluded that a transfusion protocol aimed at correcting anemia to a hemoglobin of 10 g/dL was as effective as a protocol designed to decrease the hemoglobin S concentration to less than 30% and resulted in half as many transfusion-related complications.

There seems to be no clear benefit to diluting hemoglobin S to a particular level. It then becomes necessary to determine which patients should receive prophylactic transfusion to attain an arbitrary hemoglobin level (usually a goal of 10 g/dL). Unfortunately, the clinical heterogeneity among patients with SCD makes the formation of uniform guidelines nearly impossible. However, some patient and operative characteristics allow the clinician to estimate the potential benefit of transfusion against the known risks.

The incidence of complications in patients with SCD varies widely with the type of operation. In a review by Koshy et al. (1995) of 1,079 procedures, the rates of perioperative complications were 0% for tonsillectomy and adenoidectomy, 2.9% for hip surgery, 3.9% for myringotomy, 7.8% for abdominal surgery, 16.9% for cesarean section and hysterectomy, and 18.6% for dilation and curettage. Patient characteristics that appear to be associated with increased postoperative complications include increased age, incidence of recent complications, inpatient hospital status, pregnancy, and preexisting infection (Firth and Head, 2004).

The clinician must use the above information to help decide whether the potential benefits of transfusion to reach a hemoglobin level of more than 10 g/dL outweigh the risks of transfusion in the patient with SCD who needs to have an operation. For example, a relatively asymptomatic child presenting for tonsillectomy is unlikely to benefit from transfusion for mild anemia. Conversely, it would seem that an adult female who is experiencing many symptoms because of her SCD and is going to undergo a cesarean section and hysterectomy (a procedure associated with a high incidence of perioperative complications) *may* benefit from correction of her anemia to a hemoglobin level greater than 10 g/dL.

TRANSFUSION OF FRESH FROZEN PLASMA

Indications for the transfusion of FFP in pediatric patients are essentially the same as the American Society of Anesthesiologists guidelines for adult patients (1996). FFP transfusion is indicated for the following conditions:

- Emergency reversal of the effects of warfarin
- Correction of coagulopathic bleeding with an increased prothrombin time (international normalized ratio greater than 1.5) or an increased partial thromboplastin time
- Correction of coagulopathic bleeding with massive transfusion (i.e., transfusion of more than 1 blood volume) when coagulation profiles are not easily obtained

FFP is no longer indicated for volume replacement (Consensus conference, 1985; Northern Neonatal Nursing Initiative Trial Group, 1996). If colloid therapy is thought to be more beneficial than crystalloid therapy for volume replacement, albumin or a starch-based product such as hetastarch (≤ 20 mL/kg) may be used. In addition, nearly all congenital bleeding disorders can now be treated with factor-specific therapies and should not be treated with FFP or cryoprecipitate unless these targeted therapies are unavailable. The typical dose of FFP in the pediatric patient is 10 to 20 mL/kg (American Society of Anesthesiologists Task Force on Blood Component Therapy, 1996; Hume and Limoges, 2002; Roseff et al., 2002).

TRANSFUSION OF PLATELETS

Guidelines for the infusion of platelets in pediatric patients resemble those for adults (American Society of Anesthesiologists Task Force on Blood Component Therapy, 1996). If the rest of the coagulation system is normal, platelet counts greater than $50 \times 10^9/L$ are probably sufficient for invasive procedures (McVay and Toy, 1991). If patients undergoing invasive procedures have platelet counts between $50 \times 10^9/L$ and $100 \times 10^9/L$, platelets should be readily available for transfusion if needed. For massive transfusion with microvascular bleeding, platelet counts should be obtained before transfusion if possible. However, platelets may be given during a massive transfusion if a platelet count is not readily obtainable and there is evidence of microvascular bleeding. Platelet transfusions are probably not indicated when thrombocytopenia is caused by increased platelet destruction (idiopathic thrombocytopenic purpura) (American Society of Anesthesiologists Task Force on Blood Component Therapy, 1996).

Preterm infants who are critically ill are of great concern, because they are at high risk of intracranial hemorrhage. These patients have an underdeveloped subependymal matrix that is predisposed to rupture (Sacher et al., 1989; Strauss, 1991). Some experts recommend platelet transfusion for sick preterm babies when the platelet count is less than $100 \times 10^9/L$ and for healthy preterm babies when the platelet count is less than $50 \times 10^9/L$. Andrew and colleagues (1993) randomly assigned 152 preterm thrombocytopenic babies to receive platelet transfusions to maintain a platelet count greater than $150 \times 10^9/L$ (treatment group) or greater than $50 \times 10^9/L$ (conventional group). The authors found no difference in the incidence of intracranial hemorrhage between the two groups (28% in the treatment group vs. 26% in the conventional group). They concluded that early infusion of platelet concentrates in thrombocytopenic premature infants did not alter the incidence of intracranial hemorrhage.

Platelets can be recovered from donors in two ways. One method is to remove whole blood from the donor and use centrifugal forces to separate its constituents. This results in the recovery of approximately 5.5×10^{10} platelets in 50 mL of plasma per 450 mL of whole blood removed from the donor. Typically, these platelet concentrates are then pooled with those recovered from other donors in groups of 6 to 8 for transfusion. Alternatively, apheresis can be used. This method draws blood into a circuit, separates the components with centrifugation or filtration, collects the desired blood component, and returns the remaining components to the donor. A single apheresis unit results in a similar number of platelets as 6 to 8 pooled platelet

concentrates from whole blood, with the obvious advantage of exposure to only one donor (Fasano and Luban, 2008).

When dosing platelets for children, one can expect that one platelet concentrate per 10 kg of body weight will increase the platelet count by approximately $50 \times 10^9/L$. If platelets obtained by apheresis are used, an equivalent dose would be approximately 5 mL/kg body weight.

TRANSFUSION-ASSOCIATED COMPLICATIONS

Viral Infections

The current blood supply is safer than ever from the risks of transmitting viral infections. The estimated risk of transmission for some of the major viruses is shown in Table 14-3. The incidence of viral transmission is now too low to measure, so mathematical models are used to estimate risk (Goodnough et al., 1999a). Improvement in the safety of the blood supply has been multifactorial. After early descriptions of human immunodeficiency virus (HIV) transmission through blood transfusion in 1982 and 1983, the U.S. Public Health Service recommended that persons at increased risk of HIV not donate blood (Ammann et al., 1983). In addition, blood banks began asking donors about high-risk behaviors and giving donors the opportunity to specify that their blood should not be used (Hebert et al., 1999; Tortoriello et al., 2005). These simple interventions alone resulted in significant decreases in the incidence of transfusion-related HIV infection (Busch et al., 1991). With current donor-screening techniques and modern testing of donated blood, which includes antibody screening and nucleic acid testing, patients can generally be assured that the risk of acquiring a major viral infection is quite low. However, new infectious risks, such as exposure to West Nile virus, continue to emerge and will require ongoing surveillance to ensure the safety of the blood supply (Dodd, 2003a; 2003b).

TABLE 14-3. Risk of Transfusion-Transmitted Diseases

Disease	Incidence with Transfusion	Comments
Hepatitis B virus	1 in 137,000	Decreasing because of vaccination of health care professionals and school-aged children.
Hepatitis C virus	<1 in 1,000,000	Antibody screening began in 1990; NAT testing was added in 1999.
Human immunodeficiency virus	<1 in 1,900,000	First blood test was available in 1985; NAT testing was universal in 1999.
Human T lymphotropic virus types I and II	1 in 250,000 to 1 in 2,000,000	Viruses cause blood or nervous system disease in few infected patients.

Bacterial Infections

There has been an increasing focus on the bacteriologic safety of the blood supply. Between 1985 and 1999 in the United States, 694 transfusion-related deaths were reported to the FDA. Of these, 11.1% were attributed to bacterial contamination (Dodd, 2003a). The most likely bacterial contaminant of stored RBCs is *Yersinia enterocolitica*, but other gram-negative bacteria are possible as well (CDC, 1997). The risk of contamination is directly related to the duration of storage (Goodnough et al., 1999a; 1999b). In the United States, the risk of bacterial infection from the transfusion of RBCs is less than 1 in 1 million, but the mortality rate from infection is high: 12 of 20 patients who received RBCs infected with *Yersinia* died from 1987 to 1996 (Goodnough et al., 1999a; Dodd, 2003a). Symptoms of infection usually begin during the transfusion, and patients who die usually die within the next 24 hours.

The risk of sepsis from platelets is higher than from stored RBCs because platelets are stored warm. For this reason, the shelf life of platelets stored at 20° C to 24° C is only 5 days. The reported incidence of sepsis after platelet transfusion is 10 to 138 cases per million transfusions, and risk of death from platelet-associated infection is 2 to 18 per million transfusions (Kuehnert et al., 2001; Ness et al., 2001). There is evidence that the risk of infection is higher when pooled donors are used than when an apheresed unit is transfused from only one donor. The most common bacteria causing death after platelet transfusion are *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Serratia marcescens*, and *Staphylococcus epidermidis* (Beekman and Tuuri, 1985). The clinical course for platelet-related bacterial infection is more variable than that associated with RBCs. Symptoms range from mild fever to florid sepsis with hypotension and death. The reported mortality rate is 26% (Goldman and Blajchman, 1991).

Hyperkalemia

There have been several reports of transfusion-associated hyperkalemic cardiac arrest in pediatric patients (Hall et al., 1993; Ivens and Camu, 1996; Buntain and Pabari, 1999; Chen et al., 1999; Smith et al., 2008). The RBC membrane is poorly permeable to potassium and relies on energy-dependent mechanisms to move potassium in and out of the cell. As RBCs age during storage, adenosine triphosphate synthesis and potassium pumping decrease, and potassium leaks into the supernatant (Ronquist and Waldenstrom, 2003). Indeed, among units stored for prolonged periods, the potassium concentration in the supernatant may exceed 60 mEq/L (Hall et al., 1993). In an analysis of 74 units of banked blood at the Mayo Clinic, Smith and colleagues (2008) found a range of potassium concentrations, from 7.3 to 77.2 mEq/L. In the first week of storage, the average (with SD) measured potassium was 19.0 (7.8) mEq/L; during the second week, 31.5 (14.1) mEq/L; and between 15 and 28 days of storage, 39.9 (10.3) mEq/L. Intraoperative washing of packed RBCs through autotransfusion and use of blood salvage devices may be effective at decreasing the potassium burden (Knichwitz et al., 2002). Alternatively, if notified in advance, blood banks can provide reduced-potassium blood. However, the emergent nature of many massive transfusions often precludes these interventions.

Hyperkalemic arrest seems to be more common among children than adults (Smith et al., 2008). This difference is likely because of smaller circulating volumes, immature renal function, and differences in autonomic tone. In most published

reports, some degree of acidosis, hyperglycemia, or hypothermia was present before the arrest. Therefore, it is difficult to sort out the roles of these factors in augmenting the toxicity of potassium associated with the transfusion. Regardless, the combination of all these factors results in extremely high mortality for patients with transfusion-associated hyperkalemic arrest (87.5% mortality in one series [Smith et al., 2008]).

Immunomodulation

Allogenic blood transfusions seem to lead to modulation of the immune system. Indeed, targeted transfusions were initially used in the 1970s for immunosuppression after renal transplants, but the effect of transfusions on long-term outcome is still not understood (Opelz et al., 1973). More than 100 studies have been published on perioperative transfusion and postoperative infection (Mauermann and Nemergut, 2006). Although many of the conclusions were limited by the biases of small cohorts and retrospective studies, several prospective series showed that perioperative transfusion increased the infection rate in various settings, including cardiac surgery, orthopedic surgery, trauma, and colorectal surgery (Ammann et al., 1983; Busch et al., 1991; Goodnough et al., 1999a; Dodd, 2003). However, the transfusion literature remains divided on the subject of transfusion-associated infections; for every study with positive results, a study with negative results can also be found. The situation is similar for the risk of cancer recurrence after a presumed curative operation. In a 1996 article, Landers et al. (1996) reviewed the available studies, which included various surgical patients. The authors concluded that the burden of evidence pointed toward an association between transfusion and cancer recurrence. Other experts continue to argue that this is simply an association and not a causal relation (Vamvakas and Blajchman, 2001).

Most of the discussion surrounding immunosuppression and transfusion focuses on the effects of donor leukocytes (Kuehnert et al., 2001). Leukoreduction is thought to help reduce transfusion-associated nosocomial infections. Hebert and colleagues (2003) retrospectively reviewed the effects of a universal leukoreduction program in 23 Canadian centers. The patients were undergoing cardiac, orthopedic, or trauma surgery. Although leukoreduction appeared to decrease mortality and the incidence of antibiotic use, the overall rate of serious nosocomial infections was not affected. Fergusson et al. (2004) performed a meta-analysis of all available trials that used leukoreduction and found no difference in the infection rate. Although most of the trials studying this issue have been performed with adult patients, at least one analysis of patients in a pediatric intensive care unit suggested that increased numbers of RBC transfusions were independently associated with an increased incidence of bloodstream infections in critically ill children (Elward and Fraser, 2006).

Transfusion-Associated Graft-Versus-Host Disease

Not only can transfusions depress immune function, they also may activate it in adverse ways, as in the case of transfusion-associated graft-versus-host disease (TA-GVHD), a preventable disease associated with high mortality. Typically, adults with TA-GVHD show symptoms 10 days after transfusion and neonates with TA-GVHD experience symptoms 28 days after

transfusion (Parshuram et al., 2002). The clinical features include fever, rash, diarrhea, hepatitis, and pancytopenia, with death occurring approximately 50 days after transfusion (Ohto and Anderson, 1996). Treatments include corticosteroids, azathioprine, methotrexate, cyclosporine, and bone marrow transplants. However, even with aggressive treatment, the mortality rate in children is nearly 100% (Leitman and Holland, 1985).

The pathophysiology of TA-GVHD has been described (Parshuram et al., 2002). Circulating donor leukocytes persist in transfusion recipients for up to 18 months (Lee et al., 1999). Normally these cells are recognized as foreign and are eliminated, but if they are not, donor leukocyte engraftment may occur, with proliferation of CD4 and CD8 T cells (Nishimura et al., 1997). The clinical effects are mediated by donor T-cell cytotoxicity and by recipient cytokines, including tumor necrosis factor α and interleukin 1 (Vogelsang and Hess, 1994).

The factors that may predispose patients to the development of TA-GVHD are all related to inadequate detection or removal of donor leukocytes. Immunosuppression potentially leads to both inadequate recognition and inactivation of leukocytes. Younger patients, including preterm and full-term infants and children, seem to be at higher risk, perhaps because their immune systems are immature. Congenital immunodeficiencies, including severe combined immunodeficiency syndrome, DiGeorge's syndrome, and Wiskott-Aldrich syndrome, have been associated with TA-GVHD. In addition, many children with congenital heart disease have associated immunodeficiency syndromes that may predispose them to TA-GVHD. Finally, the degree of similarity of human leukocyte antigens (HLAs) between donor and recipients is an important consideration. When donor lymphocytes are homozygous and a recipient is heterozygous for a particular haplotype, recognition of foreign leukocytes may not occur. On an individual level, this has significant implications for children receiving donor-directed platelet transfusions from family members. From an epidemiologic standpoint, the relatively high incidence of TA-GVHD in Japan may relate to a lack of HLA diversity.

Because TA-GVHD is mediated by donor leukocytes, it is preventable by removal of the same. Washing of donor RBCs and use of leukoreduction filters decrease the donor leukocyte burden but do not eliminate all the leukocytes. These methods may be effective at reducing the incidence of TA-GVHD, but they do not eliminate its occurrence (Ronquist and Waldenström, 2003; Smith et al., 2008). Gamma irradiation of 2,500 cGy is the only accepted and widely available method of preventing TA-GVHD. This degree of irradiation decreases the recovery of RBCs, so that the FDA recommends a shelf life of 28 days for irradiated RBCs compared with 42 days for nonirradiated packed RBCs (Davey et al., 1992). Potassium and free hemoglobin levels increase after irradiation and increase further with the duration of storage. Thus, it is preferable to irradiate blood products shortly before administration, particularly in small children, who may not tolerate a potassium load.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is the leading cause of transfusion-related death in the United States (Kleinman et al., 2004). Although underreporting surely exists, the estimated risk of TRALI is one in 5000 transfusions, with FFP being the most commonly associated product (Goodnough

et al., 1999a). This complication and its fatal consequences have been described in pediatric patients (Ririe et al., 2005). The originally proposed mechanism of TRALI is an interaction between antibodies from the donor and leukocyte antigens from the recipient (Opelz et al., 1973). Donor lipids and cytokines have also been implicated. Regardless of the mechanism, the end result is activation of recipient neutrophils in the pulmonary vascular bed. Neutrophil and complement activation culminates in increased pulmonary capillary permeability and pulmonary edema. Interestingly, the most commonly implicated donors are multiparous females, presumably as a result of an increase in human leukocyte antibodies to paternal antigens during pregnancy (Densmore et al., 1999).

The clinical features of TRALI are similar to those of acute respiratory distress syndrome and include dyspnea, hypoxia, and radiographic evidence of pulmonary edema without increased pulmonary capillary wedge pressure. Onset of symptoms usually occurs within 4 to 6 hours after transfusion. Treatment is supportive, because there is no evidence that corticosteroids or other specific therapy is helpful. It is estimated that 90% of patients with TRALI recover (Hebert et al., 1999). The majority of reported cases and studies of TRALI involve adults, but children are certainly at risk (Ririe et al., 2005; Church et al., 2006).

MASSIVE TRANSFUSION

Massive transfusion is typically defined as the need to transfuse more than 1 blood volume in a 24-hour period and, in the case of trauma, portends a poor prognosis (Vaslef et al., 2002; Como et al., 2004). Several potential complications of massive transfusion are listed in Table 14-4. The cause of coagulopathy during massive blood loss and resuscitation continues to be debated and is probably different for relatively controlled losses in the operating suite than for uncontrolled acute losses caused by trauma (Ketchum, 2006). The dilution and consumptive loss of coagulation factors (especially platelets) appear to vary widely. However, after losing 2 blood volumes, most adult patients have platelet counts less than $50 \times 10^9/L$, and many require correction of symptomatic thrombocytopenia before the platelet count decreases to that level (Hiippala et al., 1995). In otherwise healthy adults, the intraoperative loss of about 1.5 blood volumes requires replacement of coagulation factors with FFP. This is in contrast to trauma patients who appear to benefit from FFP administration early in the course of resuscitation (Ketchum, 2006; Shaz et al., 2009).

TABLE 14-4. Complications of Massive Transfusion

Complication	Mechanism
Acidosis	Poor oxygen delivery, lactate accumulation
Alkalosis	Citrate metabolism to bicarbonate by the liver
Hypocalcemia	Citrate binding of calcium
Hyperglycemia	Dextrose preservative in packed red blood cells
Hypothermia	Transfusion of cold blood products
Hyperkalemia	Multifactorial

Data from Smith HM et al.: Cardiac arrests associated with hyperkalemia during red blood cell transfusion: a case series, *Anesth Analg* 106(4):1062-1069, 2008.

It is difficult to conduct quality studies with patients experiencing major intraoperative blood loss, because measurements of blood loss, assumptions of intravascular volume status, and subjective observations of hemostasis are potential sources of error and bias. However, at least one observational study has attempted to identify the source of coagulopathy in pediatric patients undergoing a major operation. Murray and colleagues (1995) studied 32 patients (mean [SD] age, 15.6 [2.3] years) who lost more than 50% of their blood volume while undergoing major spine surgery and were resuscitated with packed RBCs and crystalloid solutions. In 17 of these 32 patients, coagulopathy developed, and it was felt that treatment with FFP was required. Patients with increased clinical bleeding had more blood loss and blood volume loss than the patients who did not have increased clinical bleeding. Although 30 of the 32 patients had increased prothrombin times and activated partial thromboplastin times, only 17 of these patients had excessive clinical bleeding. After loss of 1 blood volume, platelet counts estimated by regression analysis were 195,000/mL. In 14 of the 17 patients with excessive bleeding, FFP alone was adequate to achieve hemostasis. Two patients received platelets as well. The authors concluded that in pediatric patients

undergoing spinal fusion, coagulation factor dilution rather than thrombocytopenia is the major cause of coagulopathy and in the majority of cases FFP is the only blood component needed to correct the coagulopathy.

Whenever possible, the use of platelet and FFP transfusions should be guided by laboratory values, but even in an efficient hospital, prothrombin time results may not be available for 45 to 60 minutes, making laboratory guidance for blood component therapy difficult. For controlled blood loss in the operating room, therefore, the clinician must anticipate the need for blood products and evaluate coagulation status at regular intervals. As point-of-care testing becomes more widely available, values for prothrombin time and partial thromboplastin time may be accessible more quickly. Recently, thromboelastography has become an increasingly popular measure of dynamic clotting parameters (Fig. 14-13). Thromboelastography assesses the viscoelastic properties of blood under low shear conditions (Ganter and Hofer, 2008). Devices from different manufacturers use different technologies. However, the premise is similar. A pin is immersed in a blood sample. The blood sample or pin is then rotated through a specific cycle. As clot begins to form in the blood sample, torque is applied to the immersed pin.

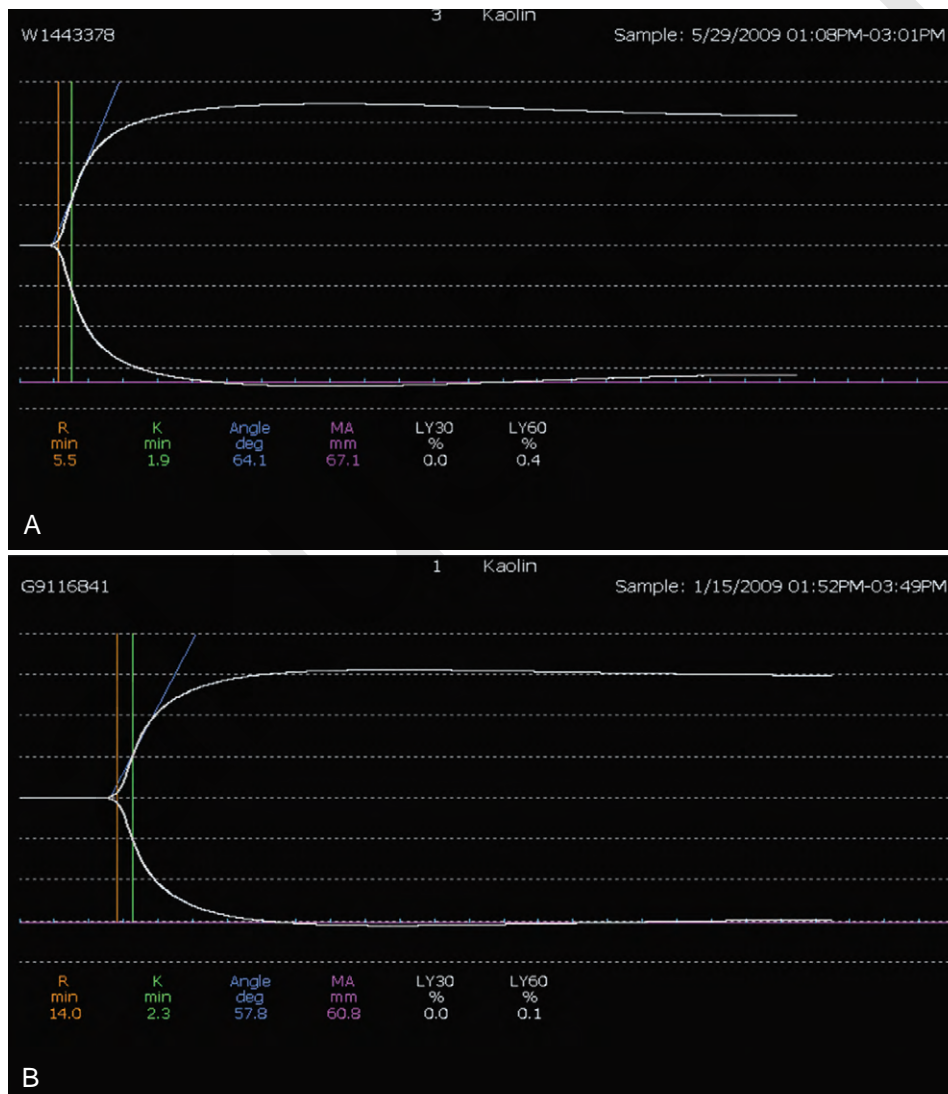

FIGURE 14-13. Thromboelastograms. **A**, Tracing shows normal clot formation. **B**, Prolonged reaction time (*R*) is shown for a child with an activated partial thromboplastin time of 56 seconds after cardiopulmonary bypass.

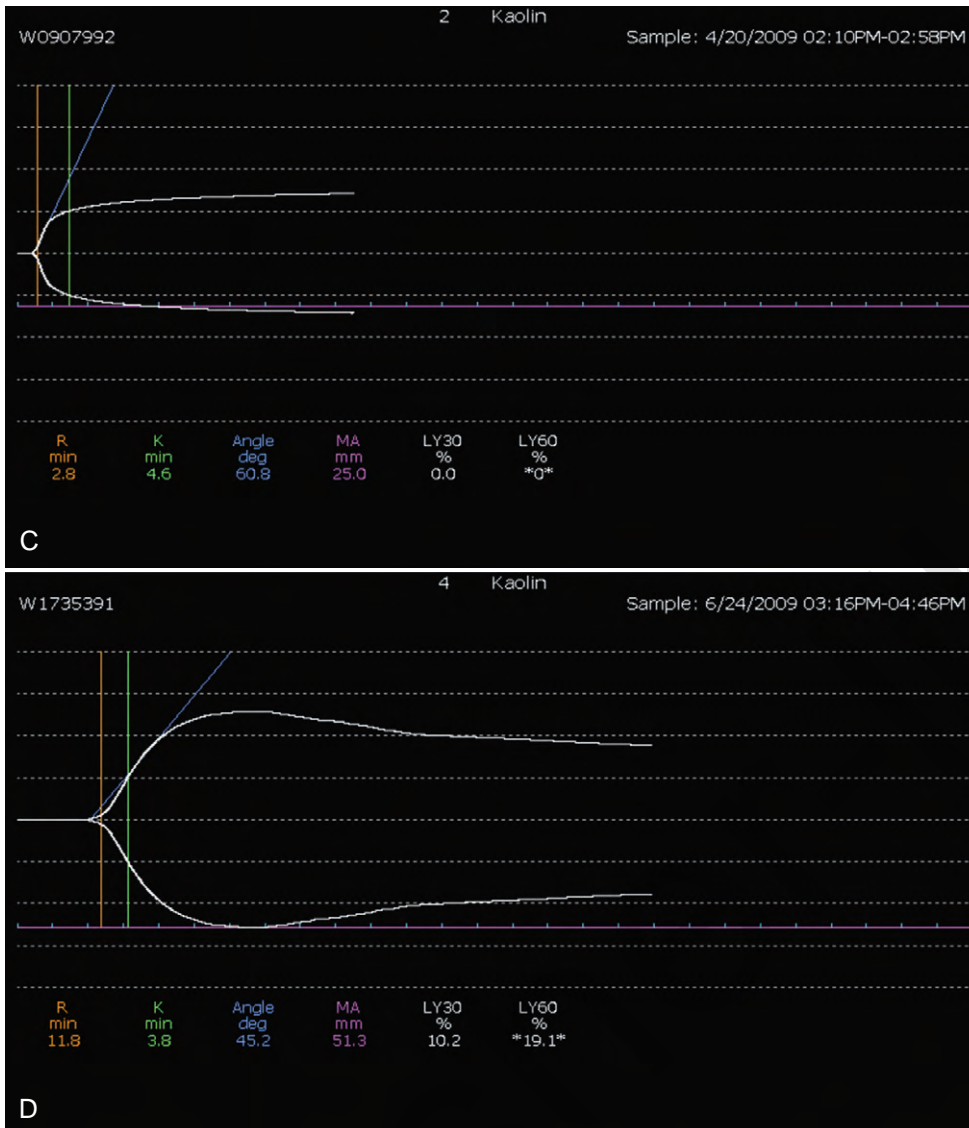

FIGURE 14-13—cont'd.

C, Tracing shows a low maximum amplitude (MA) in a child after cardiac surgery. The platelet count was $150 \times 10^9/L$, indicating that the platelets were likely dysfunctional after cardiopulmonary bypass.

D, Tracing shows relatively normal initial clot formation but excessive fibrinolysis in a child in the intensive care unit after cardiac surgery. Angle, Kinetics of fibrin formation and clot development; K, coagulation time; LY30, percentage lysis at 30 minutes after maximum amplitude; LY60, percentage lysis at 60 minutes after maximum amplitude. (All tracings were obtained using the TEG system, Courtesy of Haemoscope Corp, Niles, Ill.)

The changes in torque are transmitted to a recording device. The devices record changes in viscoelasticity at all stages of clot formation. The terminology varies between devices, but the important measurements and the corresponding stages of clot formation for the TEG system (Haemoscope Corp, Niles, Illinois) are shown in [Table 14-5](#) as an example (Ganter and Hofer, 2008).

Massive transfusion, particularly in trauma patients, predisposes the patient to hypothermia, a condition that worsens coagulopathy and blood loss. Monitoring for core body temperature is essential, and all fluids and blood products should be warmed. For small children, blood should be passed through the warmer into size-appropriate syringes for administration.

Citrate preservatives used for blood component storage must be considered in massive transfusions, because citrate binds serum calcium. Citrate metabolism is performed primarily by the liver, and patients with normal hepatic function usually do not have myocardial dysfunction as a result of citrate overload unless the transfusions are very rapid (greater than 1 unit of RBCs every 5 minutes in adults). Regardless, calcium levels should be monitored, and this can be quickly accomplished with point-of-care testing. Acidosis may occur with massive blood

loss because of inadequate oxygen delivery and the accumulation of lactate. However, with adequate resuscitation, metabolic alkalosis is common, because the liver metabolizes citrate to bicarbonate.

TABLE 14-5. Measurements and Corresponding Stages of Clot Formation for the TEG System*

Output	Stage of Clot Formation	Potential Causes of Abnormal Results
Reaction time	Initial fibrin formation	Factor deficiency, heparin
Alpha angle	Kinetics of fibrin formation and clot development	Fibrinogen deficiency
Maximum amplitude	Ultimate strength and stability of clot	Platelet deficiency or dysfunction
Clot lysis	Clot lysis	Fibrinolysis

* Haemoscope Corp, Niles, Ill.

INTRAOPERATIVE BLOOD RECOVERY

Cell salvage devices are made by several manufacturers, but they all operate under the same general principles: centrifugal and hydrostatic forces are used to differentiate between blood constituents on the basis of their different densities (Waters, 2005). Suction is used to transfer blood from the surgical field to a collection reservoir. In the reservoir, the blood must be anticoagulated with either a heparin or a citrate-based anticoagulant. When a sufficient amount of blood has been captured for processing, a cycle is activated and the blood is drained into a centrifuge bowl. Blood enters the bowl while the centrifuge is spinning. Centrifugal forces separate the various blood components, with the larger, heavier RBCs forming sediment against the walls and the lighter particles (plasma) forming sediment closer to the center of the bowl. Hydrostatic forces then draw the plasma out through the center of the bowl. After separation of the RBCs, they are washed with a balanced salt solution to remove debris. Typically, the wash volume is at least three times the bowl volume. After washing, the RBCs are transferred to a collection bag for infusion into the patient (Waters, 2005).

The average hematocrit level of a properly processed salvaged unit is approximately 60%, and the survival of salvaged RBCs is reportedly similar to that of allogenic RBCs (Williamson and Taswell, 1991). The efficacy of intraoperative cell salvage depends largely on the efficiency of capturing the patient's shed blood. High suction pressures lead to turbulence that may ultimately destroy the RBCs, so the lowest suction pressure that is effective at clearing the surgical field should be used. Suction tips with larger orifices further decrease turbulence on the RBCs. Because sponges may contain a considerable amount of shed blood, they should be rinsed and wrung out into a basin; the rinse solution is then drawn into the collection reservoir (Waters, 2005).

Studies evaluating the efficacy of intraoperative cell salvage in pediatric patients have had mixed results. One potential obstacle is the use of a large, adult-sized collection system for small children (Weldon, 2005). Although infants may lose a large portion of their blood volume during an operation, this loss is likely not of sufficient volume to allow processing. An exception is the use of an adult cell-salvage device to recover RBCs from the cardiopulmonary circuit after cardiac surgery. When a smaller, 125-mL bowl is used, the results have been more encouraging. One retrospective study found that cell salvage using a 125-mL collection bowl decreased the need for banked RBCs from 100% to 67% during craniotomostomy surgery (Jimenez and Barone, 1995). A second study, using an even smaller system that required only 35 mL of shed blood for processing, also showed a reduction in the exposure to donor RBCs (Dahmani et al., 2000). Not all cell salvage devices are equal. In a study by Booke and colleagues (1999), three cell-salvage devices were compared. Of the three devices, the Continuous Autotransfusion System (CATSplus) was the most efficient, providing the highest hematocrit and the largest volume of salvaged blood. The cost-benefit ratio of cell salvage is directly proportional to the number of units processed (Waters, 2005). Thus, with small patients, a large financial savings is unlikely to be realized. Regardless of cost, fewer donor exposures appears to have clear benefits.

Intraoperative cell salvage is not without risk. Transfer of blood directly from the holding bag carries the potential for air embolism, requiring that blood be transferred from the holding

bag to a transfusion bag with the air removed except in extreme emergencies when time does not allow. The wash solution must be a balanced salt solution, because the inadvertent substitution of sterile water would cause massive cell lysis and the readministration of lysed cells could result in potentially fatal hyperkalemia. Given that washing does not completely remove bacteria from the captured blood, gross bacterial contamination of the surgical field is a relative contraindication to the use of cell salvage (Hebert et al., 2003). Other relative contraindications include the presence of malignant cells or contaminants such as ascitic fluid, amniotic fluid, and thrombin gel.

BLOOD SUBSTITUTES

An oxygen-carrying substance that may be used as an alternative to donated RBCs for patients requiring transfusion has many potential advantages. This substance would likely have a longer shelf life, require less testing, be stored at room temperature, undergo viral inactivation, be universally biocompatible, and be easily supplied to areas where banked RBCs cannot be reliably obtained. Indeed, research has been ongoing in this area for at least 60 years. Two different substances have been studied: hemoglobin-based oxygen carriers (HBOCs) and perfluorocarbon (PFC) emulsions.

PFCs are inert substances that do not bind gases but act as solvents that can carry numerous gases, including oxygen. PFCs are insoluble in water and must be emulsified before administration. They are ultimately broken down by the reticuloendothelial system and exhaled as vapor; consequently they have a relatively short half-life (Tremper et al., 1982). Repeated administration results in hepatosplenomegaly in animals, and there appears to be a dose-dependent decrease in platelet count associated with administration (Leese et al., 2000). Because PFCs do not bind oxygen, their oxygen-carrying capacity is dependent on the partial pressure of oxygen. Patients must therefore receive high concentrations of inspired oxygen to have any meaningful oxygen delivery, and these high concentrations may carry the risk of pulmonary toxicity. In addition, unloading of oxygen at the tissue level is completely dependent on the oxygen gradients, and delivery tends to be poor. There are currently no FDA-approved PFCs, although third-generation PFCs are in preclinical development (Chang, 2000).

HBOCs were first studied in 1934 when Amberson purified bovine hemoglobin and administered it to animals (Jahr et al., 2007). These products consist of hemoglobin solutions that are polymerized or cross-linked (or both). When hemoglobin molecules are not contained by RBCs they rapidly scavenge nitric oxide, resulting in systemic (especially pulmonary) vasoconstriction, a release of proinflammatory mediators, and a loss of platelet inactivation (Wahr, 2003; Natanson et al., 2008). Cross-linking and polymerization of hemoglobin molecules has been proposed to increase the half-life of the molecules (free hemoglobin is rapidly scavenged by the reticuloendothelial system) and reduce nitric oxide-associated complications.

A meta-analysis of 16 trials that used five different HBOCs included a total of 3711 adult patients in various situations (Natanson et al., 2008). This analysis showed a significant increase in the risk of death (relative risk [RR], 1.30; 95% confidence interval [CI], 10.05 to 1.61) for patients treated with HBOCs. There was also a 2.7-fold increase in the risk of myocardial infarction for treatment patients (RR, 2.71; 95% CI, 1.67-4.40).

At present, there are no clinically viable alternatives to the transfusion of donor RBCs for the treatment of symptomatic anemia. As technology improves, more substances will be studied. However, with the poor track record of these substitutes thus far, rigorous study in animal models and adults will be required before substitutes are used in pediatric patients.

SUMMARY

In this chapter, we have attempted to provide the reader with the information required to understand hemoglobin function, techniques for RBC conservation, triggers that should prompt the clinician to consider blood product transfusion, and some of the safety and technical concerns related to the transfusion of various blood products. Ultimately, nothing can substitute for the sound clinical judgment of an experienced, well-informed pediatric anesthesiologist in the operating room

or at the bedside. The recognition of the need for transfusion in any child, although grounded in science, must ultimately rest with the judgment of the clinician. Likewise, the timing and choice of blood product are determined by myriad factors, some of which have been mentioned in this chapter. As with all aspects of pediatric anesthesia care, thoughtful application of the information derived from this chapter and text can provide the science. It is up to each clinician to provide the art that is fundamental to the safety of the children for whose care we are entrusted.

		Conclusion	451

"We must all die. But that I can save (a person) from days of torture, that is what I feel as my great and ever new privilege. Pain is a more terrible lord of mankind than even death itself" (Albert Schweitzer). The treatment and alleviation of pain is a basic human right that exists regardless of age (Yaster et al., 1997; Schechter et al., 2003). The old "wisdom" that young children neither respond to, nor remember, painful experiences to the same degree that adults do is simply untrue (Taddio and Katz, 2005). Many, if not all, of the nerve pathways essential for the transmission and perception of pain are present and functioning by 24 weeks' gestation (Lee et al., 2005; Lowery et al., 2007). Furthermore, recent research in newborn animals has revealed that the failure to provide analgesia for pain results in "rewiring" the nerve pathways responsible for pain transmission in the dorsal horn of the spinal cord and results in increased pain perception with future painful insults (Fitzgerald and Beggs,

2001; Pattinson and Fitzgerald, 2004). This confirms human newborn research in which the failure to provide anesthesia or analgesia for newborn circumcision resulted not only in short-term physiologic perturbations but also in longer term behavioral changes, particularly during immunization (Taddio et al., 1995; Maxwell et al., 1987; Taddio and Katz, 2005; Anand et al., 2006).

Providing effective analgesia to infants, preverbal children, adolescents, and the mentally and physically disabled poses unique challenges to those who practice pediatric medicine and surgery. In the past, several studies documented that physicians, nurses, and parents underestimate the amount of pain experienced by children and that they overestimate the risks inherent in the drugs used in the treatment of pain (Schechter et al., 1986; Finley et al., 1996; McGrath and Finley, 1996). This is not at all surprising; the guiding principle of medical

practice is to do no harm, *primum non nocere*. Physicians are taught throughout their training that opioids, the analgesics most commonly prescribed in moderate to severe pain, cause respiratory depression, cardiovascular collapse, depressed levels of consciousness, constipation, nausea, vomiting, and, with repeated use, tolerance and addiction. Less potent analgesics, such as nonsteroidal antiinflammatory drugs (NSAIDs), can also cause problems such as bleeding, liver dysfunction, coagulopathies, and impaired wound and bone healing. Thus, physicians at times prescribe insufficiently potent analgesics, recommend inadequate doses, or use pharmacologically irrational dosing regimens because of their overriding concern that children may be harmed by the use of these drugs. The resulting conundrum often results in inadequate treatment for pain and for painful procedures. On the other hand, the adverse effects of pain and the failure to treat it are rarely discussed. In addition to its impact on neurodevelopment, it is known that unrelieved pain interferes with sleep, leads to fatigue and a sense of helplessness, enhances the stress and inflammatory response, and may result in increased morbidity or mortality (Anand et al., 1987).

Nurses may be wary of physicians' orders (and patients' requests) as well. The most common prescription order for potent analgesics is "to give as needed" (*pro re nata*, or PRN). Thus, the patient must know or remember to ask for pain medication, or the nurse must identify when a patient is in pain. These requirements may not always be met by children in pain. Children younger than 3 years of age may be unable to adequately verbalize when or where they hurt. Alternatively, they may be afraid to report their pain. Many children withdraw or deny their pain if pain relief involves yet another terrifying and painful experience—the intramuscular injection or "shot." Finally, several studies have documented the inability of nurses, physicians, and parents to correctly identify and treat pain, even in postoperative pediatric patients (McGrath and Finley, 1996; Romsing et al., 1996; Fortier et al., 2009).

Societal fears of opioid addiction and lack of advocacy are also causal factors in the under treatment of pediatric pain. Unlike adult patients, pain management in children is often dependent on the ability of parents to recognize and assess pain and on their decision to treat or not treat it (Romsing and Walther-Larsen, 1996; Sutters and Miaskowski, 1997). Even in hospitalized patients, most of the pain that children experience is managed by the patient's parents (Greenberg et al., 1999; Krane, 2008). Parental misconceptions concerning pain assessment and pain management may therefore result in inadequate pain treatment (Romsing and Walther-Larsen, 1996; Fortier et al., 2009). This is particularly true in patients who are too young or too developmentally handicapped to report their pain themselves. Parents may fail to report pain, either because they are unable to assess it or they are afraid of the consequences of pain therapy. False beliefs about addiction and the proper use of acetaminophen and other analgesics resulted in the failure to provide analgesia to children (Forward et al., 1996; Fortier et al., 2009). In another study, the belief that pain was useful or that repeated doses of analgesics lead to medication not working well resulted in the failure of the parents to provide or ask for prescribed analgesics to treat their children's pain (Finley et al., 1996). Parental education is therefore essential if children are to be adequately treated for pain. Unfortunately, the ability to educate parents properly about this issue is often limited by insufficient resources, time, and personnel (Greenberg et al., 1999).

Fortunately, the past 25 years have seen an increase in research and interest in pediatric pain management and in the development of pediatric pain services, primarily under the direction of pediatric anesthesiologists (Shapiro et al., 1991; Nelson et al., 2009). Pediatric-pain service teams provide pain management for acute, postoperative, terminal, neuropathic, and chronic pain. This chapter reviews the recent advances in opioid and local anesthetic pharmacology, as well as the various modalities that are useful in the treatment of acute childhood pain.

PAIN ASSESSMENT

The International Association for the Study of Pain (IASP) defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (Merskey et al., 1979). Pain is a subjective experience; operationally it can be defined as "what the patient says hurts" and exists "when the patient says it does hurt." Infants, preverbal children, and children between the ages of 2 and 7 (Piaget's Preoperational Thought stage) may be unable to describe their pain or their subjective experiences. This has led many to conclude incorrectly that these children don't experience pain in the same way as adults. Clearly, children do not have to know (or be able to express) the meaning of an experience in order to have the experience (Anand and Craig, 1996). On the other hand, because pain is essentially a subjective experience, focusing on the child's perspective of pain is an indispensable facet of pediatric pain management and an essential element in the specialized study of childhood pain. Indeed, pain assessment and management are interdependent and one is essentially useless without the other. The goal of pain assessment is to provide accurate data about the location and intensity of pain, as well as the effectiveness of measures used to alleviate or abolish it.

Multiple validated instruments currently exist to measure and assess pain in children of all ages (von Baeyer and Spagrud, 2007; Crellin et al., 2007; Franck et al., 2000). The sensitivity and specificity of these instruments have been widely debated and have resulted in a plethora of studies to validate their reliability and validity. The most commonly used instruments that measure the quality and intensity of pain are "self-report measures." In older children and adults, the most commonly used self-report instruments are visual analogue scales (VASs) and numerical rating scales (0 = no pain; 10 = worst pain). However, pain intensity or severity can also be measured in children as young as 3 years of age by using pictures or word descriptors to describe pain. Two common examples include the Oucher Scale (developed by Dr. Judy Beyer), a two-part scale with a vertical numerical scale (0–100) on one side and six photographs of a young child on the other, or the Six-Face Pain Scale, first developed by Dr. Donna Wong and later modified by Bieri et al. (Fig. 15-1) (Beyer and Wells, 1989; Wong and Baker, 1988; Beyer et al., 1990). Because of its simplicity, the Six-Face Pain Scale-Revised is commonly used (Hicks et al., 2001; Bieri et al., 1990). Alternatively, color, word-graphic rating scales, and poker chips have been used to assess the intensity of pain in children. One obvious limitation of all of these self-report measures is their inability to be used in cognitively impaired children or in intubated, sedated, and paralyzed patients.

In infants, newborns, and the cognitively impaired, pain has been assessed by measuring physiologic responses to nociceptive

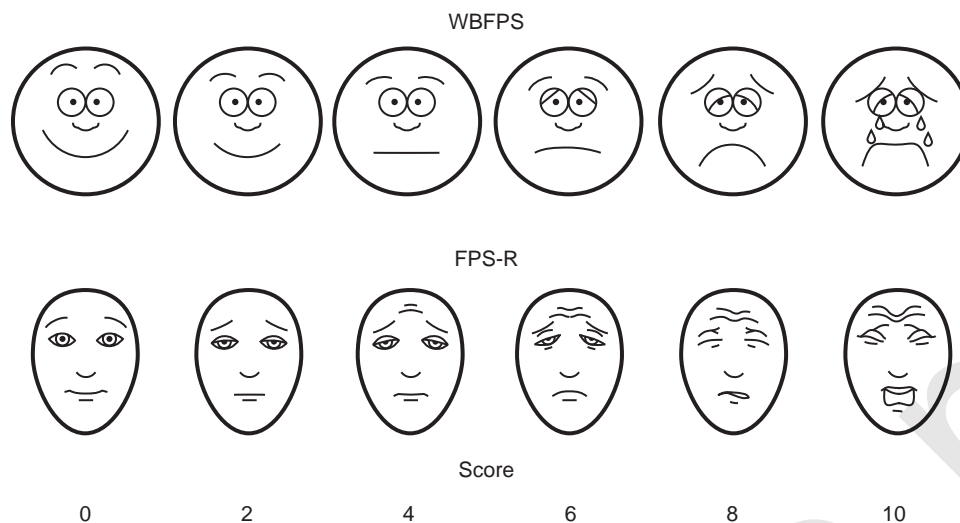

FIGURE 15-1. Six-Face Pain Scale (Top). Original scale developed by Wong et al. Lower, Modified scale by Bieri et al. (From Bieri D et al.: *The Faces Pain Scale for the self-assessment of the severity of pain experienced by children: development, initial validation, and preliminary investigation for ratio scale properties*, *Pain* 41:139, 1990; Beyer JE et al.: *Discordance between self-report and behavioral pain measures in children aged 3-7 years after surgery*, *J Pain Symptom Manage* 5:350, 1990.)

stimuli, such as blood pressure and heart rate changes (observational pain scales, OPSs), or by measuring levels of adrenal stress hormones (Krechel and Bildner, 1995). Alternatively, behavioral approaches have used facial expression, body movements, and the intensity and quality of crying as indices of response to nociceptive stimuli. The most appropriate are the Crying, Requires oxygen, Increased vital signs, Expression, and Sleepless (CRIES) score for newborns and the revised Face, Legs, Activity, Cry, and Consolability (FLACC) pain tool for children who have difficulty verbalizing pain (Tables 15-1 and 15-2) (Grunau et al., 1990; Hadjistavropoulos et al., 1994; Voepel-Lewis et al., 2002). Another commonly used pain and sedation tool that uses both behaviors and physiologic parameters is the COMFORT scale, which relies on the measurement of five behavioral variables (alertness, facial tension, muscle tone, agitation, and movement) and three physiologic variables (heart rate, respiration, and blood pressure) (Table 15-3) (Ambuel et al., 1992; Bear and Ward-Smith, 2006). Each is assigned a score ranging

from 1 to 5, to give a total score ranging from 8 (deep sedation) to 40 (alert and agitated). A modified COMFORT scale that eliminates physiologic parameters has also been developed (Ista et al., 2005). It is also important to define accurately the location of pain. This is readily accomplished by using either dolls or action figures or by using drawings of body outlines, both front and back. Finally, in the research laboratory, sophisticated new tools such as functional magnetic resonance imaging (MRI) are being used to objectively assess and map pain and its pathways through the central nervous system (CNS) (Tracey and Mantyh, 2007).

NEUROPHYSIOLOGY OF PAIN

Pain is more than simply the physiologic transmission of nociceptive input from a site of injury to the brain and its modulation within the CNS. Rather, it is a complex sensation that is integrated and given value at higher, conscious brain centers. No two people experience it the same way. It is similar to symphonic music; despite the fact that the physiology of sound transmission is the same in everyone, symphonic music to some is simply awful and to others it is glorious. As individuals integrate neural transmissions, they give them personal, subjective value based on age, culture, genes, previous experience and education, values, and state of mind. The same is true for pain.

Many if not all of the nerve pathways essential for the transmission, perception, and modulation of pain are present and functioning by 24 weeks of gestation (Fig. 15-2) (Lowry et al., 2007; Lee et al., 2005). Although neural transmission in peripheral nerves is slower in neonates because myelination is incomplete at birth, the major nociceptive neurons in neonates as well as in adults are either unmyelinated C fibers or thinly myelinated A δ fibers. After an acute injury such as surgical or accidental trauma, inflammatory mediators are released; they lower the pain threshold at the site of injury (primary hyperalgesia) and in the surrounding uninjured tissue (secondary

TABLE 15-1. CRIES Neonatal Pain Assessment Scale

Indicator	Score		
	0	1	2
Crying	No	High pitch but consolable	Inconsolable
Requires oxygen for Sat >95%	No	Fio ₂ < 30%	Fio ₂ > 30%
Increased vital signs	No	HR or BP increased <20%	HR or BP increased >20%
Expression	No	Grimace	Grimace and grunt
Sleepless	No	Wakes often	Constantly awake

Score <4: Initiate nonpharmacologic measures.

Score >4: Initiate pharmacologic and nonpharmacologic measures.

BP, Blood pressure; HR, heart rate.

TABLE 15-2. Revised FLACC for Pain Assessment in the Cognitively Impaired*

	0	1	2
Face	No particular expression or smile	Occasional grimace/frown; withdrawn or disinterested (appears sad or worried)	Consistent grimace or frown; frequent/constant quivering chin, clenched jaw (distressed-looking face; expression of fright or panic)
Legs	Normal position or relaxed	Uneasy, restless, tense (occasional tremors)	Kicking, or legs drawn up (marked increase in spasticity, constant tremors, or jerking)
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense (mildly agitated [e.g., head back and forth, aggression]; shallow, splinting respirations, intermittent sighs)	Arched, rigid, or jerking (severe agitation, head banging; shivering [not rigors]; breath-holding, gasping or sharp intake of breath; severe splinting)
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint (occasional verbal outburst or grunt)	Crying steadily, screams or sobs, frequent complaints (repeated outbursts, constant grunting)
Consolability	Content, relaxed	Reassured by occasional touching, hugging or talking; distractible	Difficult to console or comfort (pushing away caregiver, resisting care or comfort measures)

*Revised descriptors for children with disabilities shown in parentheses.
0 = Relaxed/comfortable; 1-3 = mild discomfort; 4-6 = moderate pain; 7-10 = severe pain.

TABLE 15-3. Comfort Scale

	1	2	3	4	5
Alertness	Deeply asleep	Lightly asleep	Drowsy	Fully awake and alert	Hyper-alert
Calmness or agitation	Calm	Slightly anxious	Anxious	Very anxious	Panicky
Respiratory response	No coughing and no spontaneous respirations	Spontaneous reparation with little or no response to ventilation	Occasional cough or resistance to ventilator	Actively breathes against ventilator or coughs regularly	Fights ventilator; coughing or choking
Physical movement	No movement	Occasional, slight movement	Slight movement often	Vigorous movement limited to extremities	Vigorous movement including torso and head
Blood pressure	Less than baseline	Consistently at baseline	Occasional increases of 15% or more (1-3 episodes during observation period)	Multiple increases of 15% or more (>3 episodes)	Sustained increase >15%
Muscle tone	Muscles totally relaxed; no muscle tone	Reduced muscle tone	Normal muscle tone	Increased muscle tone and flexion of fingers and toes	Extreme muscle rigidity and flexion of fingers and toes
Facial tension	Facial muscles totally relaxed	Facial muscle tone normal; no facial muscle tension evident	Tension evident in some facial muscles	Tension evident throughout facial muscles	Facial muscles contorted and grimacing

hyperalgesia). These inflammatory mediators, which include hydrogen and potassium ions, histamine, leukotrienes, prostaglandins, cytokines, serotonin (5-HT), bradykinins, and nerve-growth factors make a “sensitizing soup,” which together with repeated stimuli of the nociceptive fibers cause decreased excitatory thresholds and result in peripheral sensitization. They are also targets of therapeutic intervention (Fig. 15-3). Secondary effects of peripheral sensitization include hyperalgesia, the increased response to a noxious stimulus and allodynia, whereby non-nociceptive fibers transmit noxious stimuli resulting in the sensation of pain from non-noxious stimuli.

Sensory afferent neurons have a unipolar cell body located in the dorsal root ganglion and are classified by fiber size into three major groups (A, B, C) (Table 15-4). Group A is further subclassified into four subgroups. Sensory fibers that respond

to noxious stimulation include small caliber myelinated (A δ) or fine unmyelinated C fibers. These fibers originate as free nerve endings that can be characterized by their response to specific stimuli such as pressure, heat, and chemical irritants and arise from epidermal and internal receptive fields, including the periosteum, joints, and viscera. The A δ nociceptors transmit “first pain,” which is well localized, sharp, and lasts as long as the original stimulus. The C-fiber, polymodal nociceptors display a slow conduction velocity and respond to mechanical and chemical stimuli. This “second pain” is diffuse, persistent, burning, slow to be perceived, and lasts well beyond the termination of the stimulus.

As the primary afferent neurons enter the spinal cord they segregate and occupy a lateral position in the dorsal horn (Fig. 15-4). The A δ fibers terminate in laminae I, II (substantia

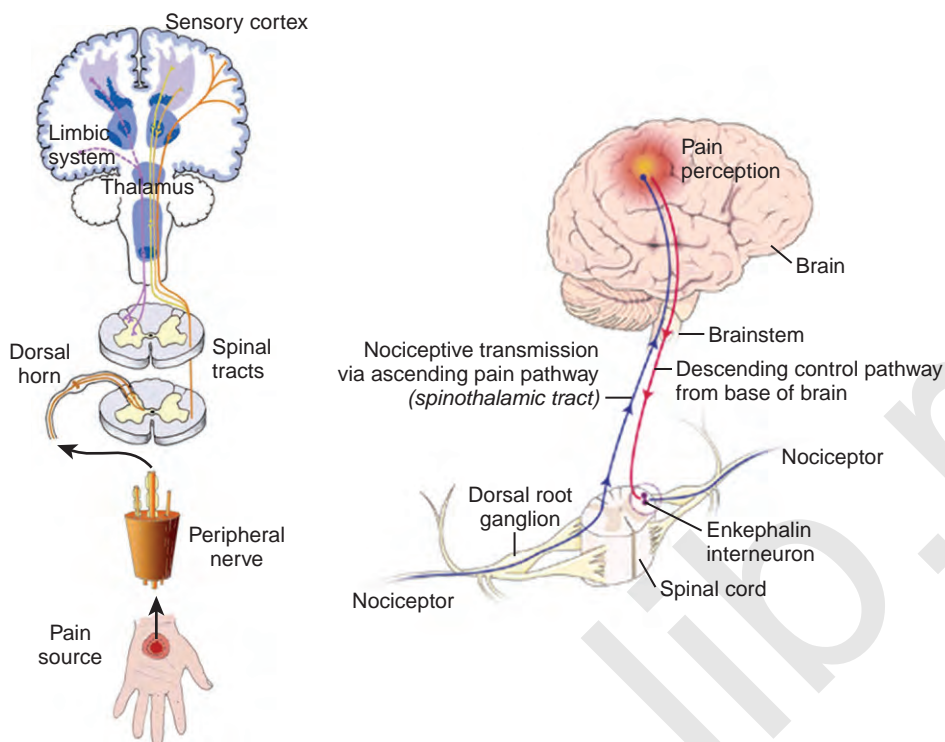

FIGURE 15-2. Nociceptive nerve pathways essential for the transmission, perception, and modulation of pain are depicted. *Left:* After an injury, nociceptive fibers carried in peripheral nerves enter the spinal cord via the dorsal horn. They are then transmitted via ascending spinothalamic, spinoreticular, and spinomesencephalic tracts to the thalamus, limbic system, and sensory cortex. *Right:* From the sensory cortex descending control pathways modulate pain in the spinal cord and in the periphery.

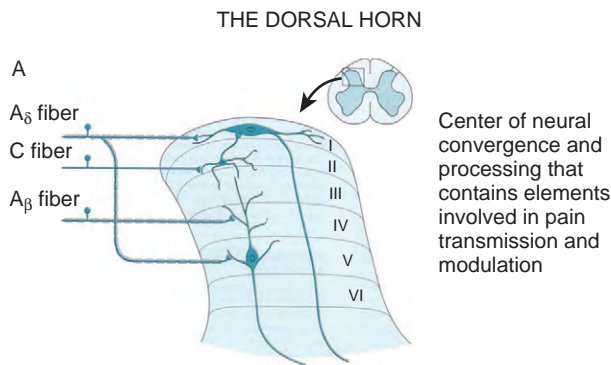

FIGURE 15-3. After an acute injury, inflammatory mediators are released. They lower the pain threshold at the site of injury (primary hyperalgesia) and in the surrounding uninjured tissue (secondary hyperalgesia). Repetitive stimulation of nociceptors and continuous neuronal discharge (peripheral sensitization) leads to central sensitization or windup. The combination of peripheral and central sensitization is responsible for a decrease in the pain threshold, both at the site of injury (primary hyperalgesia) and in the surrounding uninjured tissue (secondary hyperalgesia).

TABLE 15-4. Classification of Peripheral Nerve Fibers

Fiber Group	Innervation	Mean Diameter (mm)	Mean Conduction Velocity (mm/sec)
A α (M)	Primary muscle spindle, motor to skeletal muscle	15	100
A β (M)	Cutaneous touch and pressure afferents	8	50
A γ (M)	Motor to muscle spindles	6	20
A δ (M)	Mechanoreceptors and nociceptors	< 3	15
B (M)	Sympathetic preganglionic	3	7
C (UM)	Mechanoreceptors, nociceptors, and sympathetic preganglionic fibers	1	1

M, Myelinated; UM, unmyelinated.

gelatinosa), V (nucleus proprius), and X (central canal). The C fibers terminate in laminae I, II, and V, and some enter the dorsal horn through the ventral root. These afferent neurons release one or more excitatory amino acids (e.g., glutamate and aspartate) or peptide neurotransmitters (e.g., substance P, neurokinin A, calcitonin gene-related peptide [CGRP], cholecystokinin,

■ **FIGURE 15-4.** Primary afferent neurons enter the spinal cord, segregate, and occupy a lateral position in the dorsal horn. Their termination in distinct zones, or laminae, is depicted.

and somatostatin). Second-order neurons that receive these chemical signals integrate the afferent input with facilitatory and inhibitory influences of interneurons and descending neuronal projections. It is this convergence within the dorsal horn that is responsible for much of the processing, amplification, and modulation of pain. Furthermore, the ability to simultaneously process noxious and innocuous stimuli underlies the gate-control theory of pain described by Melzack and Wall (Melzack and Wall, 1965; DeLeo, 2006).

Second-order neurons are of two types: nociceptive specific neurons, which respond exclusively to nociceptive impulses from A_δ and C fibers, and wide dynamic range (WDR) neurons, which respond to both noxious and nonpainful stimuli. At a given dermatomal level, WDR neurons receive afferent input from the skin, muscle, and visceral nociceptors. Low-frequency stimulation of C fibers leads to a gradual increase in WDR neuronal discharge until it reaches a state of near continuous discharge called *central sensitization* or *wind-up*. Occupancy of the N-methyl-D-aspartic acid (NMDA) receptor by glutamate in the presence of glycine and the removal of the calcium channel's magnesium plug are crucial in the development of wind-up. In combination with peripheral sensitization, these two processes contribute to the postinjury hypersensitivity state that is responsible for a decrease in the pain threshold, both at the site of injury (primary hyperalgesia) and in the surrounding uninjured tissue (secondary hyperalgesia). It is largely as a result of this mechanism that pain may be prolonged beyond the duration normally expected after an acute insult. Prolonged central sensitization has the capacity to lead to permanent alterations in the CNS, including the death of inhibitory neurons, replacement with new afferent excitatory neurons, and the establishment of aberrant excitatory synaptic connections. These alterations can lead to a prolonged state of sensitization, resulting in intractable postoperative pain that is unresponsive to many analgesics.

Nociceptive activity in the spinal cord and the ascending spinothalamic, spinoreticular, and spinomesencephalic tracts carry messages to supraspinal centers (e.g., periaqueductal gray, locus coeruleus, hypothalamus, thalamus, and cerebral cortex) where they are modulated and integrated with autonomic, homeostatic, and arousal processes. This modulation, particularly by the endogenous opioids, γ -aminobutyric acid (GABA), and norepinephrine (NE), can either facilitate

pain transmission or inhibit it. Modulating pain at peripheral, spinal, and supraspinal sites helps achieve better pain management than targeting only one site and is the underlying principle of treating pain in a multimodal fashion (Fig. 15-3).

Although pain pathways are present at birth, they are often immature (Lee et al., 2005; Lowery et al., 2007). As a result, there are considerable differences in how an infant responds to injury compared with the way an adult does. Within the developing nervous system, inhibitory mechanisms in the dorsal horn of the spinal cord are immature, and inhibition of nociceptive input in the dorsal horn of the spinal cord is less than in the adult. Furthermore, dorsal horn neurons in the newborn have wider receptive fields and lower excitatory thresholds than those in older children (Torsney and Fitzgerald, 2003; Bremner and Fitzgerald, 2008; Fitzgerald and Walker, 2009). Thus, compared with adults, young infants have exaggerated reflex responses to pain. Furthermore, recent research in newborn animals has revealed that the failure to provide analgesia for pain results in “rewiring” the nerve pathways responsible for pain transmission in the dorsal horn of the spinal cord and results in increased pain perception for future painful insults (Fitzgerald and Beggs, 2001; Pattinson and Fitzgerald, 2004). This confirms human newborn research in which the failure to provide anesthesia or analgesia for newborn circumcision resulted not only in short-term physiologic perturbations but also in longer term behavioral changes, particularly during immunization (Maxwell et al., 1987; Taddio et al., 1995; Taddio and Katz, 2005).

Preemptive Analgesia, Preventive Analgesia, and Multimodal Analgesia

The possibility that pain after surgery might be preemptively prevented or ameliorated by the use of opioids or local anesthetics given preoperatively has been a concept under review (Katz and McCartney, 2002; Moiniche et al., 2002; Oong et al., 2005). Over the past few years the concept of preemptive analgesia has expanded and evolved to include the reduction of nociceptive inputs during and after surgery. This expanded conceptual framework, which includes preoperative, intraoperative, and postoperative analgesia, targets multiple sites along the pain pathway and is referred to as *preventive* or *multimodal* analgesia (Ballantyne, 2001; Katz and McCartney, 2002). Indeed, acute pediatric (and adult) pain management is increasingly characterized by a multimodal or “balanced” approach in which smaller doses of opioid and nonopioid analgesics, such as NSAIDs, local anesthetics, NMDA antagonists, and α_2 -adrenergic agonists, are combined to maximize pain control and minimize drug-induced adverse side effects (Fig. 15-5) (DeLeo, 2006). Additionally, a multimodal approach also uses nonpharmacologic complementary and alternative medicine therapies. These alternative medical therapies include distraction, guided imagery, hypnosis, relaxation techniques, biofeedback, transcutaneous nerve stimulation, and acupuncture (Rusy and Weisman, 2000). Taking this approach, activation of peripheral nociceptors can be attenuated with the use of NSAIDs, antihistamines, 5-HT antagonists, and local anesthetics (Fig. 15-5). Within the dorsal horn, nociceptive transmission and processing can be further affected by the administration of local anesthetics, neuraxial opioids, α_2 -adrenergic agonists (e.g., clonidine and dexmedetomidine),

■ **FIGURE 15-5.** Supraspinal, spinal, and peripheral targets of multimodal pain therapy are depicted. Peripheral nociceptors are targets of NSAIDs, antihistamines, 5-HT antagonists, opioids, and local anesthetics. Within the dorsal horn, nociceptive transmission and processing can be affected by the administration of local anesthetics, opioids, α_2 -adrenergic agonists and NMDA-receptor antagonists. Within the CNS, pain can be ameliorated by opioids, α_2 -agonists, α_2 - δ ligand agonists, and pharmacologic and nonpharmacologic therapies that reduce anxiety and induce rest and sleep.

and NMDA receptor antagonists (e.g., ketamine and methadone). Within the CNS, pain can be ameliorated by systemic opioids, α_2 -agonists, anticonvulsants (e.g., gabapentin and pregabalin), pharmacologic therapies (e.g., benzodiazepines, α_2 -agonists), and nonpharmacologic therapies (e.g., hypnosis, Lamaze, and acupuncture) that reduce anxiety and induce rest and sleep.

PHARMACOLOGIC MANAGEMENT OF PAIN: THE CONUNDRUM OF "OFF-LABEL" DRUG USE

Unfortunately, very few studies have evaluated the pharmacokinetic and pharmacodynamic properties of drugs in children (Conroy and Peden, 2001; Katz and Kelly, 1993). Most pharmacokinetic studies are performed using healthy adult volunteers, adult patients who are only minimally ill, or adult patients in a stable phase of a chronic disease. These data are then extrapolated to infants, children, and adolescents, and the medications are prescribed "off-label." So little pharmacokinetic and pharmacodynamic testing has been performed in children that they are often considered "therapeutic orphans" (Blumer, 1999). In addition, drug formulations designed for adults are often manipulated and altered by practitioners for use in children (e.g., tablets are dissolved to make a liquid formulation, or suppositories are cut in half). The U.S. Congress has enacted the Best Pharmaceuticals for Children Act, the Pediatric Research Equity Act, and the Food and Drug Administration (FDA) Amendments Act to promote standards and requirements for the use and labeling of pediatric drugs (BPCA, 2002; PREA, 2003; FDAAA, 2007).

PHARMACOLOGIC MANAGEMENT OF PAIN

Nonopioid Analgesics (or Weaker Analgesics with Antipyretic Activity)

The weaker or milder analgesics with antipyretic activity, of which acetaminophen (paracetamol), salicylate (aspirin), ibuprofen, naproxen, ketoprofen, and diclofenac are common examples, comprise a heterogeneous group of NSAIDs and nonopioid analgesics (Table 15-5) (Agency for Health Care Policy and Research, 1992; Yaster, 1997; Tobias, 2000b; Kokki, 2003). They produce their analgesic, antiinflammatory, antiplatelet, and antipyretic effects primarily by blocking peripheral and central prostaglandin and thromboxane production by inhibiting cyclooxygenase (COX) types 1, 2, and 3 (Fig. 15-6). These metabolites of cyclooxygenase sensitize peripheral nerve endings and vasodilate the blood vessels causing pain, erythema, and inflammation.

These analgesic agents are administered enterally via the oral or, on occasion, the rectal route and are particularly useful for inflammatory, bony, or rheumatic pain. Parenterally administered agents, such as ketorolac and acetaminophen, are available for use in children in whom the oral or rectal routes of administration are not possible (Murat et al., 2005). Unfortunately, regardless of dose, the nonopioid analgesics are limited by a "ceiling effect" above which pain cannot be relieved by these drugs alone. Because of this, these weaker analgesics are often administered in oral combination forms with opioids such as codeine, oxycodone, or hydrocodone.

Only a few trials have compared the efficacy of these drugs in head to head competition, and in general these studies have shown that there are no major differences in their analgesic effects when appropriate doses of each drug are used. The commonly used NSAIDs, such as ketorolac, diclofenac, ibuprofen, and ketoprofen, have reversible antiplatelet adhesion and aggregation effects that are attributable to the inhibition of thromboxane synthesis (Niemi et al., 1997; Munsterhjelm et al., 2006). As a result, bleeding times are usually slightly increased, but in most instances they remain within normal limits in children with normal coagulation systems. Nevertheless this side effect is of such great concern, particularly in surgical procedures in which even a small amount of bleeding can be catastrophic (e.g., tonsillectomy and neurosurgery), that few clinicians prescribe them even though the evidence supporting increased bleeding is equivocal at best (Moiniche et al., 2003; Cardwell et al., 2005). Finally, many orthopedic surgeons are also concerned about the negative influence of all NSAIDs, both selective and nonselective COX inhibitors, on bone growth and healing (Simon et al., 2002; Einhorn, 2003; Dahners and Mullis, 2004). Thus, most pediatric orthopedic surgeons have recommended that these drugs not be used in their patients in the postoperative period.

The discovery of at least three COX isoenzymes (COX-1, COX-2, and COX-3) has enhanced our knowledge of NSAIDs (Cashman, 1996; Vane and Botting, 1998). The COX isoenzymes share structural and enzymatic similarities, but they are specifically regulated at the molecular level and may be distinguished by their functions. Protective prostaglandins, which preserve the integrity of the stomach lining and maintain normal renal function in a compromised kidney, are synthesized by COX-1 (Vane and Botting, 1998; Moiniche et al., 2003; Levesque et al.,

TABLE 15-5. Dosage Guidelines for Commonly Used Nonsteroidal Antiinflammatory Drugs

Generic Name	Brand Name	Dose (mg/kg) Frequency	Maximum Adult Daily Dose (mg)	Comments
Acetaminophen (paracetamol)	Many brand names, e.g., Tylenol, Aspirin-Free Pain Relief, Panadol, Tempra	10-15 PO q 4 h 20-40 PR q 6-8 h	4000 60 mg/kg/d preterm 70 mg/kg/d term 90 mg/kg/d older	Lacks antiinflammatory activity No platelet effects Hepatic failure with overdose IV form available in Europe
Acetylsalicylic acid (aspirin)	Many brand names, e.g., Bayer, Bufferin, Anacin, Alka-Seltzer	10-15 PO/PR q 4 h	4000	Inhibits platelet aggregation GI irritability Reye's syndrome
Choline magnesium trisalicylate	Trilisate	7.5-15 PO q 6-12 h	4000	Aspirin compound that does not affect platelets
Ibuprofen	Many brand names, e.g., Motrin, Advil	4-10 PO q 6-8 h	2400	Available as an oral suspension Renal dysfunction Gastrointestinal irritability Inhibits platelet aggregation
Indomethacin	Indocin	0.3-1.0 PO q 6 h	150	Commonly used IV to close PDA (See Ibuprofen)
Naproxen	Naprosyn	5-10 PO q 12 h	1500	(See Ibuprofen)
Ketorolac	Toradol	IV or IM Load 0.5 Maint 0.2-0.5 q 6 h PO 0.25	120	May be given orally Maximum dose 30 mg Causes gastrointestinal upset and ulcer, discontinue after 5 days Expensive (See Ibuprofen)

PO, Orally; PR, rectally; PDA, patent ductus arteriosus; IV, intravenously; IM, intramuscularly.

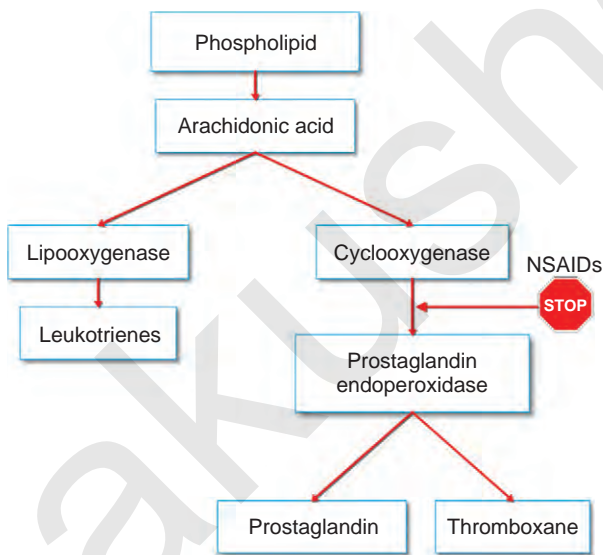

FIGURE 15-6. The peripheral and central prostaglandin and thromboxane production inhibition by cyclooxygenase is depicted. Note that the inhibition of cyclooxygenase leads to increased production of leukotrienes.

constitutively in the brain and spinal cord, where it may be involved in nerve transmission, particularly for pain and fever. Prostaglandins made by COX-2 are also important in ovulation and in the birth process (Vane and Botting, 1998; Moiniche et al., 2003; Levesque et al., 2005). The discovery of COX-2 has made possible the design of drugs that reduce inflammation without removing the protective prostaglandins in the stomach and kidneys made by COX-1. In fact, developing a more specific COX-2 inhibitor was a “holy grail” of drug research, because this class of drug was postulated to have all of the desired anti-inflammatory and analgesic properties with none of the gastrointestinal and antiplatelet side effects. Unfortunately, the controversy regarding the potential adverse cardiovascular risks of prolonged use of COX-2 inhibitors has dampened much of the enthusiasm for these drugs and has led to the removal of rofecoxib from the market by its manufacturer (Johnsen et al., 2005; Levesque et al., 2005).

Aspirin

2005). The COX-2 isoenzyme is inducible by proinflammatory cytokines and growth factors, implying a role for COX-2 in both inflammation and control of cell growth. In addition to the induction of COX-2 in inflammatory lesions, it is expressed

Aspirin, one of the oldest and most effective nonopioid analgesics, has been largely abandoned in pediatric practice because of its possible role in Reye’s syndrome, its effects on platelet function, and its gastric irritant properties. Despite these problems, a “sister” compound, choline-magnesium trisalicylate is still prescribed, particularly in the management of postoperative pain and in the child with cancer. Choline-magnesium trisalicylate is a unique aspirin-like compound that does not bind to platelets and therefore has minimal, if any, effects on platelet function

(Yaster, 1997). As a result, it can be prescribed to patients with low platelet counts (cancer patients), dysfunctional platelets (uremia), and in the postoperative period. It is a convenient drug to give to children because it is available in both a liquid and tablet form and is administered either twice a day or every 6 hours. However, the association of salicylates with Reye's syndrome limits its use, even though the risk of developing this syndrome postoperatively is extremely unlikely.

Acetaminophen

The most commonly used nonopioid analgesic in pediatric practice remains acetaminophen, although its analgesic effectiveness in the neonate is unclear (Shah et al., 1998; Anderson, 2008). Unlike aspirin and other NSAIDs, acetaminophen produces analgesia centrally as a COX-3 inhibitor and via activation of descending serotonergic pathways (Graham and Scott, 2005; Anderson, 2008). It is also thought to produce analgesia as a cannabinoid agonist and by antagonizing NMDA and substance P in the spinal cord (Bertolini et al., 2006). Acetaminophen is an antipyretic analgesic with minimal, if any, antiinflammatory and antiplatelet activity and takes about 30 minutes to provide effective analgesia. When administered orally in standard doses, 10 to 15 mg/kg acetaminophen is extremely safe, effective, and has few serious side effects. When administered rectally, higher doses of 25 to 40 mg/kg are required (Rusy et al., 1995; Birmingham et al., 1997). Because of its known association with fulminant hepatic necrosis, the daily maximum acetaminophen dosages, regardless of formulation or route of delivery, in the preterm infant, full-term infant, and older child are 60, 80, and 90 mg/kg respectively (Table 15-5). Thus, when administering acetaminophen rectally it should be given every 8 hours rather than every 4 hours. Finally, an intravenous formulation of acetaminophen is now available in Europe and can be used in patients in whom the enteral route is unavailable. This formulation has been associated with better analgesia than oral acetaminophen in clinical trials in adult patients and is equally effective and less painful than the prodrug formulation of the drug in children (Murat et al., 2005).

Opioids

Overview

Over the past 30 years, multiple opioid receptors and subtypes have been identified and classified. There are 3 primary opioid receptor types, designated mu (μ) (for morphine), kappa (κ), and delta (δ). These receptors are primarily located in the brain and spinal cord, but they also exist peripherally on peripheral nerve cells, immune cells, and other cells (e.g., oocytes) (Sabbe and Yaksh, 1990; Snyder and Pasternak, 2003; Stein and Rosow, 2004). The μ -receptor is further subdivided into several subtypes such as the $\mu 1$ (supraspinal analgesia), $\mu 2$ (respiratory depression, inhibition of gastrointestinal motility), and $\mu 3$ (antiinflammation, leukocytes), which affects the pharmacologic profiles of different opioids (Pasternak, 2001a, 2001b, 2005; Bonnet et al., 2008). Both endogenous and exogenous agonists and antagonists bind to various opioid receptors.

The differentiation of agonists and antagonists is fundamental to pharmacology. A neurotransmitter is defined as having agonist activity, whereas a drug that blocks the action of a neurotransmitter is an antagonist. By definition, receptor

recognition of an agonist is "translated" into other cellular alterations (i.e., the agonist initiates a pharmacologic effect), whereas an antagonist occupies the receptor without initiating a transduction step (i.e., it has no intrinsic activity or efficacy). The intrinsic activity of a drug defines the ability of the drug-receptor complex to initiate a pharmacologic effect. Drugs that produce less than a maximal response have a lowered intrinsic activity and are called *partial agonists*. Partial agonists also have antagonistic properties, because by binding the receptor site, they block access of full agonists to the site. Morphine and related opioids are μ -agonists, whereas drugs that block the effects of opioids at the μ -receptor, such as naloxone, are designated antagonists. The opioids most commonly used in anesthetic practice and in the management of pain are μ -agonists. These include morphine, meperidine (pethidine), methadone, and the various fentanyl. Mixed agonist-antagonist drugs act as agonists or partial agonists at one receptor and antagonists at another receptor. Mixed (opioid) agonist-antagonist drugs include pentazocine, butorphanol, buprenorphine, nalorphine, and nalbuphine. Most of these drugs are agonists or partial agonists at the κ - and σ -receptors and antagonists at the μ -receptor. Naloxone and its oral equivalent, naltrexone, are nonspecific opioid antagonists.

Opioid receptors, which are found anchored to the plasma membrane both presynaptically and postsynaptically, decrease the release of excitatory neurotransmitters from terminals carrying nociceptive stimuli. These receptors belong to the steroid superfamily of G protein-coupled receptors. Their protein structure contains seven transmembrane regions with extracellular loops that confer subtype specificity and intracellular loops that mediate subreceptor phenomena (Stein and Rosow, 2004). These receptors are coupled to guanine nucleotide (GTP)-binding regulatory proteins (G proteins) and regulate transmembrane signaling by regulating adenylate cyclase (and therefore cyclic adenosine monophosphate [cAMP]), various ion channels (K^+ , Ca^{++} , Na^+) and transport proteins, neuronal nitric oxide synthetase, and phospholipase C and A2 (Fig. 15-7) (Standifer and Pasternak, 1997; Maxwell et al., 2005; Pasternak, 2005). Signal transduction from opioid receptors occurs via bonding to inhibitory G proteins (G_i and G_o). Analgesic effects are mediated by decreased neuronal excitability from an inwardly rectifying K^+ current, which hyperpolarizes the neuronal membrane, decreases cAMP production, increases nitric oxide synthesis, and increases the production of 12-lipoxygenase metabolites. Indeed, synergism between opioids and NSAIDs occurs as a result of the greater availability of arachidonic acid for metabolism by the 12-lipoxygenase pathway, after blockade of prostaglandin production by NSAIDs (Vaughan et al., 1997). Some of the unwanted side effects of opioids, such as pruritus, may be the result of opioid binding to stimulatory G proteins (G_s) and may be antagonized by low dose infusions of naloxone (Fig. 15-7) (Crain and Shen, 1998, 1996; Maxwell et al., 2005).

Pharmacokinetics

For opioids to effectively relieve or prevent most pain, the agonist must reach the receptor in the CNS. There are essentially two ways that this occurs, either via the bloodstream (after intravenous, intramuscular, oral, nasal, transdermal, or mucosal administration) or by direct application into the cerebrospinal fluid (intrathecal or epidural). Agonists administered via the bloodstream must cross the blood-brain barrier, a lipid membrane interface between the endothelial cells of the brain

FIGURE 15-7. Opioid receptors are coupled to GTP binding regulatory proteins (G proteins) and regulate transmembrane signaling by regulating adenylate cyclase (cyclic AMP), various ion channels (K^+ , Ca^{++} , Na^+) and transport proteins, neuronal nitric oxide synthetase, and phospholipase C and A2. **A**, Under basal conditions, G proteins exist in cell membranes as heterotrimers composed of single alpha (a), beta (b), and gamma (g) subunits. The α subunits are bound by GDP, and the G protein heterotrimer is anchored to the plasma membrane by the γ subunit. **B** and **C**, After the opioid receptor (Y) is activated by a μ -agonist ligand (\blacktriangledown) (e.g., morphine), it physically associates with the α subunit, causing the latter to release GDP and bind GTP. The GTP binding causes the dissociation of the α subunit from the β - γ subunit and from the receptor. Free α and β - γ subunits are functionally active and directly regulate a number of effector proteins, such as ion channels, adenylate cyclase, and phospholipase C. **B**, Classically, the opioid receptor is thought to be a $G_{i/o}$ coupled receptor. Adenylate cyclase is inhibited, the potassium channel is open, and the calcium channel is closed. **C**, At picomolar or nanomolar concentrations, opioid receptors are coupled to G_s proteins. Adenylate cyclase is activated, the calcium channel is open, and the potassium channel is closed. (From Maxwell LG et al: *The effects of a small-dose naloxone infusion on opioid-induced side effects and analgesia in children and adolescents treated with intravenous patient-controlled analgesia: a double-blind, prospective, randomized, controlled study*, *Anesth Analg* 100:953, 2005.)

vasculature and the extracellular fluid of the brain, to reach the receptor. Normally, highly lipid-soluble agonists, such as fentanyl, rapidly diffuse across the blood-brain barrier, whereas agonists with limited lipid solubility, such as morphine, have limited brain uptake. This rule, however, does not hold true for patients of all ages. The blood-brain barrier may be immature at birth and is known to be more permeable in neonates to morphine. Indeed, Kupferberg and Way (1963) demonstrated in a classic paper that morphine concentrations were two to four times greater in the brains of younger rats than older rats despite equal blood concentrations. Spinal administration, either intrathecally (subarachnoid) or epidurally, bypasses the blood and directly places an agonist into the cerebrospinal fluid, which bathes the receptor sites in the spinal cord (substantia gelatinosa) and brain. This “back door” to the receptor significantly reduces the amount of agonist needed to relieve pain and to induce opioid side effects such as pruritus, urinary retention, and respiratory depression (Cousins and Mather, 1984; Sabbe and Yaksh, 1990). After spinal administration, opi-

oids are absorbed by the epidural veins and redistributed to the systemic circulation, where they are metabolized and excreted. Hydrophilic agents such as morphine cross the dura more slowly than more lipid-soluble agents such as fentanyl or meperidine. This physical chemical property is responsible for the more prolonged duration of action of spinal morphine and its very slow onset of action after epidural administration (Sabbe and Yaksh, 1990).

Biotransformation

Effects of Age and Disease

Morphine, meperidine, methadone, codeine, and fentanyl are biotransformed in the liver before excretion by the kidneys. Many of these reactions are catalyzed in the liver by glucuronidation or microsomal mixed-function oxidases that require the cytochrome P450 system, nicotinamide adenine dinucleotide phosphate (NADPH), and oxygen. The cytochrome P450 system

is immature at birth and does not reach adult levels of activity until the first month or two of life. The immaturity of this hepatic enzyme system may explain the prolonged clearance or elimination of some opioids in the first few days to weeks of life (Anderson and Lynn, 2009). On the other hand, the P450 system can be induced by various drugs (such as phenobarbital) and substrates, and once the infant is born, it matures regardless of gestational age. Thus, it is the age from birth and not the duration of gestation that determines how premature and full-term infants metabolize drugs.

Morphine is primarily glucuronidated into two forms: an inactive form, morphine-3-glucuronide, and an active form, morphine-6-glucuronide. Both glucuronides are excreted by the kidney. In patients with renal failure, morphine-6-glucuronide can accumulate and cause toxic side effects including respiratory depression (Murtagh et al., 2007; Lotsch, 2005). This is important to consider not only when prescribing morphine but when administering other opioids that are metabolized into morphine, such as codeine.

The pharmacokinetics of opioids in patients with liver disease and in critically ill patients requires special attention. Many disease states common in the critically ill may alter the metabolism and elimination of morphine (and other drugs). Severe cirrhosis, septic shock, and renal failure decrease the clearance of morphine and its metabolites, resulting in increased accumulation, prolonged duration of action, and possible toxicity. Oxidation of opioids is reduced in patients with hepatic cirrhosis, resulting in decreased drug clearance (e.g., meperidine, dextropropoxyphene, pentazocine, tramadol, and alfentanil) and increased oral bioavailability caused by a reduced first-pass metabolism (e.g., meperidine, pentazocine, and dihydrocodeine). Although glucuronidation is thought to be less affected by cirrhosis, the clearance of morphine is decreased and oral bioavailability is increased. The consequence of reduced drug metabolism is the risk of accumulation in the body, especially with repeated administration. Lower doses or longer administration intervals should be used to minimize this risk. Meperidine poses a special concern, because it is metabolized into normeperidine, a toxic metabolite that causes seizures and accumulates in liver disease. On the other hand, drugs that are inactive (prodrugs) but are metabolized in the liver into active forms (such as codeine) may be ineffective in patients with severe liver disease. Finally, the disposition of a few opioids, such as fentanyl, sufentanil, and remifentanil, appears to be unaffected in liver disease and are the drugs preferentially used in managing pain in patients with liver disease.

Distribution and Clearance

The pharmacokinetics of morphine have been extensively studied in adults, older children, and in premature and full-term newborns (Lynn et al., 1991, 1993). After an intravenous bolus, 30% of morphine is protein-bound in the adult vs. only 20% in the newborn. This increase in unbound ("free") morphine allows a greater proportion of active drug to penetrate the brain. This may in part explain the observation of Way et al. (1965) of increased brain levels of morphine in the newborn and its more profound respiratory depressant effects. The elimination half-life of morphine in adults and older children is 3 to 4 hours and is consistent with its duration of analgesic action. The half-life of elimination ($t_{1/2\beta}$) is more than twice as long in newborns younger than 1 week of age than in older children and adults

and is even longer in premature infants (Lynn and Slattery, 1987). Clearance is similarly decreased in the newborn compared with the older child and adult. Thus, infants younger than 1 month of age attain higher serum levels that decline more slowly than older children and adults. This may also account for the increased respiratory depression associated with morphine in this age group. Interestingly, the $t_{1/2\beta}$ and clearance of morphine in children older than 2 months of age are similar to adult values; thus, the hesitancy in prescribing and administering morphine in children younger than 1 year of age may not always be warranted. On the other hand, the use of any opioids in children who were born prematurely (fewer than 37 weeks' gestation) and are less than 52 to 60 weeks' postconceptional age or who were born at term and are younger than 2 months of age must be restricted to a monitored setting.

Based on its relatively short half-life (3 to 4 hours), one would expect older children and adults to require morphine supplementation every 2 to 3 hours when being treated for pain, particularly if the morphine is administered intravenously. This has led to the use of continuous infusion regimens of morphine and patient-controlled analgesia (see related section) or, alternatively, administration of longer-acting agonists such as methadone. When administered by continuous infusion, the duration of action of opioids that are rapidly redistributed (such as fentanyl, sufentanil, and alfentanil) and are thought to be short-acting may be longer than would be predicted simply by their pharmacokinetics (see Chapter 7, Pharmacology of Pediatric Anesthesia). An exception to this is remifentanil, a μ -opioid receptor agonist with unique pharmacokinetic properties (Burkle et al., 1996).

The pharmacokinetics of remifentanil are characterized by a small volume of distribution, rapid clearances, and low interpatient variability, compared with other intravenous anesthetic and analgesic agents. The drug has a rapid onset of action (the half-time for equilibration between blood and the effect compartment is 1.3 minutes) and a short context-sensitive half-life (3 to 5 minutes) (Bailey, 2002; Welzing and Roth, 2006). This latter property is attributable to hydrolytic metabolism of the compound by nonspecific tissue and plasma esterases. Virtually all (99.8%) of an administered remifentanil dose is eliminated during the half-life of redistribution $t_{1/2\alpha}$ (0.9 minutes) and the $t_{1/2\beta}$ (6.3 minutes). The pharmacokinetics of remifentanil suggest that within 10 minutes of starting an infusion, remifentanil blood levels will have nearly reached steady state. Thus, changing the infusion rate of remifentanil produces rapid changes in drug effect. The rapid metabolism of remifentanil and its small volume of distribution mean that remifentanil does not accumulate. Discontinuing the drug rapidly terminates its effects and has significant intraoperative implications. When remifentanil is administered intraoperatively as part of a balanced or primary opioid general anesthetic, some patients have reportedly awakened in severe pain. This can be because of inadequate loading of a longer-acting opioid, as well as "opioid-induced hyperalgesia," a paradoxical process by which opioid administration, even for short periods of time, increases the sensitivity to pain and worsens pain when the opioid is discontinued (Crawford et al., 1992; Chu et al., 2008). Finally, remifentanil may be a reasonable alternative to inhaled general anesthetics in newborn infants undergoing surgery, because it only briefly interferes with the control of breathing and because this effect is terminated shortly after discontinuing the drug (Davis et al., 2001; Galinkin et al., 2001).

Commonly Used Oral Opioids

Codeine, oxycodone (the opioid in Tylox and Percocet), and hydrocodone (the opioid in Vicodin and Lortab) are opioids that are commonly used to treat pain in children and adults, and are quite useful when making the transition from parenteral to enteral analgesia (Table 15-6). Methadone and sustained release formulations of morphine, oxycodone, oxymorphone,

and hydromorphone are commonly used to treat chronic medical pain (e.g., cancer) and in postoperative surgical or trauma patients with long recuperative times (e.g., pectus excavatum or posterior spine surgery). Codeine, oxycodone, and hydrocodone are most commonly administered in the oral form, often in combination with acetaminophen. Although the combination drugs are convenient, and acetaminophen potentiates the analgesia produced by codeine—allowing the practitioner

TABLE 15-6. Commonly Used μ -Agonist Drugs

Agonist	Equipotent IV Dose (mg/kg)	Equipotent PO Dose (mg/kg)	Duration (hr)	Bioavailability (%)	Comments
Morphine	0.1	0.3	3-4	20-40	"Gold standard," very inexpensive Seizures in newborns Histamine release, vasodilation, avoid in circulatory compromise Poor oral bioavailability; give 3-5 times the IV dose Liquid morphine available in concentrations 2-20 mg/mL Renally cleared active metabolite, morphine 6-glucuronide
Meperidine (Demerol)	1.0	N/A	3-4	40-60	Catastrophic interactions with MAO inhibitors Tachycardia; negative inotrope Metabolite normeperidine produces seizures 0.25 mg/kg effectively treats shivering Not recommended for routine use
Hydromorphone (Dilaudid)	0.015	0.05	3-4	50-70	Commonly used when morphine produces too many undesirable systemic side effects No active metabolites
Fentanyl (Sublimaze)	0.001	N/A	0.5-1		Very effective for short painful procedures Vagotonic and can cause bradycardia Minimal hemodynamic alterations Chest wall rigidity/glottic closure (>5 mcg/kg rapid IV bolus); Rx naloxone or succinylcholine or pancuronium Oral transmucosal dose 10-15 mcg/kg Transdermal patch available for chronic pain
Methadone	0.1	0.1-0.2	4-24	70-100	Liquid preparation available Long duration of action makes it ideal for cancer pain, weaning dependent patients, etc. Useful for neuropathic pain (NMDA blockade) Because of incomplete cross tolerance, when used in opioid tolerant patients, conversion to morphine may be as low as 0.01 mg/kg
Codeine Solution (codeine + acetaminophen) 12 mg + 120 mg/5 mL Tablets (codeine-acetaminophen) #2 15 mg + 300 mg #3 30 mg + 300 mg	N/A	1.2	3-4	40-70	PO only Prodrug must be converted to morphine Often combined with acetaminophen
Hydrocodone Elixir (Lortab) (hydrocodone + acetaminophen) 7.5 mg + 500 mg/15 mL Tablets (Vicodin or Lortab) Hydrocodone 2.5, 5, 7.5, or 10 mg + 325 or 500 mg acetaminophen Oxycodone Solution 1 or 20 mg/mL Tablets (oxycodone + acetaminophen) Percocet 5 mg + 325 mg Tylox 5 mg + 500 mg	N/A	0.1	3-4	60-80	PO only Usually prescribed with acetaminophen Less nausea than codeine

High abuse potential Usually prescribed with acetaminophen Less nausea than codeine

PO, Orally; IV, intravenously.

to use less opioid to achieve satisfactory analgesia—the combination of drugs significantly increases the risk of acetaminophen toxicity. Acetaminophen toxicity may result from a single toxic dose, from repeated ingestion of large doses of acetaminophen (e.g., in adults 7.5 to 10 g/day for 1 to 2 days, in children 60 to 420 mg/kg per day for 1 to 42 days), or from chronic ingestion. However, hepatotoxicity can also occur inadvertently when patients with poorly controlled pain increase the number of combination tablets they need to control their pain or when they are receiving more than one source of acetaminophen (Heubi et al., 1998). The latter occurs because so many prescription and over-the-counter drug products contain acetaminophen (e.g., cold remedies). Because of this risk, the preferred method is to prescribe opioids and acetaminophen (or ibuprofen) separately.

In equipotent doses, oral analgesics have similar effects and side effects including analgesia, sedation, cough suppression, pruritus, nausea, vomiting, constipation and respiratory depression (Table 15-6). Yet the responses of patients to individual opioids can vary markedly, even among these μ -opioid agonists (Pasternak, 2001a, 2005). Understanding this variability greatly enhances the ability to treat patients appropriately. Codeine is a case in point; although readily available, it is very nauseating, and many patients claim they are allergic to it because it so commonly induces vomiting. On the other hand, some differences may be more based on folklore rather than reality. Many physicians falsely believe that meperidine has less of an effect on the sphincter of Oddi than other opioids and therefore prescribe it for patients with gallbladder disease. In fact, meperidine offers no advantage over other opioids and has a serious disadvantage, namely catastrophic interactions with monoamine oxidase (MAO) inhibitors.

Codeine, hydrocodone, and oxycodone have an oral bioavailability of approximately 60%. They achieve their analgesic effects as early as 20 minutes after ingestion and have a $t_{1/2}$ of 2.5 to 4 hours. Unlike oxycodone and hydrocodone, codeine is a prodrug. It has no intrinsic analgesic properties and must be metabolized into morphine by the liver's cytochrome P450 (CYP) 2D6 isoenzyme to become active. In patients with normal CYP 2D6, approximately 10% of codeine is metabolized into morphine. Unfortunately, approximately 7% of the American population has a complete or partial enzymatic deficiency of 2D6 making it impossible for them to metabolize codeine into morphine. Those patients with poor metabolizing ability get little if any analgesia from codeine. More ominously, approximately 3% to 5% of the U.S. population are rapid metabolizers, and in these patients, "normal" codeine doses may be toxic

because too much is converted into morphine. There is no way to predict who is a poor or rapid metabolizer.

Morphine is also effective when given orally, but only about 20% to 30% of an oral dose reaches the systemic circulation. Therefore, when converting a patient's intravenous morphine dose to oral maintenance therapy, one must multiply the intravenous dose by a factor of 3 to 4 to provide comparable analgesic efficacy. Hydrocodone is prescribed in a dose of 0.05 to 0.1 mg/kg. The elixir is available as 2.5 mg/5 mL combined with acetaminophen 167 mg/5 mL. As a tablet, it is available in hydrocodone doses between 2.5 to 10 mg, combined with 500 to 650 mg acetaminophen. Oxycodone is prescribed in a dose of 0.05 to 0.1 mg/kg. Unfortunately, oxycodone is not available in many countries outside of the United States, and even in the United States it is not available in most pharmacies. When it is available, it is usually in concentrations of 1 mg/mL or 20 mg/mL, which could lead to potentially catastrophic dispensing errors. In tablet form, oxycodone is commonly available as Tylox (500 mg acetaminophen and 5.0 mg oxycodone) and as Percocet (325 mg acetaminophen and 5 mg oxycodone). As mentioned previously, in all "combination preparations," there is a real possibility of inadvertently administering a hepatotoxic dose of acetaminophen in patients with uncontrolled pain.

Oxycodone is also available without acetaminophen in a sustained-release tablet (Oxycontin) for use in chronic pain. These pills must be swallowed whole and cannot be administered through a gastric tube or to children who cannot swallow pills, because when ground, crushed, or chewed, tremendous amounts of oxycodone become rapidly available and may result in catastrophic respiratory and cardiovascular collapse. Unfortunately, this property has also led to its diversion and abuse. Sustained-release opioids should only be prescribed to opioid-tolerant patients with chronic pain; they should not be used in routine postoperative pain management. In addition, in patients with rapid gastrointestinal transit, sustained-release preparations may not be absorbed at all; liquid methadone may be an alternative in these patients.

Oral morphine is available as a liquid in various concentrations (as much as 20 mg/mL), a tablet (morphine sulfate immediate release [MSIR]) that is available in 15- and 30-mg tablets, and as a sustained-release preparation (MSContin and Oramorph tablets or Kadian "sprinkle capsules"). Because it is so concentrated, morphine elixir is particularly easy to administer to children and severely debilitated patients. Indeed, in patients with terminal illness who cannot swallow, liquid morphine provides analgesia when it is simply dropped into the patient's mouth (buccal absorption).

Patient-Controlled Analgesia

Historically, pain medications have been administered on a demand or PRN basis (Krane, 2008). When drugs are given PRN, the patient or caregiver must recognize that pain exists, summon a nurse and await the preparation and administration of the analgesic. Even in the best of circumstances, there is a delay between the patient's request and the provider's response (Krane, 2008). Around-the-clock administration of analgesics at intervals based on population pharmacokinetics (e.g., every 4 hours) is not always effective because there are enormous individual variations in pain perception and opioid metabolism. Knowledge of opioid pharmacokinetics suggests that intravenous boluses of intermediate-acting opioids such as morphine may be needed as often as every 1 to 2 hours in order to avoid marked fluctuations in plasma drug levels, but generally they are ordered no more frequently than every 4 hours. One way to achieve this goal is via continuous intravenous opioid infusions. This approach provides steady analgesic levels and has been used with great safety and efficacy in children; however, because neither the perception nor the intensity of pain is constant, continuous opioid infusions do not adequately treat pain in all patients (Lynn et al., 2000). For example, a postoperative patient may be very comfortable resting in bed and may require little adjustment in opioid dosing. This same patient may experience excruciating pain when coughing, voiding, or getting out of bed. Receiving the same dose of opioid in both instances may result in either oversedation or under treatment. Thus, rational pain management requires some form of titration to effect whenever any opioid is administered. In order to give patients some measure of control over their pain therapy, analgesia on demand or patient-controlled analgesia (PCA) devices were developed (Berde et al., 1991; Yaster et al., 1997). These are microprocessor driven pumps that the patient controls to self-administer intermittent, predetermined, small doses of opioid whenever a need for more pain relief is felt. The opioid, usually morphine, hydromorphone, or fentanyl is administered either intravenously or subcutaneously (Table 15-7). The dosage of opioid, number of demand doses ("boluses") per hour, and the time interval between boluses (the "lock-out period") are programmed into the equipment by the pain-service physician to allow maximum patient flexibility and sense of control with minimal risk of overdosage. Generally, because older

patients know that if they have severe pain they can obtain relief immediately, many prefer dosing regimens that result in mild to moderate pain in exchange for fewer side effects such as nausea or pruritus. Morphine is the most commonly prescribed opioid. Typically it is prescribed at a bolus dose of 20 mcg/kg, at a rate of up to 5 boluses/hour, and with a lock-out interval between each bolus of 6 to 8 minutes (Table 15-7). Variations include larger boluses (30 to 50 mcg/kg) and shorter time intervals (5 minutes).

The PCA pump computer stores within its memory how many boluses the patient has received, as well as how many attempts the patient has made at receiving boluses. This allows the provider to evaluate how well the patient understands the use of the pump and provides information to program the pump more efficiently. In addition, most PCA units allow low, continuous "background" infusions (e.g., morphine, 20 to 30 mcg/kg per hour, hydromorphone 3 to 4 mcg/kg per hour or fentanyl 0.5 mcg/kg per hour) in addition to self-administered boluses. Continuous background infusions can facilitate more restful sleep by preventing the patient from awakening in pain (Doyle et al., 1993). Although in adults a background infusion increases the potential for overdosage without significantly improving analgesia, this has not been the experience in pediatrics and in adult cancer patients (Fleming and Coombs, 1992). In these patients, a continuous infusion improves analgesia and makes the life easier for the health care provider, because with better analgesia there are fewer phone calls to rewrite orders or to change therapy (Monitto et al., 1998; Yildiz et al., 2003; Nelson et al., 2009). Contraindications to the use of PCA include inability to push the bolus button (because of weakness or arm restraints), inability to understand how to use the machine, and a patient's desire not to assume responsibility for personal care. Difficulties with PCA include increased costs; patient age limitations; and the need for physician, nursing, pharmacy protocols, education; and storage arrangements that must be instituted before its implementation. These policies, procedures, and protocols are essential for the safe use of opioids regardless of the method of administration. Essential features include age-appropriate parameters for monitoring respiratory status (e.g., respiratory rate and oxygen saturation), patient alertness, and pain assessment, as well as weight-based dosing. Additionally, because accurate prescribing requires a correct weight, proper conversion of pounds to kilograms, and the choice of an appropriate medication preparation

TABLE 15-7. IV Patient-Controlled Analgesia Dosing Guidelines

Drug (and Concentrations)	Continuous Basal Infusion* mcg/kg/hr (range, mcg/kg/hr)	Demand Dose mcg/kg (range, mcg/kg)	Lockout Interval Minutes (range)	Number of Demand Doses/Hour (range)	4-Hour Limit (mcg/kg)
Morphine (standard, 1 mg/mL; younger patients, 0.2 mg/mL; tolerant or high-need patients, 10 mg/mL)	20 (10-30)	20 (10-30)	8 (6-15)	5 (1-10)	250-400
Fentanyl (>30 kg, 0.02 mg/mL; 10-29 kg, 0.01 mg/mL; <10 kg, 0.005 mg/mL; tolerant or high-need patients, 0.05 mg/mL)	0.5 (0.2-1)	0.5 (0.2-1)	15 (6-15)	4 (1-10)	7-10
Hydromorphone (standard, 0.2 mg/mL; tolerant or high-need patients, 1 or 5 mg/mL)	4 (2-6)	4 (2-6)	8 (6-15)	5 (1-10)	50-80

*A basal infusion is not always used. It may increase the risk of respiratory depression and excessive sedation.

FIGURE 15-8. An electronic, computerized PCA provider order set is depicted. It provides clear, legible, weight-based (kg), calculated dosing using best prescription practice (e.g., no trailing zero after a decimal point). Additionally, it provides instructions to the pharmacist on the volume of drug to be dispensed and how the drug is to be prepared. Finally, it also provides the bedside nurse with monitoring guidelines and antidotes for opioid-induced complications.

and concentration, the computerization of analgesic medication prescribing is an important patient safety strategy (Wrona et al., 2007; Lee et al., 2008). Figure 15-8 is an example of an electronic, computerized PCA provider order set used in the Children’s Center of the Johns Hopkins Hospital that incorporates many of these features.

Parent- and Nurse-Controlled Analgesia (Surrogate PCA or PCA by Proxy)

Independent use of PCA requires a patient with sufficient understanding, manual dexterity, and strength to initiate a demand dose. Thus, it was initially limited to adolescents and teenagers, but over time the lower age limit of patients has fallen. In general, many have found that any child able to play a video game can successfully operate a PCA pump independently. However, in very young children or children with developmental or physical handicaps, a similar but alternate mode of therapy is parent- or nurse-controlled analgesia (PNCA), sometimes referred to as *PCA by proxy* or *surrogate PCA* (Monitto et al., 2000). When using this technique, the child receives a basal opioid infusion when PCA bolus doses are initiated by a designated surrogate, generally a parent or nurse, when they perceive that the child appears to be in pain (Monitto et al., 2000; Nelson et al., 2009).

Allowing parents or nurses to initiate a PCA bolus is controversial. In 2004, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) issued a sentinel event alert warning that serious adverse events can result when surrogates become involved in administering analgesia by proxy (Joint Commission on Accreditation of Healthcare Organizations, 2004). Of note, the JCAHO based this warning on a series of adverse events in adults who for the most part developed complications as a result of the preemptive use of the PCA bolus by spouses, children, or nurses when the patient was asleep. Although this alert was not meant to address cases in which caregivers were authorized to administer PCA boluses, it nevertheless raised serious concerns in the pediatric pain management community and changed the practice at some hospitals. Published studies have reported that up to 1% to 3% of patients receiving intravenous PCA by proxy may receive naloxone to treat cardiopulmonary complications (Monitto et al., 2000; Angheliescu et al., 2005; Voepel-Lewis et al., 2008). Interestingly, in a study comparing pediatric intravenous PCA and intravenous PCA by proxy, complication rates were similar between the two modes of therapy, but the use of naloxone was higher in the younger patients. However, it was unclear whether providers had a lower threshold for treating these children with naloxone given their younger age and an associated increased incidence of comorbidities (Voepel-Lewis et al., 2008). Because respiratory

depression does occur, safe institution of PCA by proxy as well as PCA requires close patient monitoring, established nursing protocols, and an understanding by surrogates of the appropriate use of the bolus dose.

Transdermal and Transmucosal Fentanyl

Because fentanyl is extremely lipophilic, it can be readily absorbed across any biological membrane, including the skin. Thus, fentanyl can be administered painlessly by nonintravenous routes, including transmucosal (nose and mouth) and transdermal routes. The transmucosal route of fentanyl administration is extremely effective for acute pain relief. When given intranasally (2 mcg/kg), it produces rapid analgesia that is equivalent to intravenously administered fentanyl (Galinkin et al., 2000). For transoral absorption, fentanyl is also available in a candy matrix (Actiq) attached to a plastic applicator device that looks like a lollipop. As the patient sucks on the lollipop, fentanyl is absorbed across the buccal mucosa and is rapidly absorbed (10 to 20 minutes) into the systemic circulation (Goldstein-Dresner et al., 1991; Streisand et al., 1989, 1991; Ashburn et al., 1993; Schechter et al., 1995). If excessive sedation occurs, the fentanyl is removed from the patient's mouth by the applicator. Transmucosal absorption is more efficient than ordinary oral-gastric intestinal administration because it bypasses the efficient first-pass hepatic metabolism of fentanyl that occurs after enteral absorption into the portal circulation. The candy matrix of fentanyl has been approved by the FDA for use in children for premedication before surgery and for procedure-related pain (e.g., lumbar puncture or bone marrow aspiration) (Dside et al., 1998). It is also useful in the treatment of cancer pain and as a supplement to transdermal fentanyl (Portenoy et al., 1999). When administered transmucosally, a fentanyl dose of 10 to 15 mcg/kg is effective within 20 minutes and lasts approximately 2 hours. Because approximately 25% to 33% of the given dose is absorbed, blood levels equivalent to 3 to 5 mcg/kg intravenous fentanyl are achieved with this dose. The major side effect of treatment is nausea and vomiting, which occurs in approximately 20% to 33% of patients who receive it (Epstein et al., 1996). Finally, a new, rapidly dissolving, effervescent fentanyl buccal tablet, Fentora, has become available for breakthrough pain in patients who are already receiving opioids for persistent pain and who are tolerant to opioid therapy (Messina et al., 2008; Weinstein et al., 2009). These tablets come in various doses (100, 200, 400, 600, and 800 mcg). In adults, fentanyl buccal tablets have an absolute bioavailability of 65%; approximately 50% of the total administered dose is absorbed transmucosally, and the remaining half is swallowed and undergoes slow absorption from the gastrointestinal tract. There is little published pediatric experience with this drug.

The transdermal route is commonly used to administer many drugs, including scopolamine, clonidine, and nitroglycerin. Many factors, including body site, skin temperature, skin damage, ethnicity, and age affect the absorption of transdermally administered drugs. The transdermal fentanyl patch has revolutionized adult and pediatric cancer pain management (Zernikow et al., 2007; Finkel et al., 2005). Placed in a selective semipermeable membrane patch, which is attached to the skin by a contact adhesive, a reservoir of fentanyl provides slow, steady-state absorption of drug across the skin. As fentanyl is

painlessly absorbed across the skin, a substantial amount is stored in the upper skin layers, which then act as a secondary reservoir. The presence of this "skin depot" has several implications:

1. It dampens the fluctuations of fentanyl effects.
2. It needs to be reasonably filled before significant vascular absorption occurs.
3. It contributes to a prolonged residual fentanyl plasma concentration after patch removal.

Indeed, the amount of fentanyl remaining within the system and skin depot after removal of the patch is substantial. At the end of a 24-hour period, a fentanyl patch releasing drug at the rate of 100 mcg/hr, 1.07 ± 0.43 mg fentanyl (approximately 30% of the total delivered dose from the patch) remains in the skin depot. Thus, even after removal of the patch, fentanyl continues to be absorbed from the subcutaneous fat reservoir for almost 24 hours (Grond et al., 2000).

Because of its long onset time, inability to rapidly adjust drug delivery, and long $t_{1/2\beta}$, transdermal fentanyl is contraindicated for acute pain management. In fact, the use of this drug delivery system to treat acute pain has resulted in the death of an otherwise healthy patient. Transdermal fentanyl is appropriate only for patients who have developed opioid tolerance and for those with chronic pain (e.g., cancer) (Zernikow et al., 2007; Finkel et al., 2005). Even when transdermal fentanyl is appropriate, the vehicle imposes its own constraints; the patch with the lowest dose delivers 12.5 mcg of fentanyl per hour; others deliver 25, 50, 75, and 100 mcg of fentanyl per hour. The patches cannot be physically cut in smaller pieces to deliver less fentanyl.

Methadone

Primarily thought of as a drug to treat or wean patients who are addicted to or dependent on opioid, methadone is increasingly being used in the management of acute and chronic intractable pain. Unique among the opioids, methadone exists as a racemic mixture of two active isomers; one isomer binds as an agonist to the μ -receptor and the other as an antagonist at the NMDA receptor. It is this latter property that makes methadone unique among opioids. The NMDA system is involved in wind-up and the maintenance of chronic pain as well as opioid-induced hyperalgesia and the development of tolerance (Ebert et al., 1998; Gagnon and Bruera, 1999; Gorman et al., 1997). Thus, blockade of NMDA receptors can act to acutely enhance opioid-induced antinociception, impair the development of tolerance, and prevent the development of chronic pain (Raffa, 1996).

In addition, methadone is noted for its slow $t_{1/2\beta}$, very long duration of effective analgesia, high oral bioavailability, and inactive metabolites. The $t_{1/2\beta}$ of methadone averages 19 hours, and clearance averages 5.4 mL/kg per minute in children 1 to 18 years of age (Berde et al., 1991). Methadone has the longest $t_{1/2\beta}$ of any of the commonly available opiates and can provide up to 12 to 36 hours of analgesia after a single intravenous or oral dose (Gourlay et al., 1986, 1982, 1984; Berde 1989; Shannon and Berde, 1989). Pharmacokinetically, children are indistinguishable from young adults. Because a single dose of methadone can achieve and sustain a high drug-plasma level, it is a convenient way to provide prolonged analgesia without requiring

an intramuscular injection or a continuous infusion. Berde et al. (1989) recommend methadone as a “poor man’s PCA” and suggest loading patients with an initial dose of intravenous methadone (0.1 to 0.2 mg/kg) and then titrating in 0.05-mg/kg increments every 10 to 15 minutes until analgesia is achieved. Supplemental methadone can be administered in 0.05- to 0.1-mg/kg increments administered by slow intravenous infusion every 4 to 12 hours as needed. Shannon and Berde (1989) have also reported the use of small incremental doses administered by sliding scale. “Small increments of methadone are administered intravenously over 20 minutes every 4 hours via a ‘sliding’ scale on a ‘reverse prn’ (the nurse asks the patient) basis: 0.07 to 0.08 mg/kg for severe pain; 0.05 to 0.06 mg/kg for moderate pain; 0.03 mg/kg for little or no pain, if the patient is alert; and no drug if the patient has little pain and is somnolent” (Berde 1989; Shannon and Berde, 1989).

In addition, both methadone and sustained relief morphine can be used to wean patients who have become physically dependent on opioids after prolonged analgesic therapy (Yaster et al., 1996; Suresh and Anand, 1998; Tobias, 2000a). Finally, because methadone is extremely well absorbed from the gastrointestinal tract and has a bioavailability of 80% to 90%, it is extremely easy to convert intravenous dosing regimens to oral ones. Recently, however, the conversion dose of morphine to methadone has been challenged. Traditionally, it has been thought that the ratio of morphine to methadone was approximately 1:1; it now appears that when tolerance develops and morphine doses are “high,” it is closer to 1:0.25 or even 1:0.1 (Lawlor et al., 1998; Ripamonti et al., 1998a, 1998b; Gagnon and Bruera, 1999). Tolerance to morphine and other opioids such as fentanyl is a significant problem in patients being treated for pain chronically or acutely in the intensive care unit setting. When this occurs, substituting methadone for morphine or fentanyl at the lower doses discussed in the previous section can rapidly reestablish analgesia even though all of these opioids work at the same μ -opioid receptor. This occurs because of “incomplete cross tolerance,” which may be because methadone’s antagonist actions at the NMDA receptor or because of multiple μ -receptor subtypes (Gorman et al., 1997; Ebert et al., 1998; Trujillo and Akil, 1991; Pasternak, 2001a).

Among opioid analgesics, methadone is unique as a potent blocker of the delayed rectifier potassium ion channel. This results in QT prolongation, can produce torsade de pointes ventricular tachycardia in susceptible individuals, and may explain the sudden death associated with its use (Andrews et al., 2009). The effects of methadone on the QT interval may be enhanced by hypokalemia, drugs that increase the QT interval such as erythromycin and ondansetron, or by CYP 3A4 inhibitors such as fluoxetine, fluconazole, valproate, and clarithromycin (Ehret et al., 2006). An updated list of medications causing torsade de pointes ventricular tachycardia can be found at www.azcert.org. Indeed, this is such a serious consequence of therapy that some have recommended that all patients treated with methadone have routine screening ECGs before or during their treatment.

Tramadol

Tramadol, a synthetic 4-phenylpiperidine analogue of codeine, is a centrally acting synthetic analgesic that has been used for 30 years in Europe and was approved by the FDA for adult use in the United States in 1995 (Raffa 1996; Minto and Power, 1997). It is a racemic mixture of two enantiomers: + tramadol and -tramadol (Berde, 1989; Glare and Lickiss, 1992). The

+enantiomer has a moderate affinity for the μ -opioid receptor that is greater than that of the -enantiomer (Raffa, 1993). In addition, the +enantiomer inhibits 5-HT uptake and the -enantiomer blocks the reuptake of NE, complementary properties that result in a synergistic antinociceptive interaction between the two enantiomers. Tramadol may also produce analgesia as an α_2 -agonist (Desmeules et al., 1996). A metabolite (O-desmethytramadol) binds to opioid receptors with a greater affinity than the parent compound and could contribute to tramadol’s analgesic effects as well. However, in most animal tests and human clinical trials, the analgesic effect of tramadol is only partially blocked by the opioid antagonist naloxone, suggesting an important nonopioid mechanism. Thus, tramadol provides analgesia synergistically by opioid (direct binding to the μ -opioid receptor by the parent compound and its metabolite) and nonopioid mechanisms (an increase in central neuronal synaptic levels of 5-HT and NE). Finally, animal and human studies have suggested that tramadol may have a selective spinal and local anesthetic action on peripheral nerves. Tramadol has been shown to provide effective, long-lasting analgesia after extradural administration in both adults and children and prolongs the duration of action of local anesthetics when used for brachial plexus and epidural blockade (Kapral et al., 1999; Prosser et al., 1997).

Tramadol’s intravenous analgesic effect has been reported to be 10 to 15 times less than that of morphine and is roughly equianalgesic with NSAIDs (Raffa, 1996; Naguib et al., 1998). Unlike NSAIDs and opioid mixed agonist/antagonists, the therapeutic use of tramadol has not been associated with the clinically important side effects such as respiratory depression, constipation, or sedation. In addition, analgesic tolerance has not been a serious problem during repeated administration, and neither psychological dependence nor euphoric effects are observed in long-term clinical trials. Thus, tramadol may offer significant advantages in the management of pain in children by virtue of its dual mechanism of action, its lack of a ceiling effect, and its minimal respiratory depression.

Tramadol may be administered orally, rectally, intravenously, or epidurally (Gunes et al., 2004; Bozkurt, 2005). Oral and intravenous tramadol is administered in doses of 1 to 2 mg/kg; the higher dose provides a longer duration of action without increasing side effects (Finkel et al., 2002; Rose, 2003; Bozkurt, 2005).

COMPLICATIONS OF OPIOID THERAPY

Regardless of the method of administration, all opioids commonly produce unwanted side effects such as pruritus, nausea and vomiting, constipation, urinary retention, cognitive impairment, tolerance, and dependence (Yaster et al., 2003). Many patients suffer needlessly from pain in order to avoid these debilitating induced side effects (Watcha and White, 1992). Additionally, physicians are often reluctant to prescribe opioids because of these side effects and because of their fear of other, less common but more serious side effects such as respiratory depression. Several clinical and laboratory studies have demonstrated that low-dose naloxone infusions (0.25 to 1 mcg/kg per hour) can treat or prevent opioid-induced side effects without affecting the quality of analgesia or opioid requirements in adults, children, and adolescents (Maxwell et al., 2005; Gan et al., 1997).

Opioid-Induced Bowel Dysfunction

Opioid-induced bowel dysfunction (OBD), often described as constipation, is a constellation of symptoms that includes delayed gastric emptying, slow bowel motility, incomplete evacuation, bloating, abdominal distention, and gastric reflux. OBD occurs whether opioids are administered acutely or chronically, is found in 90% of patients treated with opioids, and is a significant problem in 50% to 60% of adult patients with advanced cancer (Glare and Lickiss, 1992; Fallon and Hanks, 1999). OBD is not really a side effect of opioid therapy; rather the effects of opioids on gastric emptying, peristalsis, and bowel motility are intrinsic opioid actions. Indeed, opium has been used in the treatment of dysentery for thousands of years. However, unlike the analgesic effects of opioids, the gastrointestinal ones are not accompanied by the development of tolerance.

In the postoperative surgical patient, OBD impacts how pain is managed because the return of bowel function and the ability to take nutrients and medicines orally are often the limiting factors in hospital length of stay. Surgeons often view opioids as the primary cause of bowel dysfunction, nausea, vomiting, and delayed hospital discharge. As a result, prescription and administration of opioids can become a balancing act between the need to provide appropriate analgesia and the need to facilitate bowel recovery and hospital discharge.

Therefore, patients treated with opioids, regardless of drug, route, or method of delivery, should be considered for a prophylactic bowel regimen of stool softeners and bulking agents (e.g., senna and lubiprostone) as soon as the patient can eat or drink. Indeed, there may be value in starting these agents preoperatively. Alternatively, several new peripherally-acting opioid antagonists, methylnaltrexone and alvimopan, have recently been approved by the FDA and may be of great utility (Moss and Rosow, 2008). These medications offer promise in the treatment of OBD in patients with late-stage advanced illness (methylnaltrexone), as well as postoperative ileus in adult patients (alvimopan). However, neither of these medications has been studied or approved for use in children. If these conservative measures fail, then stimulant laxatives (e.g., polyethylene glycol 3550) and enemas should be added to this regimen.

Opioid-Induced Pruritus

Opioid-induced pruritus (OIP) is one of the most common adverse side effects associated with opioid use. The incidence of OIP varies between 20% and 100% when opioids are administered neuroaxially (intrathecally or epidurally) and between 20% to 60% when administered intravenously (Ganesh and Maxwell, 2007). Surprisingly, the pathophysiology of clinical itch remains unclear. Over 300 years ago, the German physician Samuel Hafenreffer described itch as an “unpleasant sensation that elicits the desire to scratch,” and this definition is still valid today. Much of the current research on itch focuses on identifying the neuronal mechanisms and the mediators responsible for itch in dermatological and systemic disease. OIP is primarily mediated by binding of μ -agonists with central μ -opioid receptors in the brain and spinal cord and can be blocked with centrally acting μ -receptor antagonists (Ko and Naughton, 2000). Binding of the dopamine D2 receptor and the release of prostaglandin E1 and E2 have also been implicated in the development of OIP. Blockade of the D2 receptor by antagonists such as droperidol or by inhibiting prostaglandin production with

NSAIDs significantly reduces OIP (Horta et al., 1996). Whereas histamine is a potent pruritic agent, opioid-induced histamine release from mast cells plays almost no part in OIP.

A wide variety of drugs with different mechanisms of action have been used to treat or prevent OIP. Antihistamines, such as diphenhydramine or hydroxyzine are the most common and perhaps least effective drugs used to treat established OIP. They primarily interrupt the itch-scratch cycle by providing needed sleep but are not really effective at reducing the severity of itch. A more effective approach is to prophylactically administer a low-dose intravenous infusion of the opioid antagonist naloxone (0.25 to 1 mcg/kg per hour) or the partial agonist/antagonist nalbuphine (50 mcg/kg, maximum 5 mg/dose) (Kendrick et al., 1996; Maxwell and Yaster, 2003; Nakatsuka et al., 2006). Other strategies involve rotating opioids, reducing opioid dose, or switching to the oral route of administration.

Opioid-Induced Nausea and Vomiting

Nausea and vomiting occur in more than 50% of patients treated with opioids for acute pain. The pathophysiology of nausea and vomiting are well established. Nausea, a subjective unpleasant sensation in which the patient is aware of the urge to vomit but does not necessarily do so, is mediated by several neural pathways. Vomiting, the forceful expulsion of gastric contents, is coordinated by the vomiting center and chemoreceptor trigger zone (CTZ). The CTZ is rich in 5-HT type-3 (5-HT₃), histamine type-1 (H₁), muscarinic cholinergic type-1 (M₁), dopamine type-2 (D₂), neurokinin type-1 (NK₁), and μ -opioid receptors. Stimulation of these chemoreceptor triggers activates the vomiting center. In addition, stimulation of H₁ and/or M₁ receptors in the vestibular labyrinth can, via the CTZ, also activate the vomiting center. Finally, peripheral input via gastrointestinal vagal nerve fibers stimulates the brainstem vomiting center by activation of 5-HT₃, NK₁, or D₂ receptors. Most antiemetic drugs exert their effects by blocking one or more of these receptors.

A wide variety of drugs with different mechanism of actions have been used to treat or prevent opioid-induced nausea and vomiting (Watcha and White, 1992). The most commonly used antiemetics are antihistamines (diphenhydramine), phenothiazines (prochlorperazine and promethazine), butyrophenones (haloperidol and droperidol), benzamides (metoclopramide), 5-HT₃-receptor antagonists (ondansetron, dolasetron, granisetron), and dexamethasone. A low-dose intravenous naloxone infusion (1 mcg/kg per hour) has also been shown to be effective (Maxwell and Yaster, 2003). Many of the agents listed above work synergistically. Although it does not make sense to combine two drugs that act via the same mechanism (e.g., two antihistamines such as diphenhydramine and hydroxyzine), combinations of drugs that act via different mechanisms (e.g., ondansetron, a selective inhibitor of 5-HT₃ receptors and the steroid dexamethasone) can be effective (McKenzie et al., 1994). Finally, if these measures fail, opioid dose reduction, with or without the addition of NSAIDs, or opioid rotation may be effective.

Opioid-Induced Sedation

The sedating effects of opioids in opioid-naive patients are well known and can be thought of as either a desired effect or an adverse side effect. Although tolerance to sedation and

drowsiness often develop, in some patients sedation and mental clouding are so debilitating that it leads to a reduced quality of life. Treatment is often dose reduction, opioid rotation, or the use of psychostimulants. Methylphenidate is the most commonly used stimulant to improve drowsiness, but others include dextroamphetamine, caffeine, and modafinil (Rozans et al., 2002; Prommer, 2006).

Tolerance, Dependence, and Withdrawal

Tolerance is the development of a need to increase the dose of an opioid (or benzodiazepine) agonist to achieve the same analgesic (or sedative) effect previously achieved with a lower dose (Nutt, 1996; Wise, 1996). Whereas tolerance to the sedative and analgesic effects of opioids usually develops after 5 to 21 days of morphine administration, tolerance to the constipating effects of opioids rarely occur. Additionally, cross-tolerance develops between all μ -opioid receptor agonists. However, because this cross tolerance is rarely complete, opioid rotation, that is, changing from one opioid (morphine, fentanyl, or hydromorphone) to another (usually methadone) can be helpful in preventing a continuous escalation in analgesic dosing. When it is necessary to switch, careful consideration must be given to the choice of opioid, dose, and expected degree of cross-tolerance. For example, when switching from high-dose morphine to methadone in patients who are tolerant of opioid, the equianalgesic dose is decreased by a factor of four- to fivefold. Even with this reduction, the calculated dose of methadone may be so high that it warrants a stepwise conversion while the patient remains in a high-surveillance care unit.

Physical dependence, sometimes referred to as *neuroadaptation*, is caused by repeated administration of an opioid that necessitates the continued administration of the drug to prevent the development of a withdrawal or abstinence syndrome characteristic for that particular drug (O'Brien, 1996). Physical dependence usually occurs after 2 to 3 weeks of morphine administration, but when high doses of opioid are administered it may occur after only a few days of therapy. Very young infants treated with high-dose fentanyl infusions after surgical repair of congenital heart disease and those who require extracorporeal membrane oxygenation (ECMO) have been identified to be at particular risk of developing dependence and withdrawal on discontinuation of therapy (Arnold et al., 1991, 1990; Kauffman 1991; Lane et al., 1991).

Physical dependence must be differentiated from addiction (O'Brien, 1996). *Addiction* is a term used to connote a severe degree of drug abuse and dependence that is an extreme of behavior in which drug use pervades the total life activity of the user and of the range of circumstances in which drug use controls the user's behavior. Patients who are addicted to opioids often spend large amounts of time acquiring or using the drug, abandon social or occupational activities because of drug use, and continue to use the drug despite adverse psychological or physical effects. In a sense, addiction is a subset of physical dependence. Anyone who is addicted to an opioid is physically dependent; however, not everyone who is physically dependent is addicted. Patients appropriately treated with opioid agonists for pain can become tolerant and physically dependent. They rarely become psychologically dependent or addicted (Porter and Jick, 1980).

When physical dependence has been established, sudden discontinuation of an opioid or benzodiazepine agonist produces

a withdrawal syndrome within 24 hours of drug cessation. Symptoms reach their peak within 72 hours and include abdominal cramping, vomiting, diarrhea, tachycardia, hypertension, diaphoresis, restlessness, insomnia, movement disorders, reversible neurologic abnormalities, and seizures (O'Brien, 1996; Anand and Arnold, 1994; Katz et al., 1994; Nestler 1994, 1996; Norton 1988).

Clinical and experimental data suggest that the duration of opioid receptor occupancy is an important factor in the development of tolerance and dependence. Thus, continuous infusions may produce tolerance more rapidly than intermittent therapy (Katz et al., 1994; Anand and Arnold, 1994). This is particularly true for highly lipid-soluble opioids such as fentanyl. Tolerance and dependence predictably develops after only 5 to 10 days (2.5 mg/kg total fentanyl dose) of continuous fentanyl infusions (Arnold et al., 1991, 1990; Anand and Arnold, 1994; Katz et al., 1994). Nevertheless, prolonged therapy in excess of 10 days, even by intermittent bolus administration, should be expected to produce opioid dependence. As a result, tolerance and physical dependence to both opioid and benzodiazepines is a common phenomenon in the intensive care unit (Suresh and Anand, 1998; Anand and Arnold, 1994; O'Brien, 1996; Yaster et al., 1996; Koob and Nestler, 1997; Tobias, 2000a).

Withdrawal Scales and Weaning Strategies

Hospitalization and admission to the pediatric intensive care unit (PICU) are frightening and at times painful experiences to children and their families. In many critically ill patients, pharmacologically induced sedation verging on general anesthesia is often required to facilitate respiratory care and induce protective immobility that may last for days to weeks. These infants, children, and adolescents often require prodigious, constantly escalating, and on occasion, incomprehensibly high doses of analgesics and sedatives. How to wean these children and prevent withdrawal when they recover is a common problem facing pediatric pain specialists and intensivists. In the PICU, opioid and benzodiazepine withdrawal are common iatrogenic complications of the necessary analgesic and sedative strategies used to facilitate the care of critically ill children. Just as judicious monitoring and administration of these agents correlate with improved care, appropriate assessment tools to recognize withdrawal symptoms, as well as strategies to effectively wean patients at risk for withdrawal must be used when these medications are no longer necessary.

Withdrawal and Abstinence Scales for Infants and Children

In the neonatal intensive care unit (NICU), withdrawal scores were originally developed to care for infants born to drug-addicted mothers. As in adults, neonatal opioid withdrawal is a disorder characterized by generalized irritability, respiratory and gastrointestinal distress, autonomic hyperactivity and, at times, seizures. Similar symptoms and degree of severity are seen in iatrogenic abstinence from opioids. Although less well described, comparable difficulties are also attributable to withdrawal from other sedatives and analgesics like benzodiazepines.

The most widely used tool to assess neonatal abstinence is the Finnegan scale (Table 15-8). This tool is also among the most commonly used withdrawal scales in older infants and children, even though it has never been validated for this use. The Finnegan scale is a complicated assessment measure that

uses a weighted scoring of 31 items that requires training and when used clinically, some assessment of interrater reliability. As a result, it may be too complicated for routine use. An alternative, the Lipsitz scale, offers the advantage of being a relatively simple numerical system, with a reported 77% sensi-

tivity using a value greater than 4 as an indication of significant signs of withdrawal (Table 15-9) (Lipsitz, 1975). The Lipsitz scale and the need for a scoring system to guide therapy was recommended by the American Academy of Pediatrics (AAP) in a 1998 consensus statement (AAP Committee on Drugs, 1998).

When pharmacologic treatment is needed to treat withdrawal, the AAP recommends dilute tincture of opium for neonatal opiate withdrawal. For sedative-hypnotic withdrawal, phenobarbital is the agent of choice. Agthe and others (2009) demonstrated that when tincture of opium is supplemented with oral clonidine (1 mcg/kg) every 4 hours, the duration of pharmacotherapy for neonatal abstinence syndrome is dramatically reduced. However, despite clear, evidence-based recommendations from the AAP, the management of the newborn with psychomotor behavior consistent with withdrawal varies widely. In a recently published survey of neonatal withdrawal treatment, Sarkar and Donn (2006) found inconsistent policies, scale utilization, and treatment regimens between institutions and individual physicians. These results reflect similar findings of earlier studies and reemphasize the disparity between the published evidence and recommendations supporting the use of withdrawal scoring and current clinical practice for neonatal withdrawal treatment.

Franck et al. (2004) investigated the use of an adapted neonatal assessment tool to older children. This 21-item checklist was initially used for opioid weaning and modified for the evaluation of opioid and benzodiazepine withdrawal symptoms (Franck et al., 2004). Their small study demonstrated good interrater reliability and content validity of the tool, as well as applicability to a wide range of ages (6 to 28 months). Thus, this withdrawal scale, named the *Opioid and Benzodiazepine Withdrawal Score (OBWS)*, has a wide range of applicability. Adult withdrawal assessment tools often involve personal reporting of symptoms by the patient. Recently, a clinician-administered tool (the Clinical Opiate Withdrawal Scale [COWS]) was developed to provide a simplified 11-question score to assess withdrawal symptoms and to review its applicability in iatrogenic and abuse-related opioid withdrawal scenarios (Wesson and Ling, 2003). Although simplistic and promising, its applicability to other agents (such as benzodiazepines) and to the pediatric age group is unknown.

Weaning Strategies in Infants and Children

As previously discussed, tolerance and physical dependence develop as a result of the drug, dose, method of delivery, and duration of therapy. When the risk of withdrawal is high, weaning patients should be slow (Yaster et al., 1997, 1996). Unfortunately, abrupt withdrawal of opioids and sedatives to facilitate extubation and transfer of patients out of the PICU is commonplace. If sedative or opioid use has been of short duration (i.e., less than 72 hours), acute discontinuation is reasonable. If a patient has required infusions or repeated administration of an agent for more than 5 days, then an agent-specific weaning strategy should be employed.

One approach to the weaning process is to convert all of the patient's analgesic and sedative medications to intermittent parenteral therapy whenever possible. All forms of the drugs being used therapeutically must be counted in this conversion, including PRN medications. Furthermore, because it is quite common for patients to receive multiple opioids and sedatives, all of the opioids should be converted to morphine equivalents and the

TABLE 15-9. Lipsitz Abstinence Withdrawal Scale

Signs	Score			
	0	1	2	3
Tremors (muscle activity of limbs)	Normal	Minimally increased when hungry or disturbed	Moderate or marked increase when undisturbed; subside when fed or held snugly	Marked increase or continuous even when undisturbed, going onto seizure-like movements

Fever	No	Yes		

Scoring: 0, No withdrawal symptoms; 1-2, mild withdrawal; 2-3, moderate withdrawal; >4, severe withdrawal.

benzodiazepines to diazepam equivalents (Yaster et al., 1996). How to proceed with weaning beyond this first step is not always clear, and there are no published evidence-based studies.

Initially, because of incomplete cross tolerance and because of the astronomical doses of medication that these patients are often receiving, one approach is to allow for a 24- to 48-hour transition period in which no attempt at weaning is made. During this time, opioids (e.g., methadone or morphine) and sedatives (e.g., diazepam) are administered every 6 to 8 hours around the clock and supplemental doses are allowed if symptoms of withdrawal occur. Once this transition period is completed, the patient's drug regimen is incrementally decreased. The speed of weaning is dictated by the chronicity of drug administration, the half-life of the opioid and benzodiazepine being used, the patient's sensitivity to the wean, and physician's experience and preference. Each medication is decreased by 10% to 20% of the original total dose daily. When the lowest doses are reached, usually in 5 to 7 days, the interval of drug dosing is increased from every 6 hours to every 8 or 12 hours, to once a day. Therapy is then stopped completely. If symptoms of withdrawal develop, they are treated symptomatically with clonidine 2 to 4 mcg/kg every 8 hours. Alternatively, another approach is to wean much more slowly, particularly in patients who have had a longer exposure to medication or are more physiologically fragile. In these patients, 10% of the original dose is reduced every 2 to 7 days, particularly if methadone is being used, because of its extremely long half-life. In addition, clonidine is prescribed prophylactically (in the doses previously described). If symptoms of withdrawal develop, breakthrough opioid or benzodiazepine dosing is provided as needed or the previous, higher, dose is restarted, and the weaning process is suspended for 1 to 2 days.

The α_2 -adrenergic agents help prevent or mitigate the occurrence of drug withdrawal regardless of the drug causing addiction or dependence. Agthe and others (2009) have reported

the use of clonidine in treating infants born to drug-addicted mothers as well as in patients who have become opioid and sedative dependent as a result of pain or sedation therapy. If tolerated hemodynamically, coadministered oral or transdermal clonidine (6 to 12 mcg/kg per day) can be used to ameliorate the signs and symptoms of withdrawal during the weaning process. In this instance, the clonidine is subsequently weaned. In addition, the use of dexmedetomidine has been reported to prevent withdrawal symptoms in patients dependent on opioids and sedatives (Finkel and Elrefai, 2004; Multz, 2003).

ANALGESIC ADJUVANTS

Adjuvant pain medications are drugs with a primary function that is not to treat pain, but that may have analgesic properties in specific circumstances. Many of the drugs that are discussed in the following section were initially used to treat neuropathic and chronic pain but are now increasingly being used to treat acute pain as a part of a multimodal therapeutic regimen (Fig. 15-3).

Antidepressants

Because 5-HT and NE mediate descending inhibition of ascending pain pathways in the brain and spinal cord (Figs. 15-2 and 15-3), 5-HT and NE reuptake inhibitor antidepressant medications may have efficacy in relieving pain (Saarto and Wiffen, 2007). Antidepressants that enhance NE action are more effective analgesics than those that predominantly enhance 5-HT action, such as with many of the newer antidepressants (Saarto and Wiffen, 2007). Older antidepressants, particularly the tricyclic antidepressants (TCAs) such as amitriptyline, doxepin, and nortriptyline have been the most thoroughly studied and are thought to cause analgesia by NE and 5-HT reuptake inhibition

(Wiffen et al., 2005). They also have other pharmacologic properties that may contribute to analgesia, such as reducing sympathetic activity, NMDA-receptor antagonism, anticholinergic activity, and sodium-channel blockade. Although generally administered orally, Collins et al. (1995) report using intravenous amitriptyline in eight children who could not tolerate oral medications. Newer non-TCAs seem to be less efficacious analgesics. Ironically, this may be in part because of their “cleaner” pharmacodynamic profiles. Of the newer antidepressants, duloxetine, a dual inhibitor of 5-HT and NE, has been shown to be effective in several randomized controlled trials in adult patients with fibromyalgia and other chronic pain conditions even in the absence of major depressive disorders (Arnold et al., 2009).

When using antidepressants in the management of neuropathic and other pain states, the response to therapy is at times remarkably fast. Unlike depression, in which response to these drugs may take or month or more, analgesia can be produced in as little as 1 to 2 weeks. However, side effects can limit the use of some of these drugs. Children bothered by anticholinergic side effects of TCAs, such as sedation, blurry vision, and dry mouth can be treated with nortriptyline or duloxetine. In addition, all TCAs have a quinidine-like effect on cardiac conduction. This calls for baseline and surveillance electrocardiograms in children who receive this therapy. Recent experience suggests that children, especially between 6 and 12 years of age, benefit from dividing the TCA dose to twice daily, to avoid cholinergic rebound symptoms in the afternoon when a single bedtime dose is used.

Antiepileptic Agents

Like the TCAs, antiepileptic adjuvant analgesics suffer an unfortunate name. Most families (and physicians who are unaware of their analgesic properties) question the use of an antiepileptic drug in a child who does not have seizures. Conceptually, these agents work by preventing “peripheral seizures” in the form of pathologic peripheral nerve discharge (Tanelian and Brose, 1991; Kingery, 1997; Rizzo, 1997). Carbamazepine is the most widely studied antiepileptic in the management of neuropathic pain, particularly in the treatment of lancinating neuropathic pain (such as pain caused by nerve-root compression or injury to a discrete peripheral nerve). Antiepileptic drugs can also help painful “glove and stocking” neuropathic conditions, disagreeable paresthesias, and intense sensitivity to innocuous stimuli (as seen in some human immunodeficiency virus [HIV] neuropathies and chemotherapeutic nerve injuries). Especially in oncology patients, carbamazepine’s propensity for drug-drug interactions and risk of blood dyscrasias are of concern. As a result, these drugs have largely been replaced by gabapentin and pregabalin, an interesting class of weak anticonvulsant drugs that bind at voltage-gated-calcium-channel α_2 - δ (Ca_v - α_2 - δ) proteins (Taylor, 2009). Interestingly, despite their names, these drugs are not GABAergic and produce analgesia by reducing the presynaptic release of pain-inducing neurotransmitters such as glutamate, NE, substance P, and CGRP in the spinal cord and CNS.

Gabapentin and pregabalin have been most widely studied and used for the treatment of chronic pain conditions such as postherpetic neuralgia, diabetic neuropathy, complex regional pain syndromes, malignant pain, HIV-related neuropathy, and

headaches. Increasingly, they are being used in the perioperative period as a component of multimodal pain therapy (see Fig. 15-3) (Joshi, 2005; Ho et al., 2006; Kong and Irwin, 2007; White, 2008). Adult studies have demonstrated their effectiveness (1200 mg gabapentin, 300 mg pregabalin orally) at enhancing postoperative analgesia and preoperative anxiolysis, preventing chronic postsurgical pain, attenuating the hemodynamic responses to laryngoscopy and intubation, and reducing postoperative delirium (Ho et al., 2006). The main side effect of both drugs is somnolence.

Alpha₂-Adrenergic Agonists: Clonidine, Tizanidine, and Dexmedetomidine

NE is involved in the control of pain by modulating pain-related responses through various pathways (Fig. 15-3). α_2 -Adrenergic agonists, such as clonidine, tizanidine, and dexmedetomidine, have well-established analgesic and sedative profiles and wide application in perioperative multimodal pain management. Clonidine is the prototype and most widely studied of this class of drugs. It can be administered via the epidural, oral, and transdermal routes. Clonidine is traditionally used as an antihypertensive and to minimize the symptoms of opioid withdrawal (Agthe, 2009). However, when administered orally, intravenously, or transdermally, clonidine may reduce opioid requirements and improve analgesia. Similarly, the addition of clonidine to local anesthetic solutions for neuraxial or peripheral nerve blocks may enhance and prolong analgesia. However, the analgesic benefits of clonidine remain controversial. Finally, clonidine can be a useful antineuropathic agent, especially in children who cannot tolerate oral medications or who have coexisting problems like steroid-induced hypertension (Kingery, 1997). Clonidine is empirically started at 1 to 2 mcg/kg per dose, every 8 hours, and increased incrementally over days to doses up to 4 mcg/kg per dose. Alternatively, a transdermal patch can be applied in order to administer 6 to 12 mcg/kg per day. Clonidine use is limited by its side effects, which include bradycardia, hypotension, and excessive sedation (Joshi, 2005; White, 2008).

Compared with clonidine, dexmedetomidine is more selective, has a shorter duration of action, and has opioid-sparing and analgesic effects. Because dexmedetomidine does not cause respiratory depression, despite its potent sedative effects it is increasingly being used for deep procedural sedation, as a general anesthetic adjuvant, and for sedation in intubated patients in the intensive care unit.

N-Methyl-D-Aspartate Receptor Antagonists

NMDA receptor antagonists, such as ketamine and methadone, are important modulators of chronic pain and have been shown in some studies to be useful in preventive analgesia by reducing acute postoperative pain, analgesic consumption, or both when they are added to more conventional means of providing analgesia, such as opioids and NSAIDs, in the perioperative period (Fig. 15-3) (McCartney et al., 2004). NMDA receptor antagonists may reduce pain by two nonmutually exclusive mechanisms: a reduction in central hypersensitivity and a reduction of opioid tolerance. Nevertheless, the effectiveness of NMDA receptor antagonists in preventive analgesia has been equivocal at

best (McCartney et al., 2004; Pogatzki-Zahn and Zahn, 2006). Ketamine is well known as a dissociative general anesthetic and may be an effective adjuvant in pain management when used in low doses (0.05 to 0.2 mg/kg per hour) (Tsui et al., 2007; Svetcic et al., 2008).

REGIONAL ANESTHESIA AND ANALGESIA

Overview

Since the late twentieth century, the use of local anesthetics and regional anesthetic techniques in pediatric practice has increased dramatically. Unlike most drugs used in medical practice, local anesthetics must be physically deposited at their sites of action by direct application and require patient cooperation and the use of specialized needles. Because of this, for decades children were considered poor candidates for regional anesthetic techniques. However, once it was recognized that regional anesthesia could be used as an adjunct and not a replacement for general anesthesia, its use increased dramatically. Regional anesthesia offers the anesthesiologist and pain specialist many benefits. It modifies the neuroendocrine stress response, provides profound postoperative pain relief, insures a more rapid recovery, and may shorten hospital stay with fewer opioid-induced side effects. Furthermore, because catheters placed in the epidural, pleural, femoral, sciatic, brachial plexus, and other spaces can be used for days or months, local anesthetics are increasingly being used not only for postoperative pain relief, but also for medical, neuropathic, and terminal pain (Dalens, 1989; Yaster and Maxwell, 1989; Giaufre et al., 1996; Golianu et al., 2000; Ross et al., 2000; Capdevila et al., 2003; Dadure et al., 2003). Peripheral nerve blocks provide

significant pain relief after many common pediatric procedures. Techniques range from simple infiltration of local anesthetics to neuraxial blocks like spinal and epidural analgesia. To be used safely, a working knowledge of the differences in how local anesthetics are metabolized in infants and children is necessary (Table 15-10) (Dalens, 1989, 1995; Yaster et al., 1993).

Effects of Age on Metabolism of Local Anesthetics

All local anesthetics in current use are either amino amides or amino esters and achieve their intended effect by blocking gated sodium channels. The ester local anesthetics are metabolized by plasma cholinesterase. Neonates and infants up to 6 months of age have less than half of the adult levels of this plasma enzyme. Theoretically, clearance may be reduced and the effects of ester local anesthetics prolonged. In reality this is never the case. Amides, on the other hand, are metabolized in the liver and bound by plasma proteins. Neonates and young infants (younger than 3 months of age) have reduced liver-blood flow and immature metabolic degradation pathways. Thus, larger fractions of local anesthetics are not metabolized and remain active in the plasma compared with adults. More local anesthetic is excreted in the urine unchanged. Furthermore, neonates and infants may be at increased risk for the toxic effects of amide local anesthetics because of lower levels of albumin and α_2 -acid glycoproteins, which are proteins essential for drug binding (Lerman et al., 1989). This decreased binding leads to increased concentrations of free drug and potential toxicity, particularly with bupivacaine. On the other hand, the larger volume of distribution at steady state seen in the neonate for these (and other) drugs may confer some clinical protection by lowering plasma drug levels (see Chapter 7, Pharmacology of Pediatric Anesthesia).

TABLE 15-10. Suggested Maximal Doses of Local Anesthetics (mg/kg)*

Drug (Concentration) and Technique	Spinal	Caudal/Lumbar Epidural	Peripheral†	Subcutaneous‡
Esters				
Chloroprocaine (1% infiltration) (2%-3% epidural)	NR	8-10§	8-10§	8-10§

*These are suggested safe upper limits when drug is administered at recommended location. Direct intraarterial or intravenous injection of even a fraction of these doses may result in systemic toxicity or death.

†Epinephrine should never be added to local anesthetic solution administered in area of an end artery (e.g., penile nerve block).

‡The minimal effective dose in children <10 kg is 1.5-2 mg.

§The higher dose is recommended only with the concomitant use of epinephrine 1:200,000.

¶Total adult dose should not exceed 600 mg.

NR, Not recommended. Concentrations are in mg percent. For example, a 1% solution contains 10 mg/mL.

Box 15-1 Intralipid Rescue for Local Anesthetic Toxicity

- Call for help and start CPR
- 20% Intralipid solution
- 1 to 2 mL/kg Bolus (adult dose, 150 mL)
- Once circulation is reestablished, start continuous infusion 0.5 mL/kg/minute

The metabolism of the amide local anesthetic prilocaine is unique in that it results in the production of oxidants that can lead to the development of methemoglobinemia. This occurs in adults with doses of prilocaine greater than 600 mg. Because premature and full-term infants have decreased levels of methemoglobin reductase, they are more susceptible to developing methemoglobinemia. An additional factor rendering newborns more susceptible to methemoglobinemia is the relative ease by which fetal hemoglobin is oxidized compared with adult hemoglobin. Because of this, prilocaine cannot be recommended for routine use in neonates.

Local Anesthetic Toxicity

Cardiovascular and CNS toxicity after local anesthetic administration in children is rare (Berde, 1992; McCloskey et al., 1992). Local anesthetic toxicity can be limited by careful attention to dose, route of administration, fractionating the dose, and rapidity of absorption of local anesthetic into the systemic circulation (Berde, 2004). Cardiovascular toxicity caused by bupivacaine is the most feared complication of local anesthetic administration, whether it is administered acutely (intermittent dosing) or continuously, because it presents as ventricular dysrhythmias that may be refractory to treatment. Neonates may be at increased risk for bupivacaine toxicity for reasons discussed earlier. Because of this, it is increasingly being replaced with either ropivacaine or levobupivacaine, which may have a greater therapeutic index and margin of safety (Dony et al., 2000; Groban et al., 2001). Patients who develop “lethal” cardiovascular collapse may be rescued with a 20% lipid solution bolus, 1 to 2 mL/kg or 150 mL for adults (Dagleish and Katawaroo, 2005; Weinberg et al., 2006). This dose may be repeated while resuscitation continues. Once circulation is reestablished, a continuous lipid infusion of 0.5 mL/kg per minute is initiated, and the patient is transferred to an intensive care unit for further monitoring (Box 15-1). Other therapies include prolonged resuscitation efforts, extracorporeal membrane oxygenation, or another temporary circulatory-assistance device.

Topical Local Anesthetics EMLA and ELA-Max

There are several methods for providing topical anesthesia to minimize procedural pain (e.g., venipuncture, lumbar puncture, chest-tube insertion). These include injection of local anesthetic at the procedure site, application of topical anesthetic creams and ointments, iontophoresis, and laser-assisted delivery of anesthetics. An eutectic mixture of local anesthetics (EMLA) in the form of cream is a topical emulsion composed of 2.5% prilocaine and 2.5% lidocaine and produces complete anesthesia of intact skin after application. Unfortunately, for

best effect, EMLA cream must be applied and covered with an occlusive dressing for 60 minutes before performing a procedure. This limits its use in the emergency room or office to situations in which the site can be prepared well in advance of anticipated use. Furthermore, if the procedure is a venipuncture, multiple sites must be prepared, in case the initial attempt is unsuccessful (a common problem in pediatric practice in general and more so when EMLA is applied, because it causes cutaneous blanching). Finally, as stated previously, the prilocaine component of EMLA can cause methemoglobinemia. Unfortunately, this has limited the use of EMLA in the newborn. Nevertheless, a single dose is safe and has been shown to be effective in the management of newborn circumcision (Taddio et al., 1997; Lehr and Taddio, 2007). Alternatives that do not contain prilocaine are readily available. Lidocaine 4% (ELA-Max) is as effective as EMLA and requires only 30 minutes to become effective (Koh et al., 2004).

Interestingly, the effectiveness of topical local anesthetics at reducing pain is dependent on who makes the assessment. Soliman et al. (1988) studied the efficacy of EMLA cream compared with injected lidocaine at reducing the pain associated with venipuncture. Both an observer and a physician performing the procedure judged pain relief to be virtually complete in both groups. However, the children involved in the study were not so sanguine and were equally dissatisfied with both methods, particularly if the needle used for venipuncture was visible to them. Thus, despite the fact that two observers felt that the child was pain free, the child's cooperation with venipuncture did not improve. Therefore, it is not clear whether the delay that is involved in the use of EMLA (60-minute wait for effect) is always justified. On the other hand, topical local anesthetics may be more effective in children accustomed to numerous medical procedures (e.g., oncology patients) or for procedures in which the child cannot see the needle, such as lumbar puncture or bone marrow aspiration (although there is little evidence to support the effectiveness of EMLA even in these situations).

Local Infiltration

Infiltration of wound edges with local anesthetics (field block) or by directly instilling local anesthetic into a wound (splash) effectively provides intraoperative and postoperative analgesia for many minor (e.g., inguinal herniorrhaphy, laceration repair, or tonsillectomy) and some major surgical procedures (e.g., craniotomy) (Wong et al., 1995; Casey et al., 1990). Many studies have demonstrated the effectiveness of tetracaine-adrenaline [epinephrine]-cocaine (TAC), lidocaine-epinephrine-tetracaine (LET) and bupivacaine-norepinephrine (BN) in the management of lacerations in children (Schilling et al., 1995; Ernst et al., 1996). Unfortunately, cocaine, a key ingredient in making the TAC drug combination effective, is toxic. Indeed, toxicity has been reported even when TAC has been applied appropriately and according to recommended guidelines.

The most commonly used local anesthetics for local infiltration are lidocaine, mepivacaine, bupivacaine, ropivacaine, and levobupivacaine. As mentioned previously, local anesthetic toxicity is primarily related to how rapidly and how much local anesthetic is absorbed (or deposited) in the blood. Toxicity can be limited by careful attention to dose, route of administration, and by limiting the rate of rise of local anesthetic into the systemic circulation (Table 15-11). No more than 2 to 2.5 mg/kg of

TABLE 15-11. Local Anesthetic Maximum Dosing Guideline by Weight

Local Anesthetic	Bolus Dose (mg/kg)		Infusion (mg/kg/hour)	
	Infants		Infants	
	<6 Months	Child	<6 Months	Child
Bupivacaine	1.5	2.5	0.2	0.4
Ropivacaine	2	2.5	0.2	0.5
Chloroprocaine	10	10	15	15
Lidocaine	3	5	0.8	2

bupivacaine or 5 to 7 mg/kg of lidocaine should be used. Dilute solutions of the local anesthetics can be used to provide adequate spread of the anesthetic solution without exceeding the maximum dose. Epinephrine can also be added to the solution in vascular areas to slow the uptake of the anesthetic and to prolong its action. However, in order to avoid ischemic injury, epinephrine must never be used in procedures involving end-arteries, such as the penis or distal extremities. Finally, other adjuvants, particularly clonidine, can be added to the local anesthetic solution to improve the quality and duration of neural blockade (Cucchiaro and Ganesh, 2007). When performing nerve blocks, the pain of local anesthetic administration can be minimized by using small-gauge needles (25 to 30) and warm, buffered anesthetic solutions, and by injecting slowly. Adding bicarbonate to local anesthetic solutions shortens the onset time (faster block) and reduces the pain of injection (Christoph et al., 1988; Orlinsky et al., 1992). This is best accomplished by adding 1 mL (1 mEq) of 8.4% sodium bicarbonate to 9 mL lidocaine or by adding 1 mL (1 mEq) of 8.4% sodium bicarbonate to 29 mL bupivacaine (Yaster et al., 1993, 1994b).

Neural Blockade

The anatomy of peripheral nerves and the techniques of nerve blockade are basically the same for children and adults. The use of nerve stimulators, ultrasonography, and a description of the most common nerve blocks used in pediatric practice are discussed in Chapter 16, Regional Anesthesia. In the next sections the administration of analgesics through these catheters is discussed.

Continuous Epidural Analgesia

Continuous or intermittent epidural analgesia uses local anesthetics administered either alone or in combination with opioids, α_2 -adrenergic agonists (clonidine) or NMDA receptor antagonists (ketamine) in order to block nociceptive impulses from entering the CNS and provide profound analgesia without systemic sedation (Dalens and Hasnaoui, 1989; Yaster and Maxwell, 1989; Llewellyn and Moriarty, 2007). Epidural analgesia has become the most commonly performed regional anesthetic technique for the intraoperative and postoperative management of patients with urologic, orthopedic, and general surgical procedures below the T4 dermatomal level in children. It has been used to provide continuous sympathetic blockade in

children with vascular insufficiency secondary to intense vasoconstriction (e.g., purpura fulminans), in patients with cancer unresponsive to parenteral and enteral opioids, and in the management of patients who have sickle cell trait with vasoocclusive crisis (Yaster et al., 1994a). How long an indwelling caudal or lumbar epidural catheter can be left in place without risking local or systemic infection is unknown; however, serious systemic infections after short-term (3 to 5 days) continuous lumbar and caudal epidural analgesia are extremely rare (Strafford et al., 1995; Kost-Byerly et al., 1998).

Epidural catheters can be inserted at the caudal, lumbar, or thoracic level. The closer the tip of the catheter lies to the dermatome to be blocked, the smaller the amount of drug required to produce neural blockade. Because local anesthetic toxicity is directly related to the total amount of drug infused, catheter placement plays a very important role in the overall safety of this technique. Epidural placement via the caudal and lumbar approach is most common, although even thoracic placement is advocated by some (Bosenberg et al., 1998). Of note, because the epidural space of young children is filled with loosely packed fat and blood vessels (compared with adults), it is possible to thread a caudally (or lumbar) placed catheter as far as the thorax. Bosenberg et al. (1998) first reported the use of the caudal approach for thoracic placement of an epidural catheter in children younger than 2 years of age. Gunter and Eng (1992) extended this observation to older children as well. In children under 5 years of age, caudal insertion and threading 8 to 10 cm of catheter is the preferred epidural technique for most surgery below T4. The key to success is to use short (5-cm), 18-gauge needles, through which 19- to 20-gauge, styletless catheters are inserted. The large-bore catheter offers many advantages over smaller bore (21- to 24-gauge) catheters that were initially used in pediatric epidural analgesia. These large-bore catheters allow for less resistance to flow, less likelihood of occlusion (kinking), and less back-leakage at the site of insertion.

Continuous infusions of local anesthetics either administered alone or with adjuvants (e.g., opioids or clonidine) provide pain relief during the entire period of infusion. This makes it very attractive for postoperative pain management and pain management where conventional therapy has proven ineffective (e.g., cancer or sickle cell crisis). Initially, high doses of local anesthetics, similar to those used intraoperatively, were used postoperatively, resulting in local anesthetic toxicity. Dilute concentrations given at much lower doses have been shown to provide sensory and autonomic blockade without risking local anesthetic toxicity. As an added benefit, lower concentrations of local anesthetics do not produce motor blockade, a side effect of local anesthetic administration that is disliked by patients, parents, and surgeons alike. Very dilute concentrations of local anesthetics (0.625 to 1.25 mg/mL bupivacaine or ropivacaine, 1 to 5 mg/mL lidocaine) are generally effective when combined with opioids and/or clonidine.

In North America, the most commonly used local anesthetics in continuous epidural blockade are bupivacaine and ropivacaine. Bupivacaine and ropivacaine are administered in concentrations ranging from 0.625 mg/mL (1/16th% solution) to as high as 2.5 mg/mL (0.25% solution). Concentrations above 1.25 mg/mL (1/8% solution) are rarely required for postoperative or medical analgesia and significantly increase the risks of toxicity and unwanted side effects (e.g., sensory, motor, autonomic dysfunction, urinary retention, and inability to walk). Berde, in the editorial accompanying McCloskey's report of bupivacaine toxicity

in children, recommended that bupivacaine infusions be kept below 0.4 mg/kg per hour in children and 0.2 mg/kg per hour in neonates (Berde, 1992; McCloskey et al., 1992). Although this has not been formally studied, these recommended doses have become dosing guidelines. The most commonly used (and easiest) epidural concentration of bupivacaine or ropivacaine is 0.1% (1 mg/mL). Because in concentrations of 1 mg/mL, bupivacaine and ropivacaine do not always produce reliable analgesia, opioids such as fentanyl (2 to 2.5 mcg/mL), hydromorphone (10 mcg/mL), or morphine (20 to 30 mcg/mL) are almost always added to this dilute epidural solution. Which opioid to use is based on the site of the surgical procedure. For surgical procedures performed above the umbilicus (e.g., Nissen fundoplication or thoracotomy), many practitioners prefer hydromorphone or morphine, because they are less lipophilic than fentanyl and may have better rostral spread. For pain below the umbilicus, the initial starting infusion is 0.2 mL/kg per hour (0.2 mg/kg per hour bupivacaine or ropivacaine; 0.4 to 0.5 mcg/kg per hour fentanyl, or 2 mcg/kg per hour hydromorphone, or morphine 6 mcg/kg per hour); for pain above the umbilicus, the initial starting epidural infusion is 0.3 mL/kg per hour (0.3 mg/kg per hour bupivacaine or ropivacaine; 0.6 to 0.75 mcg/kg per hour fentanyl or 3 mcg/kg per hour hydromorphone, or morphine 9 mcg/kg per hour). Generally, infusion rates do not exceed 14 to 16 mL/hour.

If bupivacaine or ropivacaine is used in older children for epidural PCA, the basal infusion is generally administered at a rate that provides 0.2 mg/kg per hour of local anesthetic, while half of the basal rate is given as a bolus (Birmingham et al., 2003). A maximum of two boluses are allowed per hour with a lockout period of 15 minutes. This approach provides a maximum of 0.4 mg/kg per hour bupivacaine or ropivacaine.

As discussed previously, cardiovascular toxicity caused by bupivacaine is the most feared complication of local anesthetic administration, regardless of the method of administration. The newborn is particularly vulnerable. Because of this, bupivacaine has increasingly been replaced by either ropivacaine or levobupivacaine, which may have a greater therapeutic index and margin of safety. However, they are also significantly more expensive. Because lidocaine can be easily measured in most hospital clinical laboratories, is less cardiotoxic than bupivacaine, and is cheaper than ropivacaine, lidocaine can be used for continuous local anesthetic infusions in neonates. In neonates, lidocaine in 1 mg/mL concentrations can be administered at a rate of 0.8 mg/kg per hour. Blood levels are measured every 12 hours, and the infusion is titrated downward if the lidocaine blood levels are greater than 4 mg/L. In children older than 2 months of age, lidocaine can be administered in doses of 1.5 mg/kg per hour (lidocaine concentrations of 3 to 5 mg/mL).

Continuous Peripheral Nerve Blockade

Local anesthetics can be infused in continuous peripheral nerve blockade using either disposable elastomeric pumps or standard electronic PCA pumps. The most commonly used solution consists of 0.125% bupivacaine, 0.15% ropivacaine, or 0.1% ropivacaine at rates of 0.1 to 0.15 mL/kg per hour (maximum rate of 12 mL/h). The choice of local anesthetic is based on the anesthesiologist's preference and the need to prevent a motor blockade. Disposable elastomeric pumps have a rate selection of 2 to 14 mL/h (even numbers only) with a reservoir that can be

filled with up to 400 mL of local anesthetic solution. They are not refillable but may be replaced to provide multiple days of peripheral neural blockade. In general, these catheters/pumps result in an opioid sparing effect as well as a low incidence of self-limited complications (Ganesh et al., 2007).

CHRONIC PAIN

For most pediatric anesthesiologists, the management of acute pain is an extension of their operating room experience, but this is not so with chronic pain. Although acute injury or disease may precede chronic or recurrent pain, once it becomes self-sustaining, chronic pain becomes its own condition independent of the original pathology that initiated it. Chronic pain in children is not unusual and can be incapacitating. Affected individuals become physically inactive and dependent on others for many of the tasks of daily living. As it progresses, it interferes with peer and family relationships and often results in the inability to go to school, which is the childhood equivalent of being unable to work. Thus, the management of chronic pain, in the absence of a treatable cause, is to restore function. This is often best accomplished through interdisciplinary cognitive-behavioral and physical rehabilitative programs that help return the child to physical activity even before pain reduction occurs. In the next sections the management of three archetypical chronic pain conditions in children and adolescents are discussed, namely complex regional pain syndromes (CRPS), abdominal pain, and headaches.

Complex Regional Pain Syndromes

CRPS as a term was first proposed by Stanton-Hicks to describe a varied and dynamic presentation of symptoms including intense, almost incapacitating, regional pain and sensory, neurovascular, motor, and pseudomotor abnormalities (Stanton-Hicks et al., 1995; Stanton-Hicks, 2003; Berde and Lebel, 2005). Although the precise pathophysiology remains unclear, multiple abnormalities have been described in the peripheral nervous system and the CNS. Sympathetic nervous system involvement has been found in many but not all patients, as demonstrated by relief of pain by sympathetic blockade of the affected extremity or an abnormal hemodynamic response to tilt-table testing (Meier et al., 2006). The diagnosis of the syndrome continues to be based primarily on the patient's history and physical examination. Presentations without identifiable trauma to nervous system structures are classified as CRPS type I, or reflex sympathetic dystrophy (RSD) in older taxonomy. In cases in which a definable peripheral nerve lesion exists, the diagnosis is CRPS type II, or causalgia. The signs and symptoms for CRPS types I and II are clinically indistinguishable.

CRPS type I has been described in children as young as 5 years of age, and type II has been observed in children as young as 3 years old (Tan et al., 2008). Although uncommon, CRPS is not rare and is increasingly being recognized and diagnosed (Sherry et al., 1999; Lee et al., 2002). Unlike in adults, in children and adolescents CRPS is predominately a disease of females (female/male ratio 5:1) and most commonly affects a lower extremity. Furthermore, if a preceding injury is described, it is usually minor. In addition, psychosocial factors are thought to play a greater role than in adults. Finally, noninvasive,

cognitive, behavioral, and physical therapies are more effective in the pediatric population than in adults (Sherry et al., 1999; Lee et al., 2002; Stanton-Hicks, 2003). However, in a minority of patients, persistent pain and a high degree of disability exist despite multimodal therapy including interventional therapy (Wilder et al., 1992).

Diagnosis

The diagnosis of CRPS is based primarily on the patient's history and physical examination rather than on laboratory testing. Examination or history often show that the affected child has sensory abnormalities such as intense, burning pain; allodynia; and hyperalgesia in the distal aspects of a single extremity. Even in CRPS type II, pain does not follow any sensory dermatomes but is present in a glove or stocking distribution. Whereas children may have all the symptoms generally associated with the syndrome, in adults there are several distinct differences: the temperature of the affected limb is often cooler in relation to the symmetric extremity, edema is less common, and atrophic changes are rare except for decreases in skeletal muscle mass (Tan et al., 2008). Just as in adults, spread of symptoms to other parts of the body, either in a continuous or in a discontinuous fashion, has been observed.

CRPS is primarily a clinical diagnosis. It is not an autoimmune, infectious, or a rheumatologic disorder. It is not associated with elevated erythrocyte sedimentation rates, and there are no elevations of any specific antigen or antibody titer. There is no fever or leukocytosis, which helps differentiate it from an infectious disease. Response to sympathetic blockade is not useful in diagnosis, because response can be seen with any form of sympathetically mediated pain.

The most common laboratory evaluations in CRPS involve nuclear medicine, quantitative sensory testing, and most recently, functional MRI (Intenzo et al., 2005; Lebel et al., 2008). Although a patient's nuclear medicine report often states that findings after bone scintigraphy are, or are not, consistent with CRPS, no particular pattern of hypofixation or hyperfixation on scintigraphic studies has been found to be diagnostic. Patients with a history and clinical presentation consistent with CRPS may have a decreased, increased, or normal uptake of tracer on a bone scan. Scintigraphy is more sensitive than plain x-rays and can be useful in supporting or confirming the diagnosis by helping to exclude other diagnoses such as arthritis, benign or malignant bony lesions, or metabolic bone diseases (Intenzo et al., 2005). Hypoperfusion corresponding to osteopenia on a plain radiograph may be used as a cautionary sign for conducting physical therapy sessions to avoid pathologic fractures.

Nerve-conduction studies (NCS) and electromyography (EMG) should be reserved for the occasional patient. These are painful tests and may not be well tolerated in highly sensitive patients. NCS and EMG are indicated when initially diffuse symptoms become more localized as therapy progresses, or when pain follows a distinct dermatomal pattern, because this may be indicative of a peripheral nerve entrapment. Quantitative sensory testing (QST) is primarily a research tool. Sethna et al. (2007) performed standardized neurologic examinations and QST in a group of 42 pediatric patients and found that cold allodynia was the most common abnormality. More than half of their patients also had mechanical, dynamic, and static allodynia and allodynia to punctuate temporal summation. The authors

suggested that these abnormal hyperexcitable sensory patterns may be consistent with a central sensitization pattern.

Finally, the importance of psychological disturbances both in the diagnosis and management of CRPS have been hotly debated. At one point, CRPS was thought to be an entirely psychosomatic disorder. Although this view is no longer tenable, the importance of psychological dysfunction and multiple stressors in affected children is clear and an important target of therapeutic intervention (Sherry et al., 1999; Tan et al., 2008). Indeed, Sherry et al. (1999) emphasize the importance of individual and family psychological issues in the perpetuation of this condition.

Treatment

There are currently no therapeutic modalities that predictably lead to resolution of CRPS. All treatment is directed at aggressive mobilization of the affected limb early in the process to prevent disability, refractoriness, and treatment failure and must include the family as well as the patient (Lee et al., 2002). Unquestionably, the key to therapy is physical reconditioning and mobilization of the affected limb by exercise, ambulation, and range of motion exercises (Lee et al., 2002). With reconditioning, affect, endurance, and pain improve. Medication may help alleviate pain, improve sleep, and facilitate physical therapy. Many drug classes, including opioids, NSAIDs, TCAs, and anticonvulsants are prescribed, but none has been subjected to the rigors of randomized controlled trials in the treatment of these patients. Finally, cognitive behavioral therapy is as important as physical therapy and medication, because it promotes positive coping skills and eliminates reinforcement of maladaptive behaviors.

Occasionally more aggressive intervention therapy, such as sympathetic nerve blocks, are used when pain is not well controlled by these more conservative measures, when allodynia is so severe that physical therapy is impossible, or when there is no improvement or even further loss of function despite adequate therapy. Sympathetic nerve blocks are not required for diagnosis and no association between the use of blocks and long-term outcome has been made. There are multiple case series and reports on the use of continuous infusions of local anesthetic with or without adjuvants such as opioids, clonidine, or ziconotide administered via peripheral nerve, lumbar sympathetic, epidural, and intrathecal catheters in these disorders (Dadure et al., 2005; Farid et al., 2007; Meier et al., 2009). Most infusions were limited to a few days, although some catheters remained in place for several months. Meier et al. (2009) demonstrated variable effectiveness of lumbar sympathetic blockade in lower extremity CRPS in the first randomized controlled crossover trial ever conducted in adolescent patients with this disease. However, no association between the response to sympathetic nerve blockade and long-term outcome has been shown. On the other hand, Sherry et al. (1999) believe that nerve blocks and medication are unnecessary and may be counterproductive because they reinforce the patient taking a passive, rather than active, role in recovery.

If blocks are considered, the practitioner along with the patient and the patient's family must weigh the risks of the procedure against their potential benefit. Which block to use is based not only on anatomy and physiology but also on local resources and availability and on the practitioner's skills with ultrasound or fluoroscopy for catheter guidance and placement.

When individual patients achieve a therapeutic response to sympathetic block, repeat blocks may be warranted, particularly if this allows the patient to more actively participate in physical therapy. The question of how often and when blocks should be repeated remains unanswered, and improvement in function is a guiding factor.

Finally, the use of neuromodulation (spinal-cord stimulators) in the management of pediatric CRPS is unclear. Spinal-cord stimulators are increasingly being used in adults with CRPS whose conservative treatment has failed, who are psychologically stable, and who can achieve functional status sufficient to participate in exercise after the procedure (Nelson and Stacey, 2006). However, their effectiveness is unclear. Initial favorable reports in adults were followed by less encouraging functional results in the same population 2 to 5 years later (Kemler et al., 2000, 2004, 2008). A case series of seven adolescent girls reported that at least some of the patients who received spinal-cord stimulators entered remission and no longer required the device at a long-term follow-up session, suggesting this modality has potential therapeutic use in pediatric CRPS (Olsson et al., 2008). However, much larger randomized controlled trials are required before this therapy can be recommended in young patients.

Functional Gastrointestinal Disorder

Functional gastrointestinal disorder (FGID) encompasses a group of conditions characterized by chronic or recurrent symptoms that are not explained by biochemical, anatomic, or structural abnormalities (Saps and Di, 2009; Yacob and Di, 2009). Normal gastrointestinal functions include transport, digestion, and absorption of nutrients, and removal of waste products. The gut is also an important immune barrier. Patients with FGIDs experience a constellation of symptoms consistent with abnormalities in these gastrointestinal functions. These include dysmotility, secretory dysfunction, malabsorption, diarrhea or constipation, and allergic enteritis. However, significant weight loss, growth failure, unexplained fever, pain far from the umbilicus, bloody diarrhea, and repeated emesis are rarely associated with FGIDs. Presence of these signs or symptoms should result in a search for an organic process, such as a tumor, mechanical obstruction, infection, or inflammatory bowel disease.

FGIDs are among the most common conditions in childhood and lead to numerous school absences and loss of work by parents. The FGIDs include functional abdominal pain (previously called recurrent abdominal pain), functional dyspepsia, irritable bowel syndrome, and abdominal migraine. Functional or recurrent abdominal pain is a description and not a diagnosis. It is commonly defined by at least three bouts of abdominal pain severe enough to affect the school-aged child's activities over a period of at least 3 months and is not feigned (malingering). The pain is often described as aching, cramping, and persistent and is commonly associated with headaches, recurrent limb pains, pallor, and vomiting. Additionally, there is no, or only an occasional, relationship of the pain with physiologic events such as eating or menses. The etiology is unclear. A diagnosis of abdominal migraine requires at least three or more episodes within 12 months. It is a paroxysmal, intense, acute, midline abdominal pain lasting 2 hours to several days with intervening symptom-free intervals lasting weeks to months. Associated with this abdominal pain are two of the following features:

headache or photophobia during the episode, family history of migraine, headache on one side only, and an aura or warning period. Finally, the patient with irritable bowel syndrome has abdominal discomfort and pain for at least 12 weeks, although not necessarily consecutive weeks over a 1-year span. The pain is relieved by defecation and is associated with a change in stooling form or frequency. To make this diagnosis, structural or metabolic abnormalities that might explain the symptoms must be ruled out.

Treatment

Therapy for FGIDs is largely supportive and has to address contributing psychosocial factors. There are no magic pills, and there is limited evidence to justify the use of drugs or herbal preparations outside of clinical trials (AAP, 2005; Huertas-Ceballos et al., 2008, 2009; Saps and Di, 2009; Yacob and Di, 2009). Pharmacologic therapy is focused on the control of symptoms with prokinetic, antispasmodic, secretory, and coating agents. Anxiolytics and antidepressants are used because of their ability to modulate pain transmission and perception, as well as their potential to address psychological comorbidities. However, if using drugs as a therapeutic trial, clinicians should be aware that these are fluctuating conditions and any response may reflect the natural history of the condition or a placebo effect rather than drug efficacy (Huertas-Ceballos et al., 2008). Indeed, this was confirmed in a large multicenter, randomized, placebo-controlled study of amitriptyline in 83 children with functional abdominal pain that found no statistical difference between amitriptyline and placebo therapy (Saps et al., 2009).

Chronic Abdominal Wall Pain

Although chronic abdominal pain arising from a visceral source is the most common type of abdominal pain, it must be differentiated from pain originating in the abdominal wall. Abdominal wall pain is localized, not diffuse, and on physical examination is exquisitely tender with abdominal wall tensing (Carnett's sign). The abdominal wall is innervated by the seventh to twelfth intercostal nerves. Entrapment of these nerves at the level of the anterior cutaneous branch, as well as in the rectus sheath, has been described in children (Skinner and Lauder, 2007). Successful treatment with rectus sheath blocks has been described and should be made easier with ultrasound guidance (Willschke et al., 2006; Skinner and Lauder, 2007).

Headache

Headaches are a universal feature of the human experience. Studies of Swedish schoolchildren have indicated that 40% of children experience a headache by age 7, 75% experience a headache by age 15, and migraine (one of the most common causes of headache in childhood) occurs in 1% of children by age 7 and 5% of children by age 15 (Bille, 1962). Headaches have a significant impact on the lives of children by causing school absences, poor school performance, and decreased extracurricular activities. Although the majority of patients have benign causes of headaches that can usually be diagnosed by a careful

history and physical examination, radiologic evaluation using computed tomography (CT), MRI, or both may be necessary in select cases. Proper diagnosis, treatment, and close monitoring of these patients are extremely important to ensure that serious etiologies are not overlooked.

Pathophysiology

The brain and most of the overlying meninges have no pain receptors and are therefore insensitive to pain. Pain referred to the head arises from intracranial or extracranial arteries, large veins or venous sinuses, cranial and cervical muscles, the basal meninges, and extracranial structures, such as the teeth and sinuses. Thus, traction on vascular structures within the head, dilation or inflammation of cranial vascular structures, displacement of intracranial contents by tumor, abscess, increased intracranial pressure (ICP), and direct pressure on cranial nerves may result in headache. Also, sustained contraction of the head and neck muscles and pathologic processes outside of the head, such as diseases of the paranasal sinuses, eyes, teeth, and bones of the head and face also may result in pain referred to the head.

Pain arising from the cranial circulation and supratentorial structures travels in the trigeminal nerve. This pain is referred to the front of the head. Pain arising from the posterior fossa travels in the first three cervical nerves and is referred to the back of the head and neck and, occasionally, the forehead. Because the posterior fossa is also innervated by the glossopharyngeal and vagus nerves, pain arising from the posterior fossa also may be referred to the ears and throat.

The pathophysiology of a migraine headache requires a more detailed discussion. Migraine is the most common cause of chronic intermittent headaches in children and is associated with cortical hyperexcitability and vasomotor tone changes. During migraine attacks, cerebral blood flow is increased in the upper brainstem, which has a crucial role in initiating the attack. Complex neurochemical changes are associated with migraine; nitric oxide has a key role in the initiation and maintenance of migraine headache. Migraines may or may not be preceded by an aura (a focal neurologic sign). Auras are caused by "cortical spreading depression." This depolarization wave propagates across the brain cortex at 2 to 3 mm/min and is associated with transient depression of spontaneous and evoked neuronal activity. Activation of the trigeminovascular system is pivotal. Afferent fibers, arising from the trigeminal nerve and the upper cervical spinal cord segments, innervate the proximal parts of the large cerebral vessels and dura mater. These sensory fibers terminate within the lower brainstem and upper cervical cord. Nociceptive information is then relayed to the thalamus and cortical pain areas. Depolarization of the trigeminal ganglion or its perivascular nerve terminals activates the trigeminovascular system, giving rise to central transmission of nociceptive information and retrograde perivascular release of powerful vasoactive neuropeptides. Release of CGRP, neurokinin A, and substance P is associated with dural vasodilation and dural plasma extravasation. 5-HT plays an important role in migraine headaches, and 5-HT agonists and antagonists play important roles in therapy. Between attacks, 5-HT plasma levels are low and increase during attacks. These findings suggest selective stimulation of 5-HT₁ receptors to control attacks. Complex genetic factors are involved in migraine, increasing its risk up to fourfold.

Diagnosis

Standardized criteria have been developed to diagnose headache and divides headache into primary and secondary etiologies (Headache Classification Committee of the International Headache Society, 1988). Primary headaches are those that are directly attributed to a neurologic basis and include migraine, tension-type headaches, cluster headaches, and trigeminal autonomic cephalalgias. Secondary headaches are headaches directly attributed to another medical condition, such as headaches associated with space-occupying lesions, inflammation, sinusitis, and abnormalities of intracranial pressure (both high and low pressure) such as pseudotumor cerebri, Arnold-Chiari malformation, or hydrocephalus. Headaches that are associated with focal neurologic signs or symptoms, or that progressively worsen in severity or frequency are suggestive of intracranial pathology, and require neuroimaging by MRI or CT scan as appropriate and subsequent focused therapy. On physical examination, the clinician should look carefully for changes in consciousness, attention, language or memory, cranial nerve asymmetry or papilledema, nuchal rigidity, abnormal tone, gait ataxia, or any new neurologic abnormality.

Migraines and tension type headaches are the most common primary headaches of childhood. Approximately 10% of school-aged children suffer from migraine (Diamond et al., 2007; Silberstein et al., 2007). Migraine duration is generally between 1 to 48 hours. Migraine quality can be unilateral or bilateral, pulsating, moderate to severe in intensity, and aggravated by routine activity. The headache may be accompanied by nausea and vomiting or by photophobia and phonophobia (Headache Classification Committee of the International Headache Society, 1988). About 14% to 30% of children with migraine also experience a migraine aura, indicating focal cortical or brainstem dysfunction. Typical auras include spots, colors, images distortions, and visual scotoma. Interestingly, in adult patients a high prevalence of right-to-left shunting has been described in patients with migraine, especially migraine with aura, and symptoms have improved in some patients after closure of a patent foramen ovale (Nahas et al., 2009).

Migraine variants are headaches that are accompanied or manifested by transient neurologic symptoms. For example, hemiplegic migraine is characterized by the abrupt onset of hemiparesis that is usually followed by a headache. Basilar artery migraine is characterized by dizziness, weakness, ataxia, and severe occipital headache, and ophthalmoplegic migraine is associated with orbital or periorbital pain and third, fourth, or sixth cranial nerve involvement. Cyclic vomiting and recurrent abdominal pain, in the absence of primary gastrointestinal disease, are also considered migraine variants. Status migraine is defined as a severely painful, continuous unremitting headache of more than 72 hours' duration (Olesen and Lipton, 2004).

Therapy

Treatment of migraine headaches often involves both pharmacologic and nonpharmacologic therapies. Lifestyle changes can be made to eliminate identifiable headache precipitants. Although these vary from patient to patient, they can include stress, fatigue or lack of sleep, hunger, food additives (e.g., nitrates, glutamate, caffeine, tyramine, and salt), and medications (e.g., oral contraceptives or indomethacin). Prophylactic

therapy can be provided if headaches are recurrent or severe enough to interfere with the patient's life, or if they are resistant to acute therapy. The goal of prophylactic therapy is to reduce the frequency, duration, or severity of attacks. In general, these drugs can take as long as 6 to 8 weeks to show improvement in the patient's symptoms. When considering prophylactic therapy, consideration of the risks of long-term drug use as well as the side-effect profile of individual drugs must occur. Multiple classes of drugs have been used as prophylactic therapies, but few controlled studies in children are available.

Mechanisms of migraine prevention are not completely understood. In general, therapies have been focused on the three major theories proposed to explain migraine pathophysiology. The vascular theory attributes migraine pain to vasodilation. The second hypothesis focuses on cortical spreading depression, a neuronal depolarization wave followed by a suppression of bioelectric activity. The third theory postulates that migraine is related to the release of inflammatory neuropeptides from the trigeminal system, which subsequently dilate meningeal blood vessels (Galletti et al., 2009). Interestingly, mutations in voltage-gated calcium and sodium channels have been described in some patients with familial hemiplegic migraine, but whether similar pathologies occur in more standard cases of migraine is unknown (Pietrobon, 2005, 2007).

Prophylactic therapies include β -blockers (e.g., nadolol, propranolol), antidepressants (e.g., amitriptyline), cyproheptadine (peractin—an antihistaminergic, antiserotonergic drug), anticonvulsants (valproic acid, topiramate, gabapentin), and calcium channel blockers (flunarizine, verapamil). Emerging treatments in adults include angiotensin converting enzyme inhibitors, angiotensin II type 1 receptor blockers, and botulinum toxin. These classes of drugs can target multiple cortical and subcortical structures and also modulate peripheral neurogenic inflammation (Galletti et al., 2009).

β -Blockade with propranolol (1 to 3 mg/kg per day divided in 2 or 3 doses), calcium channel blockade with flunarizine, and topiramate treatment have been shown to be effective in ameliorating pediatric migraine (Victor and Ryan, 2003; Cruz et al., 2009). β -Blockade may decrease the frequency and intensity of migraines by increasing arterial tone and hampering vasodilation, or by reducing sympathetic tone. In addition, β -blockade reduces firing of some central noradrenergic neurons, and it may also interact with the serotonergic system, which plays an important role in migraine. Calcium channel blockers such as verapamil (4 to 8 mg/kg per day in three divided doses) may prevent migraine headaches by impairing the activation of neurogenic inflammation, a calcium-dependent process, or by increasing pain thresholds. Anticonvulsants can limit neuronal hyperexcitability through effects on voltage-gated sodium channels. In addition, antidepressants, anticonvulsants, and calcium channel blockers can also influence the serotonergic and dopaminergic systems, which play an important role in migraine pathophysiology.

Once a headache develops, the goals of therapy are to abort an attack and suppress pain, nausea, and vomiting. Often inducing or promoting sleep in a dark and quiet room is helpful in diminishing symptoms. Relaxation techniques, biofeedback, behavioral techniques, and acupuncture may also be helpful. Pharmacologic treatments to interrupt or abort the headache include a number of different classes of drugs. Mild analgesics such as acetaminophen and NSAIDs are often effective in chil-

dren (Hamalainen et al., 1997a; Hamalainen, 2006). Sumatriptan and other members of the triptan family are approved by the FDA for the treatment of adult migraine. Although commonly used in children, none has FDA approval for this indication. These medications are 5-HT₁ receptor agonists. Sumatriptan is available as an oral form (25 mg in adolescents), an injectable form (subcutaneous, 3 to 6 mg), and a nasal spray (5 to 20 mg). Nasal sumatriptan has been shown to be effective in pediatric migraine, whereas unlike in adults, the oral form of the drug has not (Hamalainen et al., 1997; Ueberall and Wenzel, 1999; Ahonen et al., 2004). Adverse effects associated with the use of triptans include tingling, dizziness, warm sensations, chest pain, and cardiac arrhythmias. Isometheptene and ergotamines have also been reported to be effective, especially when administered at the onset of the aura or start of the headache (Hamalainen, 2006). However, Hamalainen et al. (1997b) did not see an improvement in headaches after oral dihydroergotamine as compared with placebo in children with therapy-resistant migraines. In those children whose conservative therapy fails and who come to the hospital with status migraine, treatment with multiple doses of intravenous dihydroergotamine has been shown to be effective, although there is a significant incidence of adverse side effects, especially anxiety, nausea, and vomiting (Kabbouche et al., 2009). It should be noted that all abortive medications carry the risk of causing a headache from overuse of secondary medication, defined as a headache on more than 15 days of a month with overuse of acute treatment drugs for more than 3 months and headache that has developed or worsened during the period of medication overuse (Silberstein et al., 2005). When medication overuse headache occurs, a need for multisystem treatment approach may be beneficial (Pakalnis et al., 2007).

Sickle Cell Disease

Sickle cell disease (SCD) is an autosomal-recessive chronic hemolytic anemia characterized by the production of abnormal hemoglobin. A point mutation in the sickle cell β -globin gene results in the substitution of the hydrophobic amino acid valine for a glutamic acid at position 6 in the globin chain. When hemoglobin S tetramers become deoxygenated, valine is able to interact with other hydrophobic residues on neighboring globin chains to form insoluble globin polymers. Whereas polymerization rapidly reverts to normal once hemoglobin is reoxygenated, cells can become irreversibly sickled as a result of oxidative damage to the cell membrane after repeated cycles of sickling and unsickling. Sick cells display abnormal adhesion to endothelial cells and initiate microvascular occlusion (Vijay et al., 1998; Kaul et al., 1989). Resultant hypoxia causes further sickling, tissue infarction, and the release of inflammatory cytokines. Repeated vasoocclusive crises (VOC) predispose to multiorgan dysfunction and shorten survival (Platt et al., 1991, 1994). In addition, patients with SCD are susceptible to bacterial infections caused by splenic autoinfarction as well as abnormal cell-mediated immunity. Other consequences of SCD include gallstone disease as a result of chronic hemolysis, priapism, and stroke. Acute chest syndrome, caused by infection or embolic phenomena, is the leading cause of death (Vichinsky, 1991) (see Chapter 36, Systemic Disorders).

VOC are often characterized by excruciating and at times incapacitating pain. It is the most common and debilitating

problem encountered by patients with SCD. Many factors have been associated with the onset of acute pain crises, including cold, dehydration, alcohol intake, stress, and intercurrent infection. However, over one half of episodes have no identifiable precipitant. Acute sickle cell pain is primarily the result of tissue ischemia and occlusion of the microcirculation, whereas acute bone pain appears to be the result of avascular necrosis of the bone marrow (Shapiro, 1989; Stinson and Naser, 2003). Painful episodes can begin as early as 6 months of age. Younger children often suffer from finger, toe, and limb pain, whereas in adolescents back and abdominal pain may be the most prominent symptoms. Acute painful episodes include a prodromal period followed by an infarctive phase. Subsequently, a postinfarctive phase characterized by signs of inflammation and persistent severe pain develops and is then followed by a resolving phase during which the pain gradually remits.

Although there is no intervention that completely abolishes sickle cell pain, provision of analgesics is the cornerstone of management, and their use is titrated to the individual patient by taking into account age, developmental status, and emotional state. Painful crises are often managed at home with hydration and oral analgesics. Treatment of mild-to-moderate pain generally includes NSAIDs or acetaminophen. However, because patients with SCD may have hepatic or renal impairment, care must be taken in prescribing these drugs to avoid systemic toxicity. If pain persists, an oral opioid is added to this regimen.

Patients coming to the hospital with sickle cell pain have commonly failed home therapy or may be unable to tolerate oral analgesics because of nausea and vomiting. Sickle cell crisis pain can be excruciating and is the leading cause of emergency room visits and hospital admissions in these patients. When studied, average VAS scores of 9.5 ± 0.63 out of 10 have been reported (Ballas, 1997). In that setting, the use of parenteral opioids is common. Once pain has been appropriately assessed, medication is titrated to provide pain relief (Benjamin et al., 1999). Initial doses of opioid are based on a history of what has provided adequate analgesia in the past. Although historically, meperidine was the most commonly prescribed opioid for treatment of SCD pain, it is no longer a first line treatment of acute pain because of the CNS toxicity of its metabolite, normeperidine (Latta et al., 2002). In general, titration schemes involve administration of a loading dose of opioid (e.g., morphine 0.1 to 0.2 mg/kg or hydromorphone 0.01 to 0.04 mg/kg) followed by additional smaller bolus doses (generally one fourth or one half of the loading dose) or initiation of PCA (National Heart, Lung, and Blood Institute, 2002). A prospective controlled trial of morphine PCA showed that PCA was as effective as intermittent nurse-administered intravenous doses of morphine, with 80% of patients describing the PCA analgesic regimen as good to excellent (Shapiro et al., 1993). Once pain has stabilized and the patient can tolerate oral intake, analgesics can be transitioned to an equianalgesic sustained-release oral opioid, in conjunction with rescue analgesia, to treat breakthrough pain.

Unfortunately, even with aggressive, proactive pain management, pain in SCD is often difficult to treat, resulting in therapeutic failure and frustration for both patients and their health care providers. Patients with acute sickle cell crisis pain often report higher pain scores than postoperative patients until they enter the resolving phase of their crisis. They often report 10 out of 10 on a pain scale, even when they appear to their physicians and nurses to be comfortable. This disconnect between subjective and objective assessments can result in a therapeutic

dilemma in which patients request more and more opioids and their physicians prescribe less and less. This lack of trust is in part caused by race and a fear of producing drug addiction (Geller and O'Connor, 2008). SCD is a disease primarily of African Americans and it is clear from other studies that African Americans are less likely than Caucasian and Hispanic Americans to be prescribed opioids for even common conditions in the emergency department, such as migraine headaches and fractures (Tamayo-Sarver et al., 2004, 2003).

Although patients with SCD do develop tolerance, as well as physical dependence and at times hyperalgesia, to opioids if they are administered for prolonged periods of time, they do not develop drug addiction at a higher rate than patients with other conditions (Waldrop and Mandry, 1995). Nevertheless, the failure to provide adequate analgesia often results in pseudoaddiction (Elander et al., 2003). Pseudoaddiction arises when a patient's pain is inadequately managed, and the response to this undertreatment is used as evidence for the diagnosis of drug addiction. Pseudoaddiction is postulated to progress through three phases. The cycle begins with "as-needed" dosing of inadequate analgesics for the treatment of continuous or recurrent pain. Initially, the patient merely requests more pain medication. When these requests are overlooked or ignored, the patient then tries to convince the physician of pain by moaning, grimacing, or crying. The physician interprets this behavior as aberrant and again refuses the requested dose escalation. Finally, the crisis phase occurs when the patient increases the level of bizarre, drug-seeking behavior. The cycle continues, with the patient persistently trying to acquire the drug and the physician consistently refusing to treat the pain, resulting in a lack of trust between the two parties and ultimately in the patient being viewed as a drug addict (Weissman and Haddox, 1989).

Opioids, even at high doses, often have limited efficacy in ameliorating sickle cell pain and often produce unwanted side effects such as sedation, constipation, nausea, and vomiting. Thus, other treatments have been used in place of or in conjunction with opioids in an attempt to diminish these side effects. Whereas single doses of an NSAID do not appear to significantly impact on opioid use, multidose parenteral NSAID infusions do seem to result in a significant opioid-sparing effect. Thus, ketorolac is often added to parenteral opioids in an attempt to improve analgesia and diminish opioid consumption. However, because of its impact on renal function, it is recommended that it not be given for more than 5 days in a given month (Feldman et al., 1997). Studies of parenteral corticosteroids also suggest that pain and length of hospital stay can be shortened by their use without producing short-term adverse effects (Dunlop and Bennett, 2006). However, concerns regarding increases in recurrent pain episodes, as well as the side effects of chronic steroids, have limited their clinical use in this setting (Couillard et al., 2007). Although not routinely employed, epidural analgesia with local anesthetic and opioid has also been shown to be effective in treating sickle cell pain and improving respiratory status in patients whose conventional therapy has failed (Yaster et al., 1994a). However, this modality is only effective if pain is localized to areas of the body that can be effectively blocked by epidural analgesia (e.g., chest, abdomen, and lower extremities). In addition, the impact of repeated epidural placements for the treatment of pain in patients with repeated pain crises is unknown. Finally, self-hypnosis, biofeedback, relaxation, and acupuncture have

all been reported to be effective in reducing pain in some patients (Zeltzer et al., 1979; Sodipo, 1993).

In addition to recurrent, acute pain, patients with SCD are also at risk of developing chronic pain that can be physically and psychologically debilitating. Causes of chronic pain include arthritis, arthropathy, avascular necrosis, skin ulcers, and vertebral body collapse (National Heart, Lung, and Blood Institute, 2002). Although there are no studies addressing the management of chronic pain in patients with sickle cell disease, sustained-release opioids, such as MS-Contin or methadone, are at times prescribed to provide consistent analgesia (Dunlop and Bennett, 2006). Adjuvant drugs can be prescribed as well.

Ultimately, the best method of sickle cell pain control may involve therapies that decrease the likelihood of VOC by preventing sickling. Hydroxyurea was approved by the FDA for treatment of adults with sickle cell anemia in 1998, and in 2002 the National Heart, Lung, and Blood Institute issued recommendations for its use in children with SCD (National Heart, Lung, and Blood Institute, 2002; Strouse et al., 2008). Hydroxyurea acts in part by inducing the induction of fetal hemoglobin production, which inhibits hemoglobin polymerization and sickling. It also decreases hemolysis and reduces the expression of cell-adhesion molecules that contribute to vasoocclusion (Benkerrou et al., 2002). Studies in children have shown an increase in fetal hemoglobin concentration, a decline in the yearly rate of hospitalizations, and a reduction in pain crises, but long-term effects of hydroxyurea treatment in SCD are still unknown (Strouse et al., 2008).

PALLIATIVE CARE

Despite dramatic advances in the diagnosis and treatment of many pediatric diseases, death during childhood remains a persistent reality, and caring for children during their final days remains a compelling clinical responsibility for pediatric health care providers (Kang et al., 2007). The past decade has seen an enormous shift in the attitudes, beliefs, and practices of pediatric palliative medicine. Palliative care is increasingly being recommended for a variety of pediatric illnesses, including those for which a cure remains possible or even likely (Field and Behrman, 2009; Goldman et al., 2009). The most obvious are those life-threatening diseases for which curative treatment is possible but might fail, such as cancer. Less intuitive, are conditions with long periods of treatment devoted to prolonging life, but without cure, such as Duchenne's muscular dystrophy or children with severe neurologic disabilities (Wusthoff et al., 2007).

The goal of palliative care is to achieve the best quality of life possible for patients and their families. Control of pain, other physical symptoms, and psychological, social, and spiritual problems are vital components of this care. Pediatric palliative care focuses on three prominent aspects of care (Kang et al., 2007; Field and Behrman, 2009; Goldman et al., 2009). First, and arguably most important, is communication. Understanding how disease processes and a person's innate abilities and liabilities affect that communication is essential to building a foundation of collaboration and a sense of teamwork with the patient and family. Second, psychosocial aspects of pediatric palliative care are important to the present and future well-being of the child, the family, and the practitioner. Acknowledging and facil-

itating a family's spiritual needs and involvement in religious traditions that are comforting to them often helps provide meaning to this distressing experience (McSherry et al., 2007). For many families and health care providers the incorporation of religion and spirituality into the medical care of their child and patient can be an integral part of providing comprehensive high-quality palliative care (McSherry et al., 2007). Focusing on these and other issues that affect the children's, families', and practitioners' physical and mental health must be central when caring for dying children. Finally, the aspect that is most easily translated into clinical practice is caring for the specific physical needs of the child being treated. In the ensuing discussion, strategies are provided for managing common symptoms, including pain, dyspnea, agitation, gastrointestinal complaints, and seizures (Lin et al., 2009).

Pain Management

Assessing a child's and family's beliefs about the experience of pain and what it means, as well as the meaning of changes in pain medication, is an important part of pain interventions in palliative care. Pharmacologic management of pain is only one component of treatment and should always be accompanied by behavioral pain management strategies that pay attention to the beliefs that children and family have about the role of pain in the dying process. Communication within the multidisciplinary team is crucial in integrating information from all sources to provide the most accurate and complete assessment. In addition, addressing the family's concerns, as well as those of professional colleagues, openly and with clarity, is extremely important. This form of communication should happen regularly, with enough time for family members to express their concerns and for team members to address them.

No parent or health care provider wishes any child to suffer pain unnecessarily, particularly if they are dying. Indeed, watching a child die in pain is often a caregiver's greatest fear. And yet, there is often reluctance on the parts of parents and health care providers to manage pain aggressively. For many parents, the words *morphine* or *methadone* conjure up a fear of giving up. They also worry that their child will become addicted, that the drugs are too strong, or that the child's quality of life will be impaired by opioid-induced side effects, particularly excessive sedation. Health care providers share many of these beliefs and they may also worry that opioids will shorten their patient's life by inducing respiratory depression. Additionally, there is a fear that escalating opioid doses will induce tolerance and make pain control more difficult as the underlying disease progresses. Thus, there can be a concern about starting analgesics too soon.

Previously in this chapter the principles of pain assessment and the multimodal approach to pain management were discussed. In palliative care, the choice of appropriate analgesics often depends on both the nature of the patient's pain and on a medicine's formulation and route of administration. Thus, it is important to know whether the child is able to swallow liquid, sprinkles, or pills, or if medication can be administered via gastrostomy tube, rectally, or intravenously. For example, extended-release opioid preparations can be applied topically (transdermal fentanyl) or swallowed intact; however, the latter cannot be safely crushed for administration. Sprinkle

formulations of morphine are very useful but clog feeding tubes and stick to bottles or cups. When oral administration is not an option, opioids can be given rectally if necessary, but it is preferable to use the intravenous route when available. Because of its unique long $t_{1/2}$ and its NMDA-antagonist effects, methadone is increasingly a favored opioid to use in this patient population. It is equally effective orally and intravenously, can be administered 2 or 3 times a day, and it is particularly useful in managing opioid tolerance and neuropathic pain.

When prescribing opioids for palliative care (or chronic pain) it is essential for the prescriber to ascertain if the patient's local pharmacy has the drug and if the pharmacy will dispense it with subsequent refills. Furthermore, to avoid licensing authority investigation and error, prescribers must use best-prescribing practice (i.e., the prescriptions must be dated, signed, and clearly state that the opioid is being prescribed for a legitimate purpose [palliative care or chronic pain]) (Lee et al., 2008). Unfortunately, even when complying with these regulations, many pharmacies do not fill prescriptions for oral or parenteral methadone or sustained-release oxycodone. Furthermore, individuals who write these prescriptions are at risk of punitive investigations by their licensing authorities and the Drug Enforcement Agency (Jung and Reidenberg, 2006). Indeed, a practice with a large percentage of its patients who are patients with chronic pain and treated with opioids may be a trigger for an investigation.

Gastrointestinal Symptoms

The management of gastrointestinal symptoms, such as nausea, vomiting, constipation, diarrhea, anorexia (loss of appetite), and cachexia (involuntary weight loss and wasting) is fundamental in palliative care (Stanton-Hicks et al., 1995; American Academy of Pediatrics Subcommittee on Chronic Abdominal Pain, 2005). Although opioids are a common cause of these complaints, other causes must be suspected and ruled out. These include increased intracranial pressure, other medications (e.g., chemotherapeutics and antibiotics), metabolic abnormalities (e.g., uremia or hepatic failure), intestinal obstruction (e.g., gastric outlet or bowel), and mucositis. The management of opioid-induced nausea, vomiting, and constipation has been discussed previously, and the treatment strategies are the same in patients receiving palliative care.

Weight loss and malnutrition are often unavoidable symptoms experienced by patients at the end of life and are commonly associated with poor clinical outcome and increased morbidity and mortality (Stanton-Hicks et al., 1995; American Academy of Pediatrics Subcommittee on Chronic Abdominal Pain, 2005). Furthermore, eating and food can hold important meaning for patients and families; thus, anorexia and cachexia can have a negative impact on quality of life far in excess of their clinical impact. Mealtime commonly holds cultural, emotional, and religious significance, and the inability to enjoy food can affect the entire family. Families may believe that providing nutrition may stave off or reverse wasting; however, for children with certain malignant tumors or advanced disease, weight loss may be largely irreversible. Even so, several drugs have shown some benefit in palliating the cachexia associated with advanced cancer and disease. Appetite stimulants such as progestational drugs, corticosteroids, and cannabinoids can offer some improvement in appetite and weight gain, albeit primarily in adipose and not skeletal muscle tissue (Stanton-Hicks, 2003;

Tan et al., 2008). In addition, megestrol acetate and medroxyprogesterone, synthetic progestins, tend to increase a sense of well-being in addition to stimulating appetite (Stanton-Hicks, 2003; Tan et al., 2008).

Neurologic Symptoms

Many children who require end-of-life care may experience seizures, agitation, and somnolence or loss of consciousness as a result of a primary neurologic illness, an overwhelming systemic illness (chronic or acute), a metabolic derangement (e.g., hyponatremia, hypernatremia, or hypoglycemia), or disease progression (e.g., cerebral metastases) (Sherry et al., 1999). Although it is beyond the scope of this chapter to discuss the etiologies and management of these problems in great detail, a general overview of management is provided.

Seizures are paroxysmal discharges of neurons in the brain resulting in alteration of function or behavior. They are an indication of CNS irritability or disease and typically cause significant stress and distress to patients and families. Parents who have witnessed a child seizing commonly state that they believed their child was dying and that they never want to see their child have another seizure. Patients are more likely to express the fear of future mental handicap and embarrassment about losing control of consciousness, bladder, and/or bowel function in front of friends and family. Many seizures are provoked by fever, infection, and electrolyte abnormalities (e.g., hypoglycemia, hyponatremia, hypocalcemia, hypomagnesemia, or hypoxia). If no precipitating cause is found and the events witnessed are real seizures (some conditions, such as syncope, cardiac arrhythmias, and migraines, mimic seizures), the next step in management is to determine the type of seizure that is occurring, because most antiepileptic drugs are prescribed based on seizure type (Sherry et al., 1999).

The most common types of seizures are generalized and partial-onset seizures. Generalized seizures have no apparent focal onset, whereas partial-onset seizures have a focal onset and may remain focal or secondarily generalize. [Table 15-12](#) lists the most common anticonvulsants and their routes of administration. Like opioids, which anticonvulsant to use depends in part on the anticonvulsant's formulation and the route of administration. For children who have recurrent seizures, physicians and caregivers must also plan for the possibility of status epilepticus. Status epilepticus is a single continuous seizure or repetitive seizures lasting more than 30 minutes without recovery of consciousness. Enabling caregivers to initiate treatment of prolonged or repetitive seizures can improve outcome, decrease anxiety, and prevent visits to an emergency department. Several abortive therapies are available. When intravenous access is not available, the most widely used anticonvulsant is rectal diazepam gel (0.2 to 0.5 mg/kg), although intranasal and buccal midazolam are effective alternatives (Farid and Heiner, 2007; Dadure et al., 2009; Rochette et al., 2009). The risk for respiratory compromise is lower with rectal diazepam than with intravenous formulations of the same medication, because absorption is slower and peak concentrations remain lower. When intravenous access is available, status epilepticus is best treated with lorazepam (0.05 to 0.1 mg/kg, at a rate of 2 mg/min) or with a slow infusion of fosphenytoin (20 mg/kg administered at a rate of 3 mg/min).

Agitation is an unpleasant state of increased arousal. It may present as loud or angry speech, crying, increased muscle

TABLE 15-12. Anticonvulsants

Drug	Dose	Therapeutic Plasma Levels (Toxic Levels)	Advantages	Disadvantages
Carbamazepine (Tegretol)	5-10 mg/kg two or three doses/day; Max dose: 35 mg/kg/day up to 1000 mg	8-12 mg/L	Sustained release formulation available Easily obtained blood levels	Bone marrow suppression, idiosyncratic leukopenia, aplastic anemia No IV formulation May sedate initially Hepatic enzyme inducer
Clonazepam (Klonopin)	Initial dose 0.005-0.015 mg/kg two or three doses/day; Max dose: 0.05 mg/kg/day	20-80 ng/mL (>80 ng/mL)	Oral rapid dissolving tablet Anxiolytic	Sedation
Lamotrigine (Lamictal)	Children >16 yr; Initial dose: 50 mg/day	0.25-0.29 mcg/mL	Not sedating Not requiring BID dosing	No IV formulation Slow titration
Levetiracetam (Keppra)	Initial dose: PO/IV, 2.5-5 mg/kg two doses/day	6-20 mg/mL	Not sedating BID dosing IV formulation No drug interactions	Renal dosing required May exacerbate behavioral problems
Phenobarbital	Initial dose: PO/IV 2.5-4 mg/kg one or two doses/day	10-40 mg/L	Can quickly load via bolus dosing IV formulation Long half-life Readily available blood levels	Sedation Hepatic enzyme inducer Hyperactivity in younger children

IV, Intravenous; PO, oral; BID, twice daily.

tension, increased autonomic arousal (such as diaphoresis and tachycardia), or irritable affect. It can and often does evolve into delirium with sleep disturbance, confusion, and impaired attention. There are many treatable causes of agitation including pain, dyspnea, muscle spasm, bowel dysmotility, and bladder distention. In addition, acute withdrawal from several drugs, including opioids, benzodiazepines, corticosteroids, and some anticonvulsants can also cause agitation. The initial management of agitation is intuitive and nonpharmacologic. Familiar objects from home, a gentle touch, or a soothing voice are always the first steps. If these fail, and they often do, pharmacologic intervention may be warranted with either benzodiazepines, antipsychotics, or barbiturates (Truog et al., 1992; Sherry et al., 1999; Intenzo et al., 2005).

Dyspnea

Dyspnea, or a feeling of breathlessness, occurs when the respiratory system is unable to meet the body's need for oxygen uptake or carbon dioxide elimination. It commonly occurs in terminal illness either because of an increased oxygen demand (e.g., sepsis or organ system failure) or an inability to excrete carbon dioxide (e.g., muscle fatigue, pneumonia, interstitial lung disease, cystic fibrosis, or neoplasm) (Meier et al., 2009; Lin et al., 2009). There are several ways that dyspnea can be treated, namely positive pressure mechanical ventilation, noninvasive promotion of gas exchange (continuous positive airway pressure [CPAP] or supplemental oxygen), or pharmacologic measures to decrease or suppress the sensation of dyspnea. Positive pressure ventilation and CPAP may improve the physiologic disturbances causing dyspnea, but because they cannot reverse the underlying process, they are generally inappropriate in end-of-life situations. However, supplemental oxygen is not. Although

supplemental oxygen can often ameliorate the symptoms of hypoxemia and dyspnea, oxygen may also reverse the hypoxic drive to breathe and precipitate apnea.

Opioids are the drugs of choice in the treatment of dyspnea (McGrath et al., 2008; Meier et al., 2009; Saps and Di, 2009). All opioids raise the apneic threshold and shift the carbon dioxide response curve to the right; thus, there is no particular opioid that is superior to another for dyspnea. In a patient already receiving opioids, an increase of 25% in baseline dose effectively treats dyspnea. The use of nebulized morphine is controversial but has its advocates (McGrath et al., 2008; Meier et al., 2009; Saps and Di, 2009). It is hypothesized that the receptors in the lungs involved in the sensation of dyspnea are J-type stretch receptors and that the output from these receptors is attenuated by topically applied inhaled opioids (Sethna et al., 2005). Finally, dyspnea can cause anxiety, which can further worsen the sense of dyspnea. When this occurs, benzodiazepines are useful therapeutic adjuncts.

CONCLUSION

The past 30 years have seen a significant increase in research and interest in pediatric pain management. In this brief review the most commonly used agents and techniques in current practice have been consolidated in a comprehensive manner.

Regional anesthesia in infants and children has witnessed an increasing popularity over the years that has taken it from a practice of spinal and caudal procedures, to peripheral and truncal nerve blocks taking advantage of sonographic technology (Rochette et al., 2007). The advances that increased its popularity have presumably also improved the safety of blocks in children, which will ultimately encourage further use of this important practice in intraoperative and postoperative pain management. Despite the advances, it is still important to understand the basics of the practice: the pharmacokinetics and toxicities of local anesthetics and their additives, the anatomy of children at different ages, and the indications and complications of specific regional blocks.

LOCAL ANESTHESIA IN CHILDREN

The pharmacokinetics and pharmacodynamics of local anesthetics differ with the age of the child being treated. Amides, one class of local anesthetics, undergo enzymatic degradation in

the liver and should be used carefully, particularly in neonates, infants, and children, because they lack the ability to distribute and metabolize these agents effectively. Ester anesthetic agents are metabolized by plasma cholinesterase and have fewer age-related metabolic differences.

Amides include lidocaine, etidocaine, prilocaine, mepivacaine, bupivacaine, ropivacaine, and levobupivacaine. Although all of these agents have been used for regional anesthesia in adults, etidocaine, mepivacaine, and prilocaine are rarely used in children. The choice of local anesthetic depends not only on the desired onset time and duration of action of the regional block, which will be discussed later, but also on the safety of the agent.

Amide anesthetics are primarily protein bound in the plasma. Bupivacaine, ropivacaine, and levobupivacaine are more than 90% bound to two plasma proteins: α 1-acid glycoprotein (high affinity for local anesthetics) and albumin (high volume and relatively low affinity for local anesthetics). It is the free or unbound fraction of the local anesthetic that is physiologically active and is responsible for its effect on the cardiovascular system and the

central nervous system (CNS). Infants less than 6 months of age have decreased levels of plasma proteins, resulting in a larger free fraction of local anesthetic, which consequently places this age group at a greater risk for toxicity from these agents (Lerman et al., 1989; Berde, 1992). As an infant matures, the level of plasma proteins increases, and the plasma free-fraction of the drug decreases. Adult levels of protein binding are reached near 1 year of age (Fig. 16-1). Of interest is that α_1 -acid glycoprotein levels increase in response to surgical stress, and the increased α_1 -acid glycoprotein ultimately decreases the free fraction of local anesthetic agent. This phenomenon occurs even when total plasma concentration appears to be near toxic levels (Tucker, 1994, 1996; Booker et al., 1996). The liver's cytochrome P450 system is responsible for the metabolism of amide local anesthetics. These enzymes reach adult activity by the first year of life. The immaturity of liver enzymes in neonates and infants contributes to the decreased clearance of amide local anesthetics seen in this time period.

Ester anesthetics such as chlorprocaine and tetracaine depend on plasma esterases for their elimination. The decreased levels of plasma proteins in neonates and infants are reflected in decreased levels of plasma esterases (Zsigmond and Downs, 1971). However, this has not been shown to be of clinical significance, and tetracaine is commonly used for spinal anesthetics in premature infants for inguinal hernia repairs. Chlorprocaine, although not a commonly used pediatric local anesthetic, has been used for caudal anesthesia. It is thought to afford a greater level of safety than amide anesthetics because of its rapid metabolism (Henderson et al., 1993; Tobias et al., 1996).

Safety Issues

Although numerous safety issues need to be considered when taking care of any patient for regional block, the specific issues in children that must be addressed include the age-related risks of local anesthetic toxicity, the placement of regional blocks in anesthetized children, direct nerve toxicity, risk for infection, and the risk for compartment syndrome. Other safety issues will be discussed in their respective sections as they pertain to specific blocks.

Local Anesthetic Toxicity

Children may be at increased risk for toxicity of local anesthetics because of their relatively increased cardiac output

and increased systemic uptake of the agent. This increased systemic uptake may result either in direct CNS toxicity by increasing the amount of local anesthetic available to cross the blood-brain barrier, or in direct cardiac toxicity. Lidocaine at plasma levels of 2 to 4 mcg/mL acts as an anticonvulsant, but at 10 mcg/mL it produces convulsions (Dalens, 1995). Neonates, for example, will manifest symptoms of neurotoxicity such as depressed Apgar scores from lidocaine at umbilical venous blood concentrations of 2.5 mcg/mL, significantly lower than the 5 mcg/mL that is associated with neurotoxicity in adults (Foldes et al., 1960; Shnider and Way, 1968; Ralston and Shnider, 1978; Tucker, 1986).

In unmedicated patients, initial symptoms of neurotoxicity include headache, somnolence, vertigo, and perioral or lingual paresthesia. These symptoms and any objective signs of neurotoxicity such as tremors, twitching, shivering, or even convulsions may not be detected in infants and children under general anesthesia. Diagnosis of local anesthetic toxicity in the child under general anesthesia can be made with indirect signs such as muscular rigidity, hypoxemia without other causes, unexplained tachycardia, dysrhythmias, or cardiovascular collapse. General anesthetics are protective from the CNS effects, but general anesthetics are not protective against cardiac toxicity and may even further contribute to the toxicity (Badgwell et al., 1990). In fact, one study found that in anesthetized ewes, blood concentrations of local anesthetics were doubled because of decreased whole-body distribution and clearance (Copeland et al., 2008a). Net uptake of the local anesthetics in both the heart and brain were greater, with slower efflux, under general anesthesia. Although general anesthesia contributed to local anesthetic-induced cardiovascular depression and changed the overall pharmacokinetics, cardiovascular fatalities occurred only in conscious ewes—there were no fatalities in anesthetized ewes that received intravenous local anesthetics (Copeland et al., 2008b).

The original model that existed was that cardiac toxicity occurs because the local anesthetic prevents the fast inward sodium channels in the myocardium from opening. However, the action leading to toxicity is not at only one specific site, and there is evidence that potassium channels are involved with neuronal excitability and nerve conduction (Kindler and Yost, 2005). Manifestations of toxicity from bupivacaine consist of dysrhythmias with evidence of a high degree of conduction block, widening of the QRS, torsades de pointes, ventricular tachycardia related to reentry phenomena, and major cardiovascular collapse with decreased myocardial contractility (deLaCoussey et al., 1992). Bupivacaine may produce cardiac

FIGURE 16-1. **A**, Age-related changes in plasma concentration of α_1 -acid glycoprotein. **B**, Age-related changes in plasma free-fraction of bupivacaine. (From Mazoit JX, Denson DD, Samii K: *Pharmacokinetics of bupivacaine following caudal anesthesia in infants*, *Anesthesiology* 68:387, 1988.)

and CNS toxicity at serum concentrations of 2 mcg/mL (Tucker, 1986; Dalens and Mazoit, 1998). Although 4 mcg/mL is considered the toxic threshold for bupivacaine in adults, the true toxic concentration of unbound bupivacaine is unknown in humans, particularly children (Knudsen et al., 1997; Luz et al., 1998; Meunier et al., 2001).

Bupivacaine. Bupivacaine is a racemic mixture of equimolar amounts of the enantiomers R(+) bupivacaine and S(−) bupivacaine. For many years, racemic bupivacaine was the only amide local anesthetic with long duration and therefore the most commonly used amide local anesthetic in children. Pharmacokinetic studies of a single dose of racemic bupivacaine (2.5 mg/kg) injected in the caudal space have demonstrated differences between infants and children (Ecoffey et al., 1985; Desparmet et al., 1987; Mazoit et al., 1988). Infants have a greater volume of distribution (3.9 L/kg versus 2.7 L/kg), an increased elimination half-life (7.7 versus 4.6 hours), and decreased clearance (7.1 versus 10.0 mL/kg per minute) compared with older children (Table 16-1). Although side effects from bupivacaine are rare, they can be serious, ranging from CNS excitation to cardiovascular collapse from direct cardiotoxicity. A series of case reports of possible toxicity of racemic bupivacaine secondary to continuous infusions of bupivacaine were reported in the early 1990s (Agarwal et al., 1992; McCloskey et al., 1992). In the report of McCloskey and coworkers, children had continuous caudal infusions of 0.25% bupivacaine at dosages between 1.67 and 2.5 mg/kg per hour. One neonate sustained bradycardia and hypotension, and two older children developed seizures. Bupivacaine serum concentrations at the time of the event ranged between 5.6 and 20.3 mcg/mL. In the cases reported by Agarwal and associates (1992), one child who developed a seizure had an intrapleural catheter with a bupivacaine infusion rate of 0.5 mg/kg per hour. The seizure occurred with a plasma bupivacaine level of 5.6 mcg/mL. The other child in this report had a continuous bupivacaine epidural infusion at 1.25 mg/kg per hour, and seizures occurred with a plasma bupivacaine level of 5.4 mcg/mL. Thus, all children in the reports from the McCloskey and Agarwal groups had plasma bupivacaine levels that exceeded bupivacaine's toxic threshold of 4 mcg/mL.

These early cases of toxicity prompted an editorial by Berde (1992), who addressed the false generalization that children were more resistant to local anesthetic toxicity than adults. Although earlier studies involving children noted no evidence of toxicity in patients with plasma concentrations of bupivacaine from 1 to 7 mcg/mL, the use of benzodiazepines in those children may have been protective (McIlvaine et al., 1988). Badgwell and coworkers (1990) reported greater resistance to toxicity in 2-day-old piglets compared with older piglets. However, the direct application of this study to neonates is difficult, because neonates have lower plasma protein concentrations and lower bupivacaine clearance. Berde (1992) recommended that maximal allowable dosages of local anesthetics should not be exceeded (Table 16-2), that infusion rates should be reduced in children with risk factors for seizures, and that the maximal allowable dosages should be reduced by at least 30% for infants less than 6 months of age.

Ropivacaine. Ropivacaine has become a commonly used local anesthetic in pediatric patients, with onset times similar to bupivacaine, and durations of actions that are similar or perhaps slightly longer than bupivacaine (Ivani et al., 1998; DaConceicao

et al., 1998, 1999; Lonnqvist et al., 2000; Hansen et al., 2001a; Ivani, 2002). Controversy remains as to the potency of ropivacaine when compared with bupivacaine, and adult studies do not correlate with pediatric studies (Ivani, 2002). Although not confirmed, ropivacaine at 0.2% exhibits the same analgesic effect as 0.25% in children, perhaps because of the intrinsic vasoconstrictive activity that is evident at the lower concentrations used in children (Kopacz et al., 1989; Ivani, 2002). Ropivacaine has a lower risk for CNS and cardiac toxicity than bupivacaine. In fact, inadvertent intravenous ropivacaine in a 1-year-old child failed to produce neurotoxic or cardiotoxic signs or symptoms (Thong et al., 2000). In a pharmacokinetic study of ropivacaine in children ages 1 to 8 who were administered 1 mL/kg of 0.2% ropivacaine for caudal block, the free plasma concentrations were well below toxic levels (Lonnqvist et al., 2000). Clearance of the drug was 7.5 mL/kg per minute, and the terminal half-life was 3.2 hours. Hansen and associates (2001a) studied the pharmacokinetics of caudal ropivacaine in infants less than 1 year of age (see Table 16-1). In this study, infants less than 3 months of age were compared with infants 3 months to 1 year. Although the maximum free concentration of ropivacaine was significantly higher in the younger age group (99 mcg/L versus 38 mcg/L), the total and free plasma concentrations in all of the children less than 1 year were within the range of concentrations previously reported for adults and older children (Lonnqvist et al., 2000; Wulf et al., 2000).

Epidural ropivacaine in children aged 1 to 9 years was studied to determine pharmacokinetics and safety of 24- to 72-hour infusions (Berde et al., 2008). After a 2-mg/kg bolus, an infusion of 2 mg/mL at 0.4 mg/kg per hour was delivered and resulted in plasma concentrations that remained stable throughout the infusion and were well below toxic levels.

Levobupivacaine. Levobupivacaine is the S(−) enantiomer of bupivacaine and is less toxic to the CNS or heart than the racemic bupivacaine (Mazoit et al., 1993; Graf et al., 1997; Huang et al., 1998). The decreased risk for cardiotoxicity from levobupivacaine has been shown in healthy adult volunteers after intravenous administration of either levobupivacaine or racemic bupivacaine (Bardsley et al., 1998). Although similar intravenous studies have not been done in children, animal and human studies suggest less toxicity and equipotency of levobupivacaine compared with bupivacaine (Mather and Chang, 2001; McLeod and Burke, 2001; Gristwood, 2002). In pediatric studies, levobupivacaine has resulted in wide ranges of plasma concentrations when given in the caudal space (Chalkiadis et al., 2004, 2005). When levobupivacaine 0.25% was given in a single-shot caudal dose of 2 mg/mL in children less than 2 years of age, Chalkiadis and coworkers (2004) found that the time to peak plasma concentration ranged between 5 and 60 minutes and was reached later in children less than 3 months of age, and the plasma concentration ranged between 0.41 and 2.12 mcg/mL. In a similar study, but at a dosage of 2.5 mg/kg, the range was 0.62 to 2.4 mcg/mL, with the highest maximum concentration found in a 1-month-old infant (Cortinez et al., 2008). The authors suggested using caution when administering levobupivacaine at 2.5 mg/kg in the caudal space in this age group.

Toxicity Comparison among Commonly Used Local Anesthetics

Multiple studies have compared the risk for toxicity of various local anesthetics. Single high-dosage intravenous injection of

TABLE 16-2. Local Anesthetics: Guidelines for Maximal Allowable Dosage

Local Anesthetic	Single Dose	Continuous Infusion Rate	Continuous Infusion Rate in Infants (< 6 mo)*
Bupivacaine	3 mg/kg	0.4-0.5 mg/kg/hr	0.2-0.25 mg/kg/hr
Levobupivacaine	3 mg/kg [†]	0.4-0.5 mg/kg/hr	0.2-0.25 mg/kg/hr
Ropivacaine	3 mg/kg [†]	0.4-0.5 mg/kg/hr	0.2-0.25 mg/kg/hr
Lidocaine	5 mg/kg	1.6 mg/kg/hr	0.8 mg/kg/hr
Lidocaine with epinephrine [‡]	7 mg/kg	NA	NA

Modified from Berde CB: Convulsions associated with pediatric regional anesthesia, *Anesth Analg* 75:164, 1992.

*For infants, rate should be reduced by an additional 30% after 48 hours.

[†]Maximal allowable may be up to 4 mg/kg (under investigation).

[‡]Epinephrine added to local anesthetic at 5 mcg/mL or 1:200,000.

NA, Not applicable.

the local anesthetics in the ewe model revealed that bupivacaine had the most pronounced changes in electrocardiographic and hemodynamic variables compared with ropivacaine, levobupivacaine, and lidocaine (Guinet et al., 2009). In addition, only the bupivacaine ewes experienced ventricular tachycardia. A recent review suggested that overall, ropivacaine has the greatest margin of safety of the long-acting local anesthetics that are currently available, partially because lipophilicity is a major determinant in local anesthetic toxicity (Zink and Graf, 2008).

Reducing Risks of Toxicity

Several safety measures can reduce the risks of toxicity from local anesthetics in children. One primary safety measure is to avoid overdosing by adhering to recommendations for maximal allowable dosages. For a bolus injection, the maximal recommended dosage of lidocaine is 5 mg/kg. Because epinephrine decreases uptake and absorption of local anesthetic, the dosage of lidocaine can be increased to 7 mg/kg when epinephrine (5 mcg/mL) is added to the local anesthetic. The maximal allowable bolus dosage for bupivacaine, ropivacaine, and levobupivacaine is 3 mg/kg, and the addition of epinephrine does not change the maximum (Agarwal et al., 1992; McCloskey et al., 1992). Recommendations for maximal dosing of continuous infusions (see Table 16-2) are the same for bupivacaine, levobupivacaine, and ropivacaine (Berde, 1992). For epidural infusions, the infusion rates should not exceed 0.4 to 0.5 mg/kg per hour for patients older than 6 months, and the recommendation for neonates is not to exceed 0.2 to 0.25 mg/kg per hour. Based on the clearance of bupivacaine and using the guidelines in Table 16-2, the plasma concentrations should remain below 2.5 mcg/mL and therefore below the toxic level of 4 mcg/mL (Tucker, 1986; Desparmet et al., 1987; Mazoit et al., 1988). These infusions assume a loading dosage of 2 to 2.5 mg/kg of bupivacaine and should be reduced by 25% in patients with risk factors for seizures (i.e., past history of febrile seizures, hypomagnesemia, and hyponatremia) (Agarwal et al., 1992; Berde, 1992).

Although there is extensive literature on maximal allowable dosing of local anesthetics, recommendations in children are mostly extrapolated from adults. Additionally, the recommendations for adults are not evidence based and are in turn extrapolated from animal experiences, blood concentration studies, local anesthetic toxicity case reports, and pharmacokinetics (Rosenberg et al., 2004). In the adult literature, it has

even been suggested that the idea of maximal blanket dosing be abandoned, as it is not scientifically valid or clinically relevant (Heavner, 2004). This criticism suggests that the maximum dosages that are quoted to be valid in all patients are not truly valid, and one blanket recommendation does not actually cover all types of patients or all types of blocks. Instead, block- and site-specific guidelines are needed so that dosing is tailored to the patient's situation. In addition, dosing must be based on children's per-kilogram weight; this is the only way to safeguard the risk of overdosing local anesthetics in different age groups.

The use of ultrasound, because the local anesthetic is deposited directly at the target location, has been shown to reduce overall amounts of local anesthetic needed for specific blocks. This will be discussed in more detail in the section on ultrasound.

In addition to dosing guidelines, the risk for toxicity is also affected by hypothermia, hypoxia, hypercarbia, acidosis, or hyperkalemia (Broadman, 1996). These factors enhance the toxicity of local anesthetics by different mechanisms. Another factor that leads to increased toxicity is the speed of injection of the local anesthetic agent. Rapid injections can cause toxicity by resulting in a rapid high peak that may not allow the sodium channels to adapt for the local anesthetic action.

When local anesthetics are combined, their toxicities are additive. Therefore, if the maximal allowable dosage of one local anesthetic has been reached, another local anesthetic agent should *not* be delivered (Giaufre et al., 1996). Although combining local anesthetics may be common at some centers, maximal allowable dosing should be calculated for each of the anesthetics used and decreased based on the relative percentage of each.

The choice of local anesthetic is a clinical decision. The risks for potential cardiotoxicity have been discussed and should help guide practitioners in choosing a local anesthetic that they feel has the greatest safety margin. After the local anesthetic is chosen, the concentration must be considered. In general, lower concentrations of local anesthetics such as 0.25% bupivacaine or levobupivacaine and 0.2% ropivacaine may be used in infants and small children, and higher concentrations such as 0.5% bupivacaine, levobupivacaine, or ropivacaine should be reserved for older children. Higher concentrations result in longer duration of action and increased motor block, but the total milligram dosage must be calculated carefully. Additionally, in young children there is a risk for direct local anesthetic toxicity

on developing nerves (Selander, 1993; Lambert et al., 1994; Radwan et al., 2002). The age at which this is no longer a concern is unknown.

Test dosing. Before injecting local anesthetics, it is essential to determine that the agent will not be injected into the intravascular space. The absence of blood aspiration when administering a pediatric block is not a reliable indicator that the needle is not in a vessel. Infants, in particular, may be at greatest risk of intravascular injection (Freid et al., 1993; Ved et al., 1993; Flandin-Blety and Barrier, 1995). Although clinical practice has relied on a *test dose* to elicit a tachycardia when the test drug is inadvertently injected systemically, the test dose was often considered unreliable in the anesthetized patient and its usefulness continues to be questioned (Desparmet et al., 1990; Sethna and McGowan, 2005). In Desparmet's study of children anesthetized with halothane, only 16 of 21 children who received a test dose of 0.1% lidocaine with epinephrine 1:200,000 had an increase in heart rate that was greater than 10 beats per minute (bpm). Therefore, under halothane anesthesia, an increase of 20 bpm with prior administration of atropine improves the efficacy of the test dose. Sethna and associates (2000) determined that, with the patient under isoflurane anesthesia and after pretreatment of atropine, 0.75 mcg/kg epinephrine was more reliable than 0.5 mcg/kg. All patients in the 0.75-mcg/kg group had heart rate increases of 10 bpm or greater. Isoproterenol has also been used as a test drug, but although it is a more reliable indicator of an intravascular injection in patients anesthetized with halothane (Perillo et al., 1993; Kozek-Langenecker et al., 1996), its safety with neuraxial administration has not been determined, so it is not recommended for this use presently. The validity of test dosing has been studied and reviewed (Tanaka and Nishikawa, 1998, 1999; Tobias, 2001b). With the patient under sevoflurane anesthesia, Tanaka and Nishikawa (1998, 1999) were able to demonstrate that an increase in heart rate of 10 bpm, an increase in T-wave amplitude of 25%, or an increase in blood pressure of 15 mm Hg or more defines the criteria for a positive test dose. Prior administration of atropine did not affect these criteria. Varghese and coworkers (2009) had similar results when 0.1 mL/kg of intravenous 1% lidocaine with 5 mcg/mL epinephrine was injected in children under sevoflurane anesthesia to determine if T-wave amplitude would be visibly detectable on the monitor. An increase in T-wave amplitude in lead II was detected on the electrocardiographic (ECG) monitor in 91% of children and noted on the ECG strip in 94% of children. The amplitude change was considered more reliable for detecting intravascular injection than the increase in heart rate of 10 bpm, which occurred in 64% of children, or the increase of 15 mm Hg or greater in systolic blood pressure, which occurred in 76%. The increase in T-wave amplitude occurred within 30 seconds, as was found in other studies (Tanaka and Nishikawa, 1998; Kozek-Langenecker et al., 2000). Langenecker and associates (2000) delivered an epinephrine solution at 0.5 mcg/kg without being mixed in a local anesthetic and also concluded that the T-wave criterion was more reliable than hemodynamic criteria for a positive test dose.

A test dose can be a useful tool for identifying intravascular injection when the appropriate criteria are used. The test dose should not, however, be a replacement for slow incremental dosing of the total volume of the local anesthetic, with attention to vital sign and ECG monitoring throughout the drug administration. A recommended test dose under sevoflurane anesthesia

is 0.1 mL/kg of the chosen local anesthetic with epinephrine 5 mcg/mL added, not to exceed 3 mL. A heart rate increase of 10 bpm, a systolic blood pressure increase of 15 mm Hg, a T-wave amplitude increase of 25% or greater from baseline, or bradycardia should alert the practitioner to possible intravascular injection (Freid et al., 1993; Fisher et al., 1997; Tanaka and Nishikawa, 1998, 1999; Tobias, 2001b).

Although it has not been extensively tested under total intravenous anesthesia (TIVA), there is evidence that the test dose criteria used for determining intravascular injection differ between TIVA and inhaled anesthesia (Polaner et al., 2010). Arterial blood pressure was the most consistent finding, with an increase in all patients of at least 30% within 2 minutes of injection. Heart rate increased by 10 bpm in only 73% of children, and t-wave amplitude was not reliable. Of note in this study, the injectate was 0.1 mL/kg bupivacaine 0.25%, with epinephrine 1:200,000.

Another advantage of epinephrine administration in regional anesthesia is that, in addition to its being a reliable marker for intravascular injection, its use decreases systemic absorption of the local anesthetic (Eyres et al., 1983, 1986). Children may be at increased risk for local anesthetic toxicity from increased systemic absorption because of their relatively higher cardiac output and regional blood flow. In a study comparing bupivacaine with epinephrine 5 mcg/mL to bupivacaine alone in children for fascia iliaca block, Doyle and coworkers (1997) demonstrated that the peak plasma concentration was lower in the bupivacaine-with-epinephrine group (0.35 mcg/mL versus 1.1 mcg/mL), and that the time to peak concentration was more gradual (20 minutes versus 40 minutes from injection). Similarly, the addition of epinephrine to caudal ropivacaine significantly lowers the maximal concentration, thus improving the safety profile in children (Van Obbergh et al., 2003). In adults, this same delay in systemic absorption and a reduced peak plasma concentration have been shown when epinephrine was added to ropivacaine for paravertebral block (Karmaker et al., 2005). These findings do not suggest that the addition of epinephrine extends the duration of analgesia, but they do demonstrate the effects of epinephrine on the pharmacokinetics of local anesthetics, including those with intrinsic vasoconstrictive properties. Epinephrine (2.5 to 5 mcg/mL) should be added to local anesthetic doses, particularly when large volumes are used, to reduce the risks of local anesthetic toxicity (Rosenberg et al., 2004).

Management of Local Anesthetic Toxicity

Despite all efforts to safely deliver a local anesthetic to a child, it is still possible for local anesthetic toxicity to occur, either by undetected intravascular injection or from inadvertent overdose. When it is apparent that there is local anesthetic toxicity, the practitioner must act quickly to prevent the serious cardiac complications that may ensue. The first steps should focus on the basics, with attention to oxygenation, ventilation, and cardiovascular resuscitation. In particular, hypercarbia must be avoided when resuscitating a patient with local anesthetic toxicity, as an increased $Paco_2$ displaces local anesthetics from their plasma protein binding sites (Burney et al., 1978).

A significant change in the overall management of local anesthetic toxicity has been the introduction of the delivery of a lipid emulsion (Weinberg, 2006). In the clinical arena, lipid emulsion has been used to treat the neurotoxicity and cardiotoxicity

that occur from bupivacaine, levobupivacaine, ropivacaine, and mepivacaine (Foxall et al., 2007; Litz et al., 2008; Warren et al., 2008; Marwick et al., 2009). These long-acting local anesthetics are highly soluble in lipid emulsion, and this high binding capacity explains the clinical efficacy of action, although several mechanisms of action have been proposed (Weinberg et al., 2006).

When comparing lipid emulsion (Intralipid) with epinephrine for bupivacaine-induced cardiotoxicity in a rat model, the lipid infusion resulted in better overall resuscitation hemodynamics than epinephrine (Weinberg et al., 2008). In addition, epinephrine resulted in higher lactate levels, hypoxemia, a mixed acidosis, and persistent ventricular ectopy. When compared with saline, epinephrine had similar hemodynamic and metabolic metrics during resuscitation.

Although several case reports in adults have shown success in resuscitation after local anesthetic-induced toxicity, little information related to children has been published (Ludot et al., 2008b). However, there has reportedly been successful resuscitation in at least one infant using lipid rescue for bupivacaine cardiotoxicity (personal communication at Seattle Pediatric Regional Conference, 2009).

Many questions remain regarding the use of Intralipid, and no clear consensus has been reached as to when Intralipid should be delivered (Weinberg, 2009). One school of thought is that the potential risks of administering the high dosages of Intralipid are yet uncertain, and therefore it should be used only after advanced cardiac life support has failed (Corman and Skledar, 2007). Potential risks include infection, intravenous thrombophlebitis, altered inflammatory responses, anaphylaxis, and fat emboli (Brull, 2008). Serum amylase increases and the risk for acute pancreatitis are concerns (Marwick et al., 2009). Certainly for the neonate, who is less likely to be able to handle a large Intralipid load, caution should be used and the risk-benefit ratio weighed prior to dosing. These risks certainly exist, but withholding Intralipid in the event of a local anesthetic-induced arrest would not be advised. The question remains whether it should be the first step in the resuscitation. Intralipid impairs return of cardiac function in the presence of profound hypoxia (Harvey et al., 2009). Likewise, Mazoit and associates (2009) found that a drop in pH, as might occur during resuscitative efforts, decreases the affinity of lipid emulsion for the local anesthetics ropivacaine and bupivacaine. Particularly after the use of epinephrine at dosages of 10 mcg/kg or higher, there is a decrease in successful resuscitation efforts in the presence of bupivacaine toxicity (Hiller et al., 2009). Although epinephrine results in a faster onset of spontaneous circulation than lipid rescue, the effect is not prolonged, and the overall inefficiency in resuscitation in the presence of this dosage of epinephrine probably results from high levels of lactate. These studies would support the early use of Intralipid for improved result.

To effectively use Intralipid, it should be immediately available with clear instructions attached for the practitioner. Dosing guidelines are presented in **Box 16-1**. As discussed, no specific guidelines have yet been established, and dosing relies only on a series of case reports and animal studies. Nevertheless, having some starting point is essential. A sufficient quantity of Intralipid must be immediately available, as it is possible for a patient to have recurrence of cardiotoxicity after lipid rescue that may require additional support (Marwick et al., 2009). It is important to distinguish that a 20% lipid emulsion has been

Box 16-1 Dosing Guidelines of Intralipid Infusion for Local Anesthetic Toxicity

INITIAL DOSE

1 to 1.5 mL/kg of 20% Intralipid over 1 minute

REPEAT DOSE

effective for resuscitation, not propofol, which is 10% Intralipid and 1% propofol and would contribute further to cardiovascular depression in the arrest situation (Weinberg et al., 2004).

A website (<http://lipidrescue.org>) was developed to disseminate information about lipid rescue therapy and to allow practitioners to share their experiences.

Regional Anesthesia in the Anesthetized Child

A significant difference between adult and pediatric regional anesthesia is that children typically receive their regional anesthetic while they are under general anesthesia. This practice remains controversial outside of the pediatric arena (Bromage, 1996; Bromage and Benumof, 1998; Rosenquist and Birnback, 2003). Because of issues regarding patient cooperation, the practice of performing a regional anesthetic in children differs greatly from placing a block in an adult. Performing regional anesthetic blocks during general anesthesia in children, including thoracic epidural blocks, is an accepted practice as long as the individual has the proper training and expertise. Over 50 international pediatric anesthesiologists signed an editorial by Krane and coworkers (1998) to support the placement of blocks in anesthetized children. In fact, "It would be considered malpractice to perform such techniques in patients who were *not* fully anesthetized" (Dalens, 1999), and "Any performance of a block in an agitated and moving child is not only unethical, but could be dangerous when the needle approaches the delicate nervous structures" (De Negri et al., 2002). A large retrospective study of 4298 adult thoracic surgical patients who underwent epidural catheter placement while under general anesthesia revealed no neurologic complications including radicular symptoms or persistent paresthesias (Horlocker et al., 2003a).

In children who are under general anesthesia or who are heavily sedated, it may be difficult to recognize intravascular injection of a local anesthetic. Even in the awake child, recognizing the signs or symptoms of local anesthetic toxicity is challenging, and it would be optimistic to think that the child would be able to relay this information early in the injection phase. For this reason, the practice of test dosing with a local anesthetic with the addition of epinephrine has been readdressed, and this should be a common practice as it is more reliable than patient report for detecting or preventing intravascular injection (Tobias, 2001b; Bernards et al., 2008). It is also argued that an anesthetized child cannot warn the practitioner of a significant paresthesia and the potential risk for neurologic injury

from intraneural placement of a needle or anesthetic. This is a hypothetical risk that has not been supported by reports of large series of pediatric regional anesthetics (Pietrapaoli et al., 1993; Goldman, 1995; Giaufre et al., 1996).

The American Society of Regional Anesthesia and Pain Medicine issued a practice advisory that was based on evidence and expert opinion as it pertains to performing procedures on anesthetized or heavily sedated patients (Bernards et al., 2008). These recommendations (see [Box 16-2](#)) differ somewhat from the recommendations set forth for adults.

An additional concern with regional anesthesia in an anesthetized child is that of “wrong-side block” for a unilateral extremity procedure. Universal protocols must be followed in the conscious child: the operative extremity must be appropriately marked by the surgical team with concurrence of a witness as well as the parent, and the consent must be checked for accuracy regarding the appropriate site. A time-out should occur before blocking the anesthetized child, to again check the consent and marked site. See related video online at www.expertconsult.com.

Direct Nerve Toxicity

The use of local anesthetics and neurotoxicity on the developing nerve is an area that continues to be addressed. Animal data have demonstrated that all local anesthetics are potentially neurotoxic, and this neurotoxicity parallels their anesthetic potency (Selander, 1993). The factors that contribute to the

mechanism of the neurotoxicity include the concentration of the local anesthetic and the time of exposure of the nerve to the local anesthetic. This is important in children, particularly in neonates, who may be at greatest risk for direct neurotoxicity during nerve development and therefore should not receive the higher concentrations of local anesthetics. Studies on rabbit nerve fibers have demonstrated an increased sensitivity to the blocking effects of local anesthetics in young nerves (Benzon et al., 1988). Additional *in vitro* biological investigation has demonstrated that lidocaine, bupivacaine, mepivacaine, and ropivacaine are all capable of producing growth cone collapse and neurite degeneration (Radwan et al., 2002). However, the incidence of growth cone collapse with bupivacaine and ropivacaine is insignificant when compared with lidocaine and mepivacaine. This finding has not been consistent. When looking at cytotoxicity of local anesthetics on peripheral nerves by measuring viability and apoptotic activity, although all local anesthetics decreased cell viability in a concentration-dependent fashion, bupivacaine had the greatest effect (Castro-Perez et al., 2009). The order of the killing potency (based the concentration at which 50% of cells are killed, or the median lethal dose [LD₅₀]), from high to low, was bupivacaine, then ropivacaine, then chloroprocaine, then lidocaine, then mepivacaine, and finally, with much lower effect, procaine. Only bupivacaine and lidocaine killed all cells with increasing concentration and could cause apoptosis with either the increased concentration or time of exposure. The authors of the study concluded that cytotoxicity-induced nerve injury may have different mechanisms for the various local anesthetics, and that the targets may not be neurons, because they found that bupivacaine was the most toxic local anesthetic that they tested, but it has a history of having a low incidence of producing transient neurologic symptoms in the postoperative period.

Additional investigation in this area is needed to better understand the mechanisms behind neural injury and how it may affect nerves in children of different ages.

Risk of Infection

Another safety consideration concerns the risk for infection. An initial way to avoid infection is by preparing the skin prior to a regional block. Before placing any block, sterile preparation of the skin should be performed, but this is particularly important for central blocks, to reduce the risk for meningitis or epidural abscess. Chlorhexidine, despite its labeling, is the agent of choice for preparing the skin prior to regional anesthetic block (Hebl, 2006). It is recommended over the use of povidone iodine (Povidine), as it has been shown to decrease colonization when used in young children for epidural catheter placement (Kinirons et al., 2001; Wagner and Prielipp, 2003). In addition, povidone iodine may be harmful to the very sensitive skin of an infant. If used, the povidone iodine should be allowed to dry and not be carried centrally with the needle into the epidural or subdural spaces. After the block has been placed, the iodine should be washed from the skin to avoid iodine burns.

The actual risk for infection from regional techniques, however, is extremely low. For indwelling caudal catheters, the incidence of catheter tip colonization is 20%, as opposed to 4% for indwelling epidural catheters (McNeely et al., 1997b). No patients with bacterial colonization of the catheters exhibited systemic signs of infection. Strafford and associates (1995) studied 1620 children who received epidural catheters. There were

Box 16-2 Recommendations* for Performing Regional Anesthesia in Anesthetized or Heavily Sedated Children

LIMITING LOCAL ANESTHETIC SYSTEM TOXICITY

The potential ability of general anesthesia or heavy sedation to obscure early signs of *systemic local anesthetic toxicity* is not a valid reason to forgo performing peripheral or epidural nerve blocks in anesthetized or heavily sedated patients. (Class I)

LIMITING NEURAL INJURY

There are no data to support the concept that peripheral nerve stimulation or ultrasound guidance, or injection pressure monitoring, reduces the risk for peripheral nerve injury in patients under general anesthesia or heavy sedation. (Class I)

The benefit of ensuring a cooperative and immobile infant or child may outweigh the risk of performing neuraxial regional anesthesia in pediatric patients undergoing general anesthesia or heavy sedation. The overall risk for neuraxial anesthesia should be weighed against its expected benefit. (Class II)

Regardless of wakefulness, infants and children may be unable to communicate symptoms of potential peripheral nerve injury. However, uncontrolled movement may increase the risk for injury. Therefore, the placement of peripheral nerve blocks in children undergoing general anesthesia or heavy sedation may be appropriate after duly considering the individual risk-to-benefit ratio. (Class II)

Modified from Bernards CM, Hadzic A, Suresh S, et al: Regional anesthesia in anesthetized or heavily sedated patients, *Reg Anesth Pain Med* 33:449, 2008.

*Level of evidence is reported in parentheses.

no infections in the children who had the catheters placed for postoperative analgesia, and only one significant infection in an immunosuppressed child who received a long-term catheter for pain secondary to her malignancy (Strafford et al., 1995). Adult review has confirmed that infections are typically limited to long-term indwelling catheters in cancer patients (Ruppen et al., 2007). Giaufre and coworkers (1996), in a prospective study of over 24,000 regional techniques performed in children by members of the French-Language Society of Pediatric Anesthesiologists, reported no infections.

Compartment Syndrome

A concern often cited for failure to perform a regional anesthetic in pediatric patients for orthopedic procedures is the risk of an unrecognized compartment syndrome. Compartment syndrome puts the child at risk for muscle ischemia or loss of limb and must be recognized early so that decompressive fasciotomy may occur if necessary prior to these serious complications. The concern focuses on the possibility that the use of a local anesthetic in a regional block may mask the initial symptoms of the sensation of pressure in the limb that occurs with compartment syndrome (Dunwoody et al., 1997). Case reports in children have demonstrated that a successful epidural block with a low concentration of local anesthetic does not mask the symptoms of compartment syndrome. A literature review to assess the risk for compartment syndrome in children who have received epidurals revealed 12 cases (Johnson and Chalkiadis, 2009). In all cases, pain was the primary finding and was considered more severe than the clinical situation would explain. Five of the patients had compartment syndrome as a result of lithotomy position rather than operative site edema. The authors concluded that warning signs of compartment syndrome are the presence of increasing pain or pain that is remote to the site of surgery, an increase in analgesic requirements, paresthesia not due to analgesia, reduced perfusion, swelling, and pain on passive movement. They suggested that the presence of the epidural catheter did not result in delayed diagnosis but instead contributed to deficiencies in the system. Recommendations made included the following: educate staff as to the signs and symptoms of compartment syndrome, identify which patients are particularly at risk through discussion with the surgeon, use dilute local anesthetic solutions, site epidural catheters as close as possible to involved dermatomes, and assess distribution and density of block frequently. Serial examinations should be performed on children to assess the operated extremity in the presence of good analgesia. For the high-risk child, or if any question exists, measure compartmental pressures postoperatively, particularly in children who would clearly benefit from infusions of local anesthetic, such as those who have undergone microvascular surgery or amputation.

Consent Issues

Performance of a regional block must follow the same guidelines as performance of a surgical procedure with consideration of the risk-benefit ratio, a discussion of complications, and appropriate documentation to support its use. Not only should the more common complications be discussed, but the rare, serious complications should also be part of the preoperative consent process with regard to block placement in a

child (Domino, 2007). The manner by which this occurs varies with the country in which the procedure is performed, but some effort must be made to make the parents aware of the purpose, benefits, and risks of regional anesthesia for their child (Lonnqvist et al., 2009).

Reviews of Safety of Regional Anesthesia in Children

Despite the issues of the safety of regional anesthesia in children, studies have shown that the risks and complications of regional anesthesia in children are quite low and often preventable (Dalens and Hasnouai, 1989; Pietropaoli et al., 1993; Giaufre et al., 1996; Dalens and Mazoit, 1998). The largest of these studies was published by the French-Language Society of Pediatric Anesthesiologists (ADARPEF) (Giaufre et al., 1996). This prospective report included 24,409 regional blocks performed over 1 year in children. Central blocks accounted for greater than 60% of the blocks, whereas peripheral nerve blocks and local anesthetic techniques made up the remaining 38%. Only 25 complications occurred in the study, and all the complications occurred in children who received central blocks. Thus, the overall complication rate of regional anesthesia was 0.9 per 1000. The most common complications from regional blockade were inadvertent dural puncture ($n = 8$), inadvertent intravascular injection of local anesthetic ($n = 6$), technical problem ($n = 3$), and overdosing of local anesthesia leading to dysrhythmias ($n = 2$). In addition, two children had transient paresthesias, one child had apnea after central morphine, and one child had a skin lesion after a caudal anesthetic administration. There were no deaths secondary to any of the complications. The conclusion from this study of regional anesthesia in children was that complications were rare and minor, and that they occurred most often in the operating room where they were readily managed. In addition, when appropriate, a peripheral nerve block may be preferable to a central block.

The use of appropriately sized equipment for pediatric regional blocks cannot be overemphasized. The ease of performing a block in a small child is enhanced with the use of shorter, smaller-gauge needles that allow for exact placement. Eleven of the reviewed 23 complications in the large ADARPEF safety study could be attributed to the use of inappropriate equipment.

In a retrospective review of 24,005 regional anesthetics administered over a 10-year period, Flandin-Blety and Barrier (1995) reported 108 events without sequelae (0.45%). However, in this review, five events resulted in severe neurologic injury, including tetraplegia in three children, paraplegia in one child, and one child with cerebral lesions. All five of the children were healthy and less than 3 months of age. Four of the five children had loss of resistance to air used in their technique to identify the epidural space. The true pathophysiologic causes for the neurologic injuries in these children are unknown, but the authors recommended that air not be used to identify the epidural space, and a lower concentration of epinephrine (e.g., 2.5 mcg/mL) be used to avoid possible ischemic injury. In addition, the authors recommended that the indications for regional anesthesia be reconsidered in children less than 18 months of age because of their incomplete myelination of neuronal fibers.

Recent studies have also looked at new technology and whether these advances have improved the practice of regional

anesthesia. Rubin and associates (2009) reviewed the literature on ultrasound-guided blocks and suggested that improved safety features included the need for a lower volume of local anesthetic, and better visibility. How these findings extrapolate to whether ultrasound improves overall safety of regional blocks in children is unclear and not adequately demonstrated except for ilioinguinal blocks.

INTRODUCTION TO ULTRASOUND

Before discussing specific blocks in pediatric anesthesia, the place of ultrasound in the practice of pediatric regional anesthesia should be appreciated. The use of ultrasound for regional anesthesia has experienced immense growth in recent years. The premise of image guidance for nerve localization could not have a better suitor than a developing pediatric anatomy that defies predictable landmarks and has a narrow margin of safety. Despite the demonstrated reduction in the volume of local anesthetic required, the faster onset and longer duration of sensory and motor blocks, and improved quality of sensory block, randomized, controlled studies examining the safety and efficacy of ultrasound-guided nerve blocks in children have been lacking (Marhofer et al., 1997, 1998, 2004; Willschke et al., 2005, 2006a). Therefore, this subject should be approached with the understanding of its evolving nature.

The development of ultrasound technology stems from the principles of piezoelectricity, the ability of crystals and certain other materials to generate an electric potential in response to applied mechanical stress. This effect was first described by brothers Pierre and Jacques Curie in 1880, shortly followed by the demonstration of the converse piezoelectric effect (strain to crystals when an electric field is applied) by Gabriel Lippmann in 1881. However, it took the military innovations of World War I, where ultrasound (sonar) was used to detect submarines, to fuel its use in the medical arena. The first Doppler-assisted nerve block was described in 1978 to locate the subclavian artery for placement of supraclavicular brachial plexus block, but it was not until 1994 that the two-dimensional imaging improved to allow for real-time visualization of the supraclavicular brachial plexus with observation of local anesthetic spread (la Grange et al., 1978; Kapral et al., 1994). Ultrasound guidance has since been used to visualize most remote peripheral and central nerves in both adults and children. This field continues to expand as portable machines with high-resolution capabilities are perfected and three-dimensional ultrasound delineates additional sonoanatomy (Clendenen et al., 2009).

Physics of Sonography

Medical ultrasound produces sound with frequencies in the range of 2 to 15 MHz, in contrast to the range of human hearing (20 to 20,000 Hz). The piezoelectric crystal in the ultrasound transducer propagates pulsed sound waves through the medium and at a regular interval switches to a receiver mode to detect echoes reflected off the tissue interface. Because the velocity of sound in human soft tissue is assumed to be constant at 1540 m/sec, the time lag for sound waves to return to the transducer infers the depth of the reflecting structure, which allows the ultrasound processor to construct an image. The speed of sound is a product of wavelength and frequency

($v = f \times \lambda$). Therefore, high-frequency sound waves have shorter wavelengths and generate higher image resolution, and as frequency is lowered, wavelength is increased with diminished image resolution.

Attenuation refers to loss in amplitude of the original signal as the depth of penetration increases. It results from acoustic energy loss to absorption, reflection, and scattering. The degree of attenuation is frequency dependent, with high-frequency waves experiencing a high degree of attenuation, resulting in poor tissue penetration, whereas low-frequency waves achieve deep tissue penetration. The absorption of energy by biological tissues can in theory result in warming of tissues and formation of cavitations. Although no adverse clinical effects have been observed from diagnostic ultrasound, it is prudent to restrict ultrasound use when possible.

Echogenicity is a function of the tissue's ability to reflect oncoming ultrasound beam. Strong reflectors, such as bone, diaphragm, and pericardium, block ultrasound wave transmission and appear as hyperechoic (or bright) images, whereas fluid- and blood-filled structures are ideal sound conduction media and return no reflection, resulting in anechoic (dark) spots. Intermediate reflectors such as solid organs produce hypoechoic (gray) images.

Doppler

When performing regional blocks, it is important to visualize and avoid vascular structures. Color Doppler ultrasonography uses the Doppler effect (a frequency shift that occurs when either a wave source or receiver moves) to assess blood flow and overlays the color velocity mapping on the two-dimensional gray image. The moving red blood cells act as a reflecting medium in the vessels and amplify the perceived signal frequency (red) when moving toward the transducer or diminish it when moving away (blue). The red and blue reflect the direction of the flow to the transducer, *not* whether the flow is arterial or venous. The image appears black when the wave hits red blood cells perpendicular to the flow. Power color Doppler is a recent alternative that enhances flow detection regardless of the angle of incidence, but it lacks directional information (Rubin et al., 1994).

Artifacts

The complex physics behind ultrasound image derivation frequently creates image distortions with no anatomic basis. Accurate interpretation not only avoids erroneous needle adjustment but also guides corrective action (Sites et al., 2007a, 2007b). Suspect structures can be confirmed by examining them in a second plane.

Air or contact artifact is most commonly encountered. It is caused by loss of acoustic coupling between transducer and skin, and it also results from trapped air bubbles under the sterile probe cover. Liberal use of conductive gel, probe cover adjustment, and firm pressure with the transducer corrects this phenomenon.

Acoustic enhancement artifact presents deep to the sonolucent structures (i.e. blood vessels) and results as the beam accelerated by high fluid conduction hits a tissue with a higher attenuation coefficient.

Acoustic shadow artifact results from high beam attenuation by a strongly reflecting surface (bone, kidney or gallbladder stones, and metallic implants) and appears as hypoechoic regions deep to the surface outline.

Reverberation artifact, or ghost images on the deep side of the needle, is caused by repetitive reflection of the ultrasound waves by the transducer–skin interface or another surface with different acoustical resistance. As the reverberated wave gets reflected by the same needle and returns to the transducer, it gives an erroneous impression of having traveled twice the distance of the original wave and is processed as a second needle twice the distance from the original.

Types of Ultrasound Transducers

Selection of transducer type, footprint size, and frequency are critical to successful nerve block performance (Fig. 16-2). Linear transducers produce rectangular images and offer superior sonographic views for superficial structures (<4 cm). This ability makes this type of transducer ideally suited for the majority of pediatric examinations. Hockey-stick probe configuration offers the additional advantage of smaller footprint (25 mm), ergonomic shape capable of navigating the pediatric landscape, and a broadband frequency (6 to 13 MHz) adequate to examine even deep pediatric blocks such as the psoas compartment block. Curvilinear probes create a wedge-shaped image capable of reaching deep structures, but they sacrifice lateral resolution as the beam disperses in the far field of the curved array. This type of transducer is useful for working with teenagers and obese children to perform deeper blocks or for epidural guidance. Phased-array transducers have the smallest footprint and electronically guide their beam to diverge distally. They produce deep panoramic views most suited for transthoracic echocardiography and hold little use for regional practice.

Ultrasound Handling and Image Adjustment

Four basic movements guide transducer handling and facilitate communication for training purposes. *Alignment* is a technique of sliding the transducer to follow the course of the target structure (nerve or needle). *Rotation* refers to clockwise or counterclockwise movement of the probe to capture the needle shaft in the narrow ultrasound beam or to switch from transverse to longitudinal structure sonodissection. Applying *pressure* to the transducer increases depth of the field and helps to differentiate vascular structures (arteries are pulsatile and veins are compressible). *Tilting* denotes angling of the transducer; it improves image quality by changing nerve anisotropy. As the transducer is tilted, scanning the distant field occurs faster than the proximal field. To avoid muscle fatigue and unintended

probe movements, it is helpful to stabilize the transducer by holding the hand against a fixed surface on the patient.

Gain adjustments change amplification of the returning wave and determine brightness of the echo. Both over- and under-gain reduce resolution and lead to loss of information. Modern ultrasound machines allow selective changes to gain in the near/far or entire field and may even be programmed to automatically adjust amplification.

Needle Handling and Tip Localization

Two simple nomenclatures describe needle advancement in relation to the ultrasound transducer. *Out-of-plane* or *cross-sectional* technique positions the needle transverse to the observed image. Although this approach offers the shortest skin-to-nerve distance, with a potential benefit of decreased patient discomfort, the needle shaft and tip are not clearly visualized and are deduced by transducer tilting or alignment, and by tissue movement. *In-plane* or *in-line* technique advocates longitudinal advancement of the needle. This allows complete shaft/tip imaging but requires training, may create reverberation artifact, and may be inappropriate for continuous catheter placement. Hydrolocation refers to injection of a small amount of liquid (0.5 mL) to find the needle tip on the ultrasound image. Needle visualization requires considerable training and is often a source of frustration for beginners. It is prudent to adjust the image by manipulating the transducer rather than by blindly advancing the needle.

Training and Safety

Inexperience is highly correlated with an increased complication rate, and in this age of heightened patient safety, awareness may preclude talented physicians from realizing the benefits of ultrasound-guided regional anesthesia. Recent publications have increasingly focused on optimizing the learning environment and on designing a learner-centered curriculum (Sites et al., 2007c; Smith et al., 2009). The most common novice behavior patterns that were associated with poor block outcomes are as follows: (1) advancement of the needle when the tip was not well visualized, (2) unintentional probe movements, (3) failure to recognize an intramuscular location of the needle tip before injection, (4) poor ergonomics, (5) failure to identify maldistribution of local anesthesia, (6) operator fatigue, (7) failure to correctly correlate ultrasound sidedness to patient's anatomy, and (8) inappropriate choice of needle insertion site and angle.

■ **FIGURE 16-2.** Types of ultrasound transducers.

Role of the Nerve Stimulator in the Age of Ultrasound

Regional anesthesia took a giant step forward when it abandoned paresthesia and field infiltration for nerve localization and developed a scientifically based, quantitative technique of nerve stimulation (NS). In its 30-year reign, NS has demonstrated a high degree of safety and success rates (Neal et al., 2002). Today, ultrasound guidance offers a qualitative anatomic endpoint, provides the ability to observe local anesthetic spread during injection, and can be used to identify abnormal anatomy. However, it is difficult to be a staunch proponent of solo methodology when both modalities offer complementary evidence of needle-to-nerve proximity and may reduce the time necessary for trainees to successfully reach the desired peripheral nerve block (Orebaugh et al., 2007). Pediatric regional anesthesia presents the additional challenges of working with anesthetized patients unable to report pain on injection, and smaller nerve size that is difficult to locate by NS alone, especially in patients less than 10 years of age (Gurnaney et al., 2007). In addition, NS may yield functional information on proximity to other nerves (phrenic stimulation in parascalene/supraclavicular nerve blocks) and alert to intrafascicular injection when evoked motor response is present with less than 0.2 mA, although this is not a uniform finding (Tsai et al., 2008). Thus, it is reasonable to advocate dual guidance in performing nerve blockade on nerves capable of NS (Gebhard et al., 2008).

The use of ultrasound and peripheral nerve stimulation will be discussed in more detail with regard to specific blocks.

CENTRAL NEURAXIAL BLOCKADE

Central blockade is performed in children for many of the same reasons that it is performed in adults, such as for bilateral lower extremity, abdominal, and thoracic procedures. The risks and benefits to performing central blocks are inherent to the type of block chosen. Central blocks performed in children include spinal blocks and epidural blocks, with the caudal technique being the most commonly used approach to the epidural space. Contraindications to central blockade include a child on anticoagulation therapy, a patient with a preexisting coagulopathy, and a patient or parent who refuses consent for the procedure. The guidelines for regional anesthesia and anticoagulation therapy in adults should be reviewed, as they may be useful for guiding the management of the child (Horlocker et al., 2003b).

Spinal Anesthesia

Spinal anesthesia was a very early form of regional anesthesia that was considered useful for children (Bainbridge, 1901; Tyrell-Gray, 1909). Since that time, spinal anesthetics have become an important anesthetic technique for reducing the incidence of postoperative apnea in premature and ex-premature infants (Harnik et al., 1986; Welborn et al., 1990; Krane et al., 1995; Somri et al., 1998). Infants who have continuing apnea at home, or a hematocrit of less than 30% are at particular risk for postoperative apnea (Cote et al., 1995; Welborn et al., 1991). Spinal anesthesia may also reduce the need for postoperative mechanical ventilation in infants who are less than 60 weeks of postconceptual age and after hernia repair (Huang and

Hirshberg, 2001). The ability of a spinal anesthetic to densely block the dermatomes involved in inguinal hernia repair has kept this regional technique a popular choice in pediatric anesthesia for inguinal surgery. Often, a spinal anesthetic combined with liberal clear liquids until 2 hours before the procedure, and a pacifier intraoperatively, are enough to keep an ex-premature infant comfortable while he or she undergoes inguinal hernia repair. However, any ex-premature infant up to 44 weeks of postconceptual age, and up to 60 weeks of postconceptual age if the infant has risk factors such as anemia or ongoing apnea, should be a candidate for overnight monitoring after the surgery, whether or not a pure regional technique was used.

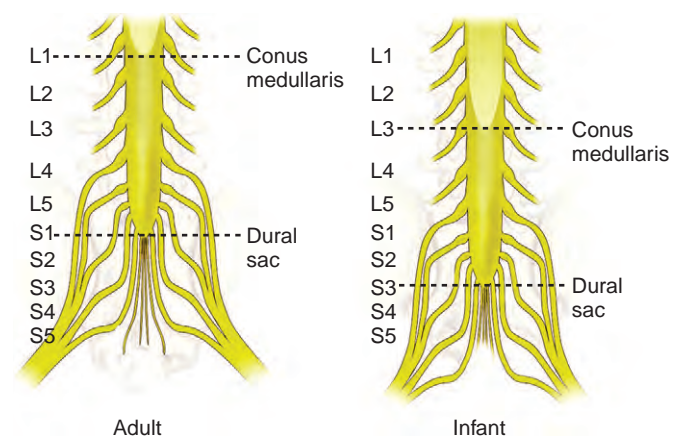

Although spinal anesthesia may be used in any age group, there are relatively few true indications for a spinal anesthetic in older children, who may be at increased risk for post-dural puncture headaches (PDPHs) from the technique (Wee et al., 1996).

Anatomy

The anatomic differences between an infant and a young child or adult are clinically significant and must be taken into consideration when performing a spinal technique. Common teaching has always suggested that the dural sac in a newborn ends at S3, and the conus medullaris may be located at L3 (Fig. 16-3). Willschke and coworkers (2007), however, in a study of 145 neonates using ultrasound for epidural catheter placement, determined that the termination of the spinal cord in neonates actually ended at a median of L2. Likewise, Shin and associates (2009) found that the end of the dural sac was at a median level of the upper S2 in children less than 36 months of age. Even in children up to approximately 6 years of age, the dural sac ascended only slightly on sonographic examination, to remain near the level of S1 or S2 (Shin et al., 2009). This differs significantly from the final position in adults.

Technique

To administer a spinal anesthetic, one may position the infant on the side with the back flexed, but with the head extended to avoid airway compromise. Some practitioners prefer to have the awake neonate or infant in the sitting position to improve success of the block by increasing the chance of good cerebral spinal fluid (CSF) flow through the needle by increasing the

■ **FIGURE 16-3.** Levels of the conus medullaris and dural sac in infants, compared with the older child or adult.

hydrostatic pressure. In either position, it is important that an assistant keep a firm grasp of the awake infant during the placement of the spinal block. An assistant with a firm hold increases the likelihood of a successful block and decreases the chance of complications.

A sterile preparation and a clear plastic drape are used so that the anatomy may be seen (Fig. 16-4). For neonates and infants, a 1½-inch 22-gauge spinal needle is inserted at the L4-5 interspace. The stylet of the needle should be in place when it is passed through the skin. This avoids the remote risk for an epidermoid tumor (Shaywitz, 1972; Barnitzky et al., 1977). Using this size needle in this age group, a pop will be felt as the needle enters the ligamentum flavum, and another pop as the needle enters the dura. The stylet is removed to check for the flow of CSF. In a baby positioned in the lateral position, if no CSF is evident after what seemed to be appropriate needle placement, then the procedure may be repeated with the infant in the sitting position to improve CSF flow.

In children older than 2 years, a longer needle with a smaller gauge may be used. The smaller-gauge needle may decrease the incidence of PDPH, but it may also make it more difficult for the practitioner to feel the distinctive pop of the needle through the ligamentum flavum. The smaller size needle may inhibit the flow of CSF.

After confirmation of position into the subarachnoid space as evidenced by free flow of CSF through the needle, the local anesthetic solution is slowly injected. After the injection, the needle is removed and the child is placed in the supine position. It is extremely important that the child remain supine and that the legs not be raised for any reason, including placement of electrocautery pad. Lifting the legs will cause the local anesthetic to migrate and result in an undesirable high spinal blockade (Wright et al., 1990).

Dosing

The total volume of CSF in a neonate is 4 mL/kg, compared with 2 mL/kg in an adult, and the hydrostatic pressure is 30 to 40 mm H₂O, lower than that of an adult. In addition, almost half of the total CSF volume is in the spinal subarachnoid space, whereas only one fourth of the total volume in adults is found in the spinal region. These factors play an important part of dosing spinal blocks, as the local anesthetics are quickly diluted by the CSF in a neonate on injection. Infants require higher volumes based on weight, but the duration of action of spinal blocks are shorter than in adults (Rice et al., 1994).

■ **FIGURE 16-4.** Performance of spinal anesthetic in the neonate. Note how the back is flexed, but the neck remains extended for airway patency. Drape was removed to show anatomy. IC, Iliac crest.

Although many different dosing regimens have been used, tetracaine either with or without epinephrine is a commonly employed local anesthetic for spinal anesthesia. Rice and associates (1994) studied 100 infants to determine the duration of spinal block, and the authors compared three groups: lidocaine 3 mg/kg with epinephrine, tetracaine 0.4 mg/kg plain, and tetracaine 0.4 mg/kg with epinephrine. The duration in the lidocaine with epinephrine group was 56 ± 2.5 minutes, the tetracaine plain group was 86 ± 4 minutes, and the tetracaine with epinephrine group was 128 ± 3 minutes.

When using 1% tetracaine for a spinal block in an infant, a dosage of 0.5 mg/kg mixed in an equivalent amount of 10% dextrose to make the solution hyperbaric should provide at least 90 minutes of surgical analgesia. Yaster and Maxwell (1989) suggested that regardless of the infant's weight, 1.5 to 2 mg of tetracaine is the minimal effective dosage. To achieve 5 mg/mL of tetracaine, mix 1 mL of 1% tetracaine with 1 mL of 10% dextrose in water (D10W). The delivered volume is then 0.3 to 0.4 mL for infants less than 10 kg in weight. If 0.01 mL/kg of epinephrine is added to 0.75 to 1 mg/kg of hyperbaric tetracaine, surgical analgesia can be extended up to 120 minutes. Similarly, the use of clonidine will extend a spinal block in a former preterm infant, but the risk for apnea may be increased (Rochette et al., 2005). When using bupivacaine for spinal block, 0.5 to 0.6 mg/kg of either isobaric or hyperbaric bupivacaine will provide an average of 80 minutes of surgical analgesia (Dalens, 2000). Dosing of bupivacaine should be reduced for infants and young children who are greater than 5 kg in weight, because of changes in CSF volume. For infants or toddlers 5 to 15 kg, the dosage of hyperbaric bupivacaine or tetracaine is 0.4 mg/kg or 0.08 mL/kg, and for children weighing more than 15 kg, the dosage of bupivacaine or tetracaine is 0.3 mg/kg or 0.06 mL/kg (Dalens, 1995).

Isobaric ropivacaine has been studied in children for spinal anesthesia at a dosage of 0.5 mg/kg up to 20 mg (Kokki et al., 2005). The mean highest sensory level of block was T6 and duration was 96 minutes with a range of 34 to 210 minutes. Additional study on intrathecal ropivacaine is warranted.

Complications

Complications during spinal anesthesia in children are uncommon. In the ADARPEF study, an intravascular injection during spinal anesthesia was the only reported complication in 506 cases (Giaufre et al., 1996). Although considered to be a rare occurrence in children, the incidence of PDPH is actually between 10% and 50% in children aged 10 to 18 years (Oliver, 2002; Wee, 1996). The onset of symptoms from a PDPH typically occurs within 48 hours, with the hallmark symptom being a frontal or occipital headache that is postural. The cause of PDPH is most likely a persistent leakage of spinal fluid that causes a net decrease in CSF volume and intracranial pressure. The supine position helps to alleviate the symptoms of PDPH by decreasing the effect of gravity on the CSF leak. The size of the dural perforation is the primary predictor of the development of PDPH. To reduce the risk for PDPH, smaller-gauge needles are used, and the needle is inserted with the bevel parallel to the dura's longitudinal fibers (Kokki and Hendolin, 1996). Electron microscopy has revealed that the collagen fibers of the dura are arranged in several layers, and that the thickness of the dura is more predictive of whether a leak will occur than the orientation of the needle's bevel (Turnbull and Shepherd, 2003). This explains the unpredictability of PDPH.

If a diagnosis of PDPH is made, simple measures such as bed rest and hydration can decrease the volume of CSF loss. In addition, analgesics to reduce the headache and intravenous caffeine may be administered. Caffeine is effective because of its ability to cause cerebrovascular vasoconstriction, resulting in decreased cerebral blood flow. In one study, when caffeine was used prophylactically in adults, visual analog pain scores and analgesic demand after PDPH were lower (Yucel et al., 1999). There is no current pediatric dosage recommendation for caffeine. The oral dosage for adult patients is 300 to 500 mg once or twice a day (Turnbull and Shepherd, 2003). The intravenous formulation of caffeine is administered with sodium benzoate. The adult intravenous dosage is 500 mg. This may be repeated within 2 to 4 hours if the headache is unchanged after the first dose (Janssen et al., 2003).

If conservative measures to treat PDPH are ineffective after 48 hours, an epidural blood patch should be considered. This requires that blood be drawn sterilely from a peripheral vein. The blood is then injected into the epidural space under aseptic technique. An epidural blood patch is most effective 48 to 72 hours after the dural puncture, and it may be ineffective if performed immediately after dural tap because high leakage of CSF may interfere with blood clotting (Oliver, 2002). If a child is awake during the placement of an epidural blood patch, the practitioner should stop the injection once the child feels either discomfort or pressure in the back. If a child is anesthetized during the performance of an epidural blood patch, no more than 0.3 mL/kg of blood should be injected into the epidural space (Ylonen and Kokki, 2002).

Total spinal block with respiratory arrest and bradycardia is another complication of spinal anesthesia (Desparmet, 1990). The preganglionic sympathetic blockade that is commonly seen in adults secondary to a high spinal is not typically seen in children, particularly in infants (Oberlander et al., 1995; Finkel et al., 2003; Somri et al., 2003). Dohi and coworkers (1979) were the first to describe the lack of hemodynamic changes after spinal block induced sympathetic blockade in children. They found that children less than 5 years of age had little or no hemodynamic response to a T3-level tetracaine spinal anesthetic, whereas children older than 8 years had cardiovascular responses that were more similar to adults. The mechanism for this lack of hemodynamic sympathectomy was postulated to be the immaturity of the sympathetic nervous system as well as differences in CSF volume and spinal cord surface area. In addition, it is also possible that the smaller blood volume that is present in the lower extremities of a young child compared with that of an adolescent or adult may account for less venous pooling and therefore less hemodynamic change (Dohi et al., 1979; Dohi and Seino, 1986). Despite the typical lack of cardiovascular compromise, neonates occasionally require ventilatory support or pharmacologic intervention because of a high spinal anesthesia with a resulting blockade of the cardiac accelerator fibers or a decrease in stimulation of the right atrial stretch receptors (Wright et al., 1990). Investigation has shown that even former premature infants in the absence of fluid loading tolerate high spinal anesthesia with minimal autonomic changes (Oberlander et al., 1995).

Caudal Anesthesia

Although regional anesthesia in children has a broader scope with the advent of ultrasound, a commonly employed

regional block in pediatric practice remains the caudal epidural block. The reasons for the success of this regional technique include not only its extensive safety record for children but also the ease of performing the block and teaching of the technique. See related video online at www.expertconsult.com. Schuepfer and associates (2000) evaluated the technical skills of residents in anesthesiology to determine the learning curve for performing a caudal block in a child. They found that there was a high success rate after only a limited number of cases.

Caudal blocks have great utility in ambulatory surgical patients and for inpatients. They can be administered as a single injection or as a continuous infusion. A caudal block can be used for any surgery that is performed on the lower abdomen or lower extremities (i.e., procedures involving innervation from the sacral, lumbar, and lower thoracic dermatomes). Commonly performed pediatric surgery such as inguinal hernia repair and orchiopexy with their dermatomal distribution below T10 make the caudal block a useful adjunct to the anesthetic. Caudal blocks result in improved patient pain scores when compared with patients having general anesthesia alone (Londergan et al., 1994). Single-shot caudal anesthesia when combined with postoperative ketorolac administration allows children who have undergone intravesical ureteronecystostomy to be discharged on the day of surgery (Miller et al., 2002). For outpatient urologic procedures, caudal block with light general anesthesia was superior to local nerve block or general anesthesia alone. Single-shot caudal anesthesia has also been used in premature infants as the sole anesthetic, to decrease the incidence of postoperative apnea, and to avoid the use of general anesthesia and narcotics (Bouchut et al., 2001b).

The practice of placing a caudal block before the incision would seem likely to improve postoperative care by providing preemptive analgesia. The benefit of providing preemptive analgesia through regional block has not been confirmed in pediatric caudal studies. Holthusen and coworkers (1994) noted that there were no significant differences in cumulative postoperative analgesic requirements or cumulative pain scores between children having caudal blocks placed either before or after their circumcisions. In a separate study comparing two groups of children who received caudal blocks for clubfoot repair, Goodarzi (1996) noted that there were no significant differences in the time to first postoperative analgesic administration or in cumulative analgesic requirements for the first 48 hours between the group that received the block before the incision and the group that received the block after the incision. However, it should be realized that placing the caudal at the end of the procedure does not allow the benefit of lower inhaled anesthetic agent concentrations to be used intraoperatively.

Relative contraindications to performing caudal anesthetics in children include the presence of a pilonidal cyst or abnormal superficial landmarks at the sacral level. The presence of these may suggest that the dural sac and cord may not be in their normal anatomic positions. Hydrocephalus and intracranial tumors decrease intracranial compliance and should be considered, at the very least, relative contraindications to caudal or epidural anesthesia. Absolute contraindications include true meningomyelocele of the sacrum or meningitis. Progressive degenerative neuropathy is not an absolute contraindication, but it carries medicolegal implications.

Anatomy

The caudal space is the result of a defect caused by the nonfusion of the fifth sacral vertebral arch. This area of the nonfusion forms the sacral hiatus, the entry into the caudal epidural space. The landmarks around the sacral hiatus are the sacral cornua, the posterior superior iliac spines, and the coccyx (Fig. 16-5). To find the sacral hiatus, one palpates the sacral cornua and the indentation that is immediately caudal and in the midline. If the cornua are difficult to palpate, the general area of the sacral hiatus may be found by palpating the two posterior superior iliac spines, and assuming that a line between these would be the base of an equilateral triangle, the apex should be at the location of the sacral hiatus.

The caudal space itself lies underneath the sacrococcygeal ligament that runs through the sacral hiatus under the skin. At around 7 years of age, the child's caudal space begins to become more angulated and may be difficult to enter. Although it is possible to perform a caudal block in adolescents and adults, the formation of a presacral fat pad in puberty adds to the difficulty of placing the block. It should be remembered that the distance from the skin to the caudal space in neonates is minimal (Fig. 16-6), and because the dural sac may extend to S3 in neonates, the possibility of entering the dural sac in this age group is increased.

Technique

The choice of needle to be used depends on whether the caudal anesthetic is to be a single shot or whether additional dosing will be required. For a single-shot caudal, it is advantageous to use a short-beveled needle with a stylet. One may also use needles such as a blunt 22-gauge needle or an intravenous catheter that do not have stylets, but there is a remote risk of developing an epidermal inclusion cyst or tumor if the epidermis is carried through the shaft of the needle into the neuraxial space (Shaywitz, 1972). A Crawford needle is similar to an epidural Touhy needle, as it has a stylet and is blunt, but a Crawford needle's bevel is in alignment with the shaft of the needle so that a catheter will exit the needle in a straight line rather than at an angle, such as with a Touhy. The Crawford needle is ideal for either single-shot local anesthetic injection or for placement of a caudal epidural catheter.

With the child in the lateral position, flex the hips with the dependent leg less flexed than the top leg (Simm's position).

■ **FIGURE 16-5.** Caudal block. Note that an equilateral triangle is formed with the fingertips from the posterior superior iliac spine (PSIS) to PSIS to needle insertion at the sacral hiatus (SH). SC, Sacral cornua; TC, tip of coccyx.

■ **FIGURE 16-6.** Depths to perineural, epidural, and subarachnoid spaces according to age. (From Dalens B, editor: Regional anesthesia in infants, children and adolescents, Philadelphia, 1995, Williams & Wilkins, p 32.)

Near the cephalad margin of the gluteal crease, feel for the sacral cornua and the sacral hiatus, a depression immediately inferior to these and in the midline. This is the sacral hiatus (see Fig. 16-5). After sterile preparation and draping, identify the sacral hiatus again with the nondominant gloved hand and place the needle into the skin in the midline at a 45-degree angle or less to the skin, aiming cephalad. Resistance might be felt as the sacrococcygeal ligament is penetrated with a pop once the needle has passed into the epidural space. If using a single-injection technique, local anesthetic may be delivered once the sacrococcygeal ligament has been pierced. Frequent aspiration for blood or CSF should occur, as small movements may result in misplacement of the tip of the needle. If using an intravenous catheter for entry into the caudal space, the angle of the needle must be dropped once the sacrococcygeal ligament has been pierced, to align the needle and intravenous catheter with the epidural space. The needle should then be advanced approximately 2 to 3 mm more, so that the catheter may be directly threaded into the epidural space. After a negative aspiration for blood and CSF, the local anesthetic should inject easily without resistance. A finger should palpate the skin cephalad to the injection to ensure that the agent is not being injected subcutaneously. Although air has been used to check for crepitus after injection, this practice is not recommended because of the risk for air embolism (Guinard and Borboen, 1993; Schwartz and Eisenkraft, 1993).

Technique Using Ultrasound

The superficial and mostly cartilaginous posterior vertebral segments of neonates and infants permit sonographic imaging of the neuraxial structures and have been applied to screen for the presence of spinal dysraphism (Kriss and Desai, 1998; Dick et al., 2002; Deeg et al., 2008). The ultrasound-guided caudal single-shot placement has been described in both children (Park et al., 2006; Roberts, 2006) and adults (Klocke et al., 2003; Chen et al., 2004). It decreases the failure rate by locating the sacral hiatus in the difficult-to-palpate patients (obese or older children), and by confirming the cannula placement in the caudal epidural space, thus limiting the incidence of intraosseous, intrathecal, and intravascular injections (Roberts et al., 2005).

A linear ultrasound transducer set at the highest operational frequency should be used to achieve maximal resolution of the superficial neuraxial anatomy. The child is positioned either prone or in a lateral position, with the operator next to or behind the patient, respectively, and with the ultrasound machine in the operator's direct line of view. The ultrasound transducer is placed in a longitudinal midline plane between the two sacral cornua, and the sacrococcygeal ligament is identified (Fig. 16-7, A). The sacral hiatus, visualized between the sacral and dorsal sacra, contains the dural sac and cauda equina. Progressive vertebral ossification limits midline neuraxial imaging in children older than 3 months, but a longitudinal paramedian angle may overcome this problem by scanning through a window lateral to the spinous processes (Marhofer et al., 2005). A needle is advanced in-plane via the sacrococcygeal ligament at approximately a 20-degree angle, and a saline test bolus of 0.1 to 0.3 mL/kg is administered to confirm correct needle position (Park et al., 2006). This injection should produce ventral displacement of the dura, and dilation of the caudal epidural space (see Fig. 16-7, B: Go to www.expertconsult.com to view this image online). In the absence of dural displacement, intrathecal or intravascular needle placement should be considered and the needle replaced. The needle may not be visible under real-time guidance if the insonating angle is misaligned, as may occur with paramedian scanning. If the sacral cornua are not palpable, scanning with the probe in a transverse plane starting at the coccyx and moving cephalad will identify these structures as two hyperechoic mounds connected by a hyperechoic sacrococcygeal ligament.

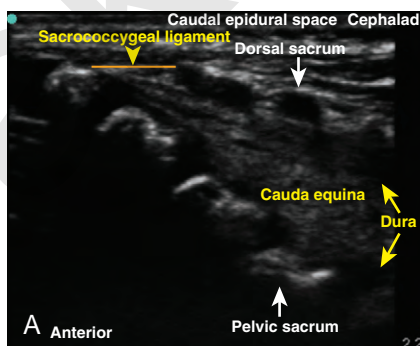

FIGURE 16-7. A, Caudal sonoanatomy. B, Caudal sonoanatomy showing space after injection of local anesthetic. (Go to www.expertconsult.com to view part B online.)

Dosing

For single-shot caudal anesthesia that will not involve repeat dosing, the goal is to provide the appropriate intraoperative level and a prolonged postoperative analgesia. Although formulas have been developed for determining levels for injection of a single-shot caudal, delivery of 1 mL/kg of local anesthetic with epinephrine (1:200,000) will provide thoracic level anesthesia with a duration of 4 to 6 hours depending on the local anesthetic chosen (Armitage, 1979) (Fig. 16-8). Although 1 mL/kg of local anesthetic would never be injected into the epidural space of an adult, the anatomy of the caudal epidural space in children is such that a high volume is needed to fill the loosely packed space and to spread to reach the appropriate dermatomes. The caudal space communicates freely with the perineural spaces of the spinal nerves, which allows a lower concentration of local anesthetic to be effective. Dosing guidelines are in Table 16-3. Although convention suggests that an increased volume of local anesthetic would be required for adequate block and duration of action, one study found that there was no advantage to increasing the volume of local anesthetic to greater than 0.7 mL/kg (Schrock et al., 2003). In children 1 to 6 years of age undergoing inguinal hernia repair, Schrock and associates (2003) compared three groups, all of whom received 0.175% bupivacaine administered at different volumes (0.7 mL/kg, 1 mL/kg, and 1.3 mL/kg). The durations of action as determined by the time of the first postoperative analgesic were similar for all three groups: 4.2, 3.6, and 4.8 hours, respectively. In addition, there were no differences among the groups with regard to first time to void, ambulate, or discharge. However, in another study, Vergheze and coworkers (2002) noted that 1 mL/kg of bupivacaine 0.2% was more effective than a smaller volume (0.8 mL/kg) of 0.25% bupivacaine in blocking the peritoneal response of spermatic

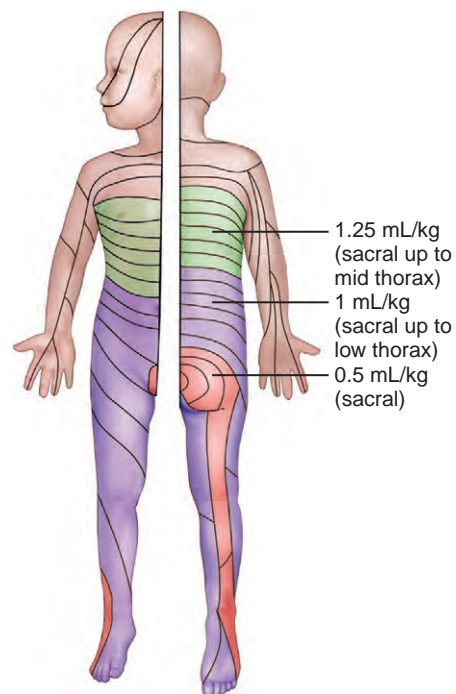

FIGURE 16-8. Dermatomal distribution of different volumes of local anesthetic for single-shot caudal block.

TABLE 16-3. Dosage Recommendations for Caudal and Epidural Blocks

	Concentration	Dose	Possible Additives
Single-dose caudal	0.175%-0.5%	0.75-1.25 mL/kg, not to exceed 3 mg/kg	Epinephrine 2.5-5 mcg/mL Clonidine 1-2 mcg/kg Morphine 30-70 mcg/kg
Continuous caudal or lumbar epidural catheters	0.1%-0.25%	0.4 mL/kg/hr or 0.2-0.4 mg/kg/hr	Fentanyl 2-5 mcg/mL Hydromorphone 5-10 mcg/mL
Continuous thoracic epidural	0.1%-0.25%	0.3 mL/kg/hr or 0.1-0.2 mg/kg/hr	Fentanyl 2-5 mcg/mL Hydromorphone 5-10 mcg/mL

Bupivacaine, levobupivacaine, or ropivacaine may be used. Greater concentrations and larger dosages should be reserved for levobupivacaine or ropivacaine. Dosages and concentrations should be reduced in infants. Children less than 2 years of age who receive morphine centrally require 24-hour monitoring after its delivery.

cord traction during orchiopexy. The quality of postoperative analgesia was similar in the two groups. When keeping the total dosage of local anesthetic consistent, a higher volume is much more effective than a higher concentration. Hong and associates (2009) demonstrated this effect by comparing a high-volume (1.5 mL/kg), low-concentration (0.15%) ropivacaine solution with a low-volume (1 mL/kg), high-concentration (0.225%) ropivacaine solution and found that the higher volume spread to T6 whereas the lower volume spread to T11. Although there were no differences in postoperative pain scores between the groups, the first time to oral pain medication was at 554 minutes for the high-volume group, compared with 363 minutes for the low-volume group, suggesting a longer analgesic duration when overall dosage is kept constant.

The recommended concentration of bupivacaine for a single-shot caudal is 0.125% to 0.25%, although Gunter and coworkers (1991) in a dose-range study concluded that 0.175% offered the best combination of analgesia and rapid recovery with the least number of side effects.

When performing a single-shot caudal in expremature infants for hernia repair, a combination of agents has been shown to be successful (Bouchut et al., 2001b). A mixture of 0.5 mL/kg of 1% lidocaine, along with 0.5 mL/kg of 0.5% bupivacaine, was used in 25 infants. This combination provided surgical analgesia for 60 minutes. However, one of the 25 infants developed a total spinal block and two children developed postoperative apnea.

Ropivacaine has been evaluated in children for caudal anesthesia and has been found to provide onset and analgesic duration similar to that of bupivacaine (Ivani et al., 1998). In some studies, when compared with bupivacaine, ropivacaine produced less of a motor block at 0.25% and 0.375% concentrations (DaConceicao and Coelho, 1998, 1999). When 0.2% ropivacaine, 0.25% levobupivacaine, and 0.25% bupivacaine were compared in children for caudal anesthesia, postoperative

analgesia was not significantly different among the groups, nor was the time for the first postoperative analgesic (Ivani et al., 2002b; Locatelli et al., 2005). The only difference was a slight reduction in the incidence of motor block in the ropivacaine group.

When using 1 mL/kg of 0.2% ropivacaine, free plasma concentrations were well below toxic levels (Lonnqvist et al., 2000). To determine the effective concentration of ropivacaine for single-shot caudal analgesia, Bosenberg and associates (2002b) compared 1 mL/kg of 0.1%, 0.2%, and 0.3% ropivacaine in 110 children aged 4 to 12 years. The median times to first analgesic were 3.3, 4.5, and 4.2 hours in the groups, respectively. Pain scores were significantly higher in the 0.1% group than in the 0.3% group. Motor block was 0%, 13%, and 28% in the 0.1%, 0.2%, and 0.3% groups, respectively. Bosenberg and coworkers concluded that 1 mL/kg of ropivacaine is effective for postoperative pain in children after inguinal surgery, and that the lower concentration of 0.1% is not effective, and the higher concentrations result in a higher rate of motor block.

In other dosing studies with ropivacaine, Koinig and associates (1999) compared 0.75 mL/kg of 0.5% ropivacaine, 0.25% ropivacaine, and 0.25% bupivacaine in children aged 1.5 to 7 years undergoing inguinal hernia repair. The remarkable finding in this study was the duration of analgesia afforded by 0.5% ropivacaine. The duration in the ropivacaine 0.5% group was 1440 minutes, whereas the 0.25% ropivacaine and 0.25% bupivacaine groups were 208 minutes and 220 minutes, respectively.

For neonates and infants up to 12 months, a single dose of 0.2% ropivacaine at 1 mL/kg resulted in plasma levels that were well below toxic dosages and followed a one-compartment open model (Rapp et al., 2004). The mean peak plasma concentration was 0.83 mg/L for total ropivacaine, and 0.042 mg/L for unbound ropivacaine. The time to first analgesic was 3.9 hours.

Levobupivacaine, the S(-) enantiomer of bupivacaine, has also been used clinically as an alternative to bupivacaine. Ivani and coworkers (2002b) compared 1 mL/kg of caudal 0.25% levobupivacaine with 0.2% ropivacaine and 0.25% racemic bupivacaine in children and noted no significant difference in intraoperative or postoperative analgesia among the three groups. In children less than 2 years of age, a dose of 2 mg/kg of 0.25% levobupivacaine had an efficacy similar to that of racemic bupivacaine, and levobupivacaine had a duration of action of 7.3 hours (Taylor et al., 2003). Ivani and associates (2003) noted the optimum concentration of levobupivacaine at 1 mL/kg for a single-shot caudal without any additive was 0.2%. This dosage provided 118 minutes of postoperative analgesia, compared with 60 minutes for 0.125% and 158 minutes for 0.25%. The advantage of using 0.2% instead of 0.25% was the decreased incidence of motor blockade. Dosing guidelines for levobupivacaine are similar to those for bupivacaine (see Table 16-3). The relative potencies of levobupivacaine and ropivacaine have been compared and found to be similar (Ingelmo et al., 2009). At one minimum alveolar concentration (MAC) of sevoflurane, the median effective dose (ED₅₀) for levobupivacaine was 0.069%, and for ropivacaine it was 0.075% in boys aged 1 to 6 years receiving single-shot caudal anesthesia for unilateral groin surgery. The results of the study suggest that the ED₉₅ for the local anesthetics would be 0.2% for levobupivacaine and 0.225% for ropivacaine.

Caudal Additives

One of the disadvantages of single-shot caudal anesthesia is the relatively short duration of postoperative analgesia in children, even when using long-acting local anesthetics. Many agents have been studied in an attempt to find an additive that would prolong the duration of analgesia for single-shot caudal anesthesia. Lonnqvist (2005a) addressed the use of adjuncts to caudal block in an editorial. In particular, the editorial pointed out that there are options such as clonidine and ketamine that enhance postoperative analgesia with acceptable safety profiles, and that anesthesiologists should adhere to existing literature and evidence-based medicine for the use of additives to the caudal space.

Epinephrine

The use of epinephrine for regional anesthetic techniques in children was discussed earlier. It is recommended that epinephrine be added to single-dose local anesthetics at a dosage of 5 mcg/mL or a concentration of 1:200,000. The hypothetical disadvantage of the use of epinephrine is vasoconstriction and possible cord ischemia from impaired flow to the artery of Adamkiewicz (Cook and Doyle, 1996). Therefore, an epinephrine dosage of 2.5 mcg/mL, or a concentration of 1:400,000 may be used as an additive for central blocks (Flandin-Blety and Barrier, 1995).

Epinephrine will serve as a marker for intravascular injection and decrease systemic absorption of local anesthetic. Additionally, epinephrine may prolong the duration of a regional block. Warner and coworkers (1987) compared children aged 3 months to 17 years receiving single-shot caudal block with 0.5 mL/kg bupivacaine 0.25%. One group received the bupivacaine plain, and for the other group, epinephrine 5 mcg/mL was added to the local anesthetic. Epinephrine prolonged the duration of the caudal block analgesia compared with the blocks that did not include epinephrine. The duration of analgesia decreased with increasing age, with the greatest effect on children less than 5 years of age. Children aged 5 years or less had a mean duration of analgesia 10 to 13 hours longer if epinephrine was in the solution. In children aged 6 to 10 years, epinephrine increased the duration of effect by 2 to 3 hours, whereas in children older than 11 years, epinephrine increased the block by 1 to 2 hours. However, in other studies, epinephrine was not shown to prolong a caudal block with bupivacaine (Fisher et al., 1993; Cook et al., 1995).

Ketamine

Preservative-free ketamine has been described for caudal use in children to prolong a bupivacaine block after hernia surgery. Naguib and associates (1991) compared three groups of children receiving either plain bupivacaine 0.25%, ketamine 0.5 mg/kg, or bupivacaine 0.25% plus ketamine 0.5 mg/kg. The group who received only 0.5 mg/kg ketamine had superior analgesia and longer duration of action than the group who had received plain 0.25% bupivacaine. The ketamine group also had similar analgesia and duration of action to the group who received the combination of ketamine and bupivacaine. No postoperative behavior changes were noted in the ketamine groups. These findings have been confirmed in subsequent

studies using 0.5 mg/kg ketamine as an additive to either 0.25% bupivacaine or 0.2% ropivacaine in the caudal space (De Negri et al., 2001a; Weber and Wulf, 2003). Cook and coworkers (1995) studied children aged 1 to 10 years who received caudal anesthesia using 1 mL/kg of 0.25% bupivacaine with the addition of either ketamine 0.5 mg/kg, clonidine 2 mcg/kg, or epinephrine 5 mcg/mL. The ketamine group had a mean duration of analgesia of 12.5 hours compared with 5.8 hours for the clonidine group and 3.2 hours in the epinephrine group. When used alone in the caudal space, ketamine at this dosage of 0.5 mg/kg had a shorter duration of action than bupivacaine 0.25% with 1:200,000 epinephrine, but ketamine 1 mg/kg provided surgical and postoperative analgesia that was equivalent to that of bupivacaine (Marhofer et al., 2000).

Another study using simply ketamine for caudal analgesia without local anesthetic compared a group who received ketamine 1 mg/kg with two other groups who received, in addition to ketamine, clonidine 1 or 2 mcg/kg (Hager et al., 2002). The ketamine group had a mean duration of postoperative analgesia of 13.3 hours. When clonidine 1 mcg/kg or 2 mcg/kg was added to the ketamine, the mean durations were 22.7 hours and 21.8 hours, respectively. This particular study prompted a letter to the editor by Eisenach and Yaksh (2003) that stressed concern over the performance and publications of studies that subjected healthy children to agents that have not had adequate preclinical toxicity studies. Eisenach and Yaksh further discussed the potential risks of neurotoxicity using S(+)-ketamine in the epidural space without significant benefits to the otherwise healthy child. The response to this letter from the authors of the study defended their position with a number of papers on ketamine in the epidural space (Marhofer and Semsroth, 2003). The issue remains controversial, as pointed out in a systematic review of nonopioid additives by Ansermino and associates (2003). This review summarized the findings of randomized control trials performed on children using nonopioid additives in the caudal space and concluded that although clonidine, ketamine, and midazolam increase the duration of analgesia, the potential for neurotoxicity remains a concern with ketamine and midazolam. They also concluded that the routine use of nonopioid adjuvants for elective outpatient surgery had not been shown to improve patient outcome.

What is clear from the studies and editorials is that only preservative-free ketamine should be used when administering it for regional blocks, particularly in the neuraxial space.

Clonidine

Clonidine, an α_2 -adrenergic agonist, at 1 to 2 mcg/kg, has been used with success and may result in an additional 4 to 6 hours of analgesia when combined with bupivacaine (Jamali et al., 1994; Lee and Rubin, 1994; Constant et al., 1998; Tripi et al., 2005). Clonidine at 1 mcg/kg, when combined with bupivacaine for caudal block, provided a mean duration of 987 minutes compared with 377 minutes in a group of children who received bupivacaine with epinephrine, versus 460 minutes in children who received bupivacaine plain (Jamali et al., 1994). Ivani et al. (2000) demonstrated that 0.1% ropivacaine plus clonidine 2 mcg/mL provided superior analgesic quality to a caudal block compared with 0.2% ropivacaine without clonidine. The true mechanism of analgesic action of clonidine remains unknown, but there is evidence that it has both central and peripheral sites

of action (Ivani et al., 2002a). Although clonidine may cause some sedation, particularly at the higher dosages, and although the sedation has not been considered clinically significant in controlled studies, caudal clonidine has been implicated in case reports as a cause of apnea in neonates (Breschan et al., 1999; Bouchut et al., 2001a).

De Negri and coworkers (2001a) compared ketamine with clonidine to determine which agent would more effectively prolong a ropivacaine caudal anesthetic. Children 1 to 5 years of age received 0.2% ropivacaine 2 mg/kg, ropivacaine plus clonidine 2 mcg/kg, or ropivacaine plus ketamine 0.5 mg/kg for caudal anesthesia. Postoperative analgesia was significantly longer in the ropivacaine with ketamine group (701 minutes) than in the ropivacaine with clonidine group (492 minutes) and the ropivacaine plain group (291 minutes). There were no clinically significant side effects in any of the groups. These findings were similar to the study by Cook and associates (1995) that compared clonidine 2 mcg/kg with ketamine 0.5 mg/kg as additives to 0.25% bupivacaine caudal anesthesia.

When clonidine is directly compared with opioids, its use offers comparable analgesia with fewer side effects. To illustrate this, Vetter and coworkers (2007) used single-shot caudal anesthesia for pediatric patients undergoing ureteral reimplantation. Each child received 1 mL/kg of 0.25% ropivacaine with epinephrine with a caudal additive. The three additive groups were 2 mcg/kg clonidine, 10 mcg/kg hydromorphone, or 50 mcg/kg morphine. Caudal morphine afforded the greatest duration of analgesia, although there was not a statistically significant difference overall. Clonidine appeared to be superior to either caudal morphine or hydromorphone because of its similar analgesic profile and lower incidence of postoperative nausea and vomiting.

Tramadol

Tramadol, an analgesic that acts centrally at opioid receptors, has been compared with bupivacaine alone and a tramadol-bupivacaine combination for caudal analgesia (Prosser et al., 1997; Batra et al., 1999; Gunduz et al., 2001). When 1 mg/kg of tramadol was added to bupivacaine, patients had lower pain scores and longer durations of analgesia than with bupivacaine alone (Batra et al., 1999). When 2 mg/kg of tramadol was added to bupivacaine, some children had sedative effects, but this was not considered to be clinically significant (Gunduz et al., 2001). Caudal tramadol 2 mg/kg provides reliable postoperative analgesia similar to caudal morphine 30 mcg/kg for children undergoing herniorrhaphy (Ozcengiz et al., 2001).

Neostigmine

The use of neostigmine in the epidural space in children is not yet common practice but shows promise. Its action may be attributed to either direct action on the spinal cord via inhibition of the breakdown of acetylcholine in the dorsal horn, or by peripheral antinociceptive effect (Shafer et al., 1998; Yang et al., 1998). A study in children compared three groups to determine the effectiveness of neostigmine (2 mcg/kg) as a caudal analgesic for hypospadias repair, either alone or in combination with bupivacaine (Abdulatif and El-Sanabary, 2002). The groups received 1 mL/kg of either 0.25% bupivacaine plain, bupivacaine with neostigmine 2 mcg/kg, or neostigmine

plain. The combination of bupivacaine and neostigmine provided superior analgesia to either of the other two groups, with a mean duration of 22.8 hours compared with 8.1 hours in the bupivacaine plain group and 5.2 hours in the neostigmine plain group. This prolonged duration when compared with plain local anesthetic has been demonstrated in other studies as well (Mahajan et al., 2004; Kumar et al., 2005). When compared in boys who received levobupivacaine caudal anesthetics for urologic surgery, the addition of neostigmine 2 mcg/kg compared with 4 mcg/kg provided similar duration of postoperative analgesia (15 hours and nearly 20 hours, respectively) and total analgesic consumption (Karaaslan et al., 2009). The higher dosage offered no advantage, and either dosage improved analgesia beyond levobupivacaine plain.

The combination of bupivacaine with neostigmine has been compared not only with plain bupivacaine, but also with other combinations of additives for single-shot caudal anesthetics (Kumar et al., 2005). Duration of analgesia with the bupivacaine-neostigmine group (19.6 hours) was similar to that of a group with bupivacaine and midazolam (16.8 hours), and longer than the bupivacaine plain group (7.6 hours) and bupivacaine-ketamine group (11.6 hours). The dosage of neostigmine used as an additive in this study was 2 mcg/kg. At dosages of 10 mcg/kg and higher, there may be an increased incidence of postoperative nausea and vomiting, which would make this an unattractive alternative as an adjunct to epidural anesthesia; however, no study has attempted to define whether antiemetics will decrease the incidence of nausea and vomiting in this population (Lonnqvist, 2005a; Almenrader and Passariello, 2006).

Note that neostigmine, which typically contains methylparabens and propylparabens as preservatives, should be used only in a preservative-free form when injected into the epidural space. Investigation as to its effect on neural structures is ongoing, and skepticism remains as to whether neostigmine is a viable option for pediatric caudal use (Lonnqvist, 2005a).

Opioids

Opioids have commonly been used in caudal blocks with or without local anesthetic agents. There are two distinct classes of opioids: hydrophilic and lipophilic. In general, hydrophilic opioids such as morphine are capable of rostral spread, whereas lipophilic opioids such as fentanyl remain more localized to the area of injection. This difference accounts for the greater incidence of sedation and respiratory depression that occurs with hydrophilic agents.

Opioids may be used to improve the quality and duration of a block, but there are advantages and disadvantages to spinal axis opioids (Lonnqvist et al., 2002). The major disadvantage of opioid additives is the risk for respiratory depression. In children less than 1 year of age, the risk for respiratory depression from caudal morphine is significantly higher than in children older than 1 year (Valley and Bailey, 1991). In this study of 138 children who had received 70 mcg/kg of caudal morphine, the incidence of clinically significant respiratory depression was 8%. Ten of the 11 children with respiratory depression were less than 1 year of age and weighed less than 9 kg. Seven of the 11 patients also received intravenous opioids. All episodes of respiratory depression occurred within 12 hours of the caudal morphine injection. Spinal axis opioids, because of the risk for delayed respiratory depression, are contraindicated in

ambulatory surgical patients. Patients under 1 year of age and patients receiving supplemental intravenous opioids should be carefully monitored postoperatively.

Another disadvantage of neuraxial opioids is the increased incidence of postoperative pruritus, nausea, and vomiting. Although fentanyl 1 mcg/kg may prolong a caudal block, the incidence of pruritus and vomiting also increase (Constant et al., 1998). In one study, the investigation was actually halted because of the unacceptable incidence of postoperative vomiting in a group of children who had received caudal buprenorphine (Khan et al., 2002). Urinary retention is a side effect of caudal morphine and required urinary catheterization in 30% of children in one study using 70 mcg/kg morphine (Irving et al., 1993). Another reason to avoid neuraxial opioids is the availability of alternative additives. As previously discussed, additives such as clonidine and ketamine have been used as adjuncts for central blockade with success and result in fewer side effects compared with opioids.

Despite the pitfalls of using opioids as a component of central blockade, the practice continues because of the relative advantages these agents offer. Preservative-free morphine more than doubles the duration of a single-shot bupivacaine caudal (Krane et al., 1987). In a study of children aged 1 to 16 years, there was a slightly greater incidence of urinary retention, pruritus, and nausea in the group who received caudal morphine, but there was no evidence of delayed respiratory depression even at dosages of 100 mcg/kg in this age group. A caudal morphine dosage of 30 mcg/kg has been recommended for children to provide the advantage of increased analgesic duration with decreased incidence of side effects, particularly respiratory depression (Krane et al., 1989). In children who were undergoing open-heart procedures, a dosage of 70 mcg/kg morphine provided lower pain scores and decreased incidence of atelectatic changes on radiograph compared with a control group who had not received caudal morphine (Rosen and Rosen, 1989). Plasma levels of morphine given via the caudal route peak at 21 ± 4.8 ng/mL approximately 10 minutes after injection (Wolf et al., 1991). These levels are lower than those associated with systemic administration of morphine.

Lipophilic opioids do not offer the same risk for respiratory depression as hydrophilic agents. The disadvantage of the lipophilic agents is the shorter duration of postoperative analgesia than what is provided by morphine, and there may actually be no benefit to the addition of fentanyl to local anesthetic for a single-shot caudal. In most reports, caudal fentanyl 1 mcg/kg has not been shown to increase the duration of analgesia produced by 0.125% bupivacaine, 0.25% bupivacaine, 2% lidocaine, or 0.2% ropivacaine (Jones et al., 1990; Campbell et al., 1992; Joshi et al., 1999; Baris et al., 2003; Kawaraguchi et al., 2006). In contrast, Constant and associates (1998) demonstrated prolongation of analgesia in a study in which fentanyl 1 mcg/kg was added to a mixture of bupivacaine and lidocaine in children aged 6 to 108 months. The mean duration of analgesia in the group was 253 ± 105 minutes compared with 174 ± 29 minutes in the control group without fentanyl. Vomiting occurred in 4 of 15 children who had extradural fentanyl, and in none of the 14 children who had not received fentanyl.

Fentanyl and morphine were compared for efficacy and side effects in children aged 1 to 16 years (Lejus et al., 1994). The children all received a preincision epidural dosage of 0.5% bupivacaine, 0.75 mL/kg, and were then divided into two groups. The morphine group received a preoperative bolus of

epidural morphine 75 mcg/kg and the same morphine bolus dose 24 hours later. The fentanyl group received 2 mcg/kg before incision, followed by a continuous infusion of 5 mcg/kg per day. The group who received the fentanyl infusion had comparable analgesia with the morphine group with less pruritus (20% versus 53%), and less nausea and vomiting (0% versus 33%).

Complications

Complications from caudal anesthesia include risks during the performance of the block, risks from injection of local anesthetic, and side effects from the agents used. During the performance of a caudal block, the needle could be accidentally placed into the intravascular space, the subarachnoid space, or the sacral marrow. The incidence of intravascular injection should be decreased with the use of a short-beveled needle, and a test dose should reveal whether the needle is intravascular or in the vascular marrow (Dalens and Hasnaoui, 1989). The detection of a subarachnoid injection may be difficult if CSF is not clearly seen on aspiration prior to local anesthetic injection. In the safety study of Giaufre and coworkers (1996), inadvertent dural puncture was the most frequent complication, but it was still uncommon. In the event the subarachnoid space has been entered, it is possible to reintroduce a needle for a caudal anesthetic; however, the agent should be injected very slowly to avoid the possible migration of local anesthetic solution into the subdural space through any previous puncture sites.

Children differ from adults in that hypotension secondary to centrally delivered local anesthetic is not generally a significant side effect from caudal or neuraxial regional anesthesia. Even without intravascular volume loading before the administration of a central blockade, hypotension is typically not observed in children less than 5 years of age (Dohi et al., 1979; Dohi and Seino, 1986). This may be because of the immature sympathetic nervous system, or because the lower extremities, in proportion to overall body size, do not provide a significant volume for venous pooling.

Studies have been performed in children to investigate the hemodynamic response to caudal analgesia. Doppler studies to investigate hemodynamic changes have demonstrated that cardiac output does not change during caudal anesthesia in infants (Payen et al., 1987). A study to investigate pulmonary Doppler flow revealed that the pulmonary flow velocity changes during caudal anesthesia, presumably secondary to an increase in pulmonary artery resistance (Ozasa et al., 2002). Because the change may have reflected local anesthetic-induced vasoconstriction, the authors concluded that caudal epidural anesthesia is not recommended in children with pulmonary hypertension.

Urinary retention, although a concern, is not considered a frequent side effect in single-shot caudal anesthetics. Fisher and associates (1993) reviewed the postoperative voiding interval in children who received either bupivacaine caudal anesthesia with and without epinephrine, or ilioinguinal hypogastric nerve blocks. They noted no significant difference in the time to micturition among these groups. Although the range of times to first micturition varied widely, from 25 to 630 minutes, no children required any intervention for urinary retention.

Complications from intravascular injection and accumulation of local anesthetics have previously been discussed.

Continuous Caudal Catheters

Intraoperatively, an indwelling catheter may be placed in the caudal epidural space. These catheters allow additional dosing of the local anesthetic agents at the end of the procedure or in the recovery area prior to catheter removal. A repeat or second dose of local anesthetic can be safely administered 90 to 120 minutes after the initial dose as long as the maximal allowable dosage is not exceeded in that time period. In addition, continuous caudal block may be used as an alternative to spinal anesthesia in the premature infant who is at risk for postoperative apnea while undergoing inguinal hernia repair. This technique has been used with success with and without a concomitant general anesthetic (Henderson et al., 1993; Peutrell and Hughes, 1993; Tobias et al., 1996).

The presence of a caudal catheter allows continued postoperative pain management in children. Continuous infusions, although commonly used because of their ability to provide complete postoperative analgesia, have come under scrutiny because of a lack of prospective outcome studies that demonstrate benefit (Chalkiadis, 2003). Audits of postoperative infusions have demonstrated that 17% to 22% of patients require premature termination of the infusions. In 67% of these patients, the termination was because of an unacceptable rate of side effects or complication (Wilson and Lloyd-Thomas, 1993; Wood et al., 1994). This high rate leads one to question the benefit of neuraxial analgesia over intravenous analgesia (Chalkiadis, 2003). This side effect may be greater for lipophilic infused epidural opioids (e.g., fentanyl), because the catheter tip must be positioned at the interspace corresponding to the dermatomes of the surgical procedure. Another issue that argues against placing and maintaining a continuous epidural catheter includes the dissatisfaction of having a motor block in children. There may also be an increased incidence of postoperative urinary retention and pruritus in children who receive infusions of neuraxial opioids (Lloyd-Thomas and Howard, 1994). Although these side effects are not necessarily dangerous, they do result in increased workload for medical staff, additional medications, and child and parent distress. More serious issues with continuous caudal infusions include the rare risks of epidural hematomas, epidural infection and abscesses, and respiratory depression from central opioids. In addition, there is the cost of the epidural catheter kits, the operative time to insert the caudal and urinary catheters, and the postoperative costs for pharmacy, nursing, on-call staff, and a pain service. Therefore, it has been suggested that continuous infusions be reserved for those children who would truly receive a direct benefit.

Technique

The anatomy of and entry into the caudal space for placing a continuous catheter via the caudal route have already been described. In threading a caudal catheter, the space should first be dilated with a push of preservative-free normal saline. The catheter is then threaded through the needle until the tip of the catheter reaches the estimated desired level. The caudal approach to placing a lumbar or thoracic catheter in infants was described by Bosenberg and coworkers (1988). Because of the loosely packed fat in the epidural space, a catheter should be advanced easily. If resistance is felt, it is most likely because

the catheter has coiled or doubled back in the epidural space. In older children who may have more densely packed epidural fat, the use of a catheter with a stylet may increase the success rate (Gunter and Eng, 1992). In addition to using a catheter with a stylet, other means to improve success are dilating the space with preservative-free normal saline prior to catheter placement, flexing the hips to straighten the spine, and using fluoroscopy to ensure proper catheter tip position. If an angiocatheter has been used for insertion of the catheter, the catheter may be withdrawn, twisted, and advanced through the plastic introducer until the desired position as determined by radiography is obtained. Catheters should not be withdrawn through metal needles because of the risk of shearing the catheter into the epidural space.

Success in placing a thoracic catheter via the caudal route is variable. In a study of 86 infants who had caudal placement of a thoracic catheter that was confirmed by x-rays, the positions of 28 of these catheters were considered to be inadequate (Valairucha et al., 2002). Of the 28, 10 were determined to be in the high thoracic or cervical regions and were able to be pulled back, 17 were coiled in the lumbosacral area, and one was outside the epidural space in the presacral area. Thus, radiographic confirmation of catheter tip position for thoracic catheters that are threaded from the caudal route is essential, and 0.5 mL Omnipaque 180 (Amersham Health, Princeton, NJ) may be used for this indication. Rather than using radiographic evidence to help determine proper placement of the catheter tip, Tsui and associates (1998) described the use of low-current electrical stimulation during advancement of the catheter, resulting in muscle twitching at the corresponding dermatome. Although the immediate feedback on location of catheter tip helps to identify desired placement, it is unclear whether this method offers advantages over or higher success rate than conventional methods such as cutaneous landmarks and simple catheter measurement (Goobie et al., 2003).

Technique with ultrasound. The advancement of the epidural catheter from the sacral hiatus and tip positioning under the ultrasound guidance has been described (Chawathe et al., 2003; Roberts and Galvez, 2005). This technique avoids patient exposure to radiation and contrast injection and is independent of the neuromuscular blockade or local anesthetics use (Asato and Goto, 1996; Tsui et al., 1998; Valairucha et al., 2002). The catheter is introduced via a previously positioned caudal cannula and is advanced while being sonographically imaged. The catheter is followed cephalad with the ultrasound probe in the longitudinal paramedian plane by direct visualization, which is easiest with stylet catheters, or its level is inferred by the anterior dural displacement with saline injection. Scanning the neuraxial structures in the transverse plane allows direct catheter visualization and is less dependent on bony ossification (Fig. 16-9).

Dosing

Continuous caudal catheters that have their tip in the sacral or lower lumbar areas will be dosed differently from those that have been threaded to the low to mid thoracic levels. Suggestions for dosing are in Table 16-3. Continuous caudal catheters require large volumes of local anesthetic to fill the loose caudal epidural

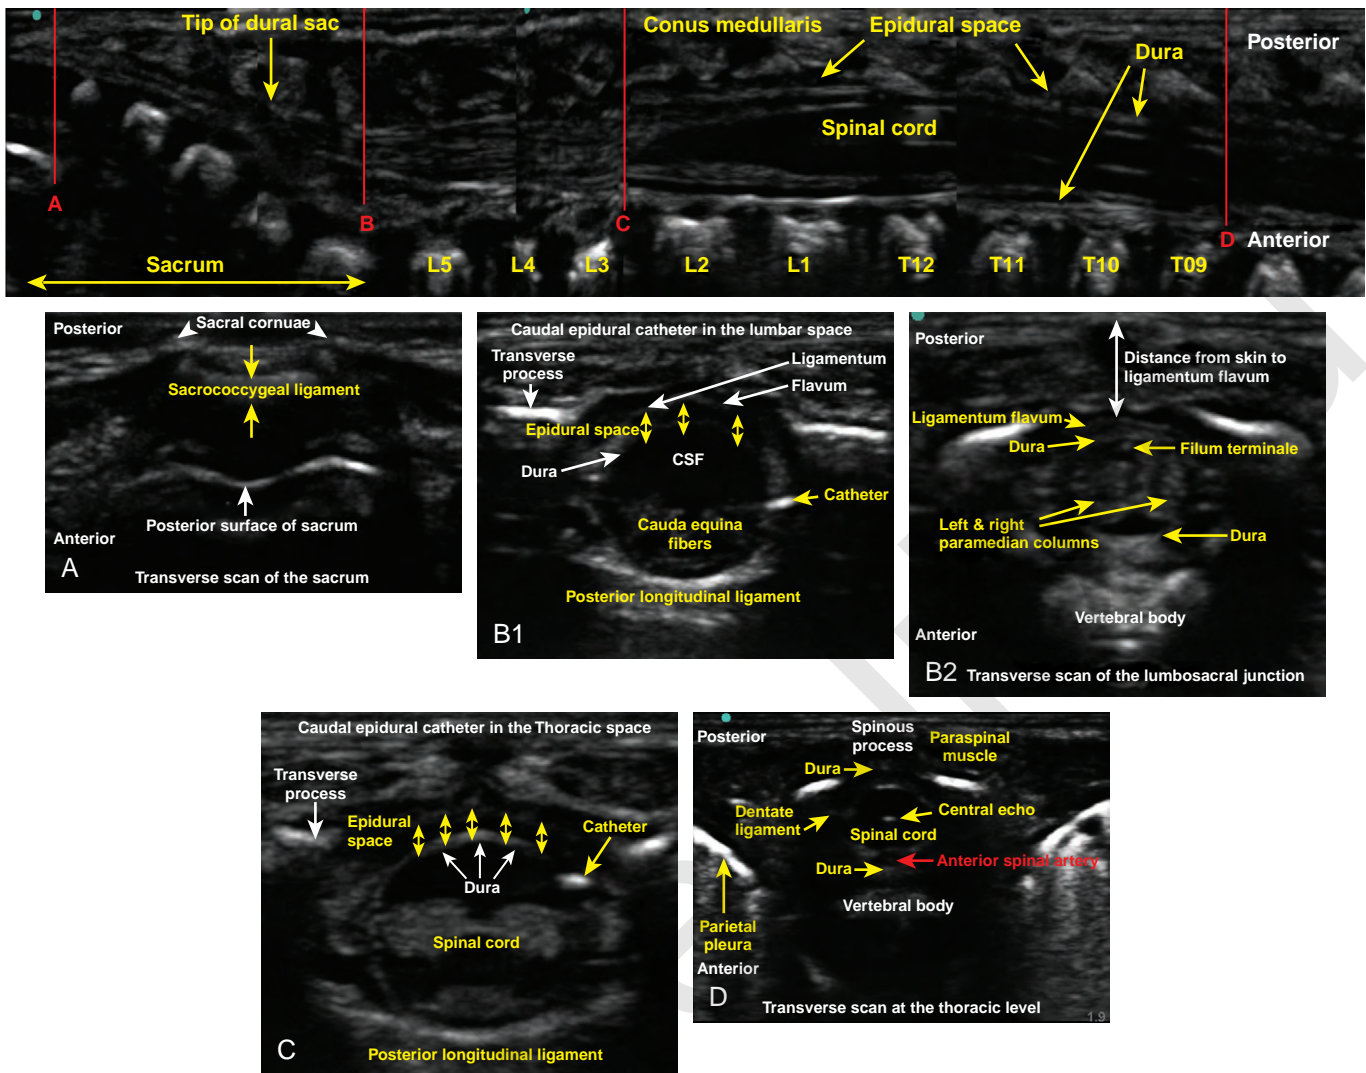

FIGURE 16-9. Panoramic view of epidural space. **A**, Cross-section at sacral cornuae. **B**, Cross-section at lumbosacral junction. **C**, Cross-section at lumbar spine. **D**, Cross-section at thoracic spine.

space and to spread the anesthetic cephalad to the desired dermatomal level. It is important to refer to the maximal allowable dosing recommendations so that these rates are not exceeded in an attempt to “drive up” the epidural block from the caudal space (see [Table 16-2](#)). Bupivacaine, ropivacaine, and levobupivacaine may be used for continuous caudal anesthesia, with or without additives. It is possible to improve the analgesia of a continuous caudal catheter by adding a hydrophilic opioid such as preservative-free morphine or hydromorphone to the infusion.

In addition to a continuous infusion, children can also benefit from patient-controlled epidural analgesia, which allows the patient to receive analgesia at the press of a button. Its popularity in children began in the late 1980s with intravenous opioids and has expanded to local anesthetic infusions for a variety of blocks. In a study of children who had undergone a total of 132 procedures and who used patient-controlled epidural analgesia postoperatively, more than 90% had satisfactory analgesia with no significant adverse effects (Birmingham

et al., 2003). This study confirmed that children as young as 5 years have the cognitive ability to use of patient-controlled analgesia.

Complications

Complications of continuous caudal infusions are typically secondary to the agent that is being delivered. The risk for local anesthetic toxicity has been discussed, and there is ample evidence that the use of bupivacaine at dosages over 0.2 mg/kg per hour in infants and 0.4 mg/kg per hour in children older than 6 months may lead to neurotoxicity or cardiovascular collapse (Agarwal et al., 1992; Berde, 1992, 1993; McCloskey et al., 1992).

In addition to the risk for serious complications, minor complications such as urinary retention, muscle weakness, itching, or nausea and vomiting can occur. Lowering the concentrations of local anesthetics and avoiding opioids in the central infusion can reduce these risks. This regimen, however, puts the patient at greater risk of experiencing postoperative pain.

Continuous indwelling caudal catheters would seem to offer a risk for fecal contamination and infection. When caudal catheters have been compared with epidural catheters, caudal catheters were found to have a greater incidence of colonization of bacteria (20% versus 4%), with *Staphylococcus epidermidis* being responsible for the vast majority of colonizations (McNeely et al., 1997b). In addition, four of the nine caudal catheter tips that were colonized involved gram-negative bacteria. Caudal catheter tip colonization was not predicted by duration of catheterization, skin inflammation, or dressing contamination. None of the children developed signs of epidural infection, either in the hospital or during the 3-month follow-up. Another study demonstrated the absence of epidural abscess or clinically significant infection from indwelling catheters for postoperative pain (Strafford et al., 1995). An option for children who are to have prolonged analgesia provided by a continuous caudal or epidural catheter is to tunnel the catheter under the skin (Aram et al., 2001). This should allow a longer-term infusion of agents by decreasing the chance of catheter dislodgment and protecting against colonization and infection.

Epidural Anesthesia

Epidural anesthesia is commonly used for procedures that involve surgery of the mid to upper abdomen and thorax that are less amenable to a continuous caudal anesthetic. Children who have procedures that have higher morbidity rates such as Nissen fundoplication may benefit from perioperative epidural analgesia (McNeely et al., 1997a; Wilson et al., 2001). Postoperative complications and hospital stay may be reduced with the use of an epidural for this procedure compared with opioid analgesia alone (Miller et al., 2002). In addition, the use of epidural anesthesia is associated with a significantly reduced stress response to surgery in children, as determined by lower cortisol level and plasma epinephrine levels (Murat et al., 1988; Wolf et al., 1993).

Although lumbar epidurals are commonly employed, thoracic epidurals should be performed only by practitioners who are experienced in their use and should be reserved for children with pulmonary disease or who are to undergo a surgical procedure in the thoracic or upper abdominal area that is associated with significant postoperative pain. See related video online at www.expertconsult.com. As discussed, under continuous caudal anesthesia, a catheter may be threaded from the caudal space cephalad to the thoracic region to provide more site-specific analgesia without the risks associated with placing a needle in the thoracic spine. However, threaded catheters from the caudal space are frequently positioned poorly. In older children, a thoracic epidural inserted between T4 and T8 should attenuate the stress response associated with thoracic surgery and provide optimal postoperative analgesia (Hammer, 2001). Thoracic epidural catheters that are placed intraoperatively by the surgeon prior to wound closure for anterior spinal fusion and instrumentation for scoliosis have been shown to be safe and effective (Lowry et al., 2001).

Anatomy

The epidural space in children is divided into the sacral, lumbar, thoracic, and cervical levels. The caudal block enters at the sacral level. A lumbar epidural needle or catheter is typically

placed at the L3-4 interspace, which in older children is found at the center of a line drawn between the two iliac crests. Although these landmarks are accurate in older children, the intercrestal line may actually cross the L5-S1 interspace in neonates, and the L4-5 interspace in infants up to a year of age because of the lag of the growth of the spinal cord (see Fig. 16-3). Because of the developmental changes that occur with the spinal cord and dural sac positions, placing an epidural catheter below the level of the intercrestal line (e.g., the caudal area) may decrease the risk of a wet tap in a neonate or young infant.

Epidural pressures differ depending on the age of the patient. Infants have narrow epidural spaces and are more likely to exhibit leak around an epidural catheter from a backflow of solution if injected too quickly (Vas et al., 2001). Even at slow injection rates, epidural pressures in infants are higher than in adults.

The anatomy of the thoracic spine is similar to that of the lumbar spine with some exceptions. The spinous processes in the thoracic area are longer and the interspinous spaces narrower. These differences necessitate that the epidural needle be placed at a sharper angle in a cephalad direction. The ligaments in the thoracic area are more lax and may be more difficult to discern during needle placement when compared with performing a lumbar needle insertion. Third, and most important, the spinal cord occupies most of the spinal canal in the thoracic area, leaving little margin for error once the needle reaches the epidural space.

The depth to the epidural space at the L2-3 level is approximately 10 mm at birth, and this depth increases linearly with age. The approximate expected distance from the skin to the epidural space in children aged 6 months to 10 years is approximately 1 mm/kg body weight (Bosenberg, 1995). See Figure 16-6 for approximate depths from the skin to the lumbar and thoracic epidural spaces at different ages.

Technique

With the child in the lateral position and knees and hips flexed, the line that joins the two iliac crests crosses the body of S1 in neonates, L5 in infants, L4-5 in young children, and L4 in older children and adolescents (Busoni and Messeri, 1989). After sterile preparation and draping, the needle should be placed in the midline between the spinous processes that are closest to the line that crosses the iliac crests. If performing a lumbar epidural puncture, the spinous processes require the needle to be directed slightly cephalad, but mostly perpendicular to the skin. The needle is advanced slowly, with one hand firmly against the child's back and holding the portion of the needle that is entering the child's skin. This is to avoid any inadvertent and rapid advancement of the needle. The needle will pass through skin, subcutaneous tissue, supraspinous ligament, interspinous ligament, and then ligamentum flavum before entering the epidural space (Fig. 16-10). Because of the risk for air embolus, a continuous-loss-of-resistance technique using saline rather than air to confirm the epidural space is the recommended approach (Sethna and Berde, 1993). The ability to feel entry into the ligamentum flavum and the loss of resistance as the epidural space is entered is subtler in infants than in adults. Once the catheter is threaded into the epidural space and there is negative aspiration for CSF or blood, the local anesthetic with epinephrine should be injected as an initial test dose before delivering the planned dose of local anesthetic. Compared with

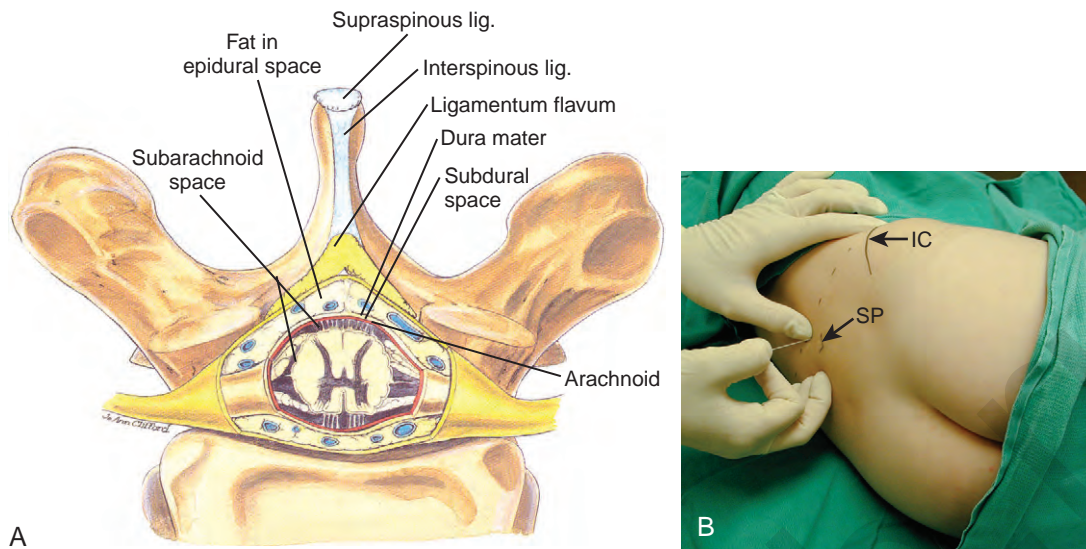

FIGURE 16-10. Epidural anesthesia. **A**, Anatomy of the epidural space. **B**, Performance of epidural block. *IC*, Iliac crest; *SP*, spinous process. (A, Reproduced from Brown DL: Atlas of regional anesthesia, Philadelphia, 1992, Saunders, p 286.)

adults, epidural pressures differ in children, particularly in infants (Vas et al., 2001). Based on the relationship between the volume and rate of injection of local anesthetics in infants and the epidural pressure, a slow rate of injection is used, perhaps 0.5 mL/min.

To place a thoracic epidural, the child is placed in the lateral decubitus position. After sterile preparation and draping, the point of needle insertion is chosen at the midpoint of the spinous processes. The needle should be at a 45- to 60-degree angle, aiming cephalad until resistance is felt as the spinous ligaments are encountered. A syringe to detect loss of resistance to saline is attached, and the needle is continuously advanced slowly with light pressure on the plunger of the syringe. A sudden loss of resistance indicates needle placement in the epidural space. One of the hallmarks of a successful thoracic epidural needle placement is the ease at which a catheter is threaded in this area. It should pass easily and without resistance.

Technique with Ultrasound

A preprocedural ultrasound scan of the vertebral column facilitates optimal site selection for the lumbar or thoracic epidural catheter insertion and allows measurement of the depth of the ligamentum flavum, thus estimating the depth at which loss of resistance will occur (Rapp et al., 2005; Willschke et al., 2007) (see Fig. 16-9). The longitudinal median view offers a slightly better correlation with actual depth than the transverse view by ultrasound (Kil et al., 2007). Real-time ultrasound-guided epidural placement has resulted in reduction in the catheter placement time and the frequency of bony contacts (Willschke et al., 2006c). This approach is challenging and requires two anesthesiologists experienced in the ultrasound-guided procedures and neonatal epidural techniques. To simplify the technique, perform a scout ultrasound scan to determine the depth of the epidural space, and then confirm catheter tip position by saline injection test once threading through the needle is completed.

Equipment

Appropriately sized equipment is readily available for epidural placement in children. Short Touhy needles and small-gauge catheters, with and without metal helices, are available. The main disadvantage of a small-gauge catheter is that it increases resistance to continuous infusion of local anesthetic. Postoperatively, this can result in kinking and frequent alarms of the infusion pump.

Dosing

Epidural catheters are typically placed so that their use can be continued in the postoperative period. Because the tip of the epidural catheter should be in close proximity to the level of surgery, and because the lumbar and thoracic epidural spaces are more compact than the caudal space, the initial bolus of local anesthetic required for lumbar and thoracic epidurals is smaller (0.3 to 0.5 mL/kg) than the volumes required for a caudal injection. Approximately 90 minutes after the initial bolus, a continuous infusion may be initiated with care to stay within the maximal allowable dose (see Table 16-2). Recommendations for epidural dosing are in Table 16-3.

When using 0.25% bupivacaine at a rate of 0.08 mL/kg per hour in the lumbar epidural space in children aged 11 months to 15 years, Desparmet and coworkers (1987) demonstrated that the terminal half-life ranges from 164 to 270 minutes, and total body clearance is similar to that after single caudal injection. Larsson and associates (1994) studied bupivacaine infusions in 12 infants. In infants, bupivacaine infusions at rates of 0.5 to 0.83 mg/kg per hour for 12 hours resulted in marked increases in plasma bupivacaine concentrations. Larsson also noted possible toxic reactions in three of the 12 infants and suggested these infusion rates were excessive for this age group.

The pharmacokinetics of epidural ropivacaine were assessed after a single injection of 1.7 mg/kg via a lumbar epidural catheter (McCann et al., 2001). The median peak plasma concentrations of ropivacaine were 610 mcg/L in infants aged 3 to

11 months, and 640 mcg/L in children aged 12 to 48 months. In both groups of children, the median peak plasma concentration was reached in 60 minutes. The calculated clearance of ropivacaine was 4.26 mL/kg per minute in infants and 6.15 mL/kg per minute in older children. No ropivacaine toxicity was observed in either group. When ropivacaine 0.2% at 0.4 mg/kg per hour was delivered as a continuous lumbar or epidural infusion for 36 to 96 hours, Hansen and coworkers (2000) noted no clinically significant side effects in 18 pediatric patients aged 4 months to 7 years. In this study, the volume of distribution of epidural ropivacaine was 3.1 L/kg, total clearance was 8.5 mL/kg per minute, and the elimination half-life was 4.9 hours (see Table 16-1). In infants and neonates who received 48 to 72 hours of continuous ropivacaine epidural infusion, Bosenberg and associates (2005) found that plasma concentrations of unbound ropivacaine were not influenced by the duration of the infusion. Although the levels of unbound ropivacaine were higher in the neonates than in the infants, all were below the level of 0.35 mg/L, the threshold that is considered toxic in adults.

Epidural Additives

The advantage of adding clonidine to single-shot caudal blocks has been demonstrated, but there are also advantages to its use for continuous epidural analgesia. In a study of 60 children who received a low lumbar epidural catheter for hypospadias repair, a postoperative infusion of ropivacaine alone was compared with ropivacaine with varying dosages of clonidine. De Negri and coworkers (2001b) evaluated plain ropivacaine 0.1% at 0.2 mg/kg per hour, and ropivacaine 0.08% at 0.16 mg/kg per hour, plus either clonidine 0.04 mcg/kg per hour, 0.08 mcg/kg per hour, or 0.12 mcg/kg per hour. The children who received the ropivacaine with the higher clonidine dosages in the 0.08 to 0.12 mcg/kg per hour range had improved pain scores, longer time to first analgesic, and reduced total supplemental analgesics without increased sedation or other side effects.

The use of neuraxial opioids was discussed (see Caudal Analgesia, earlier). In a study designed to assess the efficacy of preoperative epidural morphine, 21 children were randomized to either a group that received 30 mcg/kg epidural morphine after induction of general anesthesia but prior to surgical incision, or to a group that did not receive an epidural injection (Kiffer et al., 2001). Both groups were given intraoperative infusions of sufentanil and postoperative patient-controlled analgesia with morphine. The group that had received preoperative epidural morphine, in comparison with the control group without epidural morphine, had lower pain scores and decreased total analgesic requirements postoperatively without increased side effects.

Epinephrine is a commonly used additive for single-shot epidural blocks because of its ability to decrease systemic absorption and perhaps prolong the block while adding an additional level of safety. For continuous infusions, these benefits must be weighed against the theoretical risks of vasoconstriction of spinal vessels. Kokki and coworkers (2002) compared a combination of ropivacaine and sufentanil with and without epinephrine 2 mcg/mL in a population of children. The children who had epinephrine in their postoperative epidural infusions had significantly lower infusion requirements and fewer side effects. In adults, the addition of epinephrine to a ropivacaine epidural infusion at 5 mcg/mL reduces the early systemic plasma

concentrations of ropivacaine, and thereby may decrease the risk for toxicity from systemic absorption (Lee et al., 2002).

Complications

As discussed for caudal catheters, the risk for infection is very low. Although there have been case reports of epidural abscess, short-term epidural catheterization for postoperative courses do not appear to have the same risk for infection as those placed for chronic pain (Strafford et al., 1995). In 1620 children over a 6-year period who received epidural catheters, there were no infections or epidural abscesses in catheters that had been placed for postoperative pain management. There was only one epidural abscess found in this study, and that was in an immunosuppressed child with terminal malignancy who had *Candida* colonization of the epidural space that had been invaded by tumor and had an indwelling catheter for control of pain from her malignancy. When catheters have been removed and cultured, the incidence of catheter tip colonization in epidural catheters is 4%, lower than that found in caudal catheters (20%) (McNeely et al., 1997b).

A systematic review and pooled analysis of studies on the risk for infection of long-term epidural catheters estimated that one person in 35 may develop an epidural catheter infection (Ruppen et al., 2007). The populations reviewed were primarily adult cancer patients, and those who developed infections had catheters present for an average duration of 74 days. This population is certainly in a separate risk group from that of the typical pediatric surgical patient.

PERIPHERAL NERVE BLOCKS

The use of pediatric peripheral nerve blocks has seen the largest growth in practice and in the literature (Rochette et al., 2007). The goal of placing peripheral nerve blocks is to specifically target analgesia to the location of the surgery so that side effects are kept to a minimum (Ross et al., 2000). The safety of performing such blocks has been established, and it has been recommended by ADARPEF that peripheral blocks be used in place of central blocks when appropriate (Giaufre et al., 1996). In their safety study of regional anesthetics in children, there were no complications in the 9396 children who received peripheral nerve blocks or local anesthesia. Despite these findings, peripheral nerve blocks were often underused in children, probably related to inexperience and the perception that they may be difficult to perform or be hazardous. The use of ultrasound has changed the perception of safety and been responsible for a growth in literature on peripheral nerve blocks in children.

Success of placing peripheral nerve blocks is often a function of knowledge of the anatomy, and use of the appropriate equipment (Sethna and Berde, 1992). Insulated needles with a nerve stimulator have been used for peripheral nerve blockade in past years because the field of current is localized to the needle's tip. Unsheathed needles may be less expensive and result in successful blocks, but the current is distributed not only to the needle's tip but also along the shaft of the needle. Thus, the required stimulatory current is greater (up to 2 mA) (Bosenberg, 1995). For upper extremity nerve blocks, a 1- or 2-inch insulated needle will suffice. Lower extremity blocks may require the use of longer needles, particularly for sciatic blocks in adolescents. Another practical consideration in performing

a peripheral nerve block with a nerve stimulator is that administration of neuromuscular blockers will abolish the ability to elicit muscle stimulation with a peripheral nerve stimulator. The peripheral nerve stimulator should be capable of delivering 0.1 to greater than 1.5 mA and be set to 2 Hz. The positive electrode of the nerve stimulator should be placed at least 10 cm from the nerve to be blocked and preferentially on the opposite limb. To locate a nerve or plexus, begin with the nerve stimulator set at 1 to 1.2 mA, and advance the needle until the desired motor response is achieved. The voltage may then be decreased. When the voltage is decreased to less than 0.5 mA, the motor response should be diminished but still present. One may need to make further fine adjustments in the needle's position in order to continue muscle stimulation of the appropriate muscle group at the lower voltage. However, an increase in voltage may be required to relocate the nerve if muscle stimulation is completely lost. Once the nerve stimulator's voltage is less than 0.5 mA and slight muscle stimulation results, the local anesthetic is injected. If the needle is in correct position, the muscle stimulation should cease immediately. If there is intense muscle stimulation with 0.2 mA, the possibility of intraneural needle placement must be considered. Consequently, the needle should be withdrawn and carefully readvanced. In anesthetized children, the placement of a needle into a nerve would not be detected, so this warning sign of intense muscle stimulation at lower voltage is significant. In animal studies, motor response to less than 0.2 mA occurred only when the needle tip was intraneural (Tsai et al., 2008). Unfortunately, motor response could also be absent with intraneural needle placement at currents up to 1.7 mA.

In addition to strong twitches at low voltage, one should look for other warning signs of intraneural injection, such as difficulty with injection and increased heart rate with injection. The routine use of a 5- or 10-mL syringe for local anesthetic injection may improve success by allowing the operator to have a consistent "feel" for the pressure on injection. Animal experiments suggest that pressures of greater than 20 psi suggest intraneural injection and neurologic sequelae.

As previously discussed, the use of ultrasound for peripheral nerve blockade in children is becoming increasingly common and has replaced the use of nerve stimulation at many high-volume centers. Ultrasonography allows the practitioner to visualize the anatomy and needle, presumably resulting in improved success of block with less risk for nerve injury, although this remains unproven. The technique of using the combination approach of nerve stimulation with ultrasound has been presented and may be valuable as part of the learning process in performing peripheral nerve blocks in children.

The ultrasonographic identification of peripheral nerves requires practice. Nerves come in many shapes depending on their anatomic location; however, with systematic examination, patterns emerge. Nerve roots and proximal segments have a hypochoic core surrounded by a hyperechoic ring. Because nerve roots and trunks are clinically visualized only in the performance of the interscalene, parascalene, and supraclavicular blocks, it is generalized that nerves are dark above the clavicle. Peripheral nerves are hyperechoic with fascicular echotexture and exhibit anisotropy, which is a change in echogenicity depending on imaging angle (Crass et al., 1988; Grechenig et al., 2000). Directing the insonation angle perpendicular to the direction of the nerve fiber will optimize nerve appearance.

Although the practice has been replaced by ultrasound, surface nerve mapping was once recommended for use in children to improve the ability to locate a peripheral nerve or plexus (Bosenberg et al., 2002a). Nerve surface mapping is performed by setting the nerve stimulator at a frequency of 1 to 2 Hz and the current between 3 to 4 mA. The positive electrode should be at least 10 cm from the nerve to be mapped, and the negative electrode or alligator clamp that would normally be attached to the block needle is instead pressed against the skin at right angles across the suspected path of the nerve. Once a point of maximal motor response is found, a mark may be placed to indicate where the insulated needle may be inserted for regional blockade.

In children who are anesthetized, it is not possible to reliably test the success of a peripheral nerve block; however, one may increase the voltage of the nerve stimulator after local anesthetic injection to determine that there is loss of stimulation. Although subtle, it is also possible to determine the success of a motor block by comparing the flaccidity of the blocked limb to the muscle tone of the contralateral extremity. Vasodilation or increased skin temperature, when present in the blocked limb, may be a more reliable indicator of a successful block, but its absence does not mean that the block is unsuccessful. The absolute determinant of a successful block is the absence of response to the surgical incision. Most peripheral nerve blocks, regardless of the agent used, should provide total analgesia to the desired nerve or plexus within 20 minutes of the local anesthetic injection.

Dosing of peripheral nerve blocks will be discussed with regard to the individual block. Regardless of the local anesthetic delivered, the addition of epinephrine to the solution should provide additional safety when performing the block. Not only does the addition of epinephrine to the local anesthetic solution have the potential to serve as a marker for intravascular injection, it may also decrease overall absorption of the local anesthetic. In a study of 20 children who were to undergo unilateral surgery of the thigh, patients were administered a fascia iliaca block using 2 mg/kg bupivacaine either with or without epinephrine 5 mcg/mL (Doyle et al., 1997). The median maximal plasma bupivacaine concentration in the group without epinephrine was 1.1 mcg/mL, compared with 0.3 mcg/mL in the group of patients for whom epinephrine was added to the bupivacaine. Not only did the epinephrine group have a significantly lower peak plasma level, but the onset time to peak plasma concentration was more gradual for the group with epinephrine.

There is little information as to the use of adjuncts to local anesthetics in pediatric peripheral nerve blocks. In a database review of 435 patients at the Children's Hospital of Philadelphia, the use of clonidine 1 mcg/kg (up to 100 mcg) for peripheral nerve blockade resulted in a longer duration of sensory block of 17.2 hours versus 13.2 hours in the group who received either bupivacaine or ropivacaine with clonidine, and a prolonged motor block of 9.6 hours with clonidine versus 4.3 hours without (Cucchiario and Ganesh, 2007). This increased duration occurred in children who had received either upper or lower extremity nerve blocks for a variety of surgeries, and it was also independent of which local anesthetic was used. These findings differ from adult studies, where the use of clonidine for peripheral nerve blocks has shown to be of benefit only for upper extremity blocks, particularly axillary block, and with intermediate-acting local anesthetics (McCartney et al., 2007a). The prolongation of sensory analgesia found by Cucchiario and

Ganesh may have resulted from local effect from direct binding at α_2 -adrenergic receptors. The use of clonidine in children was also in addition to low concentrations of local anesthetics versus higher concentrations that are typically used in adults. Additional investigation is necessary to determine the overall usefulness of clonidine for peripheral nerve blocks in children. Although the early work appears promising, no prolongation of analgesia was found when 1 mcg/kg clonidine was added to bupivacaine for ilioinguinal/iliohypogastric nerve blocks in children (Kaabachi et al., 2005).

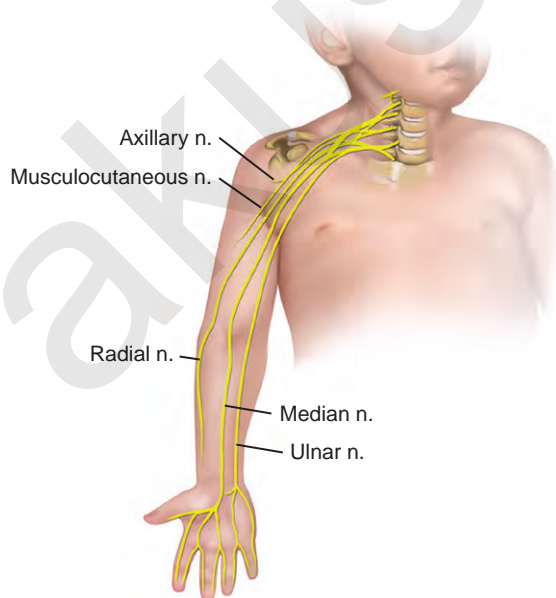

The majority of peripheral nerve block techniques are similar to those of adults. The differences from adult practice are presented here, along with blocks that are more specifically for children. Although anatomy is stressed for most of the blocks using landmark techniques, many of the blocks also have a section describing the use of ultrasound for practitioners who are proficient in its use. Some blocks where ultrasound is clearly advantageous for success or safety of the block are presented with that as the sole technique.

Upper Extremity Nerve Blocks

Upper extremity blocks may be used for surgery of the shoulder, arm, and hand. Specifically, brachial plexus blocks below the clavicle including the axillary approach are suitable for surgery on the hand and those blocks above the clavicle are useful for surgery on the shoulder and upper arm. Depending on the approach to the plexus, it is also possible to provide total analgesia to the hand with blocks above the clavicle. See related video online at www.expertconsult.com.

Anatomy

The brachial plexus contains the anterior branches of spinal roots C5 through T1 (Fig. 16-11). In the neck, these branches run between the anterior and middle scalene muscles and are enclosed in a fascial sheath. They then form three trunks

■ FIGURE 16-11. Brachial plexus anatomy.

(superior, middle, inferior) that exit the interscalene groove and run behind the subclavian artery. As they exit the interscalene groove, these cords form an anterior and posterior division. The divisions then unite to form lateral, posterior, and medial cords, depending on their relation to the axillary artery. There is a natural separation between the supraclavicular and infraclavicular plexus at the coracoid process that ultimately affects spread of local anesthetic (Vester-Andersen et al., 1986).

Understanding of the medial neck anatomy and components at each level of the plexus is crucial to avoiding complications (Fig. 16-12). Because the brachial plexus may be blocked in a number of locations, it is important to know the anatomy at each level in the neck area for successful block (Fig. 16-13). Close anatomic relationship of the carotid artery and internal jugular vein should be observed to select the ideal location for local injection. The proximity of the phrenic nerve overlying the anterior scalene muscle with founding cervical nerve roots C3 to C5 and cervical sympathetic chain explains resulting diaphragmatic paresis and Horner's syndrome from the excessive spread of local anesthetic (Neal et al., 2009).

At the level of the axilla are the peripheral nerves that innervate the arm. The radial nerve supplies the dorsal aspect of the upper extremity below the shoulder including the thumb and dorsal aspects of the index, middle, and fourth fingers. The musculocutaneous nerve provides innervation to the biceps of the upper arm and cutaneous innervation to the lateral forearm. The median nerve innervates the majority of the forearm, as well as the ventral aspects of the second, third, and lateral portion of the fourth fingers, and the medial portion of the thumb. The ulnar nerve is more limited to the hand and innervates the lateral aspect of the fourth finger and all of the fifth (Fig. 16-14).

Interscalene Block

An interscalene block has been used for surgery of the shoulder and upper arm with success in children. It also anesthetizes the musculocutaneous nerve reliably, but there is less reliability of blocking the ulnar nerve than with the other nerve blocks because the ulnar nerve's origin is at the lower portion of the plexus. Interscalene blocks are infrequently used in children because of the perceived higher risk for complications and side effects, and they are not recommended for placement in the anesthetized child because of risk for spinal cord injury (Bernards et al., 2008). For this reason, the technique will not be described.

Complications

Complications of interscalene block are not insignificant and include pneumothorax, spinal cord injury, epidural injection,

■ FIGURE 16-12. Medial neck anatomy.

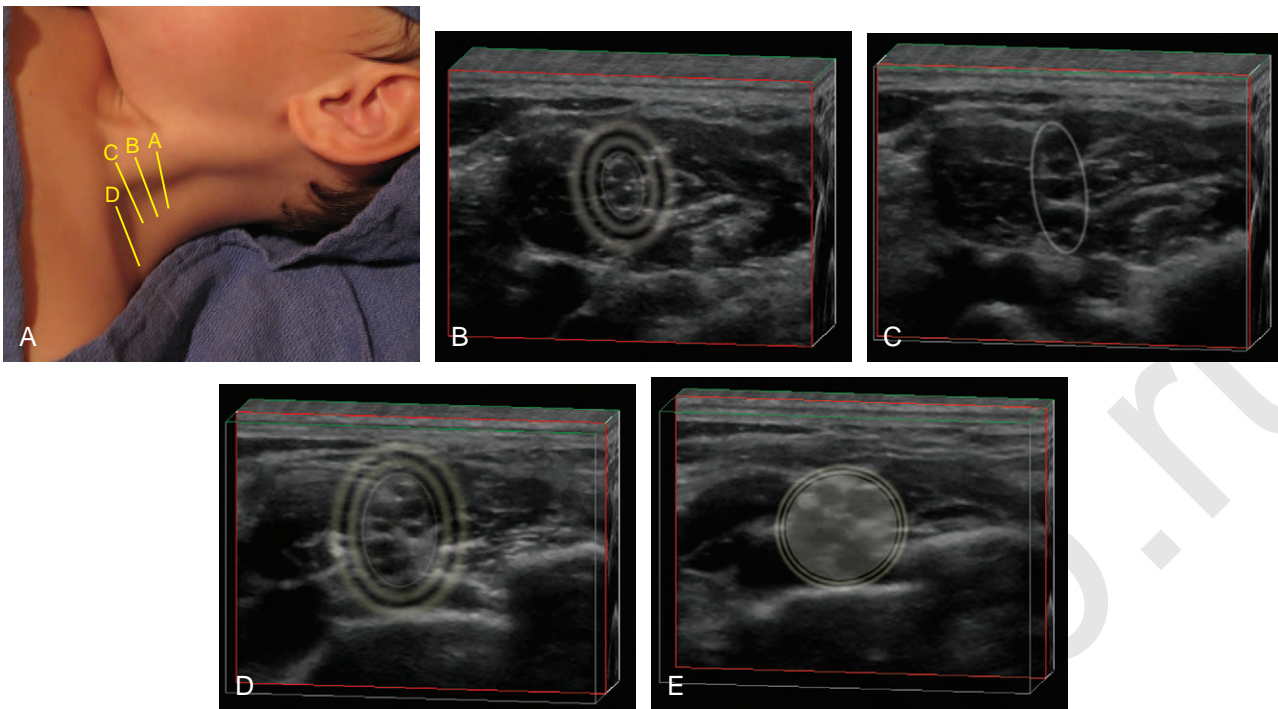

FIGURE 16-13. Brachial plexus in the neck. **A**, External landmarks. **B**, Plexus at level A (encircled). **C**, Plexus at level B (encircled). **D**, Plexus at level C (encircled). **E**, Plexus at level D (encircled).

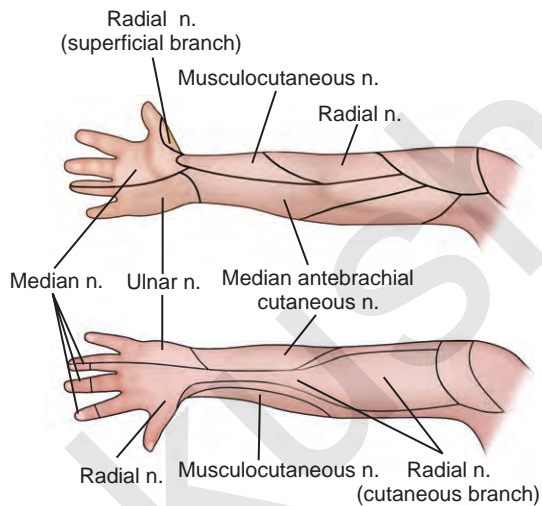

FIGURE 16-14. Dermatomal distribution of brachial plexus.

or intrathecal injection. Vertebral artery puncture may also occur, with a risk for local anesthetic delivery directly to the CNS resulting in CNS toxicity. In addition, there is a high risk for phrenic nerve block with paralysis of the hemidiaphragm. Phrenic nerve block is not well tolerated, especially in infants or patients with underlying respiratory compromise (Kempen et al., 2000). Unilateral vocal cord paralysis may also occur and result in airway compromise. Sympathetic blockade with Horner's syndrome is a common side effect of interscalene blocks.

Parascalene Block

The parascalene approach to the brachial plexus was developed by Dalens (1995) to provide effective analgesia to the shoulder and upper arm (Fig. 16-15, A) while minimizing the risks of vertebral artery puncture, dural puncture, and pneumothorax (i.e., the risks associated with an interscalene block). The parascalene block is similar to the interscalene approach, but by changing the insertion and direction of the needle, major structures in the neck are avoided. This block has been found to be easy to perform, with a 97% success rate in children on the first or second attempt (Dalens et al., 1987). See related video online at www.expertconsult.com.

Technique

With the child supine and a roll under the shoulders, the arm should be adducted next to the trunk and the head turned to the opposite side. The primary landmarks are Chassaignac's tubercle (transverse process of C6) and the midpoint of the clavicle. Draw a line between these two structures and insert a needle at the junction of the upper two thirds and lower one third of this line (see Fig. 16-15, B and C). This insertion spot should be at the level of the cricoid process near the external jugular vein. The approximate depth to the parascalene brachial plexus from the skin depends on the age of the child (see Fig. 16-6). Using low voltage, and once appropriate stimulation has been achieved, the local anesthetic solution is injected. Nerve stimulation for a parascalene block may result in muscle response in the biceps or triceps or with finger or hand movement. Shoulder muscle response suggests stimulation of the supraclavicular nerve, indicating that the needle is lateral to the plexus.

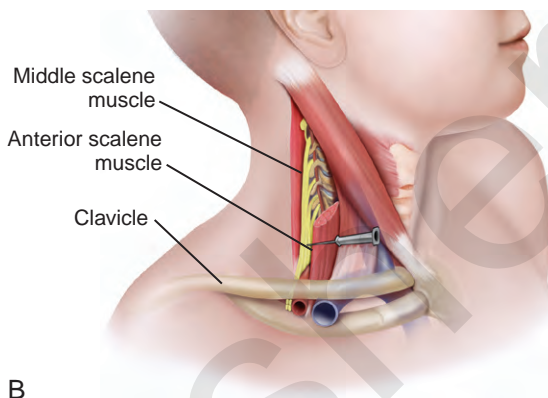

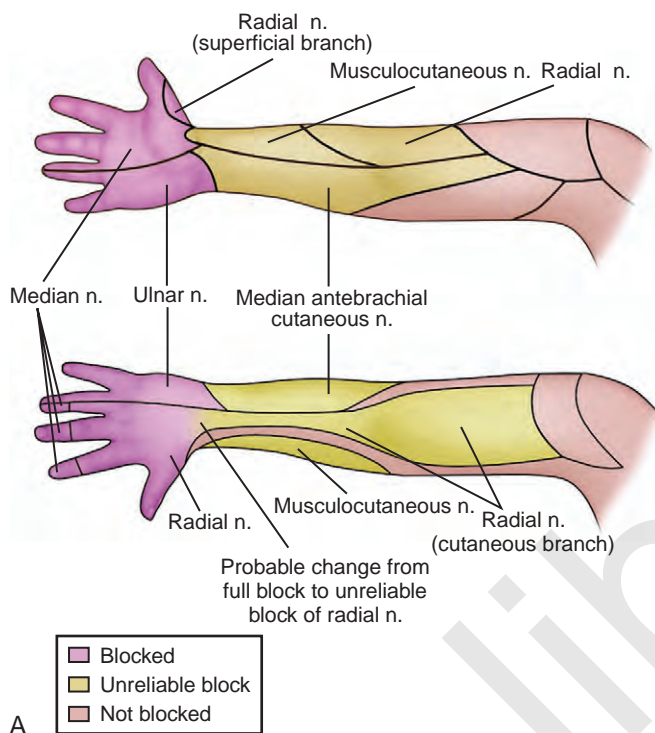

FIGURE 16-15. Parascalene block. **A**, Dermatomal distribution of parascalene block. **B**, Anatomy for parascalene block. **C**, Performance of parascalene block. MC, Midpoint of clavicle; TP, transverse process of C6.

Complications

Complications using the parascalene approach are rare but may include venous puncture, Horner’s syndrome, and hemidiaphragmatic paralysis secondary to phrenic nerve paralysis.

Supraclavicular Block

The supraclavicular block has the advantage of providing analgesia to all portions of the arm and is useful for nearly all upper extremity procedures. Despite a pneumothorax-free application of the supraclavicular block in 200 pediatric patients by landmark technique, the close anatomic relationship of pleura to the brachial plexus justifiably deters many pediatric anesthesiologists (Pande et al., 2000). The ultrasound-guided approach was demonstrated to be safe in 40 pediatric patients, had a higher success rate, and was faster to perform than the infraclavicular block (De Jose Maria et al., 2008). The ability of ultrasound to

visualize the path and the tip of the needle, as well as the course of local anesthetic spread during injection, holds promise for using these blocks in a pediatric regional practice, and this has resulted in a pneumothorax-free application of supraclavicular block in pediatric patients. Because needle tip visualization is imperative to safe application of this procedure, only experienced ultrasound practitioners should attempt this block.

Technique with Ultrasound

A linear ultrasound transducer with the smallest available footprint, set at the highest operational frequency, should be used to achieve maximal resolution of the superficial supraclavicular structures (Fig. 16-16, A). The ultrasound machine should be positioned on the contralateral side in the direct line of view of the operator. The operator sits or stands by the patient’s shoulder on the ipsilateral side with the ultrasound transducer held in the nondominant hand and positioned

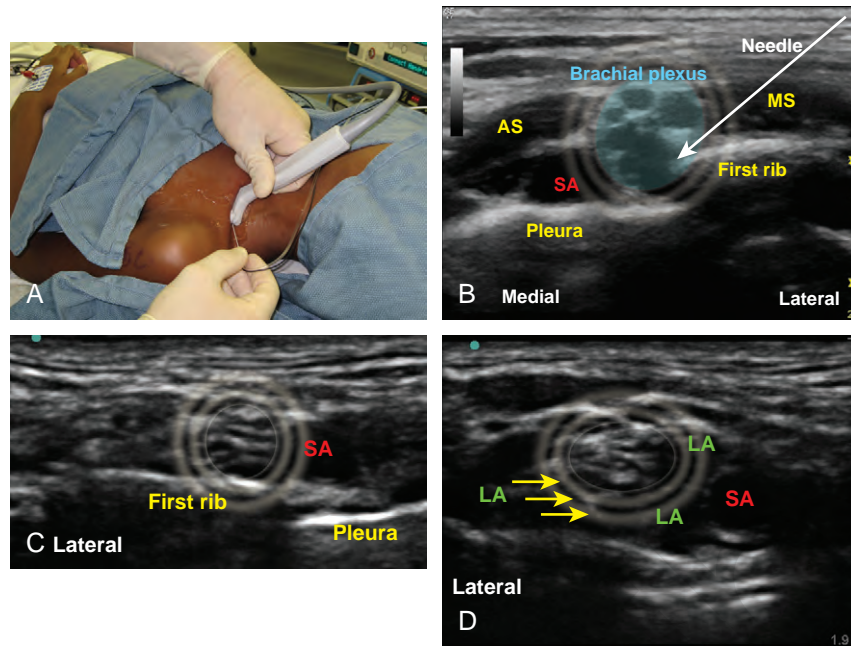

FIGURE 16-16. Ultrasound-guided supraclavicular block. **A**, Needle and transducer placement. **B**, Sonoanatomy. **C**, Before injection of local anesthetic. **D**, After injection of local anesthetic.

parallel to the clavicle in the supraclavicular groove. The subclavian artery is identified in the short axis as a round, pulsatile structure, and the cervical pleura and lung are imaged below. The brachial plexus is located posterosuperior to the artery between the insertion of the anterior and middle scalene muscle onto the first rib and has a cluster-of-grapes appearance (hypoechoic center with hyperechoic rim) (see Fig. 16-16, B). The block needle is inserted in-plane in a lateral to medial direction. Ideally, the needle tip is placed between the first rib and the most inferior aspect of the brachial plexus (see Fig. 16-16, C). Injection at this location prevents superficial image distortion; pushes the brachial plexus up and away from the pleura, thus creating a margin of safety if the needle tip needs to be repositioned; and ensures blockade of the inferior trunk (see Fig. 16-16, D). The needle should be repositioned around the middle and superior nerve structures to achieve complete envelopment of the plexus by local anesthetic. To avoid pleural puncture, the needle tip should be visualized throughout the block placement, and to rule out intravascular injection, separation of tissues with incremental local anesthetic injection should be observed.

Lateral Vertical Infraclavicular Block

A lateral vertical infraclavicular brachial plexus block was introduced for pediatric use because the block can be performed without arm abduction. In addition, the block is more reliable for anesthetizing the musculocutaneous nerve, and this block provides better analgesia of the upper arm than an axillary block (Fleischmann et al., 2003). Although other infraclavicular approaches were considered too hazardous because of the risk for pneumothorax, the more lateral and vertical approach developed by Kapral (1999) and associates provides a safe distance between puncture site and pleura. This technique has been used in adults and children and has been shown to provide a greater spectrum of block than the axillary approach (Kapral

et al., 1999; Fleischmann et al., 2003). The indications for a lateral infraclavicular block are the same as those for axillary block. See related video online at www.expertconsult.com.

Technique

With the child in the supine position, the upper arm should remain next to the trunk and the elbow flexed 90 degrees so that the forearm is on the abdomen. Palpate the coracoid process and using a nerve stimulator, insert a 1-inch 24-gauge insulated needle 0.5 cm distal to the coracoid process in a perpendicular or vertical direction while continuously aspirating for blood and/or air (Fig. 16-17). Once appropriate stimulation has been determined and continuous aspiration for blood or air has been negative, local anesthetic solution is injected. Obtaining wrist or finger movement predicts a successful block, whereas if only elbow twitches are seen, a failed block is likely to occur (Ponde and Diwan, 2009).

Complications

Complications with this approach are rare. There may still be a risk of inadvertent pleural or vascular puncture, but less so than with other approaches to the brachial plexus.

Infraclavicular Block

The infraclavicular block provides the same analgesia as can be expected from an axillary block, and it is suitable for distal upper extremity procedures. The ultrasound-guided infraclavicular block has been shown in children to offer shorter onset time, longer duration, and decreased discomfort during placement than nerve stimulation (Marhofer et al., 2004). In addition, the volume of local anesthetic needed to produce analgesia may be decreased with the ultrasound guidance, and the block can be successfully performed even in patients with altered response to

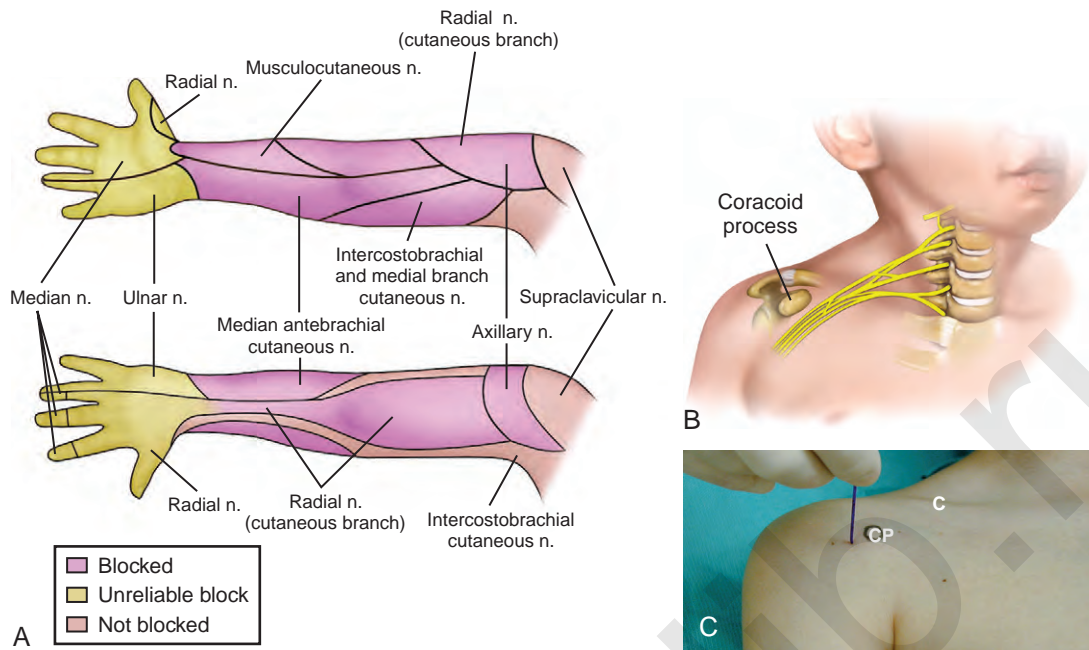

FIGURE 16-17. Lateral vertical infraclavicular brachial plexus (LVIBP) block. **A**, Dermatomal distribution of LVIBP block. **B**, Anatomy for LVIBP block. **C**, Performance of LVIBP block. C, Clavicle; CP, coracoid process.

nerve stimulation such as those with congenital abnormalities, trauma, or distal arm amputation (Sandhu et al., 2006; Ponde and Diwan, 2009). Because of the risk for pneumothorax, ultrasound-guided infraclavicular block is the preferred approach. See related video online at www.expertconsult.com.

Technique with Ultrasound

With the child in supine position and head rotated to the non-operative side, the operator stands or sits at the head of the bed and positions the ultrasound transducer below and perpendicular (sagittal plane) to the clavicle in the infraclavicular fossa, slightly medial to the coracoid process. A linear transducer with a small footprint should be used for this block, given the narrow anatomic relationship of the infraclavicular fossa. The frequency selection is size dependent: larger children with deeper anatomy benefit from medium frequency range (10 to 7 MHz), but superficial structures are imaged best with a high frequency (13 to 10 MHz) in young children and toddlers. The ultrasound machine should be positioned in the direct line of view of the operator on the ipsilateral side of the patient. The child's arm can be kept at the side when block placement is attempted in an awake child with an injured extremity; however, if tolerated or in a sedated child, the arm is abducted to 90 degrees, and external rotation and flexion at the elbow raises the plexus closer to the skin and rotates the clavicle upward, thus creating additional space for probe positioning. Sonographic examination will reveal axillary vessels immediately deep to the pectoralis major and minor muscles, and the three hyperechoic cords surrounding the second part of the axillary artery at the 3-o'clock (medial cord), 6-o'clock (posterior cord), and 9-o'clock (lateral cord) positions (Fig. 16-18, A). The needle insertion site is determined by scanning the infraclavicular fossa in the mediolateral direction, and the ideal site is where the pleura is farthest separated from the plexus (see Fig. 16-18, B). The needle

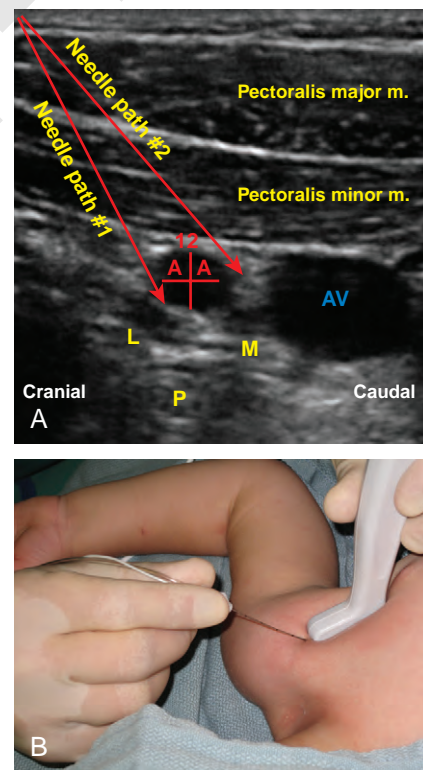

FIGURE 16-18. Ultrasound scan of infraclavicular block. **A**, Sonoanatomy. **B**, Needle and transducer placement.

is advanced in-plane from the superior part of the transducer (cranial-caudal direction), and is positioned between the posterior cord of the brachial plexus and the axillary artery. Injection should produce circumferential spread around the axillary artery in young children; however, in older children, the median

cord may be missed with a single injection and requires targeted injection to obtain a successful block. Maintaining continuous needle visualization may be challenging because of the acute angle of insertion, and it requires expertise in the ultrasound-guided techniques. Secondary confirmation of the needle tip can be gathered from tissue movement and hydro-locating with injection of 0.5 to 1 mL of normal saline.

Axillary Block

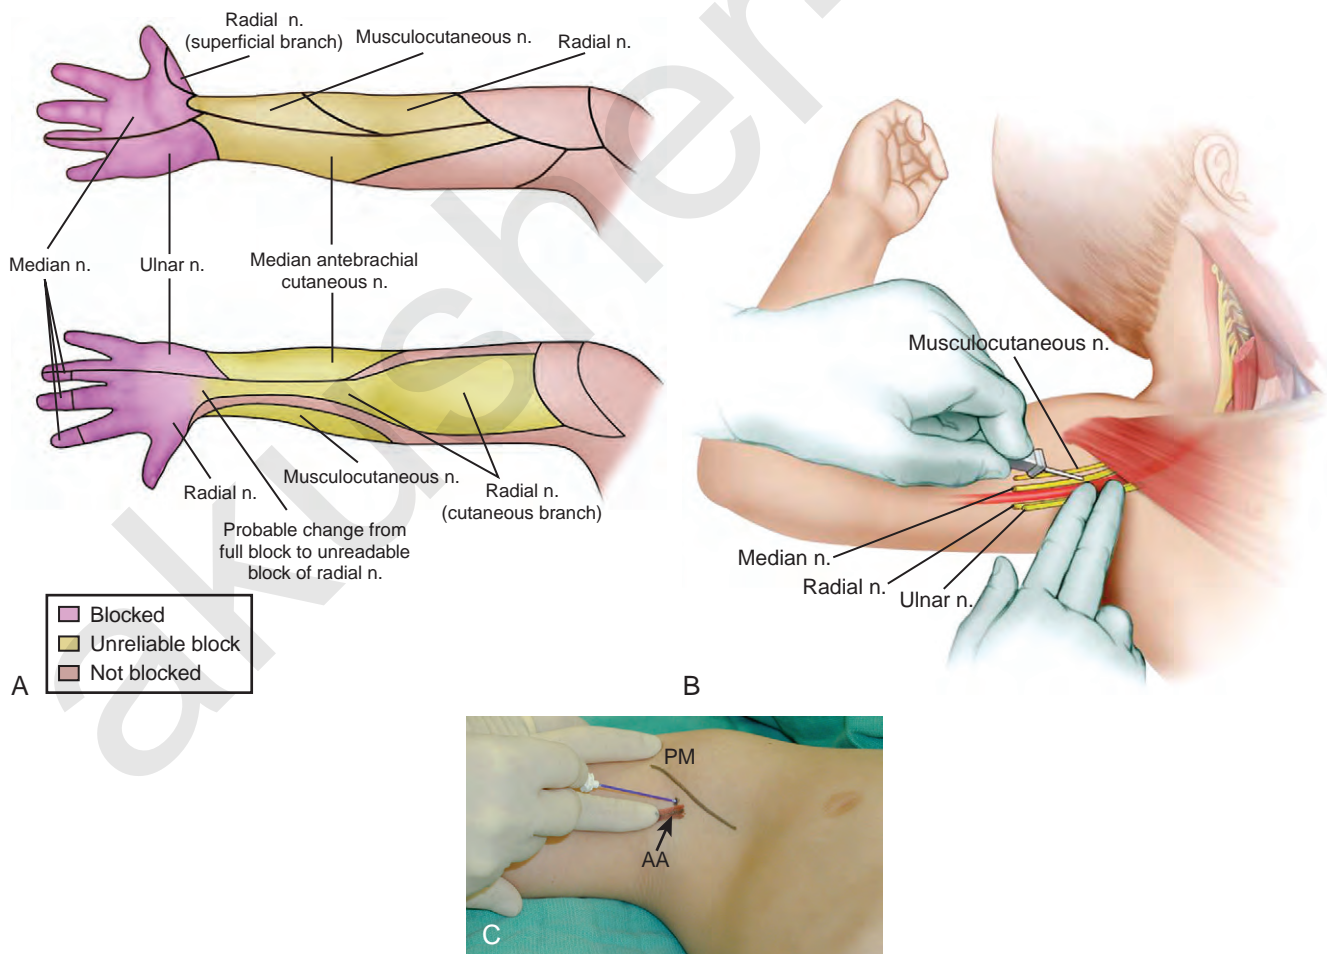

Axillary block is a common approach to the brachial plexus in children, as it is suitable for procedures on the hand such as syndactyly repair and finger reimplantation (Fig. 16-19, A). Advantages of performing an axillary block include the simplicity of the anatomy, ease of placement, and low risk for complications (Tobias, 2001a). Disadvantages include the need for a patient to be able to abduct the arm for access to the axilla, and the inability to block the musculocutaneous nerve 40% to 50% of the time because it branches higher in the axilla than the ulnar, median, and radial nerves. Because the musculocutaneous nerve innervates the lateral side of the forearm, it may need to be blocked separately for surgical procedures that involve that nerve's distribution. Many approaches for an axillary block have been described and used in children. In a study to compare a single injection versus multiple injection technique in

children, unlike in adults, there was no difference in block quality found between the two techniques (Carre et al., 2000). This study also confirmed that using either technique, separate block of the musculocutaneous nerve is still required if necessary for the surgical site.

In a study to assess the efficacy of the timing of an axillary block, 55 children received 2 mg/kg of 0.25% bupivacaine either prior to surgical incision, or immediately after surgery but before emergence (Altintas et al., 2000). In the presurgical group, 32% of the children required no additional analgesics within the first 24 hours, compared with 83% in the postsurgical group who required no additional analgesics. Although cumulative pain scores were higher in the presurgical group, nonetheless both groups had effective analgesia. See related video online at www.expertconsult.com.

Technique

A one-injection technique for axillary nerve block is accomplished by first palpating the axillary artery. The needle is then inserted immediately adjacent and superior to the artery high in the axilla, at a 30- to 45-degree angle aimed toward the mid-point of the clavicle (see Fig. 16-19, B and C). One may feel a pop as the plexus sheath is entered. Using a nerve stimulator, and after evidence of muscle stimulation in the hand is observed,

■ **FIGURE 16-19.** Axillary block. **A**, Dermatomal distribution of axillary block. **B**, Anatomy for axillary block. **C**, Performance of axillary block. AA, Axillary artery; PM, pectoralis muscle.

local anesthetic is injected. A longitudinal swelling immediately beneath the skin as the local anesthetic fills the sheath may appear, particularly in infants and young children. This swelling disappears quickly as the anesthetic spreads proximally into the sheath, and this swelling should not be confused with a subcutaneous injection, which would have a more circular distribution and not disappear quickly. After the local anesthetic has been delivered and the needle removed, the arm should be adducted, thus releasing the pressure of the head of the humerus from the fossa. This motion along with holding distal pressure at the site of injection will promote proximal spread of the local anesthetic into the sheath. With a single-injection technique, all of the local anesthetic is delivered in one location. With a multiple-injection technique, the nerves are individually anesthetized by locating at least two of them individually using the nerve stimulator or ultrasound. Either technique may miss the musculocutaneous nerve because it exits the sheath proximal to the other three distal nerves. For this reason, a separate block of the musculocutaneous nerve is generally required. The musculocutaneous nerve may be blocked by directly inserting the needle into the belly of the coracobrachialis muscle while looking for stimulation of the biceps. In addition, if a surgical tourniquet is to be used and the patient is not having a general anesthetic, the intercostobrachial nerve should be blocked. This is accomplished by placing a subcutaneous ring of local anesthetic high around the inner aspect of the arm.

Technique with ultrasound. In the adult literature, ultrasound guidance has been demonstrated to improve block success rate (Chan et al., 2007; Lo et al., 2008), diagnose abnormal anatomy (Manickam et al., 2008), and allow a decrease in the required volume of local anesthetic and the number of needle passes (Casati et al., 2007). Although not yet prospectively demonstrated in a pediatric model, and appreciating the degree of anatomic nerve variability in relation to the axillary artery, the sonographic ability to guide the needle direction should prove to be of benefit in children as well.

To use ultrasound for axillary block, the operator stands or sits by the child's ipsilateral shoulder and positions the ultrasound transducer transverse to the axilla at the crease formed by the pectoralis major and biceps muscles. A linear ultrasound transducer with the smallest available footprint, set at the highest operational frequency should be used to achieve maximal resolution of the superficial axillary plexus structures (Fig. 16-20, A). The ultrasound machine should be positioned in the direct line of view of the operator on the ipsilateral side of the patient. Sonographic examination will reveal a pulsatile axillary artery and a compressible axillary vein (or veins) surrounded by the coracobrachialis and biceps brachii (short head) muscle cranially and teres major and triceps brachii muscle caudally (see Fig. 16-20, B). The nerves of the axillary plexus exhibit fascicular appearance, appear in multiple shapes (round and oval most frequently), occupy varied locations around the axillary artery, and require dynamic distal tracing or neurostimulation to confirm the identity of each individual nerve (Retzl et al., 2001). The radial nerve is most frequently posterior or posterio-caudal (between 2 and 7 o'clock) to the axillary artery, deep to the ulnar nerve, and, when traced distally, it descends behind the triceps muscle into the spiral groove of the humerus accompanied by the radial collateral artery. The ulnar nerve is anterior or antero-caudal (between 12 and 3 o'clock) to the axillary artery, and when traced distally, it remains superficial and slides

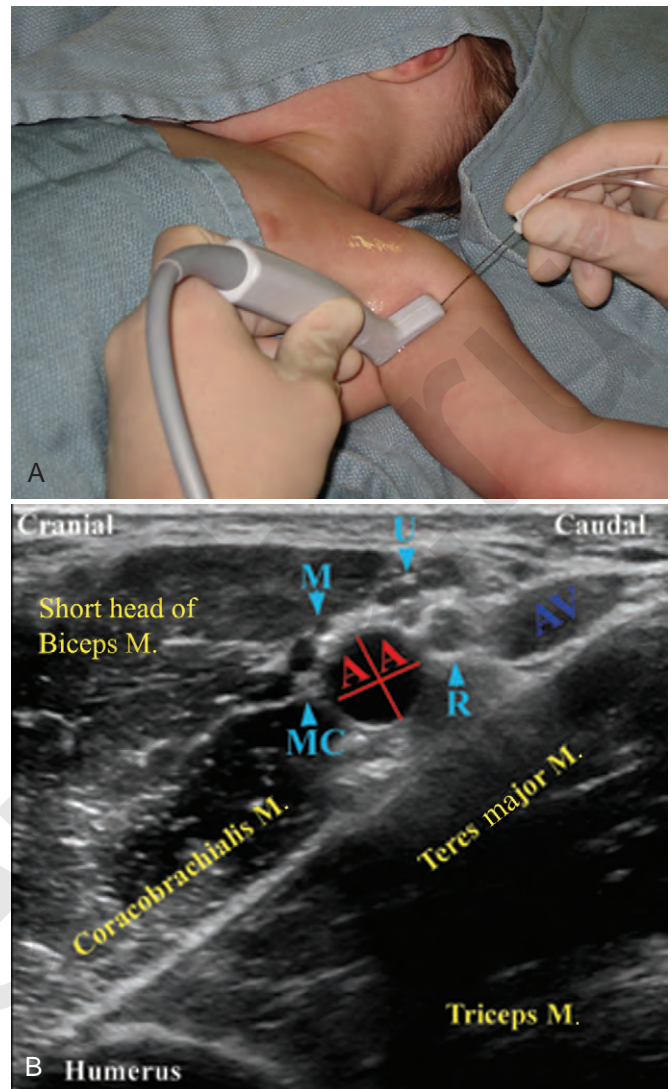

FIGURE 16-20. Ultrasound axillary block. **A**, Placement of needle and transducer. **B**, Sonoanatomy.

medially from the brachial artery on its way to the ulnar nerve sulcus. The median nerve is anterior or antero-cranial (9 to 1 o'clock) to the axillary artery, and it remains close to the brachial artery as it is traced distally. The musculocutaneous nerve has a hyperechoic appearance, changes in shape from oval to triangular, is located posterocranial to the axillary artery adjacent to the median nerve in the proximal axilla, and separates cranially to lie in a fascial plane between the coracobrachialis and the short head of the biceps brachii muscles in the distal axilla. The needle is advanced in-plane from the superior part of the transducer and is repositioned to sequentially block the radial, ulnar, medial, and musculocutaneous nerves. Injection of local anesthetic around the radial nerve first prevents the distortion of the deep anatomy and may help to localize the ulnar nerve. Median and musculocutaneous nerves can often be surrounded by local anesthetic with minimal needle adjustment when performing the block proximally in the axilla.

Continuous axillary sheath catheter placement is feasible, but displacement is easy, especially in the frequently uncooperative pediatric patient, so it is not commonly performed.

Complications

There should be few complications when performing an axillary block. There is the rare risk for hematoma and nerve compression, and for this reason a transarterial approach may not be recommended in children. If inadvertent axillary artery puncture occurs, firm pressure should be held for at least 5 minutes to avoid formation of hematoma and subsequent vascular insufficiency (Merril et al., 1981). Other complications may include relative distortion of anatomy after the first injection of local anesthetic in the axillary region, or inadvertent overdose of local anesthetic when multiple injection techniques are used (Dalens, 1995). However, these complications were not reported in the pediatric study by Carre and coworkers (2000).

Dosing of Upper Extremity Blocks

Various local anesthetics either alone or in combination have been used for upper extremity blocks. For prolonged analgesia, bupivacaine, levobupivacaine, or ropivacaine should be used. Because the brachial plexus is not highly vascular, the uptake of local anesthetic is less than that of pleural or central blocks, but the maximal allowable dosages of local anesthetic must be determined and the block dosed accordingly. When concentrations were compared, bupivacaine 2 mg/kg versus 3 mg/kg delivered for axillary block in children resulted in plasma levels of 1.35 mcg/mL and 1.84 mcg/mL, respectively (Campbell et al., 1986). These values are well below the toxic range. To compare 0.2% ropivacaine with 0.25% bupivacaine, Thornton and associates (2003) administered 0.5 mL/kg to children for axillary block. There was no significant difference between the two groups in pain scores, time to first analgesic, or total analgesic in 24 hours. The median time to first dose of analgesic was 7.25 hours in the ropivacaine group and 9.3 hours in the bupivacaine group. In general, if using 0.25% to 0.5% bupivacaine or levobupivacaine, or 0.2% to 0.5% ropivacaine, the lower concentration should be used in children 5 years of age or younger at a volume of 0.5 mL/kg. Using this volume under ultrasound guidance will result in a faster onset (Marhofer et al., 2004). Epinephrine 5 mcg/mL should be added to the solution to assist in identifying intravascular injection and to decrease the absorption of the local anesthetic. Using these dosing guidelines, approximately 4 to 12 hours of analgesia should be achieved (Table 16-4).

Clonidine 1 mcg/kg may be added to extend the duration of block and was used successfully in a large series of children (Cucchiario and Ganesh, 2007). The use of clonidine may allow lower concentrations of local anesthetic to be used with durations similar to those expected with higher concentrations, with less risk for local anesthetic toxicity.

Peripheral Nerve Blocks in the Forearm

Individual blockade of the peripheral nerves in the distal upper extremity offers selective analgesia for minor surgeries, avoids excessive motor blockade, and provides rescue for failed brachial plexus blocks. When performed using a landmark-only technique, these blocks are restricted to the superficial sites at the elbow or wrist. This may result in nerve ischemia from local anesthetic injection into a tightly bound space such as the ulnar nerve at the elbow or median nerve at the wrist, or vascular complications such as brachial artery puncture at the elbow

TABLE 16-4. Dosage Recommendations* for Peripheral Nerve Blocks

Regional Technique	Bolus Dose†	Continuous Infusion
Axillary	0.2-0.5 mL/kg	0.1-0.2 mL/kg/hr
Parascalene	0.2-0.4 mL/kg	0.1-0.2 mL/kg/hr
Femoral or LFC	0.3-1 mL/kg	0.15-0.3 mL/kg/hr
Fascia iliaca	0.5-1 mL/kg	0.15-0.3 mL/kg/hr
Lumbar plexus	0.5-1 mL/kg	0.15-0.3 mL/kg/hr
Sciatic	0.3-1 mL/kg	0.15-0.3 mL/kg/hr
ILIH	0.25 mL/kg	NA
Penile block	0.1 mL/kg	NA
Paravertebral	0.5 mL/kg	0.2-0.25 mL/kg/hr
TAP	0.3-0.5 mL/kg	0.25 mL/kg/hr

*Bupivacaine, levobupivacaine, or ropivacaine may be used. For bolus dosing, lower concentrations, such as 0.2% to 0.25%, should be used for infants and young children, whereas concentrations of 0.375% to 0.5% should be used in children older than 5 to 8 years. For continuous infusions, lower concentrations such as 0.1% to 0.2% of all agents are acceptable.

†Epinephrine 1:200,000 should be added to single-shot peripheral nerve blocks except for penile block.

ILIH, Iliioinguinal/iliohypogastric; LFC, lateral femoral cutaneous nerve; NA, not applicable; TAP, transversus abdominis plane.

and ulnar artery at the wrist, and thus these blocks have been reported to have a failure rate of 10% to 30% in adults (Delaunay and Chelly, 2001). Ultrasound imaging allows tracking of each nerve along its course in the arm and selection of the optimal block location (McCartney et al., 2007b). The aim is to visualize the target nerve at a site distant from the vascular structures and to accommodate local anesthetic without increased compartment pressures. Use of a linear ultrasound transducer with the smallest available footprint, set at the highest operational frequency, is advised for performance of these blocks.

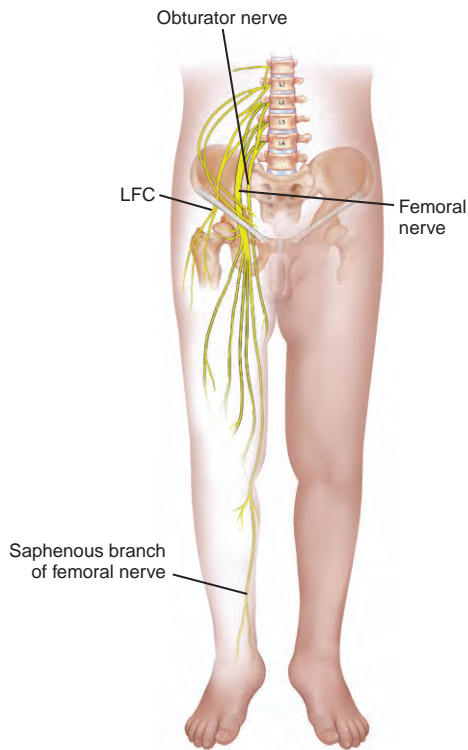

(See www.expertconsult.com to view the complete text for the median, ulnar, and radial nerve blocks in the forearm, and to view Figs. 16-21 through 16-23.)

Lower Extremity Nerve Blocks

Although central axial blocks are commonly performed pediatric regional anesthetic techniques, lower extremity nerve blocks often provide analgesia to the lower limbs with a more direct effect (McNicol, 1986; Dalens, 1995; Ross et al., 2000; Tobias, 2003). Lower extremity blocks are performed by anesthetizing the lumbar or sacral plexus, or both. See related video online at www.expertconsult.com.

The lumbar plexus is located in the psoas compartment that lies in the paravertebral space (Fig. 16-24). The union of the anterior rami of lumbar nerves L1 to L4 constitutes the primary input of the lumbar plexus with a small portion of the 12th thoracic nerve. As the plexus emerges from the paravertebral space, it divides into three nerves, the femoral, the lateral femoral cutaneous, and the obturator. Although the iliac vessels run anterior to the iliac fascia, these three nerves remain posterior to the fascia. The femoral nerve is a mixed nerve with motor innervation to the quadriceps muscles and sensory innervation

■ **FIGURE 16-24.** Anatomy and distribution of lumbar plexus.

to the anterior and medial thigh. A branch of the femoral nerve, the saphenous nerve, provides innervation below the knee to the medial aspect of the lower leg and foot near the saphenous vein. The lateral femoral cutaneous nerve is a sensory nerve with innervation to the lateral thigh, and the obturator nerve is primarily motor to the leg adductors with some sensory to the lower medial thigh and knee.

The sacral plexus is derived from the anterior rami of L4, L5, and S1 to S3, and it gives rise to the sciatic nerve and the posterior cutaneous nerve of the thigh (Fig. 16-25). The sciatic nerve is a mixed nerve that provides motor and sensory innervation to the posterior aspect of the thigh and most of the lower leg. As the sciatic nerve travels down the posterior thigh, it branches into the common peroneal and posterior tibial nerves.

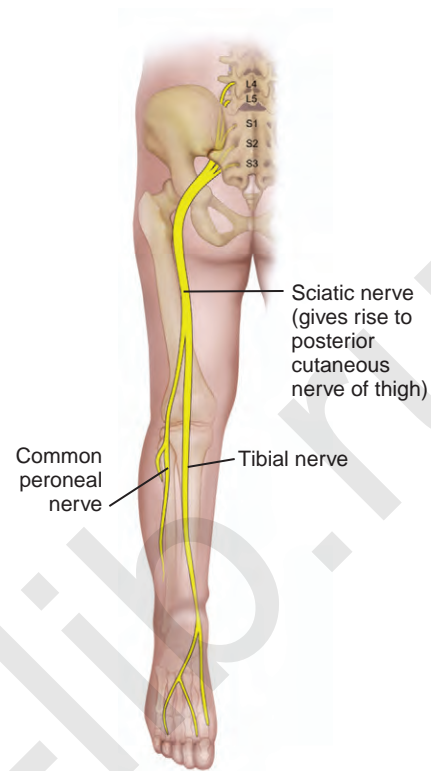

Specific blocks of the lower extremity will be described.

Lateral Femoral Cutaneous Nerve Block

Although an isolated block of the lateral femoral cutaneous nerve (LFC) is rarely needed, it may be blocked to provide analgesia for muscle biopsy of the vastus lateralis muscle during malignant hyperthermia testing (Wedel, 1989). An LFC block may also be used in combination with a femoral nerve block in high-risk children in place of a general anesthetic for complete analgesia for muscle biopsies of the thigh (Rosen and Broadman, 1986; Maccani et al., 1995). See related video online at www.expertconsult.com.

Anatomy

The lateral femoral cutaneous nerve arises from second and third lumbar nerves and travels deep to the iliacus fascia toward the anterior superior iliac spine until it emerges under the fascia lata in the upper thigh. It is a pure sensory nerve that

■ **FIGURE 16-25.** Anatomy and distribution of sacral plexus.

innervates the lateral thigh to the knee, including some terminal branches at the patellar plexus (Fig. 16-26, A).

Technique

No nerve stimulator is required to block the LFC, as it is purely a sensory nerve. In the infrainguinal approach, a blunt 22-gauge needle is inserted perpendicular to the skin, aiming in the direction of the nerve inferolaterally 0.5 to 1 cm below the inguinal ligament and medial to the anterior superior iliac spine (see Fig. 16-26, B). A pop will be felt as the needle pierces the fascia lata. Local anesthetic is then injected in a fanlike manner (McNicol, 1986).

Complications

There are no known serious complications from an isolated LFC except direct nerve trauma.

Femoral Nerve Block

A femoral nerve block may be used for any above-the-knee surgery of the lower extremity that requires analgesia of the majority of the thigh (Fig. 16-27, A). This includes analgesia for femur fracture (Ronchi et al., 1989). The block is simple to perform, either with or without a nerve stimulator, but a nerve stimulator should not be used in an awake child with a femur fracture because of the pain that may occur with muscle contraction from nerve stimulation. See related video online at www.expertconsult.com.

Anatomy

The femoral nerve, derived from lumbar nerves 1 to 3, enters the thigh in the femoral triangle below the inguinal ligament.

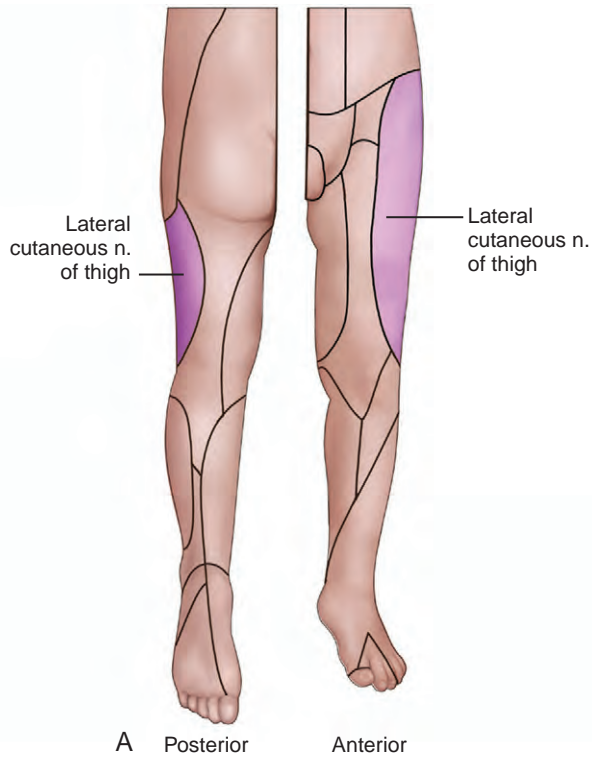

FIGURE 16-26. Lateral femoral cutaneous block. **A**, Dermatomal distribution of lateral femoral cutaneous block. **B**, Performance of lateral femoral cutaneous block. *ASIS*, Anterior superior iliac spine; *IL*, inguinal ligament.

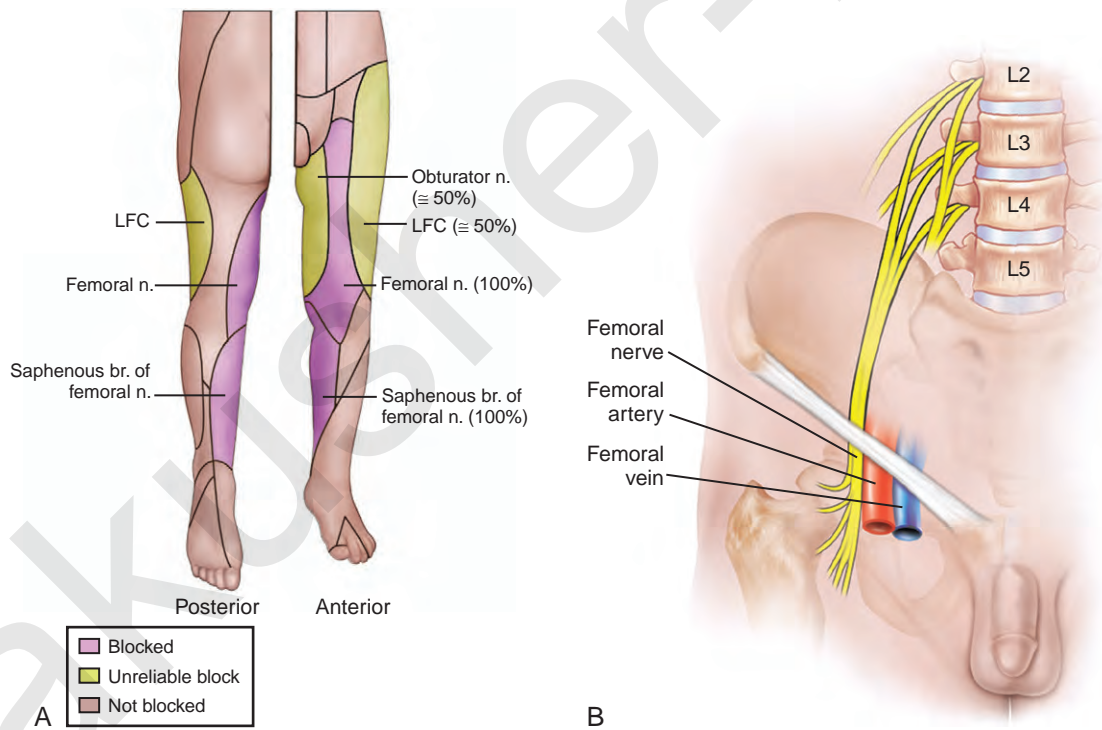

FIGURE 16-27. Femoral nerve block. **A**, Dermatomal distribution of femoral nerve block, 3-in-1, with percentages of complete block of individual nerves. **B**, Anatomy of femoral nerve block. **C**, Performance of femoral block. Needle insertion is 0.5 to 1 cm lateral to the artery. *FA*, Femoral artery; *IL*, inguinal ligament; *U*, umbilicus.

The approximate depth to the femoral nerve from the skin should be reviewed (see Fig. 16-6). The nerve is immediately lateral to the femoral artery and is covered by the fascia lata and fascia iliaca (see Fig. 16-27, B).

Technique

With the child supine and the feet rotated outward, the femoral artery is palpated immediately below the inguinal ligament. The needle is inserted at a slight cephalad angle to the skin at 0.5 to 1 cm below the inguinal ligament and 0.5 to 1 cm lateral to the artery (see Fig. 16-27, C). As the needle pierces the fascia lata, a distinct pop is felt. If a nerve stimulator is used, the desired muscle response should be contraction of the mid quadriceps with a “patellar kick” If there is muscle stimulation medial to the mid patella at the thigh adductors, the needle is slightly adjusted laterally. If there is lateral muscle stimulation, the needle is adjusted slightly medially. Because of the close proximity of the femoral vessels, continuous aspiration for blood should be performed to detect intravascular entry. Once the desired location of the needle is achieved, local anesthetic is then injected.

A 3-in-1 block is a modification of a femoral nerve block. This technique anesthetizes the lateral femoral cutaneous and obturator nerves, which lie more proximal in the sheath. The 3-in-1 technique is accomplished by performing a femoral nerve block and promoting proximal spread. The landmarks and needle insertion are exactly the same as for a simple femoral block, except that the volume of local anesthetic is increased and distal pressure is used to promote cephalad spread to the lumbar plexus with the femoral sheath as a conduit. When compared with a fascia iliaca compartment block (see later), a 3-in-1 approach can result in a higher failure rate (Dalens et al., 1989). Although it is effective in anesthetizing the femoral nerve 100% of the time, the LFC and obturator were successfully blocked in only 20% of the children. Dalens noted that the successful blocks of the LFC and obturator nerves in the 3-in-1 group were not the result of proximal spread of the local anesthetic but possibly of a fascia iliaca–like spread of the local anesthetic.

Technique with ultrasound. Ultrasound-guided femoral nerve block has been shown to improve the quality and lengthen the

duration of the block while decreasing the required dose of the local anesthetic as compared with the nerve stimulation technique (Marhofer et al., 1997, 1998; Oberndorfer et al., 2007).

A linear ultrasound transducer set at the highest operational frequency should be used to achieve maximal resolution of the superficial inguinal anatomy. The patient is positioned supine with the leg slightly bent at the knee and externally rotated. The ultrasound machine should be positioned on the contralateral side in the direct line of view of the operator. The operator sits or stands by the patient’s hip on the ipsilateral side, with the ultrasound transducer held in the nondominant hand and positioned transverse to the femoral artery, inferior to the inguinal ligament (Fig. 16-28, A). Femoral vessels are a readily recognized starting point for locating the nerve (see Fig. 16-28, B). The femoral nerve often has a triangular, hyperechoic appearance and is located lateral to the femoral artery, superficial to the iliopsoas muscle, and beneath the fascia iliaca. The block needle is inserted in-plane in a lateral-to-medial direction (see Fig. 16-28, A) and should be seen transversing the superficial fascia lata and immediately adherent fascia iliaca before the test dose is administered. Local anesthetic injection should produce circumferential spread around the nerve bundle below the fascia iliaca (see Fig. 16-28, C). Out-of-plane needle insertion is possible for the performance of this block once the inguinal sonoanatomy is appreciated, and for the placement of continuous catheters.

Complications

Complications from femoral or 3-in-1 blocks are uncommon, but they may include puncture of the femoral artery. In that event, pressure should be held for at least 5 minutes to avoid the formation of a large hematoma.

Fascia Iliaca Compartment Block

The fascia iliaca block provides analgesia of the femoral, lateral femoral cutaneous, and obturator nerves. A fascia iliaca block may be effective in more than 90% of children, compared with 20% effectiveness of the 3-in-1 technique (Dalens et al., 1989). Fascia iliaca blocks are useful for all above-the-knee lower

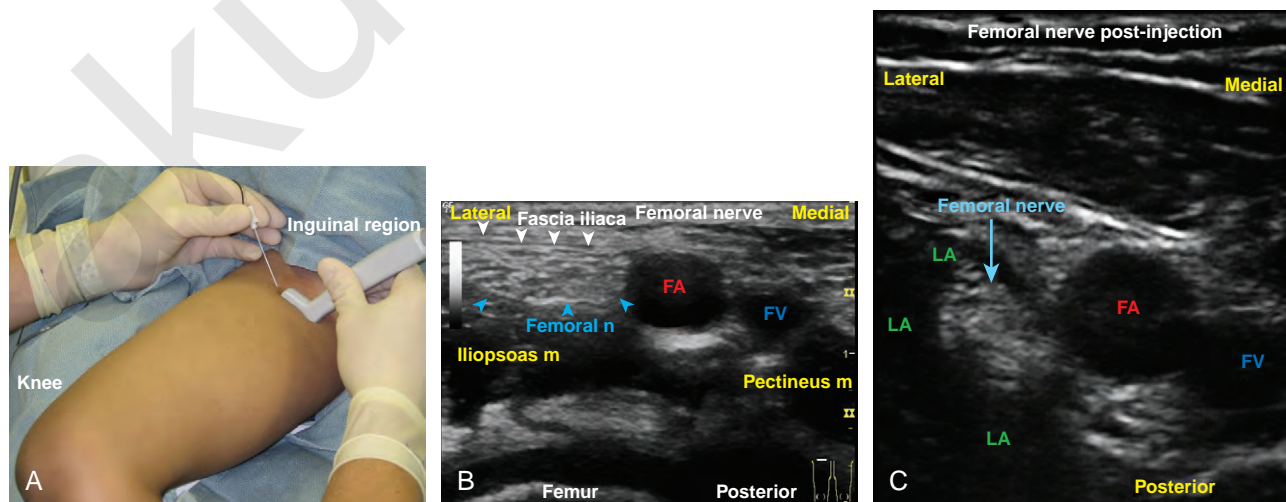

FIGURE 16-28. Ultrasound scan of femoral nerve block. **A**, Needle and transducer placement. **B**, Sonoanatomy before injection. **C**, Sonoanatomy after injection.

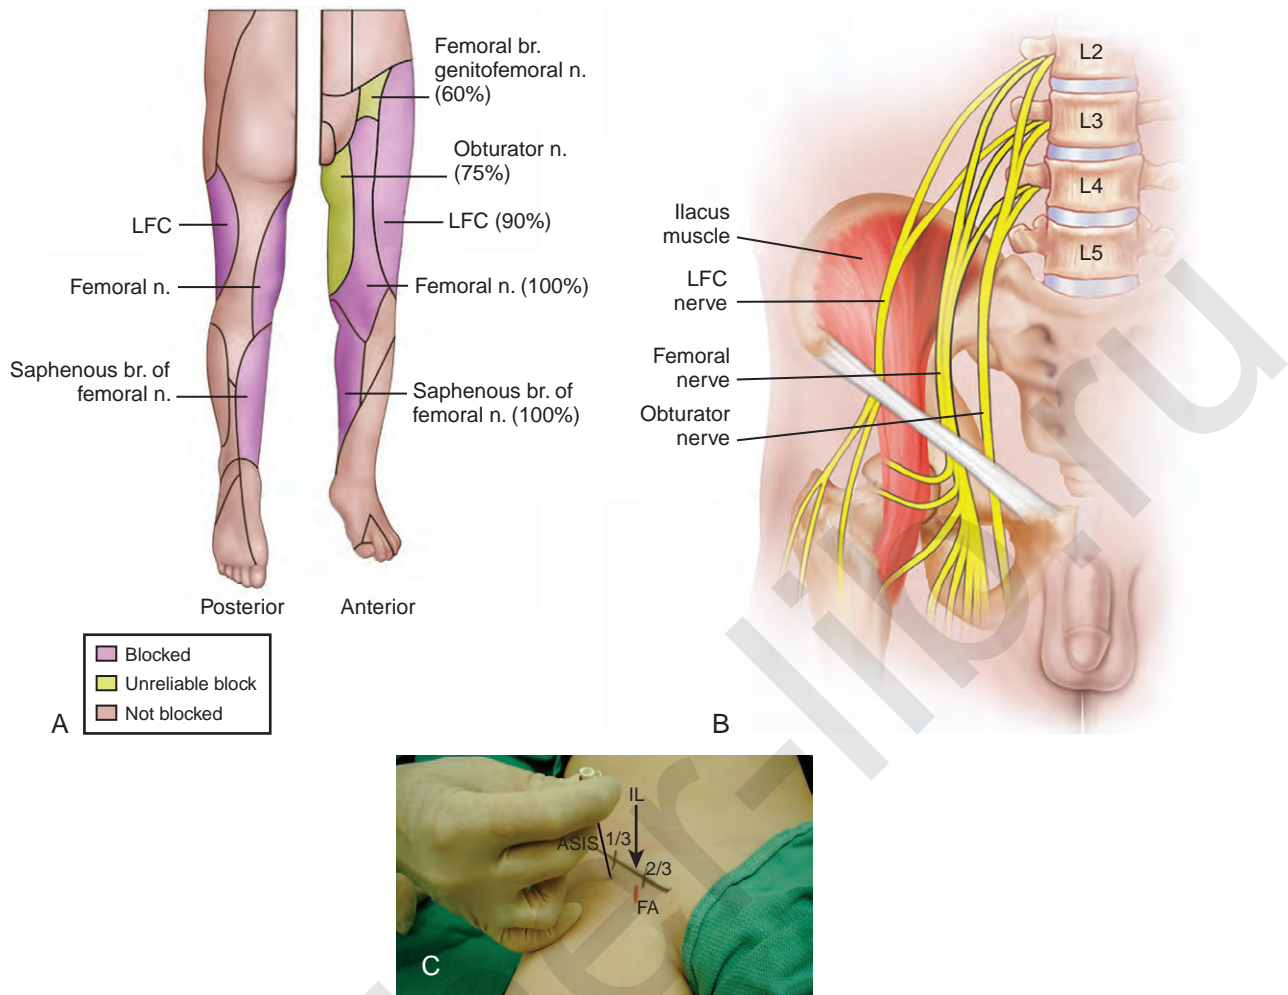

FIGURE 16-29. Fascia iliaca block. **A**, Dermatomal distribution of fascia iliaca block, with relative percentages of successful block of individual nerves by this approach. **B**, Anatomy of fascia iliaca block. **C**, Performance of fascia iliaca block. Needle insertion is 0.5 to 2 cm below inguinal ligament. *ASIS*, Anterior superior iliac spine; *FA*, femoral artery; *IL*, inguinal ligament.

extremity surgeries because of their ability to anesthetize this region in its entirety (Fig. 16-29, A). In addition, the fascia iliaca block reliably anesthetizes the femoral branch of the genitofemoral nerve, the sensory nerve supply to Scarpa's triangle. Because of its ability to block the upper leg, the fascia iliaca compartment block can be used in combination with intravenous sedation or nitrous oxide for children who are undergoing muscle biopsy of the thigh. See related video online at www.expertconsult.com.

Anatomy

The three distal nerves of the lumbar plexus, the femoral, lateral femoral cutaneous, and obturator nerves, all emerge from the psoas muscle and run along the inner surface of the fascia iliaca. A fascia iliaca compartment block delivers local anesthetic between the fascia iliaca and iliacus muscles where it spreads to bathe the three nerves (see Fig. 16-29, B).

Technique

With the child in the supine position, the inguinal ligament is located by drawing a line from the pubic tubercle to the anterior superior iliac spine. Divide the inguinal ligament into thirds.

At the junction of the lateral third and the medial two thirds of the inguinal ligament, drop a line inferiorly 0.5 to 2 cm and perpendicular to the ligament. This is the point of needle insertion (see Fig. 16-29, C). A blunt needle is inserted perpendicular to the skin. There is no need for a nerve stimulator, because the goal is to find the area behind the iliacus fascia for anesthetic injection, not to locate a specific nerve. Two pops are felt as the needle first pierces the fascia lata, then the fascia iliaca. If light pressure is held on the plunger of the syringe, a loss of resistance is felt as the fascia iliaca is pierced. With the needle in the correct position, local anesthetic solution is injected.

Complications

Complications during a fascia iliaca block might include isolated femoral block if the injection is too medial. Otherwise there are no known major complications from performing a fascia iliaca block.

Lumbar Plexus Block

Like the fascia iliaca compartment block, a lumbar plexus block provides analgesia to the three major nerves of the lumbar

plexus. This block is useful for any surgery that may occur on the upper leg because it can completely anesthetize that region. This block also anesthetizes the distal branches of the lumbar plexus, including the iliohypogastric, ilioinguinal, and genitofemoral nerves that innervate the groin area applicable to many pediatric surgical procedures (Fig. 16-30, A). See related video online at www.expertconsult.com.

Anatomy

The lumbar plexus lies in the psoas compartment between the two masses of the psoas muscle that attach to the vertebrae, and it is surrounded by fascia derived from fascia iliaca (see Fig. 16-30, B). The approximate depth from the skin to the lumbar plexus at different ages is noted in Figure 16-6.

Technique

In a study of 50 children aged 6 months to 16 years undergoing hip and upper lower extremity procedures, Dalens and coworkers (1988) compared two techniques of lumbar plexus block. In group 1, a modification by Chayen of a psoas compartment block was used. A needle was inserted at the midpoint of a line connecting the spinous process of the fifth lumbar vertebra and the posterior superior iliac spine. There were difficulties with needle insertion in 7 of 25 children, and 23 of the 25 had epidural spread of local anesthesia. In the second group, a modification of Winnie's approach was used. In this technique, a needle was inserted at the intersection of the line drawn to connect the

iliac crests and a line drawn through the posterior superior iliac spine parallel to the spinous processes (see Fig. 16-30, C). There were no problems with needle insertion, and all 25 patients exhibited a unilateral lumbar plexus block distribution. Sacral distribution occurred in 23 of the 25 children, as these two plexuses are found in the same anatomic plane. Although both techniques provided effective analgesia to the lumbar plexus, the Chayen approach resulted in epidural spread rather than being isolated to the lumbar plexus. Because of the greater ease of performance of the modified Winnie technique, this technique will be further described for use in children.

Modified Winnie approach to the lumbar plexus. With the child in the lateral position, block side up, the knees and thighs are flexed. Two lines are drawn: (1) to connect the two iliac crests, and (2) from the ipsilateral posterosuperior iliac spine running cephalad and parallel to the spinous processes. The needle is inserted perpendicular to the skin at the intersection of the two lines (see Fig. 16-30, C) and then advanced through the quadratus lumborum. If contact is made with a transverse process, the needle is directed slightly more cephalad until a strong contraction of the mid (not lateral or medial) quadriceps with a patellar kick is apparent. If hamstring contractions are observed, the needle is directed slightly more laterally. If there is isolated hip movement, the psoas has been directly stimulated. If the quadriceps and hamstrings are contracting simultaneously, the needle should be directed more cephalad to stimulate the lumbar rather than sacral plexus.

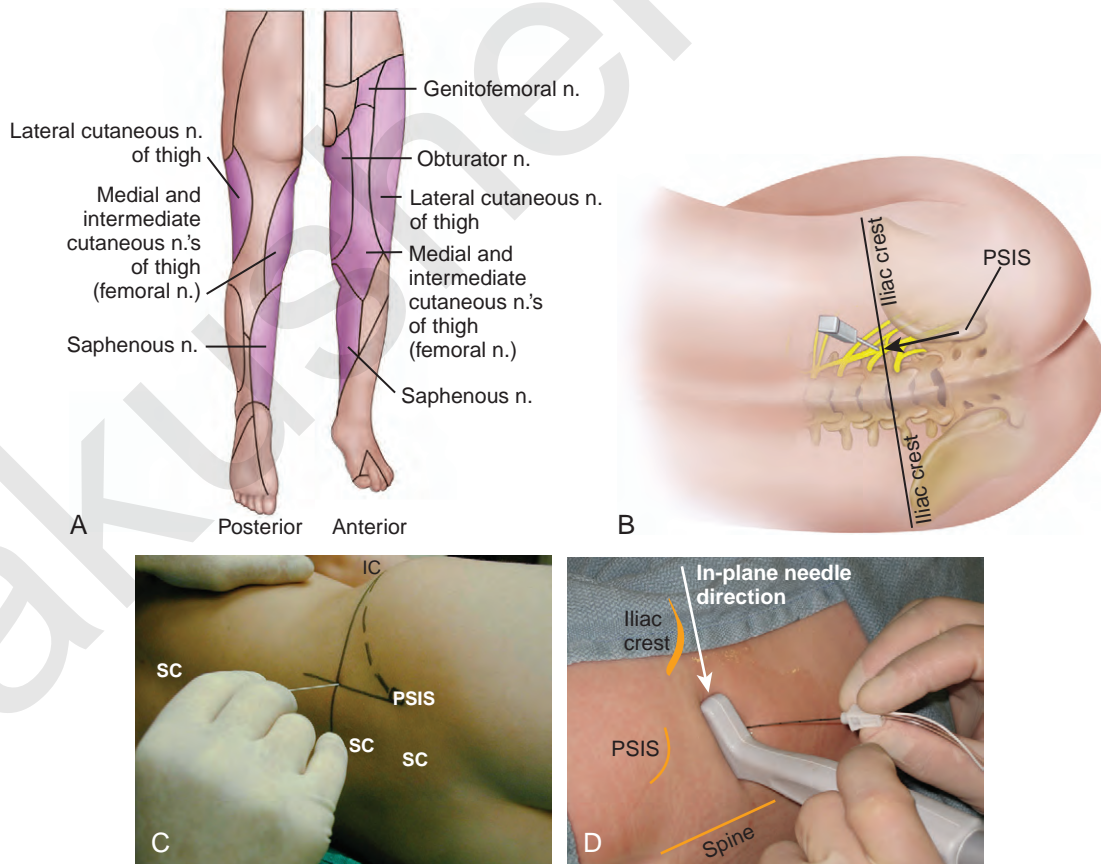

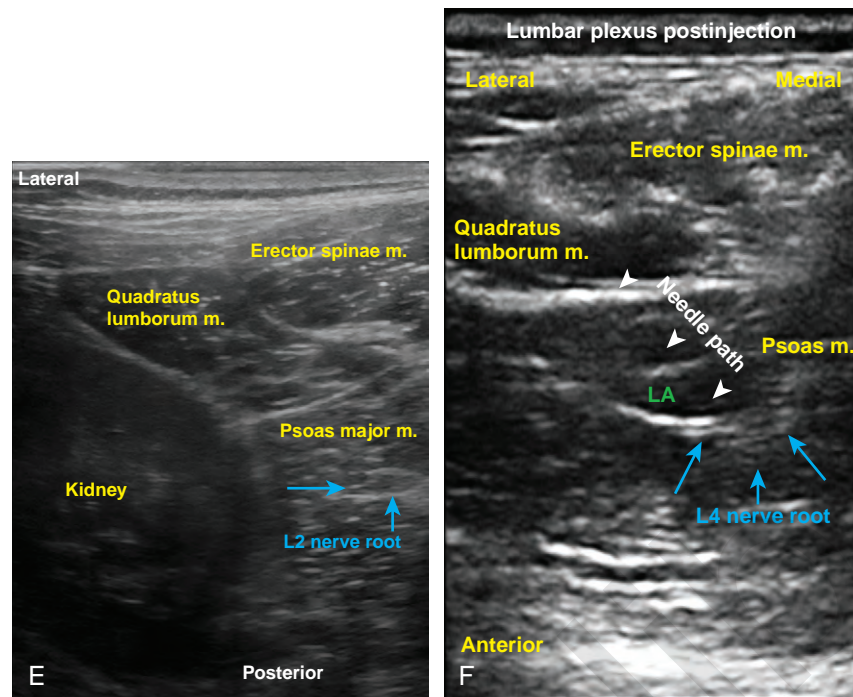

FIGURE 16-30. Lumbar plexus block. **A**, Dermatomal distribution of lumbar plexus block. **B**, Anatomy of lumbar plexus block. **C**, Performance of lumbar plexus block. Note that the needle is considerably lateral to the spinal column. **D**, Needle and transducer placement. IC, Iliac crest; PSIS, posterior superior iliac spine; SC, spinal column.

■ **FIGURE 16-30, cont'd.** **E**, Sonoanatomy prior to injection. **F**, Sonoanatomy after injection.

The needle is placed in the same location as in the landmark technique for ultrasonographic-guided lumbar plexus block (see Fig. 16-30, *D*). Sonoanatomy shows the relationship to the structures before (see Fig. 16-30, *E*) and after (see Fig. 16-30, *F*) local anesthetic injection.

Complications

Although complications are rare, they may be serious if the needle is advanced too deeply into the retroperitoneum. Retroperitoneal hematoma is a significant risk, and continuous aspiration for blood should be done while performing the block. The highest incidence of major bleeding after peripheral regional anesthetic techniques has been found to occur after a psoas compartment block (Horlocker et al., 2003a).

Saphenous Nerve Block

The saphenous nerve is the terminal branch of the femoral nerve and provides cutaneous innervation of the medial leg or foot. It enters the adductor canal lateral to the femoral artery, crosses it anteriorly, and lies medial to it at the farthest end of the canal. In the distal thigh, the saphenous nerve passes between the sartorius and gracilis muscles and pierces the deep fascia on the medial aspect of the knee. It descends down the medial side of the leg with the great saphenous vein.

Blocking the saphenous nerve provides analgesia to the medial portion of the foot immediately anterior to the medial malleolus and extending toward, but not reaching, the great toe. For procedures below the knee that include incisions on the medial anterior portion of the foot and leg, the saphenous nerve may be blocked to cover the small femoral component that has innervation below the knee.

Technique with Ultrasound

Multiple approaches to the saphenous nerve block have been described, but visualization of this nerve in a child can be challenging, so the transartorial perifemoral artery approach is preferred (Benzon et al., 2005; Tsui and Ozelsel, 2009). A linear ultrasound transducer set at the highest operational frequency should be used. The patient is positioned supine with the leg slightly bent at the knee and externally rotated. The ultrasound machine should be positioned on the contralateral side in the direct line of view of the operator. The operator sits or stands by the patient's knee on the ipsilateral side with the ultrasound transducer held in the nondominant hand and positioned transverse to the longitudinal axis of the extremity at the mid thigh (Fig. 16-31, *A*). The femoral artery in the adductor canal is a reliable landmark for locating the nerve (see Fig. 16-31, *B*). The saphenous nerve appears hyperechoic and is located anterior to the artery below the sartorius muscle. The block needle is inserted in-plane in a lateral-to-medial direction toward the nerve, and circumferential envelopment by local anesthetic is the goal. If the nerve is not clearly visualized in the adductor canal, a perivascular injection will be adequate. As the practitioner gains expertise in identifying and tracing the saphenous nerve, it may be advantageous to perform saphenous nerve blockade distally, as this will avoid motor blockade of the vastus medialis muscle because the nerve to the vastus medialis is located in the adductor canal.

Sciatic Nerve Block

A sciatic nerve block is indicated for surgical procedures that involve the lower extremity below the knee. When used in combination with blocks of the lumbar plexus, the lower extremity can be blocked in its entirety. See related video online at www.expertconsult.com.

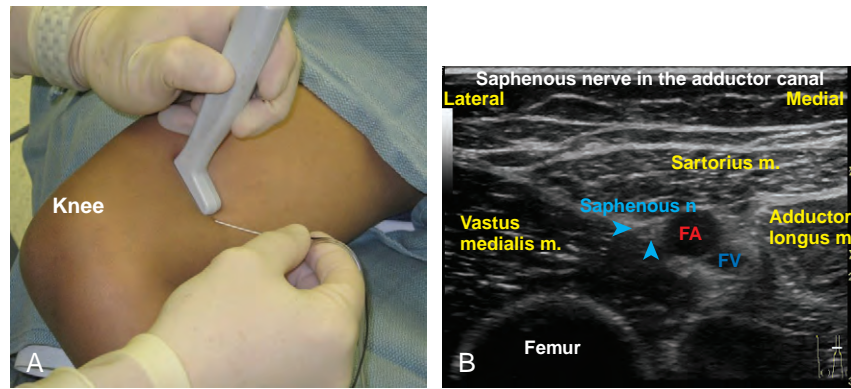

FIGURE 16-31. Ultrasound saphenous nerve block. **A**, Needle and transducer placement. **B**, Sonoanatomy.

Anatomy

The sciatic nerve is derived from the anterior rami of L4 to S3 and is the largest nerve in the body (see Fig. 16-25). It emerges through the greater sciatic foramen to run between the greater trochanter of the femur and the ischial tuberosity before taking its position in the thigh posterior to the quadriceps femoris. If the sciatic nerve is blocked in its proximal position, this will also anesthetize the posterior femoral cutaneous nerve (a branch of ventral rami of S1 to S3). This nerve innervates the posterior thigh above the knee and the hamstring muscles. The sciatic nerve primarily consists of two nerves, the tibial and common peroneal nerves, which travel in a common sheath in the posterior upper portion of the leg. These nerves typically divide near the popliteal fossa and innervate the leg below the knee.

Approaches to the Sciatic Nerve

Several approaches to the sciatic nerve have been described in children. The posterior, anterior, and lateral approaches have been compared with respect to ease of performance, efficacy of block, and rate of complications (Dalens et al., 1990). The overall success rate of all three approaches exceeded 90%. However, there were fewer difficulties reported with the posterior approach. The posterior approach resulted in an 88% success rate on first attempt, compared with 78% for the lateral approach and only 62% on the first attempt for the anterior approach. In addition, vascular punctures occurred only in children who underwent an anterior approach. Because of the higher success rate of the posterior approach and the completeness of analgesia of the sciatic nerve and posterior branches (Fig. 16-32, A), the posterior approach is described here.

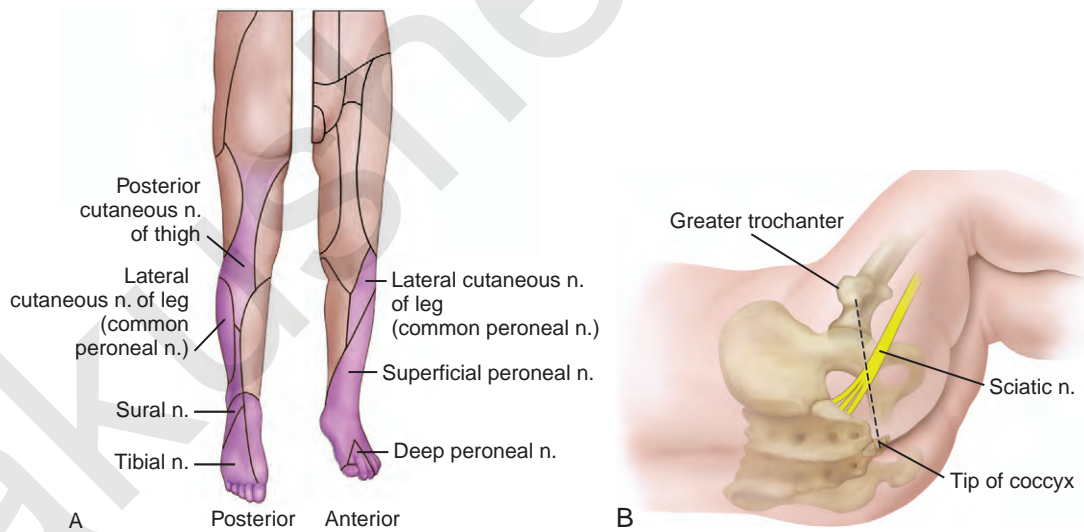

FIGURE 16-32. Posterior sciatic block. **A**, Dermatomal distribution of posterior sciatic block. **B**, Anatomy for posterior sciatic block. **C**, Performance of posterior sciatic block. *GT*, Greater trochanter; *TC*, tip of coccyx.

However, the reader is prompted to review the lateral approach, especially for use in children who are unable to be positioned for other approaches to the sciatic nerve (Dalens, 1995).

To block the sciatic nerve using the posterior approach, a modification of Labat's technique was developed by Dalens and associates (1990). The child is placed in the lateral position with the side to be blocked uppermost and the upper leg flexed at the hip and knee. Using a nerve stimulator and insulated needle, the point of needle insertion is at the midpoint of the line that extends from the tip of the coccyx to the greater trochanter of the femur. The needle should be perpendicular to the skin with slight angulation toward the lateral ischial tuberosity (see Fig. 16-32, B and C). The approximate depth to the sciatic nerve using the posterior approach depends on the age of the patient (see Fig. 16-6). Using a nerve stimulator, the motor response is a movement in the patient's foot. Plantar flexion indicates stimulation of the tibial nerve. Dorsiflexion or eversion at the ankle indicates stimulation of the peroneal nerve. Once the appropriate response is elicited, local anesthesia is injected.

Complications of the posterior approach to the sciatic nerve include vascular puncture of gluteal vessels. Constant aspiration for blood should be done during performance of the block to avoid this complication.

The Raj block was developed in 1975 and is similar to the posterior approach (Raj et al., 1975). This approach anesthetizes the sciatic nerve slightly more distal than in the classic posterior approach (Fig. 16-33, A). This block is performed in the supine child with the leg to be blocked lifted and flexed at the hip and knee. The needle is inserted at the midpoint between ischial tuberosity and greater trochanter in the sciatic groove

(see Fig. 16-33, B and C). Once appropriate muscle stimulation with less than 0.5 mA is seen at the foot, local anesthetic is injected. The advantage to this block is the reliability of the landmarks and simplicity of the block itself. By flexing the hip, the Raj technique brings the sciatic nerve closer to the skin. This improves the likelihood of a successful block, especially in obese children and adolescents.

To use some of the principles of the posterior and Raj approaches, the ultrasound-guided subgluteal approach may be performed. A linear, high-frequency probe can be used in children, but as the depth of the imaged neural structure increases with age or obesity, use of the lower-frequency, curvilinear probe is required to achieve sufficient penetration. The child is positioned in a lateral decubitus position with the operative side uppermost and the knee flexed. The operator faces the patient with the ultrasound machine across in the direct line of view. A line connecting the greater trochanter and ischial tuberosity represents a starting point for the sonographic examination (Fig. 16-34, A). The sciatic nerve is visualized between the anterior surface of the gluteus maximus and the posterior surface of the quadratus femoris muscle. It is bounded medially by the ischial tuberosity and laterally by the greater trochanter. It has hyperechoic appearance and may be oval or triangular (see Fig. 16-34, B). Tracing the nerve cranially or caudally may allow for improved sonographic visualization. The posterior cutaneous nerve of the thigh is frequently observed medial to the sciatic nerve at this location (Karmakar et al., 2007). An in-plane approach is used to guide needle advancement, and circumferential spread of local anesthetic is sought. Medial envelopment of the sciatic nerve by local anesthetic ensures blockade of the

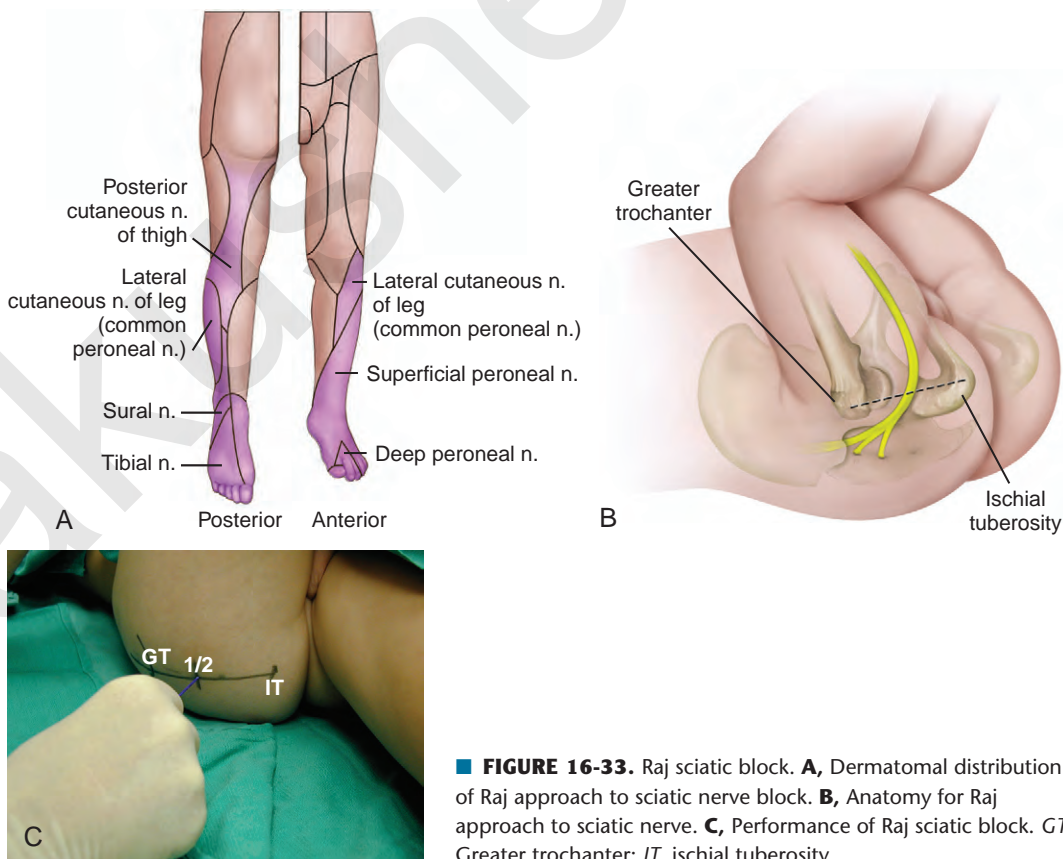

FIGURE 16-33. Raj sciatic block. **A**, Dermatomal distribution of Raj approach to sciatic nerve block. **B**, Anatomy for Raj approach to sciatic nerve. **C**, Performance of Raj sciatic block. *GT*, Greater trochanter; *IT*, ischial tuberosity.

posterior cutaneous nerve of the thigh and may require needle repositioning when thigh incision or tourniquet use is planned. An out-of-plane approach is used for continuous catheter placement because it facilitates threading and fixation of the catheter (van Geffen and Gielen, 2006).

A popliteal fossa block may be used for procedures of the distal lower extremity and will anesthetize the sciatic nerve more distally in the leg and just proximal to the knee (Kempthorne and Brown, 1984) (Fig. 16-35, *A*). See related video online at www.expertconsult.com. Near the popliteal fossa, the sciatic nerve divides into the common peroneal nerve and the posterior tibial nerve (see Fig. 16-35, *B*). The common peroneal nerve runs anteriorly to wrap around the head of the fibula, and the posterior tibial nerve travels down the posterior lower

leg. In approximately 10% of the population, the branching of the sciatic nerve occurs more proximal to the popliteal fossa and high in the posterior thigh. Therefore, there may be a variable success rate in blocking the sciatic at this level, but both nerves are usually blocked by this approach because a common epineural sheath envelops the two nerves (Vloka et al., 1997). Advantages to the popliteal approach include the relatively superficial location of the sciatic nerve (i.e., near to the skin) and the decreased risk of intraneural injection, as the sciatic nerve is not fixed against any bony structures in this location. To easily access the popliteal fossa for a single-shot block, the patient may remain in the supine position and the leg to be blocked is lifted with the knee and thigh flexed. The child may also be turned to the lateral position and the leg to be blocked

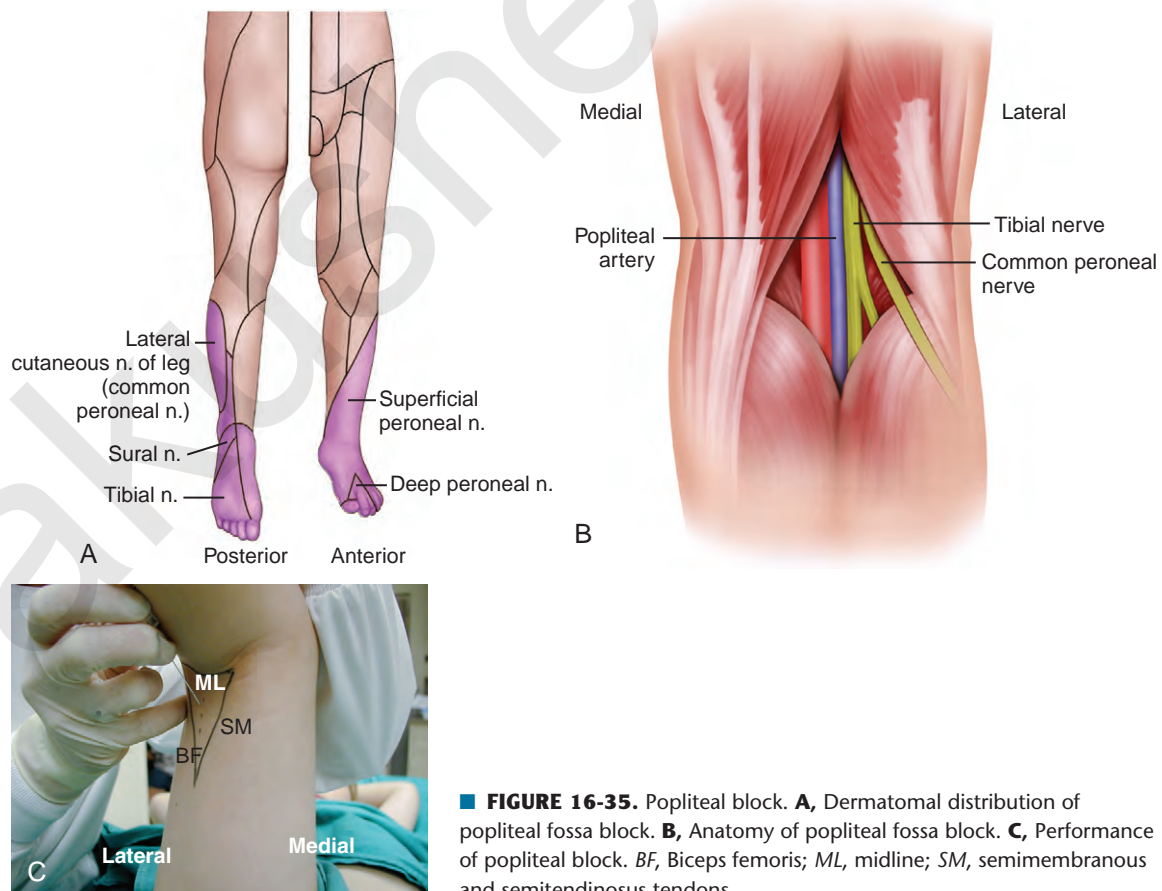

FIGURE 16-35. Popliteal block. **A**, Dermatomal distribution of popliteal fossa block. **B**, Anatomy of popliteal fossa block. **C**, Performance of popliteal block. *BF*, Biceps femoris; *ML*, midline; *SM*, semimembranous and semitendinosus tendons.

positioned uppermost. The superior triangle of the popliteal fossa has as its boundaries the semimembranosus and semitendinosus tendons medially, the biceps femoris tendon laterally, and the popliteal crease inferiorly. The needle is inserted 45 degrees to the skin, aiming cephalad and just lateral to the midline of the popliteal triangle (see Fig. 16-35, C). The distance from the popliteal fold to needle insertion is estimated based on weight. If the weight is less than 10 kg, the distance is 1 cm; if the weight is 10 to 20 kg, the distance is 2 cm (Konrad and Johr, 1998). Each 10 kg of body weight should move the needle cephalad in the triangle approximately 1 cm. Muscle stimulation of the foot in either the common peroneal or the posterior tibial distribution is a confirmation of an acceptable needle position, but stimulation of both branches suggests that the sciatic nerve has not yet separated into the two branches at this level. Local anesthetic is injected once appropriate stimulation is apparent at less than 0.5 mA.

Konrad and Johr (1998) sought to determine a system for standardization of popliteal fossa block. They performed the block in 50 children between the ages of 2 months and 18 years. They determined that the minimal distance to the sciatic nerve in the popliteal fossa was 13 mm, and the depth did not vary significantly in patients weighing less than 35 kg but did increase for children weighing more than 35 kg. All blocks in the study were successful, and there were no complications. Vascular puncture was avoided because of the lateral position of the needle in relation to the popliteal vessels.

Tobias and Mencia (1999) provided analgesia in 20 children for foot and ankle surgery by performing popliteal fossa blocks at the completion of the surgical procedure. When using 0.75 mL/kg of 0.2% ropivacaine, the duration of analgesia was between 8 and 12 hours.

The ultrasound-guided popliteal approach can also be performed with the linear ultrasound transducer set at the highest

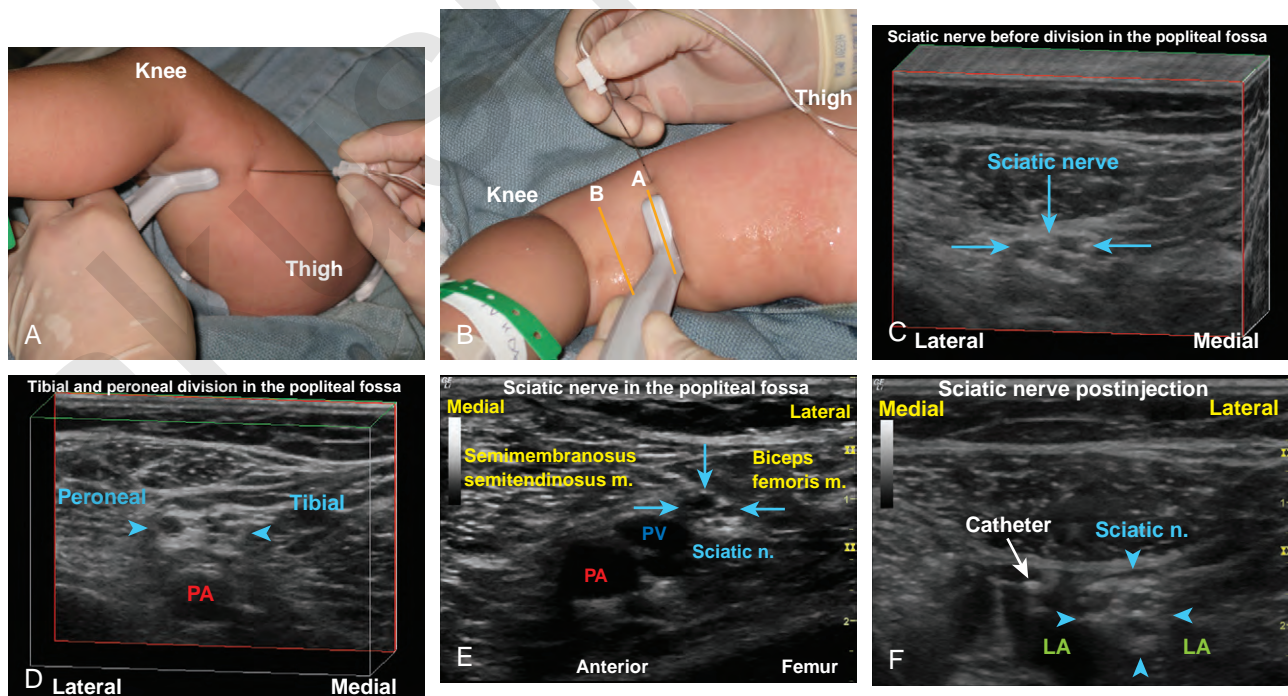

operational frequency. The child can be positioned supine with the leg elevated on a footrest or held by an assistant (Fig. 16-36, A) or lateral with the operative side uppermost and the knee flexed (see Fig. 16-36, B). The operator stands or sits by the child's ipsilateral limb with the ultrasound machine in the direct line of view. The sonographic examination begins by positioning the transducer over the popliteal fossa in an axial plane and locating the popliteal artery and vein. The tibial nerve is located superficial to the vein and has a round or fasciculated appearance. Dynamic cephalad tracing will identify the point of merger of the tibial and common peroneal components into the sciatic nerve (see Fig. 16-36, C and D). The level of the local anesthetic placement should be proximal to the division of the sciatic nerve to achieve complete blockade of the foot. The sciatic nerve exhibits a significant degree of anisotropy and is best visualized when the insonating ultrasound angle is directed caudally. An in-plane, lateral-to-medial approach is used to guide needle advancement for single-shot blocks, and the needle tip is guided posterior to the sciatic nerve to achieve the circumferential spread of local anesthetic (see Fig. 16-36, E and F). An out-of-plane approach is used for continuous catheter placement, because it facilitates threading and fixation of the catheter.

Ankle Block

An ankle block is a simple block that provides analgesia to the foot for procedures such as toe removal or simple reconstructive surgery. See related video online at www.expertconsult.com.

Anatomy

Five nerves that innervate the foot must be blocked for analgesia of the foot in its entirety (Fig. 16-37). The saphenous nerve is found near the saphenous vein on the medial side of

■ **FIGURE 16-36.** Ultrasound scan of popliteal block. **A**, Needle and transducer placement with leg up. **B**, Needle and transducer placement, lateral position. **C**, Sciatic before division. **D**, Sciatic after division. **E**, Before injection. **F**, After injection.

■ **FIGURE 16-37.** Anatomy for ankle block.

the dorsum of the foot and is somewhat superficial in its location. It innervates the skin surrounding the medial malleolus. Following the dorsum of the foot, and near the anterior tibial artery, runs the deep peroneal nerve, which is responsible for the innervation of the web space between the first and second toes. As the name implies, this nerve runs deep and is found near the tibia and between the extensor hallucis longus and anterior tibial artery. Immediately lateral to the deep peroneal nerve, but found superficially, is the superficial peroneal nerve. This nerve innervates the medial and lateral aspects of the dorsum of the foot. The plantar innervation of the foot is supplied by the tibial and sural nerves. The tibial nerve is found immediately posterior to the posterior tibial artery and medial malleolus, and the sural nerve is located posterior to the lateral malleolus.

Technique

To perform an ankle block, each of the five nerves is blocked using a 25-gauge needle. With the child supine, the saphenous nerve is blocked by injecting 1 to 5 mL of local anesthetic solution subcutaneously near the saphenous vein anterior to the medial malleolus. The deep peroneal nerve is blocked by inserting the needle lateral to the extensor hallucis longus tendon near the tibial artery and advancing it until it contacts the tibia. The needle should then be withdrawn slightly and 1 to 5 mL local anesthetic injected. The superficial peroneal nerve is blocked with a subcutaneous ring of local anesthetic across the lateral dorsum of the foot. The patient's foot then should be positioned so that the two posterior nerves can be blocked for complete analgesia of the foot. The tibial nerve is blocked midway between the medial malleolus and the calcaneus posterior to the tibial artery. The sural nerve is blocked midway between the lateral malleolus and the calcaneus. Each of the posterior nerves should receive 1 to 5 mL of local anesthetic solution.

Dosing

To ensure complete analgesia to the foot with a duration of action greater than 4 hours, bupivacaine, ropivacaine, or levobupivacaine 0.5% should be used. The volumes delivered at each nerve depend on the age and size of the patient. The larger volumes are reserved for adolescents, but the recommended maximal dosing should not be exceeded. Epinephrine should not be added to the solution because of the risk for peripheral vasoconstriction.

Complications

Risks during performance of an ankle block are rare. Because of the proximity of vessels, frequent aspiration for blood should be performed during injection. In addition, the use of epinephrine for an ankle block, particularly in an infant or young child, should be avoided to reduce the possibility of ischemia secondary to loss of perfusion to the distal foot.

Dosing of Lower Extremity Blocks

The volumes of local anesthesia depend on the nerves to be blocked. For femoral nerve blocks, 0.2 to 0.75 mL/kg is administered, whereas for plexus blocks, volumes of greater than 1 mL/kg are frequently needed (see [Table 16-4](#)). The duration of action of local anesthesia depends on the anesthetic concentration and age of the patient. When used in combination, local anesthetics are additive. It is important not to exceed maximal allowable dosing (see [Table 16-2](#)).

Continuous Peripheral Nerve Catheters

Indwelling catheters may be placed for peripheral nerve analgesia for those procedures that will result in significant and prolonged postoperative pain, or when vascular insufficiency is a risk. Commercially available continuous catheter kits allow catheter insertion after the plexus has been localized with a nerve stimulator or visualized by ultrasound. Kits that allow continuous catheter placement in children include a system using a short 18-gauge insulated Touhy needle through which a 20-gauge catheter may be threaded (B. Braun, Bethlehem, PA). Other systems use a catheter-over-needle approach, where a 20-gauge introducing catheter similar to an intravenous cannula fits over a 22-gauge insulated needle. Once the stimulation is achieved, the cannula is inserted into the sheath, the needle is removed, and a styletted 24-gauge catheter is threaded into the sheath for continuous infusion.

There is little information on the continuous infusions of local anesthetics in upper extremity catheters in children, but dosing of an indwelling catheter for brachial plexus anesthesia should adhere to maximal allowable dosing guidelines (see [Table 16-2](#)). Typical dosages should start at 0.1 to 0.2 mL/kg per hour of either bupivacaine or levobupivacaine (0.125% to 0.25%) or ropivacaine (0.1% to 0.2%) (see [Table 16-4](#)). Increases in the infusion rate may be made as needed as long as the maximal rate does not exceed 0.2 mg/kg per hour in infants less than 6 months, or 0.4 mg/kg per hour in children older than 6 months. It would be unusual, however, for peripheral nerve catheter infusions to reach maximal limits.

Continuous catheters have been used for the lower extremity in children, with early cases describing its use for femur

fractures of patients in the intensive care unit (ICU) (Johnson, 1994; Tobias, 1994). Johnson used an epidural catheter in the femoral sheath and delivered 0.125% bupivacaine at 0.3 mg/kg per hour. In these patients, plasma bupivacaine concentrations were well below toxic levels. Using a Seldinger technique, and a 3-French, 8-cm, single-lumen central line catheter (Cook Critical Care, Bloomington, IN), Tobias administered continuous infusions at 0.15 mL/kg per hour of 0.2% bupivacaine to four children with femur fractures and closed head trauma. The catheters provided adequate analgesia in the ICU setting for 4 to 6 days and there were no complications. To provide more complete analgesia of the upper portion of the leg, catheters may also be placed in the lumbar plexus or fascia iliaca compartments. Sciard and coworkers (2001), using nerve stimulation, placed 20-gauge plexus catheters (Pajunk, Albany, NY) in the lumbar plexus of children and administered continuous infusions of 0.2% ropivacaine at 0.33 to 0.4 mg/kg per hour. Paut and associates (2001) inserted 20-gauge catheters (Contiplex, B. Braun, Melsungen, Germany) through 55-mm cannulae into the fascia iliaca compartment and administered continuous infusions of 0.1% bupivacaine at a rate of 0.5 mL/kg per year of age. After 48 hours, the mean delivered dosage of bupivacaine was 0.135 ± 0.03 mg/kg per hour, and the plasma bupivacaine levels at 24 and 48 hours were not significantly different at 0.71 mcg/mL and 0.84 mcg/mL, respectively. The authors concluded that the bupivacaine plasma concentrations at the rates used in their study for a continuous fascia iliaca block are within safety margins.

When compared with a continuous epidural catheter, a continuous popliteal catheter provides similar excellent postoperative analgesia without the side effects of urinary retention, nausea, and vomiting (Dadure et al., 2006). Children in this study received a popliteal catheter infusion of 0.2% ropivacaine at 0.1 mL/kg per hour for 48 hours and received a 100% parent satisfaction score. The subgluteal approach to the sciatic nerve has been used for continuous catheters by employing an ultrasound-guided approach to placement of a stimulating catheter (van Geffen and Gielen, 2006). These children received bupivacaine 0.25% at a rate of 0.1 mL/kg per hour and had excellent pain relief, with no children receiving morphine other than those who had undergone amputation. The children who had undergone limb amputation received intravenous morphine despite pain scores of less than 4 as part of their multimodal therapy.

The use of disposable pumps for continuous delivery via a peripheral catheter of local anesthetic solutions provides a great option for postoperative pain control after outpatient orthopedic surgery. Dadure and coworkers (2003) described the use of the disposable elastomeric pumps in 25 children aged 1 to 15 years receiving continuous infusion via catheters in the popliteal, femoral, or axillary sheaths. A continuous infusion of 0.2% ropivacaine was used at a rate of 0.1 mL/kg per hour. The median pain score for all children was zero up to 48 hours, and there were no adverse events. A larger study at Children's Hospital of Philadelphia reported on the use of 226 continuous peripheral nerve catheters in children aged 4 to 18 years (Ganesh et al., 2007). There was a 2.8% incidence of complications. Three patients had prolonged numbness that resolved spontaneously, one patient had cellulitis that was treated with antibiotics, one patient developed tinnitus that was reversed with clamping of the local anesthetic catheter, and one patient had difficulty removing the catheter at home. The conclusion of this report was that it is feasible to implement a program

that provides continuous peripheral nerve catheters in children when appropriate expertise is available. Education of the patient and parents as well as frequent follow-up are important to recognize potential complications in a timely fashion.

Patient-controlled regional analgesia was investigated in 30 children who had undergone lower limb orthopedic surgery (Duflo et al., 2006). When comparing 0.2% ropivacaine delivered as a continuous infusion or by patient control, both groups had adequate analgesia, but the latter group achieved it with significantly less local anesthetic and, therefore, lower total plasma levels of ropivacaine.

TRUNCAL BLOCKS

Increased understanding of the abdominal wall anatomy has led to the introduction of new techniques capable of blocking sensory abdominal wall innervation (O'Donnell et al., 2006; Hebbard, 2008). Under sonographic guidance, the neurovascular plane housing various divisions of the thoracolumbar nerves can be safely blocked regardless of central neuroaxial abnormalities, bloodstream infections, or coagulopathy. These planes exist in continuity and can be precisely blocked at several anatomic locations depending on the area of analgesia required (Fig. 16-38).

Transversus Abdominis Plane Block

Transversus abdominis plane (TAP) block is the most recent addition in the field of abdominal wall blocks and holds the potential of blocking the sensory nerve supply of the entire anteriolateral abdominal wall with a single injection. Originally described in 2004 as a double-pop technique via the lumbar triangle of Petit (latissimus dorsi muscle [posterior], external oblique muscle [anterior], and iliac crest [inferior]), it has been demonstrated in the adult population to significantly decrease postoperative pain scores and opioid requirements after an open retropubic prostatectomy, cesarean delivery by Pfannenstien incision, and other major abdominal surgeries (O'Donnell et al., 2006; McDonnell et al., 2007a, 2007b, 2008). In a volunteer adult study, TAP block injection produced sensory deficit from the T7 to the L1 level and demonstrated radiographic evidence of contrast spread from the superior margin of the iliac crest to the costal margin and extending posteriorly to the quadratus lumborum (McDonnell et al., 2007b). However, the ability of TAP block to reliably produce sensory blockade above the T9 level was questioned in follow-up studies (Hebbard et al., 2007; Shibata et al., 2007). Ultrasound-guided TAP block dye injection

■ FIGURE 16-38. Sonoanatomy of truncal blocks.

into cadavers demonstrated involvement of only T10- to L1 nerve roots (Tran et al., 2009). An alternative subcostal TAP approach was suggested for the sensory blockade of the upper abdomen (Hebbard, 2008).

In pediatrics, this block has been successfully applied in small case studies with both landmark and ultrasound-guided techniques. TAP block via the triangle of Petit using 0.5 mL/kg of ropivacaine 0.375% was performed in 10 children aged 2 to 10 years undergoing elective unilateral inguinal hernia repair (Ludot et al., 2007). Anesthesia and postoperative analgesia were satisfactory in all children, and pharmacokinetic data determined peak plasma concentration to be 485 (\pm 115) ng/mL at 50 (\pm 15) minutes after block placement. This pharmacokinetic behavior was similar to that described for ilioinguinal and iliohypogastric block, and it was thus concluded by the authors to be safe in children (Dalens et al., 2001). In a subsequent study by the same group, unilateral TAP block was performed by loss of resistance technique at the triangle of Petit in 25 children aged 2 to 13 years undergoing appendectomy with 0.5 mL/kg of 0.25% levobupivacaine (Ludot et al., 2008a). All of the blocks were considered successful, with good abdominal relaxation reported by the surgeons. Sensory block of the T7 to L1 region was described by the older children, and the duration of analgesia was 15 ± 2 hours, as defined by the time to the first opioid dose. Several ultrasound-guided TAP block case series have now been reported in children. The earliest was performed in eight children undergoing inguinal hernia repair (Fredrickson et al., 2008). A 50:50 mixture of 1% lidocaine and 1% ropivacaine with 1:200,000 epinephrine (0.3 mL/kg) was injected in-plane under ultrasound guidance between the internal oblique and transversus abdominis muscle 5 minutes before incision, and it was deemed successful in five out of the eight patients based on the hemodynamic response to incision. An alternative ultrasound approach to pediatric TAP block has been described advocating deposition of local anesthetic closer to the origin of the thoracolumbar roots, but no quantitative data were presented (Suresh and Chan, 2009). A recent report illustrated the use of ultrasound-guided TAP block in four neonates undergoing upper or mid-abdominal surgery (Fredrickson and Seal, 2009). Effective intraoperative analgesia was achieved with injection of 0.4 mL/kg of 0.25% ropivacaine, and three of the four patients were extubated without the use of narcotics. In another report, ultrasound-guided TAP block was performed on eight patients aged 2 days to 26 months undergoing a combination of lower abdominal (inguinal hernia repair), middle abdominal (colostomy closure, Ladd's procedure), and upper abdominal (Nissen, G-tube) surgeries (Bryskin, 2008). These patients were not considered neuroaxial anesthesia candidates for a variety of reasons and received ultrasound-guided TAP block at the origin of the transversus abdominis muscle with injection of 0.25 mL/kg of 0.25% bupivacaine with 1:200,000 epinephrine. Successful intraoperative analgesia was achieved in seven of the eight patients, with a duration of action of 9.6 hours (7 to 15.5 hours), as judged by the time to the first rescue dose, and a mean skin-to-TAP depth of 1.1 cm (0.8 to 1.6 cm). See related video online at www.expertconsult.com.

Anatomy

The abdominal wall is innervated by the thoracolumbar (T6 to L1) spinal segmental nerves. The anterior divisions of thoracolumbar nerve roots emerge anterior to the quadratus lumborum muscle, penetrate the neurofascial plane (i.e., the TAP)

between the transversus abdominis muscle and the internal oblique muscle, form complex anastomotic networks in the TAP, and emerge through the rectus muscle to supply the skin anteriorly. In the midaxillary line, these nerves send a lateral branch providing lateral abdominal wall innervation. The ilioinguinal and iliohypogastric nerves often enter the TAP in the anterior third of the iliac crest and may thus be missed by TAP block if local anesthetic is deposited too laterally. Deep circumflex iliac artery transverses TAP from below and forms anastomoses with the lower intercostal, subcostal and lumbar arteries anterior to the midaxillary line.

Technique

Although the original description of the TAP block was a loss-of-resistance/double-pop approach via the triangle of Petit, only the ultrasound-guided technique will be described in this text as it minimizes the risk of intraperitoneal needle placement and provides the endpoint for local anesthetic injection. No consensus has been reached regarding the ideal location in TAP for local anesthetic injection. A linear-array transducer set at the highest resolution frequency is used to perform this block. The operator stands on the side of the patient being blocked, with the screen directly across. The transducer is positioned transverse to the child's abdomen, midway between the anterior superior iliac spine (ASIS) and the subcostal border. It is then slowly moved laterally until the tendinous insertion of the transversus abdominis muscle is visualized just lateral of the midaxillary level. The internal oblique and external oblique muscles may also be approaching their aponeurotic insertion at this level. This position is chosen because the aponeurotic layer is easy to locate, allows greater longitudinal spread of local anesthetic (thus blocking upper abdominal segments), permits easier posterior diffusion (thus blocking the L1 nerve), and is always located posterior to the midaxillary line (thus guaranteeing blockade of the lateral branch) (Fig. 16-39, A and B). The block needle is inserted in the anterior-to-posterior direction, in-plane with the ultrasound transducer, until its tip is positioned between the internal oblique muscle and the tendinous insertion of the transversus muscle. After negative aspiration, local anesthetic should slowly be injected while visualizing separation of the two fascial layers (see Fig. 16-39, C). In small children and neonates, it may be necessary to slightly elevate the child's side off the bed to create space for the transducer to move laterally.

Catheter Insertion

The TAP block provides an ideal location for catheter placement in children who require prolonged infusion of local anesthetics and are not candidates for central neuraxial blockade. The child should be turned into a lateral decubitus position with the block side up. The leg should be flexed at the hip to allow greater subcostal-to-ASIS distance, and the transducer positioned longitudinally to the abdomen, just lateral to the midaxillary line (see Fig. 16-39, D). After visualization of the three layers, a Tuohy needle is introduced in-plane to the transducer in the caudal-cranial direction, and a catheter is threaded 2 to 4 cm beyond the needle tip once negative aspiration and appropriate separation of fascial layers is visualized with ultrasound and with injection of a test dose (see Fig. 16-39, E). The approach for placement of the TAP catheter differs from the single-shot TAP injection in that the needle is introduced in the caudal-cranial

FIGURE 16-39. Ultrasound scan of transversus abdominis plane (TAP) block. **A**, Needle and transducer placement. **B**, Sonoanatomy. **C**, Ultrasonography of needle, local anesthetic. **D**, Ultrasound technique for TAP catheter placement. **E**, TAP catheter. ASIS, Anterior superior iliac spine.

direction as opposed to medial-lateral. This alteration ensures catheter placement in the TAP fascia before separation of the lateral nerve branches at the midaxillary line, extends anesthetic coverage toward superior abdominal dermatomes, and places the catheter outside the surgical field. Bilateral catheters can provide excellent pain relief in patients after major abdominal surgeries (personal experience).

Dosing

The optimal concentration and amount of local anesthetic necessary to produce complete abdominal wall blockade with TAP block in children is yet unknown. Successful outcomes after lower abdominal surgeries have been produced with the use of 0.5 mL/kg of 0.25% levobupivacaine or 0.375% ropivacaine by landmark technique, and 0.3 mL/kg of a 50:50 mixture of 1% lidocaine and 1% ropivacaine with 1:200,000 epinephrine by ultrasound-guided technique (Ludot et al., 2007, 2008a; Fredrickson et al., 2008). In the two case series describing upper abdominal surgeries, injection of 0.4 mL/kg of 0.25% ropivacaine and 0.25 mL/kg of 0.25% bupivacaine with 1:200,000 was deemed successful (Bryskin, 2008; Fredrickson and Seal, 2009). Since the injection of local anesthetic was performed into a different anatomic location in the TAP, it is difficult to draw quantitative conclusions regarding optimal dosage. In a pharmacokinetic adult study examining serum concentration of local anesthetic after a 400-mg injection of lidocaine via the triangle of Petit, a significant rise of serum concentration of local anesthetic was observed, with a maximal concentration of 2.7 to 5.5 $\mu\text{g/mL}$ 15 to 60 minutes after the block, thus indicating that TAP block can potentially cause systemic toxicity with a large dosage (Kato et al., 2009). Pediatric work indicates a safe

pharmacokinetic profile (Ludot et al., 2007). Although the data offer little conclusive evidence, it is clear that judicious use of local anesthetic is required and that the maximal dosage or concentration used in small children and neonates needs to be kept well below the toxic threshold. The use of epinephrine is advocated, as it may alert the operator to intravascular injection, whereas clonidine is unlikely to offer additional benefit judging by the ilioinguinal/iliohypogastric model (Dagher et al., 2006).

Complications

Because TAP block is essentially a lateral extension of the ilioinguinal/iliohypogastric nerve block, it is reasonable to assume that it will carry a similar complication profile. In the adult literature, a case of liver trauma has been reported during performance of TAP block in a 50-year-old woman with an enlarged liver (Farooq and Carey, 2008). In a neonatal patient with a frequently enlarged liver, this should be kept in mind, and hence performance of TAP block under ultrasound guidance is advocated. The presence of the deep circumflex iliac artery in the TAP suggests an increased risk of intravascular injection and hematoma formation, especially in patients with increased vascular congestion.

Ultrasound-Guided Rectus Sheath Block

Rectus sheath block provides analgesia to the anterior abdominal wall medial to the linea semilunaris, and it has been used for umbilical and epigastric hernia repairs, pyloromyotomy, and various laparoscopic procedures. With the advent of single-incision laparoscopic surgery via a large umbilical incision, this technique is likely to be increasingly used. An ultrasound-guided

approach has been demonstrated to be efficacious in two studies for repair of umbilical hernia in children (Willschke et al., 2006b; de Jose Maria et al., 2007). See related video online at www.expertconsult.com.

Technique

A linear-array transducer set at the highest resolution frequency is used to perform this block. The operator stands on the side of the patient being blocked, with the screen directly across. The transducer is positioned transverse to the patient's abdomen just above the umbilicus (Fig. 16-40, A). Sonographic scan reveals the rectus muscle bordered laterally by tendinous insertions of the transversus abdominis, internal oblique, and external oblique muscles, and medially by the linea alba. It is enveloped by the rectus sheath, which is an aponeurotic extension of the three lateral muscles (see Fig. 16-38). Inferior epigastric vessels can frequently be visualized posterior to or in the rectus muscle belly and can be confirmed by color Doppler. The block needle is advanced in-line in the lateral-to-medial direction until the tip is visualized between the posterior border of the rectus muscle and the posterior rectus sheath (see Fig. 16-40, B). When anatomy allows, a needle path through the linea semilunaris is chosen, as this may avoid intramuscular vessel puncture and hematoma formation. After negative aspiration, a small volume of local anesthetic or saline is injected and should produce a lenslike separation between the rectus muscle and the posterior rectus sheath. Once an appropriate position of the needle tip is confirmed, injection of 0.1 to 0.2 mL/kg of local anesthetic per side should produce effective analgesia (Willschke et al., 2006b).

Ilioinguinal/Iliohypogastric Nerve Block

Ilioinguinal/iliohypogastric (ILIH) nerve block provides analgesia to the inguinal area and provides good perioperative pain relief for patients undergoing such procedures as inguinal hernia repair, orchiopexy, and hydrocelectomy (Hannallah

et al., 1987; Casey et al., 1990; Fisher et al., 1993). Early studies compared the use of an ilioinguinal/iliohypogastric block for children aged 1 to 7 years for inguinal hernia repair. The block was performed after induction of anesthesia but before surgical incision. When this was compared with general anesthesia without the block, the group of patients who received an ilioinguinal/iliohypogastric nerve block ambulated earlier and required less analgesia in the immediate postoperative period. The ilioinguinal/iliohypogastric block group also required less analgesia for the 48 hours after surgery (Langer et al., 1987). Hannallah and associates studied the efficacy of an ilioinguinal/iliohypogastric block for orchiopexy surgery (1987). They found no advantage to a caudal block over the ILIH block for orchiopexy surgery, as there were no significant differences between the groups in postoperative pain scores, postoperative vomiting, or time to meet discharge criteria. These results have been duplicated in other studies, with no differences found between the ILIH groups and caudal groups with respect to postoperative pain scores, analgesic requirements, or times to micturition (Fisher et al., 1993; Splinter et al., 1995). However, in a similarly designed study, Somri and coworkers (2002) noted that caudal anesthesia was significantly more effective than ILIH in decreasing plasma catecholamine levels after orchidopexy.

Casey and associates (1990) investigated the effectiveness of an ilioinguinal/iliohypogastric nerve block for inguinal hernia repair and compared this to simple installation of bupivacaine into the surgical wound. There was no difference between the ilioinguinal/iliohypogastric nerve block group and the wound installation group with regard to pain scores, analgesic requirements, recovery, or discharge times. In a study to assess the effectiveness of 0.5% bupivacaine in patients receiving an ilioinguinal/iliohypogastric nerve block, a wound infiltration, or a combination of wound infiltration and nerve block, Anatol and coworkers (1997) noted that all three patient groups had effective analgesia and that there were no differences in pain scores or analgesic requirements among the three groups. See related video online at www.expertconsult.com.

Anatomy

The ilioinguinal and iliohypogastric nerves originate from the lumbar plexus and pierce the transversus abdominis muscle. The iliohypogastric nerve then takes its course between the transversus and internal oblique muscles, and the ilioinguinal runs between internal oblique and external oblique. They pass superficial to the transversus abdominis near the anterior superior iliac spine, where they can be blocked before running their separate courses to innervate the inguinal region and upper scrotum (Fig. 16-41, A). The spermatic cord also receives innervation from the genital branch of the genitofemoral nerve that originates from lumbar plexus, usually at L1 or L2.

Technique

The ilioinguinal and iliohypogastric nerves may be blocked in their location near the anterior superior iliac spine. If performed before incision and after sterile preparation of the skin, a blunt 22- or 25-gauge needle is inserted 1 cm superior and 1 cm medial to the anterosuperior iliac spine (see Fig. 16-41, B). The needle is initially directed posterolaterally to contact the inner superficial lip of the ileum, then withdrawn while injecting local anesthetic during needle movement. Once the skin is

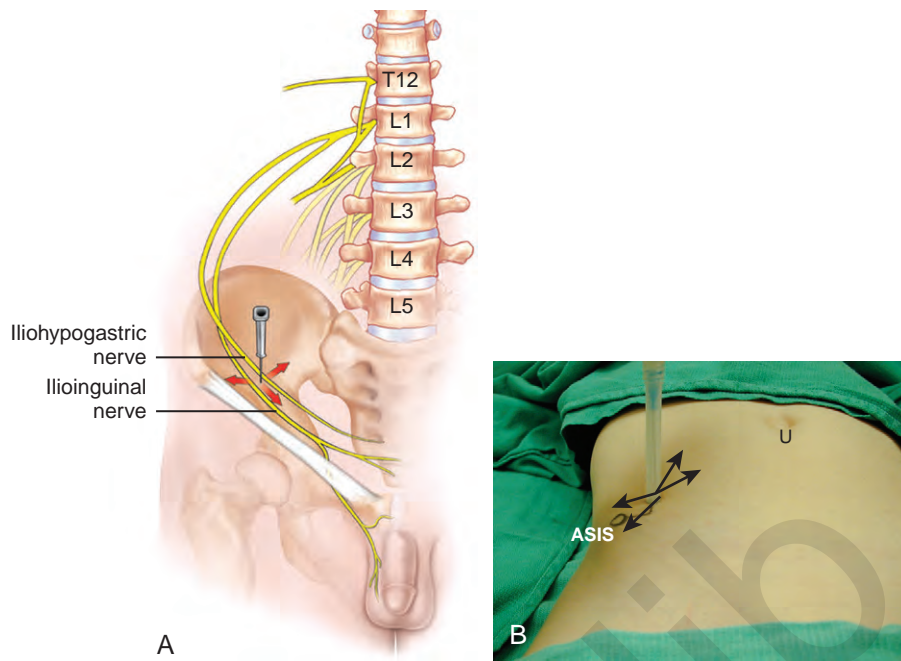

FIGURE 16-41. Ilioinguinal/iliohypogastric (ILIH) nerve block. **A**, Anatomy for ilioinguinal and iliohypogastric nerve block. **B**, Performance of ilioinguinal/iliohypogastric nerve block. A field block is performed in the direction of the arrows and inferiorly toward the inguinal ligament. ASIS, Anterior superior iliac spine; U, umbilicus.

reached, the needle is redirected toward the inguinal ligament (ensuring that the needle does not enter the ligament) and local anesthetic is injected after a pop is felt as the needle penetrates the oblique muscles. If the block is to be performed at the end of surgery, the surgeon may anesthetize the nerves under direct vision. The nerves lie at the lateral border of the incision. Lim and associates (2002) determined that there is no added advantage of a single-shot over a double-shot ilioinguinal/iliohypogastric nerve block.

In addition, continuous needle visualization under ultrasound should guard against complications that may occur with blind technique. Pharmacokinetic data indicated a faster absorption and higher local anesthetic concentration in serum when ultrasound-guided ILIH nerve block was performed, thus advocating reduction in the volume of local anesthetic when using this approach (Weintraud et al., 2009). See related video online at www.expertconsult.com.

Ultrasound-Guided Ilioinguinal/Ilioypogastric Nerve Block

Ultrasound-guided ILIH nerve block has been shown to increase accurate placement of local anesthetic around the ILIH nerves, decrease failure rate by 20% to 30%, and allow use of a smaller volume than the landmark-based ILIH nerve block technique (Willschke et al., 2005, 2006a; Weintraud et al., 2008).

Technique

A linear-array transducer set at the highest-resolution frequency is used to perform this block. The operator stands on the side of the patient being blocked, with the screen directly across. The transducer is positioned medial to the anterior superior iliac spine along the line connecting ASIS to the umbilicus (Fig. 16-42, A). The ilioinguinal and iliohypogastric nerves are found between the internal oblique and transversus abdominis muscle in close proximity to the ASIS and have an elliptical,

FIGURE 16-42. Ultrasound scan of ILIH. **A**, Needle and transducer placement. **B**, Sonoanatomy. **C**, Sonoanatomy of vascular structures. ASIS, Anterior superior iliac spine; EOM, external oblique muscle; IOM, internal oblique muscle; TAM, transversus abdominis muscle.

hypoechoic appearance (see Fig. 16-42, B). Doppler examination of the intended injection site should be performed first and may reveal vascular structures (branch of the deep circumflex iliac artery) that are not to be targeted (see Fig. 16-42, C). The block needle can be advanced in-plane either in the medial-to-lateral or lateral-to-medial direction, and it is positioned between the internal oblique and the transversus abdominis muscle. The medial-to-lateral approach is preferred as the needle tip is directed toward the ASIS, thus minimizing risk for intraperitoneal damage if the needle is inadvertently advanced outside of the ultrasound field. The lateral-to-medial needle direction can also be safely employed but requires continuous needle tip visualization. After negative aspiration, confirm needle location by hydro-dissection with 1 to 2 mL of normal saline and inject 0.2 mL/kg of local anesthetic while visualizing appropriate fascial spread.

Dosing

Bupivacaine 0.25% in a volume of 4 to 6 mL was used in a study by Hannallah and coworkers (1987) that included boys between the ages of 18 months and 12 years, and Casey and associates (1990) used 0.25 mL/kg of bupivacaine 0.25% for children 2 to 10 years for hernia repair. Both of these studies cited good postoperative pain relief for these children. Although the maximal duration of analgesia is unknown from these studies, in the study by Casey and coworkers (1990) effective analgesia was still present 180 minutes postoperatively. Levobupivacaine has been compared with placebo for patients 6 months to 12 years undergoing inguinal herniorrhaphy. In this study, Gunter and coworkers (1999) noted that 0.25 mL/kg of 0.5% levobupivacaine was effective for ILIH block and was associated with a longer time to rescue analgesic administration and lower pain scores when compared with children who had received no block. Dalens and coworkers (2001) evaluated the effectiveness and pharmacokinetic profile of 0.5% ropivacaine at 3 mg/kg for ILIH nerve block in children aged 1 to 12 years undergoing inguinal surgery. This dosage provided satisfactory pain relief, and peak ropivacaine plasma concentrations were 1.5 ± 0.93 mg/L. These levels were well below the toxic level.

Complications

Although complications from an ILIH nerve block are rare and generally minor, there have been case reports of colonic and small bowel perforation (Johr and Sossai, 1999; Amory et al., 2003). Inadvertent femoral nerve blockade and motor block of the quadriceps may occur if the local anesthetic solution spreads below the inguinal ligament during the block placement. This can yield a block similar to the fascia iliaca block (Roy-Shapiri et al., 1985). The use of ultrasound should avoid these complications.

Penile Nerve Block

A penile nerve block includes techniques such as subpubic nerve block, dorsal nerve block, and subcutaneous ring block and may be used for procedures on the distal penis including circumcision and uncomplicated hypospadias repair. Investigations have shown that newborns have a decreased stress response when undergoing circumcision with the benefit of a penile block. A ring block may be more effective than either a dorsal nerve

block or local anesthetic cream (Maxwell et al., 1987; Stang et al., 1988; Lander et al., 1997; Butler-O'Hara et al., 1998; Hardwick-Smith et al., 1998). In addition, a subcutaneous ring block may result in a lower incidence of complications than a dorsal nerve block (Broadman et al., 1987). The subpubic nerve block blocks the nerves before they enter the base of the penis. This block is less likely to disrupt the vascular or penile structures. Holder and associates (1997) compared the subcutaneous ring block in boys undergoing circumcision with a group of boys who had a subpubic block. The group anesthetized with the subpubic block had significantly lower pain scores. In addition, three boys in the subcutaneous ring block group had tissue distortion from the block, which affected surgical conditions.

When using a penile block for boys undergoing hypospadias repair, Chhibber and coworkers (1997) showed that placing the block before incision and repeating the block at the end of surgery provided better postoperative pain control than placing the block only once (i.e., before or after the surgical procedure). See related video online at www.expertconsult.com.

Anatomy

The distal two thirds of the penis are supplied by the dorsal nerves, which are branches of the pudendal nerve (Fig. 16-43, A). The pudendal nerve arises from the sacral plexus. The dorsal nerves are located near the dorsal vessels and are surrounded by Buck's fascia.

Technique

Subcutaneous ring block. A simple approach for blocking the dorsal nerves to the penis is the subcutaneous ring block. A skin wheal of local anesthetic (without epinephrine) is injected circumferentially around the base of the penis but superficial to Buck's fascia.

Dorsal nerve penile block. A dorsal penile nerve block may be performed by injecting local anesthetic directly at the nerves as they run on each side of the penis at the level of the symphysis pubis (see Fig. 16-43, B). Using a 25-gauge needle, Buck's fascia is pierced and local anesthesia (without epinephrine) is injected at the clock positions of 10:30 and 1:30 at the base of the penis. Because of the close proximity of the dorsal vessels, frequent aspiration for blood during the local anesthetic injection is necessary. Ultrasound-guided dorsal penile nerve block has been demonstrated to be effective and may be used to visualize local anesthetic spread around the dorsal nerves (Sandeman and Dilley, 2007).

Subpubic block. To perform a subpubic block, the penis is gently pulled downward and the needle is inserted perpendicular to the skin 0.5 to 1 cm lateral to the midline and caudal to the symphysis pubis. As the needle is advanced, it is directed slightly medially and caudally until Scarpa's fascia is crossed. When "give" is felt and assuming a negative aspiration for blood, local anesthetic is delivered.

Dosing

The most important point to remember about dosing a penile block is to *never use epinephrine*. The penis is an end organ, and the use of epinephrine may lead to necrosis. For all techniques of providing penile nerve block, bupivacaine 0.25%, levobupivacaine 0.25%, or ropivacaine 0.2% may be used to provide

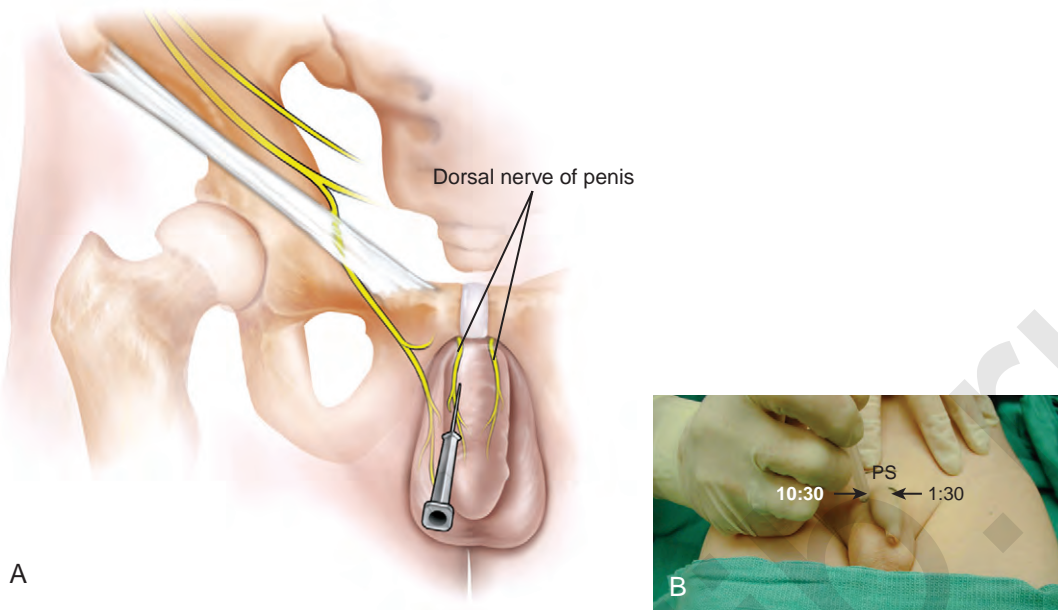

FIGURE 16-43. Dorsal nerve penile block. **A**, Anatomy for dorsal nerve penile block. **B**, Performance of dorsal nerve block. Point of needle insertion is at clock referents 10:30 and 1:30 at the base of the penis. PS, Pubic symphysis.

analgesia with a duration of 4 to 6 hours. A subcutaneous ring block should be dosed so that there is subcutaneous evidence of local anesthetic injection around the base of the penis, but the dosage must not exceed the maximal allowable recommendations for single injection (see [Table 16-2](#)). For a dorsal nerve block or subpubic block, approximately 0.1 mL/kg of local anesthetic is injected at each site. Sfez and associates (1990) showed that for a penile block with 0.1 mL/kg at each injection site of either 0.25% bupivacaine or a 1:1 mixture of 0.25% bupivacaine with 1% lidocaine, serum local anesthetic concentrations were well below the toxic range.

Complications

Epinephrine should never be used when performing a penile block, as this may lead to significant vasoconstriction and ischemia (Berens and Pontus, 1990). An adult who received 0.75% ropivacaine for dorsal nerve block developed temporary ischemia of the glans, presumably from the intrinsic vasoconstrictive effects of the high concentration of ropivacaine, so this should be kept in mind when choosing local anesthetic and concentration (Burke et al., 2000). Hematoma formation may occur from puncture of the dorsal vessels during dorsal nerve block. This can result in necrosis of the tip of the penis (Sara and Lowry, 1984). When performed properly, a subcutaneous ring block should be void of complications with the exception of tissue edema at the base of the penis. Tissue edema may affect the surgical conditions if the block is performed before the surgical procedure.

Intercostal Nerve Block

Intercostal nerve block provides limited analgesia after thoracotomy, upper abdominal procedures, rib fractures, and indwelling chest tubes. An intercostal block may be useful for these indications in the perioperative arena or in an emergency room or ICU setting. See related video online at www.expertconsult.com.

Anatomy

The intercostal nerves arise paravertebrally from the first 11 thoracic spinal nerves and are located in a groove that is found underneath the corresponding rib and shared with the intercostal vessels. Gray and white rami communicantes branch off from the spinal nerves and adjoin the sympathetic ganglia before entering the intercostal space. The intercostal space contains the intercostal nerve, artery, and vein and is bordered by the intercostal muscles ([Fig. 16-44, A](#)).

Technique

To adequately anesthetize the intercostal nerves near their origin, the block is performed lateral to the paraspinous muscles toward the posterior axillary line. The child should be in the lateral decubitus position with the arm elevated so that the posterior axillary line is easily accessed (see [Fig. 16-44, B](#)). After sterile preparation, insert a 25-gauge needle (the length depends on the age of the child) through the skin, less than 1 cm below that the lower border of the rib and aiming cephalad to make contact with the rib itself. The needle is then withdrawn and advanced to “walk under” the inferior border of the rib until a slight loss of resistance is felt as the muscles are penetrated. The nerve is located immediately inferior to the vessels but in close proximity, and this requires frequent aspiration during injection of local anesthetic. To improve success of analgesia, the intercostal nerves two segments above and two segments below should be blocked in addition to the segment corresponding to the incision. Although a single injection of an increased volume of 10 mL per segment has been shown to spread to multiple intercostal spaces in adults, this is not a common practice in children (Moorthy et al., 1992).

Dosing

A dose of 0.1 to 0.15 mL/kg per interspace (maximum of 3 mL/ interspace) of local anesthetic agent is injected after negative

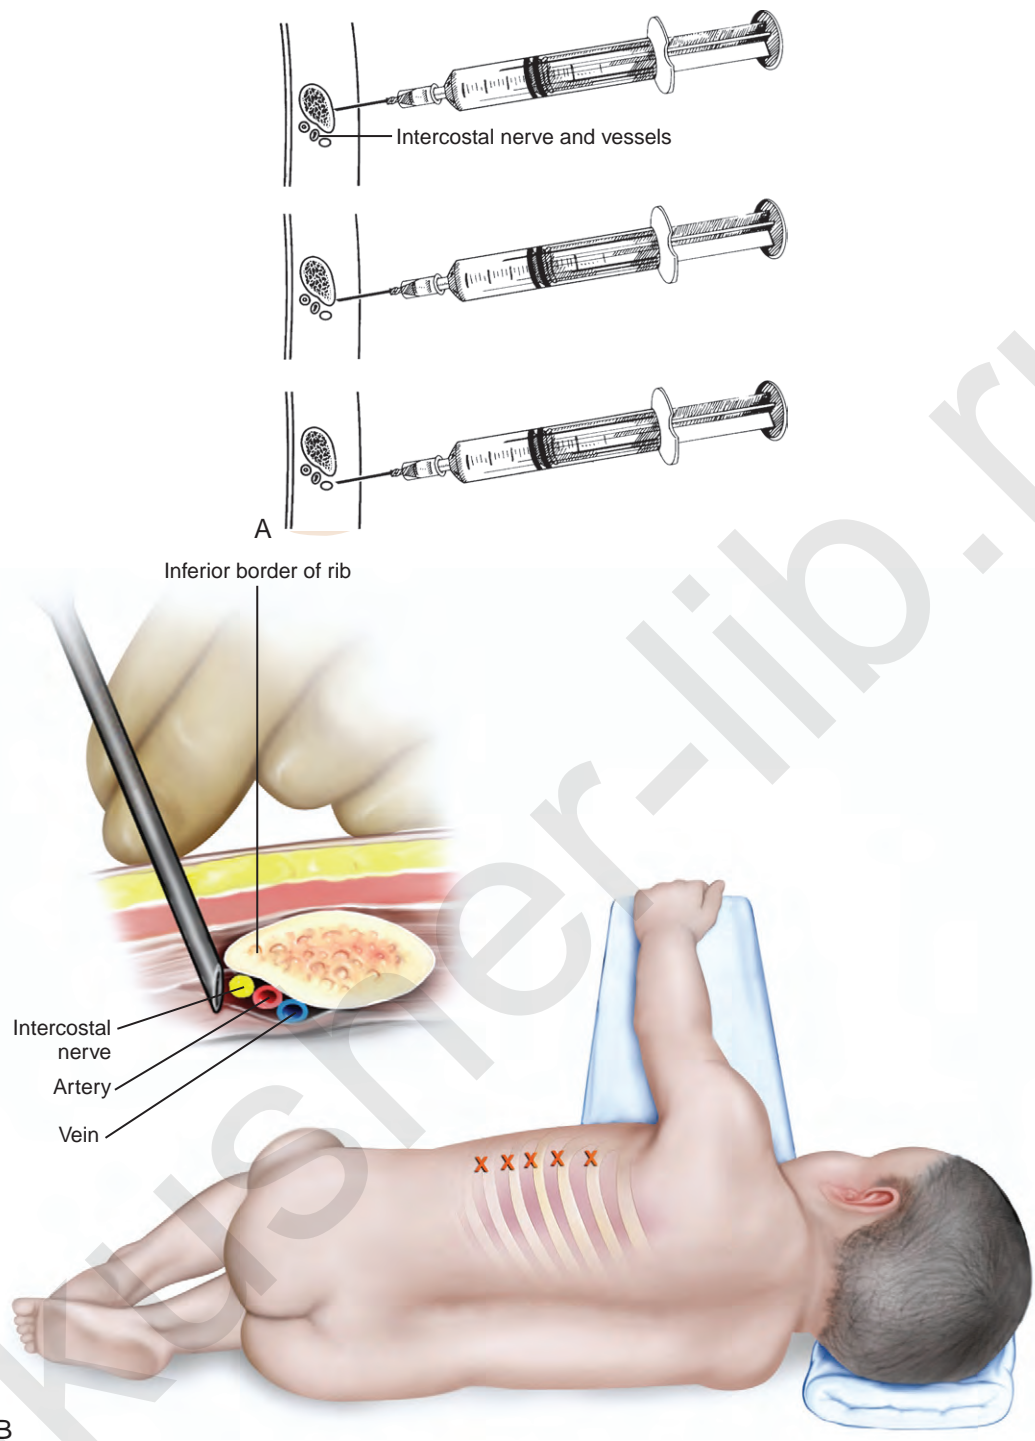

FIGURE 16-44. Intercostal block. **A**, Anatomy of intercostal nerves. **B**, Performance of intercostal block. The needle is directed to contact the inferior border of each rib to be blocked, then “walked off” posteriorly.

aspiration. Bupivacaine 0.25%, levobupivacaine 0.25%, or ropivacaine 0.2% should provide 8 to 12 hours of analgesia.

Complications

Complications of intercostal block include pneumothorax, vascular puncture, and epidural or spinal local anesthetic spread. Spread of local anesthetic to the epidural or

spinal spaces may occur if the injection travels through a dural sleeve covering the spinal root and may be more common with the posterior approach than with more anterior approaches. In addition, there may be increased risk for local anesthetic toxicity from systemic uptake or inadvertent vascular puncture than with other peripheral nerve blocks because of the close proximity of the intercostal vessels to the nerve.

Paravertebral Nerve Block

Paravertebral nerve block provides analgesia at specific dermatomes, and it is generally used for children who undergo unilateral procedures. Its use has been established in children, and the main advantages include localized pain control and the ability to avoid large volumes of local anesthetic (Lonnqvist and Olsson, 1994; Lonnqvist et al., 1995; Richardson and Lonnqvist, 1998). Continuous paravertebral block has been shown to be effective for pain management for patients after thoracotomies, renal surgery, and cholecystectomy. Paravertebral blocks may be superior to epidural anesthesia in patients undergoing unilateral renal surgery, resulting in fewer morphine requirements in the postoperative period (Eng and Sabanathan, 1992; Lonnqvist, 1992; Lonnqvist and Olsson, 1994). Bolus injection of local anesthetic in the paravertebral space has been used successfully in children for inguinal surgery (Eck et al., 2002). Paravertebral blocks may be used in any patient where intercostal nerve blocks would be appropriate. Other advantages to performing paravertebral block include the spread of analgesia beyond one dermatome and the ease of catheter insertion for postoperative pain.

In the adult literature, preincisional paravertebral block resulted in a lower incidence of chronic pain after breast surgery, perhaps because of its preemptive analgesic effects (Lonnqvist, 2005b; Kairaluoma et al., 2006). There is evidence that the technique may even reduce the risk for recurrence or metastasis of breast cancer, and there is ongoing investigation (Exadaktylos et al., 2006; Sessler et al., 2008). See related video online at www.expertconsult.com.

Anatomy

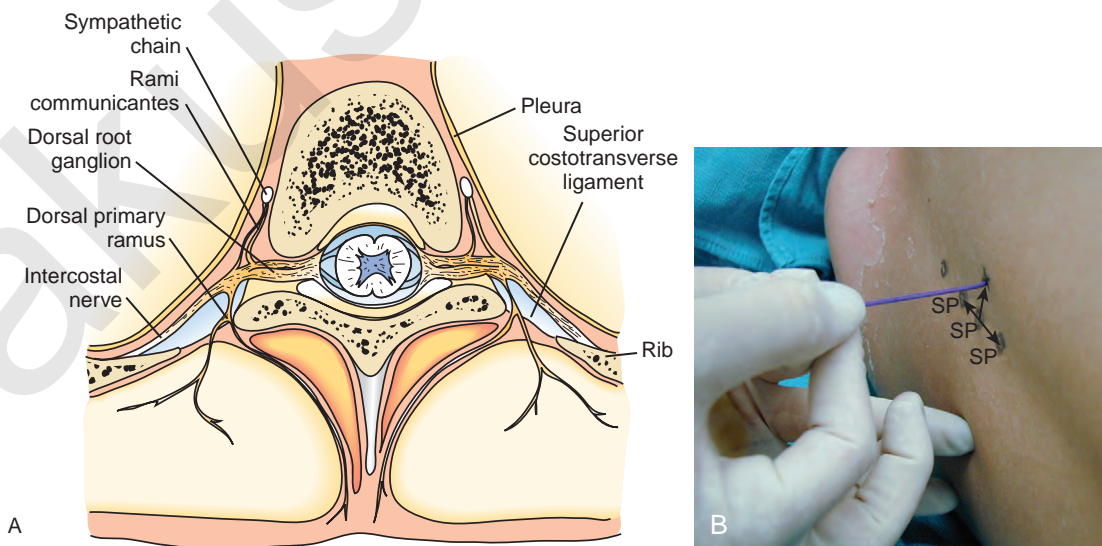

The paravertebral space is a wedge-shaped area along the vertebral column that contains the intercostal nerve, its dorsal ramus, the rami communicantes, and the sympathetic chain. The anterior boundary of the paravertebral space is the parietal pleura, and posterior to it are the superior costotransverse ligament

and posterior intercostal (Fig. 16-45, A). There are equations to determine the depth of the paravertebral space based on body weight (Lonnqvist and Hesser, 1992). The distance in millimeters from the spinous process to the paravertebral space is 0.12 times body weight (in kilograms) plus 10.2. The depth in millimeters from the skin to the paravertebral space is 0.48 times body weight (in kilograms) plus 18.7.

When local anesthetic is injected into the paravertebral space, it may spread several dermatomes because of the potential for free communication between adjacent spaces. The exception to this, however, may be at the T12 level, where the psoas major muscle inserts into the vertebral column. In human cadavers, the psoas muscle may be a limiting factor in spread of local anesthesia from the thoracic region to segments below T12 (Lonnqvist and Hildingsson, 1992). For this reason, in the study of children undergoing paravertebral blocks for inguinal surgery, Eck and coworkers (2002) administered two injections, one above T12 and the other below.

Technique

After sterile preparation and draping, with the child in the lateral position and the block side up, the spinous process of the level to be blocked is identified. The distance from the midline to the point of lateral puncture is approximately the same distance as the tip from one spinous process to another (see Fig. 16-45, B). If using a single-injection technique, a blunt spinal needle is used. If a catheter is to be threaded, a Touhy needle is necessary. Using a loss of resistance technique to saline, the needle is placed the proposed distance from the midline at the level of the spinous process. As the needle is inserted perpendicular to the skin, it will contact the corresponding transverse process. The needle is then “walked” over the cephalad margin of the transverse process. With gentle pressure on the syringe plunger, loss of resistance will occur once the needle crosses the costotransverse ligament and entry is gained into

■ **FIGURE 16-45.** Paravertebral block. **A**, Anatomy of paravertebral space. **B**, Performance of paravertebral block. *SP*, Spinous process. Lateral distance to point of needle insertion from midline should be equal to distance between spinous processes (arrows). (**A**, From Eason MJ, Wyatt R: *Paravertebral thoracic block: a reappraisal*, *Anaesthesia* 34:638, 1979.)

the paravertebral space. The loss of resistance is similar to, but less distinct than, that of going through the ligamentum flavum during epidural placement. Once the paravertebral space is identified, local anesthetic is injected into the space, and a catheter can be threaded if a continuous technique is desired. Threading a catheter through a Touhy needle into the paravertebral space may require some manipulation and cephalad angulation of the bevel of the needle. In a child, the catheter should not be threaded more than 2 to 3 cm. This avoids lateral placement of the catheter into an intercostal space and single-dermatome analgesia.

Technique with Ultrasound

The use of an ultrasound for the paravertebral nerve block placement has been described in several recent reports, with both an out-of-plane and in-plane needle advancement (Hara et al., 2007; Ben-Ari et al., 2009; Luyet et al., 2009; Shibata and Nishiwaki, 2009). Although the safety and reliability of these techniques is unknown, the in-plane technique offers the ability to visualize the block needle and may guide it away from the pleura and vascular structures.

A linear ultrasound transducer set at the highest operational frequency should be used to achieve maximal resolution. The child can be positioned either prone or in a lateral decubitus position with the operative side uppermost (Fig. 16-46, A). The operator stands or sits by the child's ipsilateral side for the prone position or faces the child for the lateral decubitus position. The ultrasound machine is positioned in the direct line of view. The sonographic examination begins by positioning the transducer in a transverse plane over the selected intercostal space and sliding it medially until the hyperechoic transverse process is visualized (see Fig. 16-46, B). The paravertebral space is located between the pleura below and the internal intercostal membrane above. The use of color Doppler, before needle placement, may help to avoid injuring the intercostal vessels. A Tuohy needle is advanced in-plane from lateral to medial until the internal intercostal membrane is pierced. Local anesthetic injection should produce downward movement of the pleura as the paravertebral space is expanded (see Fig. 16-46, C). Care should be taken to ensure continuous sonographic visualization

of the needle tip, and aspiration is performed for blood or CSF before local anesthetic injection.

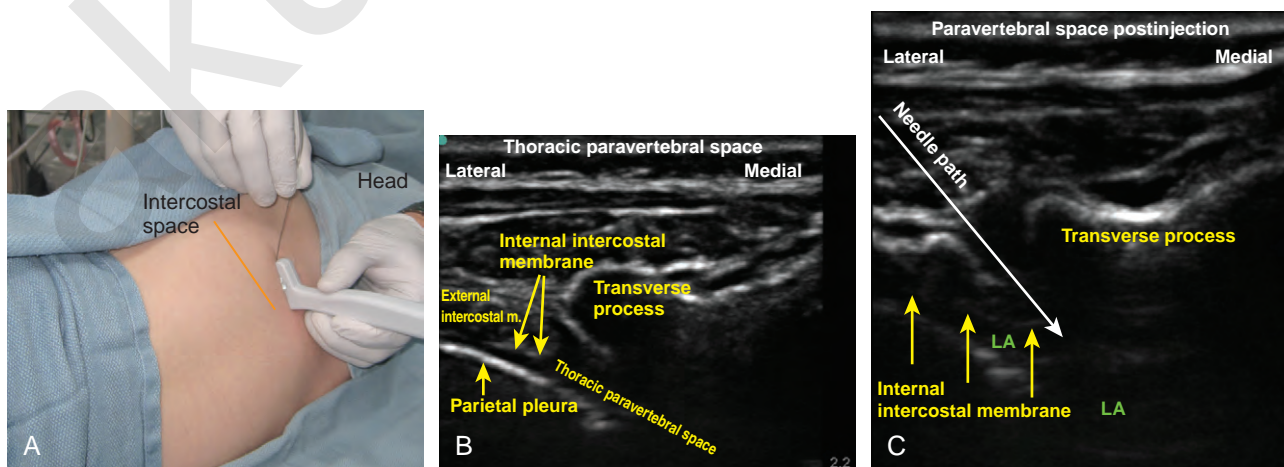

Dosing

For a unilateral paravertebral block, a bolus dosage of 0.5 mL/kg of local anesthetic provides reliable analgesia of four dermatomes (Lonnqvist and Hesser, 1993). Bupivacaine 0.25%, ropivacaine 0.2%, or levobupivacaine 0.25%, all with epinephrine (5 mcg/mL) may be used for single injection. If multiple levels are to be blocked, it is important not to exceed the maximal allowable dosing recommendations (see Table 16-2). For continuous infusions, bupivacaine 0.25%, ropivacaine 0.2%, or levobupivacaine 0.25% can be infused at a rate of 0.25 mL/kg per hour for most children, or lower concentrations at 0.2 mL/kg per hour for infants (Karmaker et al., 1996; Cheung et al., 1997).

Infants with a mean age of 5.3 weeks who received a bolus of bupivacaine 0.25% followed by infusion at 0.5 mg/kg per hour had bupivacaine serum levels that were suggestive of considerable bupivacaine accumulation. Some patients reached potentially toxic levels (Karmaker et al., 1996). In a similar study in younger infants (median age, 1.5 weeks), Cheung and associates (1997) used a lower concentration and a lower infusion rate and added epinephrine 1:400,000 in an attempt to decrease the uptake of local anesthetic. With an initial 1.25-mg/kg bolus of 0.25% bupivacaine, and an infusion of 0.125% at 0.25 mg/kg per hour, the mean serum concentration was 1.60 mcg/mL. Three patients had plasma bupivacaine measurements of greater than 3 mcg/mL between 30 and 48 hours. None of these patients had any sequelae.

Complications

In one series of 367 patients for paravertebral block, the failure rate was 10.7% for adults and 6.2% for children (Lonnqvist et al., 1995). Complications of the block included hypotension (4.6%), vascular puncture (3.8%), pleural puncture (1.1%), and pneumothorax (0.5%). Of these complications, all the patients who had hypotension were adults, none of the patients who had a vascular puncture demonstrated local anesthetic toxicity, and only one of the patients who had a pleural puncture had a pneumothorax. This study suggested that the failure rate was

■ FIGURE 16-46. Ultrasound paravertebral block. **A**, Needle and transducer position. **B**, Sonanatomy. **C**, After injection.

comparable to that of epidural blocks, but with a much lower incidence of hypotension and little risk for dural puncture. Thus, the overall safety of paravertebral blocks has been established, although this technique should be limited to those who are experienced in its use.

BLOCKS OF THE FACE AND SCALP

Infraorbital Nerve Block

The infraorbital nerve consists of four branches, which innervate the upper lip and mucosa along the upper lip, the vermilion, the lateral inferior portion of the nose, and the lower lid of the eye. Blocking the infraorbital nerve provides effective analgesia for cleft lip repair (Bosenberg and Kimble, 1995; Prabhu et al., 1999). This block is also useful for nasal procedures such as endoscopic sinus surgery, nasal septal reconstruction, and rhinoplasty.

Anatomy

The infraorbital nerve is a purely sensory nerve derived from the second maxillary division of the trigeminal nerve. The infraorbital nerve is a terminal branch that exits the skull through the foramen rotundum to enter the pterygopalatine fossa. Here it emerges from the infraorbital foramen to divide into its four branches, the superior labial, internal nasal, external nasal, and inferior palpebral nerves.

Technique

The intraoral approach to block the infraorbital nerve is achieved by advancing a 27-gauge needle along the inner surface of the lip and cephalad to the infraorbital foramen parallel to the maxillary premolar. To perform this block, first palpate the infraorbital foramen and pull the upper lip superiorly to allow room for the needle and syringe (Fig. 16-47). Keep a finger on the

■ FIGURE 16-47. Infraorbital nerve block.

infraorbital foramen during needle advancement to provide accurate measurement to the desired space.

To block the infraorbital nerve transcutaneously, locate the infraorbital foramen and insert a 27-gauge needle toward, but not into, the foramen, in a lateral direction.

Dosing

A total volume of 0.5 to 1.5 mL of bupivacaine 0.25%, levobupivacaine 0.25%, or ropivacaine 0.2% with 1:200,000 epinephrine added is injected after negative aspiration for blood.

Complications

Hematoma, particularly using the transcutaneous approach, is not uncommon. To avoid this, pressure should be applied at the site of injection for 5 minutes. Other complications are rare as long as the foramen itself is not entered so that nerve compression does not occur.

Great Auricular Nerve Block

The mastoid and external ear are innervated by the great auricular nerve. Analgesia for otoplasty and tympanomastoidectomy is provided by blocking this nerve and leads to reduction in the perioperative use of opioids for these procedures (Cregg et al., 1996; Suresh and Wheeler, 2002).

Anatomy

The great auricular nerve is a sensory nerve branch of the superficial cervical plexus (C3). Its course at the level of the cricoid cartilage follows the posterior border of the belly of the clavicular head of the sternocleidomastoid muscle.

Technique

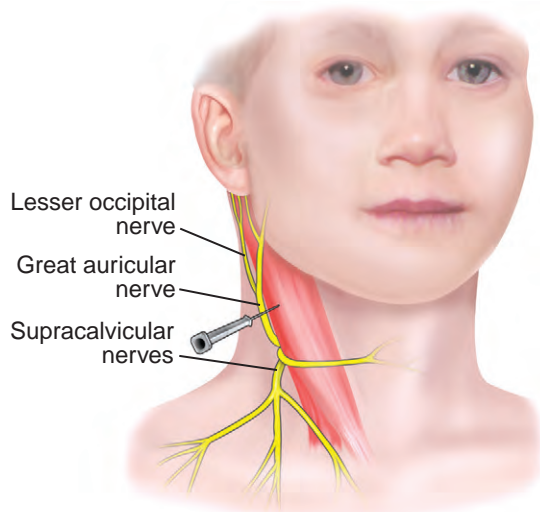

The great auricular nerve is blocked at the level of the cricoid cartilage at C6. The clavicular head of the sternocleidomastoid muscle is identified, and local anesthetic is injected superficially along the belly of the muscle approximately 5 to 6 cm below the ear (Fig. 16-48).

Complications

Complications from a great auricular nerve block may be significant and include intravascular injection because of the close proximity of the carotid artery and jugular veins. In addition, deep placement of the needle can result in phrenic nerve block, cervical plexus block, and Horner's syndrome.

Supraorbital and Supratrochlear Nerve Blocks

Anesthetizing the supraorbital and supratrochlear nerves can provide pain relief for procedures of the anterior scalp and forehead, including excision of skin lesions, neurosurgical procedures with incisions of the scalp or forehead, and laser therapy for hemangiomas (Suresh and Wheeler, 2002).

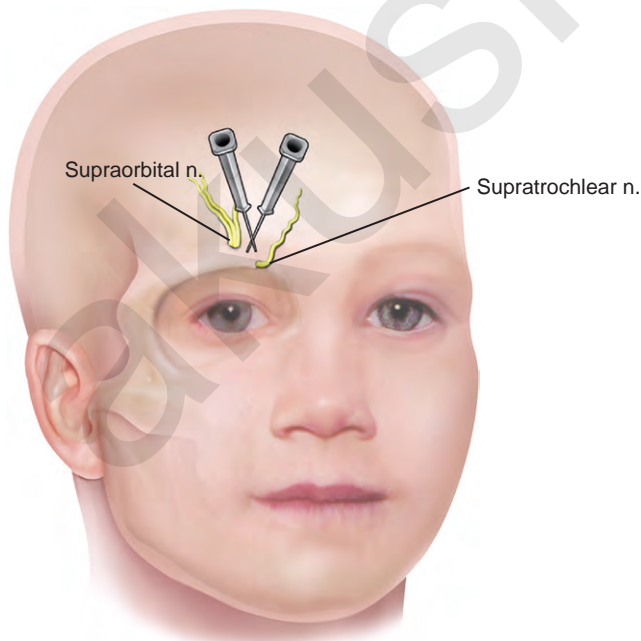

■ **FIGURE 16-48.** Anatomy for great auricular nerve block.

Anatomy

The supraorbital and supratrochlear nerves are terminal branches of the ophthalmic division of the trigeminal nerve (V_1). These nerves supply the forehead and the scalp anterior to the coronal suture. They are found immediately above the eyelid area, where the supraorbital nerve exits through the supraorbital foramen and the supratrochlear nerve exits the orbit between the trochlea and the supraorbital foramen (Fig. 16-49).

Technique

After identifying the supraorbital notch, a 27-gauge needle is inserted perpendicular to the skin at the notch until it contacts

■ **FIGURE 16-49.** Anatomy for supraorbital and supratrochlear nerve blocks.

bone, then withdrawn slightly, and local anesthetic is injected after negative aspiration. The supratrochlear nerve is blocked by withdrawing the needle back to the skin and aiming slightly medially.

Complications

Periorbital edema and ecchymosis are common side effects when performing blocks around the eye. To avoid this side effect, pressure can be applied to the supraorbital area for 5 minutes after the block has been placed.

INTRAVENOUS REGIONAL ANESTHESIA

Intravenous regional anesthesia (IVRA), or Bier block, is a technique whereby an extremity is anesthetized by injecting local anesthetic intravenously and containing it within the extremity by using a tourniquet. This technique is useful only for intraoperative analgesia, as the effect of the local anesthetic dissipates with release of the tourniquet. Intravenous regional anesthesia has been used in children for forearm fracture reduction and is considered safe and effective for most procedures of distal extremities that require pain relief for a short period (Davidson et al., 2002). IVRA should not be used for procedures that have a potential of lasting greater than 90 minutes.

Technique

A separate intravenous line is placed in the limb that is to be blocked, and a double tourniquet is applied to this extremity. The limb should then be elevated and exsanguinated by wrapping the extremity with an elastic bandage, beginning with the digits and proceeding toward the tourniquets (Fig. 16-50: Go to www.expertconsult.com to view this image online). If the limb is fractured, exsanguination with the bandage should be deleted in an awake child to avoid excessive pain. The proximal tourniquet is then inflated to greater than 50 mm Hg above the baseline systolic blood pressure (Fitzgerald, 1976). If the operation is occurring on the lower extremity, inflation pressures should be closer to 100 mm Hg above systolic blood pressure. After proximal tourniquet inflation, local anesthetic is slowly injected into the venous cannula in the operative limb. Onset of block should occur within 5 minutes of injection. After testing for successful block, the procedure may begin. Once it is evident during the procedure that tourniquet pain is being experienced, the distal tourniquet is inflated. The proximal tourniquet may then be released. Tourniquet pain is typically not an immediate issue on inflation of the distal tourniquet because that area remains anesthetized. Most children require sedation in addition to the IVRA.

At the end of the procedure, the distal tourniquet may be released for 15 seconds, then reinflated. The tourniquet may be released and reinflated two additional times. This allows some of the local anesthetic into the systemic circulation at short intervals to avoid local anesthetic toxicity from a large amount of local anesthetic being released all at once. At least one cuff should remain inflated for at least 20 minutes after injection of the local anesthetic, regardless of the length of the procedure.

Dosing

Either lidocaine or prilocaine may be used for intravenous regional anesthesia. Bupivacaine is contraindicated because of its ability to produce cardiotoxicity if it reaches the systemic circulation. When using lidocaine 0.5% or prilocaine 0.5%, use 0.6 mL/kg for the upper extremity and 1 mL/kg for the lower extremity.

In a study of 249 children older than 3 years, either lidocaine 0.5% or prilocaine 0.5% was used for reduction of forearm fracture (Davidson et al., 2002). The dosage used in this study was 0.6 mL/kg (or 3 mg/kg of local anesthetic). The group who had received the lidocaine had better analgesia than the prilocaine group, with fewer cases of what was considered to be unacceptable pain during reduction of the fracture. There were no adverse events.

To improve block conditions, fentanyl 1 mcg/kg or pancuronium 0.01 mg/kg may be added to the local anesthetic solution. Although used in adults, these additives have not been proven to be beneficial in children.

Complications

Prilocaine can produce methemoglobinemia if injected systemically. Neurotoxicity and seizures may occur from lidocaine if the tourniquets fail or are released prematurely. For this reason, IVRA is not indicated for children with underlying seizure disorders. Children with sickle cell disease or vascular insufficiency should not receive IVRA because of the risk of prolonged tourniquet time.

TOPICAL ANESTHESIA

Topical anesthesia for a child may be applied as a cream, by local infiltration to anesthetize the skin, or by topical application of local anesthetic directly to mucous membranes.

Topical local anesthetic cream was developed in the 1990s and has found popularity in the pediatric population for anesthetizing the skin before minor procedures. Eutectic Mixture of Local Anesthetic (EMLA) cream, a mixture of prilocaine and lidocaine, was the first commercially available agent that anesthetized intact skin to a depth of 5 mm (Ehrenström et al., 1983). This mixture of prilocaine and lidocaine results in an oil-and-water emulsion that has a total local anesthetic concentration of 5%. It has been found to be effective for superficial procedures such as venipuncture, laser treatment of port wine stains, and neonatal circumcision (Mannuksela and Korpela, 1986; Ashinoff and Geronemus, 1990; Taddio et al., 1997). EMLA cream has been found to reduce the neonatal physiologic response to circumcision when compared with placebo, but it is not considered as effective as dorsal nerve block or penile ring block (Lander et al., 1997; Taddio et al., 1997; Howard et al., 1999).

EMLA cream is applied to intact skin at least 1 hour before the time of the procedure and covered with an occlusive dressing (Morgan-Hughes and Kirton, 2001). Heating the EMLA cream with an external heat pack after application has been shown to reduce the time to efficacy to 20 minutes, although a 60-minute waiting period is better (Liu et al., 2003). EMLA cream should not be applied to traumatized or inflamed skin or to mucosal membranes because of its potential for rapid absorption and systemic toxicity.

ELA-Max, which consists of 4% liposomal lidocaine, is commercially available for use as a topical anesthetic for minor procedures and is marketed as requiring only 30 minutes to be effective. In a study comparing ELA-Max with EMLA during venipuncture in 120 children, the local anesthetic creams were applied at either 30 or 60 minutes before the procedure (Eichenfield et al., 2002). Both were effective, and the study demonstrated that a 30-minute application of ELA-Max without an occlusive dressing was as effective as a 60-minute application of EMLA with an occlusive dressing.

Local infiltration prior to minor procedures is effective as a method to provide pain relief during needle puncture or superficial incision. Although any local anesthetic can be used for injection, there is no benefit to using higher concentrations for most indications. Lidocaine 0.5% will provide immediate analgesia to the site and be effective for 90 minutes. If a longer duration is desired for pain relief after the procedure, bupivacaine 0.25% can be used and will provide 2 to 3 hours of postprocedure analgesia. When using bupivacaine for local infiltration, one must be extremely careful to avoid injecting the local anesthetic into vascular structures. To decrease bleeding at the site during the procedure, epinephrine 2.5 to 5 mcg/mL is added to the local anesthetic solution. Plastic surgeons often increase the amount of epinephrine to 10 mcg/mL or 1:100,000 to keep the field clear of blood.

Maximal allowable dosage guidelines are the same for local infiltration as they are for other regional blocks. A total of 5 mg/kg of lidocaine, or 7 mg/kg lidocaine when epinephrine is added, can be used safely (Berde, 1993). When using bupivacaine with or without epinephrine, 3 mg/kg is the maximal allowable dosage. A simple rule of thumb when using bupivacaine 0.25% (2.5 mg/mL) is to not exceed 1 mL/kg of local anesthetic solution; therefore, the child never receives more than 2.5 mg/kg.

To use local infiltration in an awake child, measures should be taken to decrease the pain of the injection. The child should be secured to limit movement during the injection and the procedure. A small-gauge (e.g., 27-gauge) needle should be used, and the injection should be performed slowly to minimize the pain that occurs with dissection of the superficial layers of the skin during injection. To further minimize pain, sodium bicarbonate is added to the solution at 1 mL per 10 mL of lidocaine to increase the pH of the solution to physiologic values (Momson et al., 2000). This buffered solution will decrease the discomfort from the injection, because the lidocaine without buffer is more acidic (Christoph et al., 1988; Orlinksky et al., 1992).

Topical anesthesia may be applied by several methods to the *mucous membranes* of the nose and nasopharynx to decrease the discomfort associated with bronchoscopies, nasotracheal intubation, nasogastric tubes, or nasal airways. Lidocaine is available as a 5% ointment or a 2% jelly. For mucous membranes, the 2% jelly is easy to apply and can be used on a greater surface area because of its lower concentration. The jelly may be simply applied to the nares and the tube for passage into the nose, and pledgets with the lidocaine jelly applied to the tip can be gently placed posteriorly in the nasopharynx to anesthetize that region. Although there are methods of delivering lidocaine as a nebulizer or spray, it is difficult to control the amount delivered, and at concentrations of 4%, it is easy to overdose a small child with this method. Peak plasma concentrations that are greater than the toxic levels are reached within 1 minute

after the application of the 4% lidocaine spray because of its fast absorption (Eyres et al., 1978). If this route is preferred by some practitioners, every attempt should be made to provide only the maximal allowable dosage and to be alert for the potential of local anesthetic toxicity that can occur because of the high uptake from this vascular area.

PRACTICAL CONSIDERATIONS TO PEDIATRIC REGIONAL ANESTHESIA

Despite the demonstrated benefits of regional anesthesia, there are many obstacles to its incorporation. Start-up regional programs face a multitude of challenges and require tools and education for success. The following are suggestions to incorporate regional anesthesia into your pediatric practice.

The dilemma of time: Regional anesthesia procedures in pediatrics are frequently performed in the operating room arena (whereas for adults, they usually occur in a presurgical block room), and are thus frequently met with resistance by surgeons who view them as an anesthesia delay. This misperception can be broken by starting the practice with the blocks that take the least time to perform, and by being efficient and demonstrating consistent results. Find simple approaches to each block, get proficient with these as you establish yourself and the regional program, and then branch out as the program grows. A satisfied parent and calm child will quickly convince the surgeons of the benefits of regional techniques.

Streamline the process: Any new undertaking has natural limiting steps, but by standardizing the process you will save time and energy. Patient and parent preoperative education can be simplified by distributing brochures describing the basic concepts of regional anesthesia, at their preoperative visit. A standardized form that adheres to documentation and billing criteria should help with the process (Gerancher et al., 2005). The steps required to gather equipment can be eliminated by devising block carts that contain all the necessary supplies. Postoperative block order sheets will improve patient care and minimize pain-related phone calls.

Money talks: Regional supplies and additional personnel consume departmental and hospital resources. To be appropriately reimbursed, review procedural coding and billing for the various blocks and postoperative pain management procedures.

Education: Regional anesthesia produces results only when a team approach is used. Involve and educate your surgeons, nurses, physical therapists, and pharmacists on the perioperative expectations for your patients. This includes benefits of techniques and adjunctive therapies, and how to recognize complications.

SUMMARY

Regional anesthesia for children continues to progress because of the development of improved local anesthetics and pediatric-sized equipment, the advent of ultrasound, improved patient safety, and efficacy. As the field grows, it may become the primary method of providing both intraoperative and postoperative analgesia if strategies continue to diminish the risks, and if studies are carried out to promote the benefits (Goldman, 1995; Dalens and Mazoit, 1998).

Experienced practitioners in pediatric regional techniques provide an important service to children. Additional research must be directed at outcome studies to determine the true risks and benefits of these techniques in large populations of children. With advanced training and appropriate use of agents and equipment, the practice of pediatric regional anesthesia as a means of providing superior analgesia will continue to be an essential part of the overall care of children in the perioperative period.

Advances in obstetrics and neonatology have greatly improved neonatal survival, especially for preterm neonates (Fig. 17-1). Because the survival rate of premature infants is on the rise, so is the need for anesthesia and surgery for these patients. To safely care for newborns in the operating room, anesthesiologists must appreciate and understand the enormous physiologic variability that exists among infants born between 23 and 44 weeks of gestation, so they can better understand how immature organs respond to surgery and anesthetic agents. Fetal development is also relevant, because fetal surgery is a reality in many medical centers, and providing anesthesia for midgestation fetuses (20 to 23 weeks' gestation) via the mother poses a completely new set of challenges (Hirose et al., 2004). The purpose of this chapter is to present background information that will allow anesthesiologists to better understand the problems of neonates and to provide safe care for these patients based on an understanding of neonatal physiology. The preoperative evaluation of the neonate is arguably the most important part of anesthetic care.

Although some congenital anomalies are obvious at birth, others, such as gastrointestinal dysfunction, various central nervous system (CNS) malformations, or metabolic disorders, may not develop until later in life. In general, if one congenital anomaly is present, the anesthesiologist must be

suspicious that there are others. Box 17-1 provides a list of disease entities and coexisting anomalies, and this list may be useful as part of a preoperative assessment (Jones and Pelton, 1976).

Neonatologists and the intensive care nurses are the best sources of information required for the anesthesiologist to understand a patient's clinical status. Because they have spent hours at the infant's bedside, the neonatal intensive care nursery (NICU) staff are able to provide critical insight about effective ventilatory strategies, positioning and its effect on oxygenation, responses to and requirements for intravenous fluids (e.g., blood pressure, heart rate, and urine output), tolerance to glucose administration, and temperature stability. Preparation for anesthesia and surgery requires detailed preoperative consultation with the NICU staff to establish the framework for temporarily transferring care to the operating room while avoiding dangerous and unnecessary alterations in care. In fact, developing an effective relationship with the NICU staff makes it easier to rapidly obtain intraoperative consultation with the primary medical team and communicate with the family. The anesthesiologist must understand the principles of neonatal anesthesia and surgery, the normal course of development, the pathophysiology of neonatal disease states, and the glossary of terms used to describe both neonates and their diseases

■ **FIGURE 17-1.** Percent mortality for low-birth-weight infants born at University of California, San Francisco.

DEVELOPMENT OF THE FETUS AND THE INTRAUTERINE ENVIRONMENT

The intrauterine environment has dramatic effects on growth and on the ability of neonates to adapt to extra-uterine life. Although the impact of intrauterine events is most obvious during the first few hours and days of life, the effects of these events can last much longer. For example, phenytoin, thalidomide, alcohol, and maternal drug use has caused well-described syndromes, alterations in somatic growth, or drug-dependence and withdrawal (e.g., opioids or amphetamines). Exposure to drugs during pregnancy has been associated with anomalies of the heart, pulmonary circulation, brain, and other organs (e.g., cleft lip and palate) (Puhó et al., 2007).

During intrauterine life, fetuses expend little energy maintaining their body temperature. The placental circulation provides essential substrates and eliminates waste products. The fetus' primary activity is growth, which proceeds under conditions that at first glance appear hypoxic. However, fetal P_{aO_2} of no more than 20 to 30 mm Hg, plus a hemoglobin concentration of 18 to 20 g/dL, an oxygen dissociation curve that is shifted to the left (P_{50} , 18 mm Hg), and a higher cardiac output (CO)/kg, provide sufficient oxygen content in blood to the fetal heart and brain. This can be demonstrated with the following formula:

$$([\text{Hb} \times 1.34 \text{ cc O}_2/\text{g Hb}] \times \text{Sao}_2) + 0.03 \text{ cc O}_2 \times \text{Pao}_2$$

However, the fetus is at a great disadvantage—it has no store of oxygen beyond that in its blood, because the lungs are filled with fluid and not gas (Dudenhausen et al., 1997). After only a minute of umbilical cord occlusion, the fetus'

- Intracranial mass
- Skull fracture
- Hydrocephalus
- Subdural hemorrhage
- Spinal tumor

P_{aO_2} is less than 5 mm Hg. At the same time, the P_{aCO_2} steadily rises and the pH rapidly declines. The effects of intrauterine asphyxia can be sudden and profound, and they are often associated with severe hypoxia, hypotension, and acidosis (Fig. 17-2).

LABOR AND DELIVERY AND PERINATAL EVENTS

The neonate's respiratory rate increases briefly with the onset of asphyxia (see Fig. 17-2). Primary apnea quickly follows and lasts a variable amount of time. This is followed by slow gasping respirations and then by terminal apnea and death unless resuscitation is begun (Dawes, 1968). The heart rate and arterial blood pressure increase moderately, and bradycardia and

■ **FIGURE 17-2.** The effects of intrauterine asphyxia on vital signs and blood gases. BP, blood pressure; CC, cardiac compression; IPPV, intermittent positive pressure ventilation. (From Sinha SK, Donn SM: *Fetal-to-neonatal maladaptation*, Semin Fetal Neonatal Med 11:166-2006.)

hypotension follow. Because Cardiac Output (CO) is mostly dependent on heart rate in neonates, the severe, deep reduction in heart rate associated with asphyxia significantly reduces CO (Klopfenstein and Rudolph, 1978). To compensate for this reduction, blood flow is centralized to maintain blood flow and oxygen delivery to the brain, heart, and adrenal glands. The arterial blood pressure increases during gasping respirations and decreases markedly during terminal apnea. Heart rate, CO, and arterial blood pressure quickly improve with resuscitation. However, the metabolic component of acidosis may worsen as the pH_a is corrected, because fixed acids are washed out of the periphery by the improved peripheral perfusion. If the pH does not improve with ventilation alone, an infusion of tromethamine (Tham) or sodium bicarbonate may be necessary. The lungs should be ventilated if sodium bicarbonate is administered, because each milliequivalent of sodium bicarbonate (when fully reacted with hydrogen ion) produces 25 cc of CO_2 that must be removed via the lungs.

Labor and Delivery

Labor, fetal movements, and uterine contractions initiate removal of the 30 mL/kg of fluid that are normally present in the fetal lungs (Harding and Hooper, 1996). During labor, compression of the fetal chest by the uterus and vagina removes some of the lung fluid (Harding et al., 1990). After birth, breathing increases clearance of the lung fluid via the pulmonary capillaries and the lymphatics (see Pulmonary System, p. 518). The specific mechanism that initiates breathing at birth remains unclear, but several factors are known to play critical roles. First, placental factors that inhibit breathing in utero are removed by clamping the umbilical cord (Alvaro et al., 2004, 1997). Second, at birth the sudden release of the circumferential pressure around the chest allows the neonatal chest to recoil outward and draw gas into the lungs (Karlberg et al., 1962). Third, tactile stimulation and environmental thermal changes at birth stimulate breathing (Sinha and Donn, 2006). Lastly, the effects of hypoxia and hypercarbia on the chemosensors stimulate breathing (Taeusch et al., 2005).

Neonatal Asphyxia

Chronic intrauterine asphyxia affects placental blood flow, and placental infarction adversely affects fetal growth. In cases of chronic intrauterine asphyxia, labor may be poorly tolerated and neonatal resuscitation may be necessary. When neonatal resuscitation is required, primary or secondary consequences of asphyxia, including acidosis, seizures, transient cardiac dysfunction (e.g., cardiomyopathy or tricuspid insufficiency), pulmonary hypertension, renal insufficiency (e.g., acute tubular necrosis), gastrointestinal/hepatic insults (e.g., necrotizing enterocolitis [NEC]), or clotting abnormalities may occur.

Postnatal asphyxia is often the result of a continuum of intrauterine events, but it may also be caused by events that occur during labor and delivery. Immature respiratory control mechanisms can predispose neonates, especially premature neonates, to life-threatening responses to asphyxia. For example, the response to hypoxia during the first 3 to 4 weeks of life can be paradoxical, in that hypoxia produces a brief period of hyperpnea that is followed by bradypnea (Cross and Oppe, 1952; Brady and Ceruti, 1966). Hypothermia and hypercapnea blunt the initial hyperpnea (Ceruti, 1966; Rigatto et al., 1975). The ventilatory response to carbon dioxide increases with both postnatal and gestational age (see Chapter 3, Respiratory Physiology in Infants and Children) (Rigatto et al., 1975).

Although hypoxia may inflict long-term consequences on the fetus and newborn, hyperoxia can also cause significant morbidity, especially for preterm infants. For example, hyperoxia exposes preterm infants, especially those born before 32 weeks' gestation, to a significant risk for retinopathy of prematurity (ROP; see below) and, in some cases, blindness (see Chapter 27, Anesthesia for Ophthalmic Surgery) (Sylvester, 2008). The normal Pao_2 of a fetus is 20 to 30 mm Hg. After birth, a Pao_2 of 60 mm Hg is probably hyperoxic for infants born at 24 to 36 weeks' gestation. To avoid the effects of oxidative stress in the newborn, the oxygen saturation for premature infants is usually maintained between 88% and 93% (Pao_2 of 45 to 60 mm Hg) in the NICU, and similar Sao_2 levels are appropriate in the operating room. Continuous measurement of Sao_2 makes it easier to maintain the desired oxygen saturation. Of note is one preterm infant, who never had an elevated Pao_2 except in the operating room, but who developed ROP after surgery (Betts et al., 1977).

Metabolic Status: Early Postnatal Period

Thermal Environment

In a neutral thermal environment, neonates expend the least amount of energy to maintain their body temperature. The oxygen consumption ($\dot{V}O_2$) of normal neonates is 6 cc/kg per minute, twice that of resting adults. During the first week of life, $\dot{V}O_2$ increases to about 10 cc/kg per minute and may be twice that during heat-related stress. Because of their high oxygen consumption, greater CO, and smaller reserve of oxygen (i.e., smaller functional residual capacity [FRC]), neonates, especially preterm neonates, develop hypoxia more quickly than adults. In fact, hypoxia may develop in as few as 10 seconds in apneic neonates, whereas it takes several minutes for this to occur in adults (Peabody et al., 1978a, 1978b).

Sodium, Calcium, and Glucose

Box 17-2 contains common fluid and electrolyte requirements for neonatal infants. Because premature, large-for-gestational age (LGA), small-for-gestational-age (SGA), and asphyxiated neonates are often hyper- or hypoglycemic, intravenous glucose may be required to maintain normoglycemia (serum glucose concen-

tration of 40 to 90 mg/dL; see Glucose Metabolism, p. 537) (Jain et al., 2008). Similarly, calcium homeostasis is often difficult to achieve in sick infants (Bass and Chan, 2006). Initial calcium administration is usually based on normal neonatal requirements and on need, as determined by serial ionized calcium measurements. Calcium should be infused into a well-functioning intravenous catheter to avoid extravasation of calcium into the tissues and severe tissue necrosis. During surgery the calcium infusion site is usually under the surgical drapes and hard to see. Therefore, calcium should be infused into a reliable intravenous catheter, preferably a central venous catheter.

For the first 2 to 3 hours of life, the neonate's electrolyte concentrations reflect those of the mother and of perinatal events (e.g., asphyxia, or placental or umbilical cord hemorrhage). Afterward, the electrolyte concentrations reflect a balance between normal metabolism, renal and hepatic function, and ongoing metabolic derangements (e.g., sepsis, inherited metabolic diseases, hemolysis, or inborn errors of metabolism). Until tissue perfusion is adequate, resuscitated neonates usually have ongoing metabolic acidosis.

In full-term and near-term infants, sodium is seldom added to intravenous fluids during the first 24 hours of life. Urine output is low, despite the fact that 30 mL/kg of fluid must be removed from the lungs during and after birth (Herin and Zetterström, 1994). On the second day of life, maintenance sodium (2 to 4 mEq/kg per day) is added to the intravenous fluids to replace renal and gastrointestinal tract sodium losses, to compensate for abnormal fluid metabolism, or to counter the effect of diuretics (e.g., furosemide). In the extremely low-birth weight (ELBW) infant, fluid that contains sodium is often administered to maintain adequate intravascular volume, especially when transcutaneous fluid losses are excessive. After the first few days of life, an adequate sodium intake is essential for infants of all gestational ages to permit normal growth.

GESTATIONAL AGE

The SGA Infant

In part, perinatal problems are related to gestational age and birth weight (Box 17-3). Infants who weigh less than the 10th

Box 17-2 Common Intravenous Fluid and Electrolyte Requirements in the Newborn

GLUCOSE

Most newborns require 2 to 4 mg/kg per minute. SGA and LGA infants may require >15 mg/kg per minute on days 1 to 3 of life. Glucose tolerance may fluctuate significantly in VLBW and ELBW infants.

SODIUM

Most newborns require no sodium for the first 24 hours of life. On day 2 and beyond, most newborns receive 2 to 4 mEq/kg per day. Sodium requirements may change dramatically in response to gastrointestinal, genitourinary, or transcutaneous losses, or drug or metabolic effects. The ELBW infant may have huge transcutaneous fluid losses, requiring meticulous monitoring and replacement.

POTASSIUM

Requirements for potassium are minimal for the first 24 to 48 hours of life. Subsequently, maintenance delivery is about 1 to 3 mEq/kg per day, always in the presence of a normal urine output. Serum levels in the newborn, especially VLBW and ELBW infants, are higher than in older infants. Replace gastrointestinal, genitourinary, or iatrogenic losses cautiously.

CALCIUM

Requirements for calcium range between 200 and 400 mg/kg per day (calcium gluconate). Requirements for calcium vary with gestational age, history of asphyxia, and growth disturbances (SGA, LGA). Serum levels can be obtained for total Ca^{2+} or ionized Ca^{2+} .

Box 17-3 Common Metabolic and Structural Problems in SGA and LGA Infants

SGA

Congenital anomalies
Chromosomal abnormalities
Chronic intrauterine infection
Heat loss
Asphyxia

Polycythemia and hyperbilirubinemia

LGA

Birth injury (brachial, phrenic nerve, fractured clavicle)
Asphyxia
Meconium aspiration
Metabolic abnormalities (hypoglycemia, hypocalcemia)
Polycythemia and hyperbilirubinemia

percentile of weight for gestational age at birth are usually considered to be small for their gestational age. SGA infants have different problems from those of preterm infants (fewer than 37 weeks' gestation) of the same weight (Lubchenco et al., 1963). Consequently, it is necessary to relate birth weight to gestational age. Although primary fetal (e.g., chromosomal disorders) and maternal (e.g., smoking or chronic disease) factors have been linked to intrauterine growth retardation, SGA is often the result of placental insufficiency. SGA newborns are often hypoglycemic because they have abnormally low glycogen stores. They commonly respond to placental insufficiency by increasing their red-blood-cell mass. Although an increase in red-blood-cell mass (polycythemia) increases the oxygen-carrying capacity of blood, polycythemia also has been associated with hyperviscosity, as well as renal failure, NEC, and CNS injury, especially if the hematocrit value exceeds 65% (Pallotto and Kilbride, 2006; Rosenberg, 2008). If the hematocrit value is higher than 65% in well-hydrated neonates, an exchange transfusion should be considered to reduce the hematocrit level to 55% or lower before surgery, although there is no evidence that doing so for patients who are not having surgery improves outcome (Dempsey and Barrington, 2006). However, the combination of polycythemia, hypotension, and dehydration that are common in sick SGA infants during anesthesia and surgery may increase their risk for hyperviscosity-related problems. Arterial blood pressure should be kept normal or slightly elevated throughout surgery. SGA infants may be relatively dehydrated at birth and usually do not lose the normal 200 to 300 g of weight that appropriate-for-gestational-age (AGA) neonates lose over the first 2 to 3 days of life. SGA neonates usually gain weight from birth. In spite of their low birth weights, the heart rates and blood pressures of SGA infants are similar to those of AGA infants of similar gestational ages. SGA neonates have similar incidences of hyaline membrane disease (HMD) to AGA babies of the same gestational age.

The LGA Infant

LGA infants are prone to birth injuries (e.g., fractures or intracranial bleeds) (Lawrence, 2007). Those born to diabetic mothers (a common reason for LGA) may have difficulty maintaining normal blood glucose concentrations and glucagon may be required to do so (Van Howe and Storms, 2008). On occasion, tracheal intubation may be difficult in LGA babies because of fat deposits in their mouth, tongue, and neck. Finding adequate insertion sites for intravenous fluid may be difficult because the veins are buried in tissue. It may be necessary to insert a central venous catheter or an external jugular vein catheter to ensure adequate intravenous access.

Very Low-Birth Weight and Extremely Low-Birth Weight Infants

Further subclassification of infants by both age and weight have been created and give further prognostic information regarding morbidity and mortality. In the 1960s, *low birth weight (LBW)* defined infants weighing less than 2500 g. As survival improved in these infants, the term *very low birth weight (VLBW)* was used to describe infants with birth weights of 1500 g or less. As survival of infants weighing less than 1000 g improved, the term *extremely low birth weight (ELBW)* was used to categorize these infants.

THE PREMATURE INFANT

Prematurity is defined as birth before 37 weeks of gestation. Premature infants account for 12.8% of all births in the United States (646,047 of 4,265,996), and the incidence has increased 21% since 1990 (Martin et al., 2008). The increase has been most dramatic between the gestational ages of 34 to 36 weeks (Davidoff et al., 2006). While the rates of VLBW (fewer than 1500 g) and ELBW (fewer than 1000 g) deliveries remained relatively unchanged from 2005 to 2006, the percentage of moderately low birth weight (1500 to 2499 g) deliveries increased slightly. In 2005, short gestation and low birth weight was the second leading cause of infant death (16.5%), ranked only below congenital malformations (19.5%) (Martin et al., 2008). However, in non-Hispanic black, and Puerto Rican infants, disorders related to short gestation and low birth weight were the leading causes of death. Today, the Centers for Disease Control (CDC) recognize prematurity, not birth defects, as the leading cause of infant mortality in the United States (Andrews et al., 2008).

Although premature infants share some common features, the physiologic variability between 24 and 36 weeks' gestation is enormous. An infant at 36 weeks' gestation is much more similar to a term infant than to infants born before 30 weeks' gestation. For this discussion, premature infants are arbitrarily divided into subgroups based on gestational age.

Late Preterm (35 to 37 Weeks' Gestation)

In the absence of congenital anomalies or perinatal asphyxia, infants born between 35 and 37 weeks' gestation usually do well and have few of the common medical or surgical problems found in more premature infants. However, late preterm birth is associated with increased mortality (threefold higher than term infants), respiratory distress or apnea requiring support, and rehospitalization (Escobar et al., 2006; Tomashek et al., 2007). In addition, sepsis and intrapartum complications, centered on the placenta and cord, have contributed to increased mortality in late preterm infants (Tomashek et al., 2007). In addition, late-preterm infants may have some difficulty attaining full feeds, and the incidence of hyperbilirubinemia (not associated with Coombs' positivity or ABO/Rh incompatibility) occurs more commonly in late preterm infants than in term infants. Late-preterm infants born to diabetic mothers may have pulmonary immaturity and respiratory distress syndrome (RDS) (Deorari et al., 1991). Late-preterm infants born to nondiabetic mothers usually have similar lung function to that of term infants. Most surgical intervention in this group of patients is for treatment of congenital anomalies.

The rate of late preterm birth has increased 25% since 1990, and attention has been drawn to the increased mortality associated with late-preterm compared with term gestation (Escobar et al., 2006; Shapiro-Mendoza et al., 2006; Engle et al., 2007; Tomashek et al., 2007; Martin et al., 2008; McIntire and Leveno, 2008). The morbidity and mortality rates of late-preterm infants are particularly noticeable because of the large number of births at this developmental stage; in 2006, late-preterm births accounted for more than 71% of all preterm births (9.14%) (Martin et al., 2008). However, the long-term outcome of this group has not been well documented, in part related to the longstanding view of this group as "near term" rather than late preterm (Jain, 2007).

30 to 34 Weeks' Gestation

For the sake of this discussion, infants born between 30 and 34 weeks' gestation are considered to be similar, but the physiologic differences between a 30- and a 34-week gestation newborn can be significant. Infants at 30 weeks' gestation (≈ 1200 g) have more of the common problems of prematurity than infants at 34 weeks' gestation (≈ 2000 g).

Before the introduction of exogenous pulmonary surfactant into clinical practice, this group of infants often had RDS, also known as HMD (see Respiratory Distress Syndrome, p. 520). Complications of their respiratory care, including pneumothorax, pulmonary interstitial emphysema, chronic lung disease (CLD), and blood loss from repeated blood sampling, were common. Treatment of RDS with surfactant has dramatically reduced the incidence and severity of this disease and its complications. The sequelae of pulmonary immaturity and of the supportive care used to treat lung immaturity are fewer and less severe since the introduction of exogenous surface-active material (SAM). However, a new form of bronchopulmonary dysplasia (BPD), called *new BPD*, occurs in small preterm infants (Bancalari, 2001; Bancalari and del Moral, 2001). Approximately 20% to 25% of these infants have some form of CLD.

Although uncommon in infants after 34 weeks' gestation, newborns with a gestational age of 30 to 32 weeks often demonstrate temperature instability, especially if they are septic or asphyxiated. Feeding intolerance is also common, and it may take weeks before effective oral feeding and consistent weight gain occur. Before adequate enteral feeds are established, infants born at 30 to 34 weeks' gestation are often hypocalcemic or hypoglycemic. They are also prone to NEC, especially if they have a large patent ductus arteriosus (PDA) with significant left-to-right shunting of blood (Kitterman, 1980). Because enteral feeds must be advanced slowly, peripheral or central intravenous alimentation may be required for some time. Parenteral nutrition, for even 1 to 2 weeks, can cause hepatic and renal toxicity (Moreno Villares, 2008).

The incidence of a PDA is high (20% to 30%) in infants of this gestational age, but the hemodynamic consequences are often mild. Their PDA commonly closes spontaneously. If it does not close, chemical (with indomethacin) or surgical closure of the PDA may be necessary. The incidence of intracerebral hemorrhage (ICH) is higher in this age group and increases with decreasing gestational age, sepsis, asphyxia, or precipitous birth. Apnea is also more common at this developmental stage, especially in those infants who have sepsis, temperature instability, metabolic abnormalities (e.g., hypoglycemia or hypocalcemia), or anemia (Theobald et al., 2000).

27 to 29 Weeks' Gestation

The incidence and severity of pulmonary, cardiovascular, gastrointestinal, and neurologic complications are magnified in infants of this gestational age. A key feature is the variability of their disease processes. Some become "growing preemies" after 1 to 2 weeks, and others have multisystem dysfunction and poor growth and development for months.

The fragile skin and the absence of subcutaneous tissue in infants with fewer than 30 weeks' gestation result in temperature instability, enormous caloric expenditure to maintain body temperature, and significant transcutaneous fluid losses. Perioperative apnea is much more common in this group.

Fewer than 26 Weeks' Gestation

This group of patients is rapidly increasing because of increased survival rates, and they often have long-term pulmonary, neurologic, and gastrointestinal sequelae. The rate of progress in the NICU, in the incidence and severity of complications, and in the amount and urgency of surgical procedures is enormously variable at this gestation.

In this group of patients, the CNS is fragile, and ICH is common (Kadri et al., 2006). The severity of ICH is a common determinant of an infant's prognosis and long-term outcome, and it correlates with later neurologic injury (see The Central Nervous System, p. 528). Apnea and perioperative pulmonary insufficiency occur often and may persist for months. From the first few weeks to the first months of life, most infants of this developmental stage require mechanical ventilation, continuous positive airway pressure (CPAP), or an increased inspired oxygen concentration after surgery. Ventilatory support is often required, even if these interventions were not necessary preoperatively. Prolonged tracheal intubation is occasionally required and may lead to subglottic stenosis and lower airway obstruction.

REVIEW OF SYSTEMS AND DEVELOPMENTAL PHYSIOLOGY

Head and Neck

Anatomic differences of the head and neck between neonates and older patients make the management of the neonate's airway challenging (Dickison, 1987). The cricoid ring is the narrowest portion of the neonate's upper airway because the larynx has been thought to be cone shaped, rather than cylindrical as it is after 5 years of age (Coté et al., 1993). However, this concept has been challenged (Litman et al., 2003; Dalal et al., 2009; Motoyama, 2009). These newer studies indicate that the shape of the larynx is cylindrical, as it is in adults, but the cricoid ring remains the fixed and narrowest point of the upper airway system.

The narrowest portion of the cone is the cricoid ring. This is, in part, because the neonate's posterior larynx is more cephalad than the anterior larynx. When looking from above, the cricoid ring is really an ellipse and not a circle. By 5 years of age, the posterior larynx descends, the cricoid ring is circular, and the vocal cords are the narrowest portion of the airway (as they are in adults). These anatomic differences place the neonatal larynx in a more cephalad position than it is later in life. The epiglottis is relatively large, which makes it more difficult to lift with a laryngoscope blade. In fact it is easier to use a straight laryngoscope blade like a curved blade, place the tip in the vallecula, and pull up and out at a 45-degree angle to bring the glottic opening into view. The cephalad larynx and relatively large tongue also make it more difficult to maintain an airway or to intubate the trachea. However, the neonate's large occiput naturally places the head (when looking straight forward) in the "sniffing" position (i.e., an optimal position to ventilate the lungs and intubate the trachea). Extension or flexion of the head usually makes it more difficult to bag-and-mask ventilate the lungs and to intubate the trachea. A small jaw (micrognathia) or receding jaw (e.g., Pierre-Robin or Treacher-Collins syndromes) may make it difficult or impossible to directly visualize the vocal cords. A large tongue (as with

hypothyroidism, Down syndrome, or Beckwith-Wiedemann syndrome) can also make tracheal intubation difficult or impossible. Techniques other than direct laryngoscopy may be needed to intubate the trachea of these infants (see Chapter 12, Airway Management).

Cleft lip, with and without a cleft palate, occurs in 1:600 to 1000 live births and is associated with other congenital defects in 13% to 50% of patients (see Chapter 25, Anesthesia for Plastic Surgery) (Arosarena, 2007). Tracheal intubation is occasionally more difficult in patients with a cleft palate because it may be difficult to fix the patient's tongue against the palate with the laryngoscope blade. If the tongue cannot be fixed against the palate, it may flop over the laryngoscope blade and block the view of the glottis. Choanal atresia occurs in 1:7000 to 1:8000 live births and is often diagnosed in the delivery room when a catheter cannot be passed through a nostril into the pharynx or when the neonate cannot breathe and becomes cyanotic and bradycardic when the mouth is closed and the airway is totally obstructed (see Chapter 12, Airway Management) (Samadi et al., 2003). Thus, when using bag-and-mask ventilation on patients who have choanal atresia, the mouth must be kept open or an oral airway must be inserted. Some patients who have choanal atresia have the CHARGE association, which is defined through the acronym as follows: *C*, Colobomatous malformation; *H*, Heart defect; *A*, Atresia choane; *R*, Retardation; *G*, Growth deficiency/Genital hypoplasia; and *E*, Ear anomalies (Sanlaville and Verloes, 2007).

Hemangiomas, lymphangiomas, and hygromas of the neck often obstruct the upper airway. Careful preoperative evaluation, including computerized tomography (CT) scan when appropriate, helps determine whether a lesion impinges on the airway. Patients with laryngeal or tracheal hemangiomas are of special concern, because tearing the hemangioma during tracheal intubation may result in airway hemorrhage and blood aspiration.

The Pulmonary System

Development

Lung development is divided into the following five stages:

1. The embryonic stage (weeks 4 to 6 of gestation), when early upper airways appear.
2. The glandular stage (weeks 7 to 16), when the lower conducting airways form.
3. The canalicular phase (weeks 17 to 28), when the acini develop.
4. The terminal sac period (weeks 28 to 36), when the first respiratory units for gas exchange (terminal air sacs and surrounding capillaries) make their appearance.
5. The alveolar phase, when alveoli develop.

The latter stage begins at about 36 weeks' gestation and continues until at least 18 months of age (Langston et al., 1984; Kotecha, 2000a, 2000b; Joshi and Kotecha, 2007). Knowledge of these phases of lung development allows estimation of when the various lung malformations occur in utero. For example, malformations of the conducting airways (e.g., cystic adenomatoid malformation) occur before 16 weeks' gestation. Upper airway abnormalities occur by 6 weeks' gestation, bronchial malformations between 6 and 16 weeks of gestation, and lung hypoplasia after 16 weeks' gestation. In general, extrauterine viability

is increased after 26 weeks' gestation, because the respiratory saccules have developed and the capillaries are in close approximation to the developing distal airways. Before this time, both the vascular network and surface area in the lungs may be inadequate for gas exchange. However, in the past decade many babies have survived after 24 to 25 weeks' gestation, usually with enormous effort and cost; these extremely premature infants often survive with severe CLD (Langston et al., 1984).

Most alveoli develop after birth, increasing from 20 million terminal air sacs at term to about 300 to 400 million alveoli at 18 months of age (Thurlbeck, 1982; Kotecha, 2000a, 2000b). Specific cell types are not recognizable in the lung until the canalicular stage of development (17 to 28 weeks' gestation). During the last 10% to 20% of gestation, type II pneumocytes are more commonly identified. Although present in the human fetus by 22 weeks' gestation, type II pneumocytes are more prominent after 34 to 36 weeks of gestation. The major distinguishing feature of type II cells is the presence of osmophilic lamellar bodies, which correlate closely with the presence of SAM in the lungs (Kotecha, 2000a, 2000b). The alveolar-capillary barrier is formed by type I pneumocytes (see Chapter 3, Respiratory Physiology in Infants and Children).

By 16 weeks' gestation, all subdivisions of the conducting airways have formed, including the main-stem bronchi and the conducting and terminal bronchioles. Preterm infants often require mechanical ventilation or CPAP and supplemental oxygen, which interfere with the normal, complex process of lung and airway development. The barotrauma, oxidative stress, and inflammatory injury associated with these life-saving interventions and the effects of superimposed infections predispose preterm infants to airway and lung injury and to abnormal airway resistance and reactivity (Van Marter, 2005).

The diaphragm arises in part from the third through fifth cervical somites, and myoblasts from these somites migrate into the septum transversum to form diaphragmatic muscle (Mitchell and Sharma, 2009). The central tendon of the diaphragm arises from the mesoderm of the septum transversum. Somites of the lateral chest wall form the lateral portions of the diaphragm. The nerve supply of the diaphragm is from the third through fifth cervical somites. Bilateral pericardioperitoneal canals, located lateral to the developing diaphragm, cause a Bochdalek hernia if the canals fail to close. Complete closure of the diaphragm normally occurs at 10 to 12 weeks' gestation, when the bowel is returning to the abdominal cavity from the amnion, where it resides in early gestation. If the diaphragm is incompletely formed, the returning bowel follows the path of least resistance and enters the chest. When this occurs lung growth ceases on the ipsilateral side. The mediastinum is then pushed into the opposite chest by the bowel and abdominal organs and contralateral lung growth is also reduced. Consequently, neonates who have a left-sided diaphragmatic hernia must survive with approximately two thirds of one lung or less (de Lorimier et al., 1967). In some cases, the amount of lung present is insufficient for survival (see Chapter 18, Anesthesia for General Surgery in the Neonate).

Failure of the lung buds to separate from the foregut causes a tracheal esophageal fistula (see Chapter 18, Anesthesia for General Surgery in the Neonate). The connection usually is found between the distal esophagus and the trachea, just above the carina. Failure of the distal and proximal ends of the esophagus to connect with each other results in esophageal atresia. Patients with esophageal atresia usually have copious secretions in the proximal esophageal pouch, and placing the

patient flat without removing the secretions may cause aspiration of the secretions. Placing a suction catheter in the proximal esophageal pouch and connecting it to suction reduces this likelihood.

Early Postnatal Period: Changes in Oxygenation and Pulmonary Vascular Resistance

Although removal of fluid from the fetal lung begins during labor and delivery, the major transition to an air-filled lung occurs immediately after birth. The first active inspiration after birth produces a negative intrapleural pressure of 80 to 100 cm H₂O, which is required to overcome the high surface tension, low compliance, and high resistance of the liquid-filled lungs (Scarpelli and Mautone, 1984; Vyas et al., 2005). These pressures are not necessary when artificially ventilating neonatal lungs, however. In fact, delivering large tidal volumes and high airway pressures injure neonatal lungs (Bjorklund et al., 1997). In full-term neonates, the initial few spontaneous breaths are of 20 and 80 cc O₂ each. A small fraction of this volume is expired. The gas remaining in the lung forms the residual volume (RV) and the FRC, which are required for adequate gas exchange (Avery, 1974). If removal of lung fluid is delayed (e.g., with cesarean section) transient tachypnea of the newborn (TTN) develops (Guglani et al., 2008). Neonates with TTN breathe 60 to 150 times a minute and are often hypoxic and hypercarbic. Many of them require supplemental oxygen, and some require mechanical ventilation. Diuretics fail to induce a diuresis and improve lung function until a spontaneous diuresis occurs several days after birth (Lewis and Whitelaw, 2002).

Labor reduces pulmonary vascular resistance (PVR) by approximately 10%, but the most significant decrease occurs with the onset of breathing (Bland, 1983). Lung expansion increases alveolar and arterial P_{O₂}, which dilates the pulmonary arterioles, decreases PVR and increases pulmonary blood flow (Dawes, 1974). These changes in PVR and blood flow are critical for conversion of the fetal circulation to the adult form of circulation (see Chapters 3, Respiratory Physiology, and 4, Cardiovascular Physiology). That is, transition to the gas-filled lung at birth, increased F_{IO₂} (air), and increased pH (decreased P_{aCO₂}) all interact to reduce PVR and increase pulmonary blood flow. Over the next 1 to 2 months, PVR decreases to adult levels. However, infants with cyanotic congenital heart disease (CHD) or large left-to-right shunts may have elevated PVR for months or longer (Rudolph, 2007).

The dramatic rise in pulmonary blood flow at birth increases the left atrial pressure and functionally closes the foramen ovale, preventing right-to-left shunting of deoxygenated blood through this structure. An increase in systemic vascular resistance that exceeds PVR dramatically reduces right-to-left blood flow through the ductus arteriosus. The rise in arterial oxygen tension at birth constricts and physiologically closes the ductus arteriosus in full-term but not in preterm neonates (Clyman et al., 1978). Nitric oxide (NO) and prostaglandins are important for anatomic closure of the ductus arteriosus, which usually occurs by 2 to 3 weeks of age (Born et al., 1956; Seidner et al., 2001; Clyman, 2006). If during this time hypoxia, acidosis, cold, or excessive airway pressures are present, the right atrial pressure increases and right-to-left shunting of blood can occur at both the atrial and the DA levels. When right-to-left shunting of blood occurs, hypoxemia ensues. The resulting pulmonary blood flow pattern mimics

the pattern present in utero and is often referred to as persistent fetal circulation (PFC).

Establishing normal pulmonary blood flow and ventilation increases both arterial and mixed venous oxygen tensions. Although the transition to air breathing increases the oxygen content of blood, the P_{aO₂} of the neonate is usually 55 to 85 mm Hg for the first month of life, rather than the 95 to 100 mm Hg present after that. The lower P_{aO₂} is the result of a very compliant, cartilaginous neonatal chest wall that does not recoil outward at end-expiration, as it does in older children and adults (Koch and Wendel, 1968; Davis and Bureau, 1987). Failure to recoil outward produces a transpulmonary (intrapleural) pressure of 0 cm H₂O—not -5 cm H₂O pressure, as occurs in older patients. Because negative intrapleural pressures are important for maintenance of a normal FRC, neonates are predisposed to atelectasis and a lower P_{aO₂}. In fact, application of sufficient negative pressure around the neonate's chest to produce a pleural pressure of -5 cm H₂O, increases the P_{aO₂} from about 65 mm Hg to nearly 100 mm Hg, indicating that the negative intrapleural pressure expands the lungs, increases FRC, reduces atelectasis, and improves the match of ventilation to perfusion (Thibeault et al., 1968). Application of negative intrapleural pressure, positive end expiratory pressure (PEEP), or CPAP also reduces the amount of atelectasis and improves oxygenation (Gregory et al., 1975).

In addition to its effects on transpulmonary pressure, the newborn's compliant rib cage has another unwanted effect on ventilation. That is, the cartilaginous, compliant chest wall tends to collapse inward (retract) during spontaneous inspiration, causing paradoxical chest-wall motion and limiting airflow (Knill et al., 1976). The circular configuration of the rib cage (rather than the ellipsoid rib cage of adults) and the horizontal angle of insertion of the diaphragm (rather than the oblique angle in adults) also distort the rib cage and make the diaphragm less efficient (Muller and Bryan, 1979).

Other factors also affect the infant's work and efficiency of breathing. For instance, the full-term infant's diaphragm is comprised of only 25% fatigue-resistant, slow-twitch, highly oxidative type I fibers, and the preterm infant has only 10% (the adult diaphragm has 55%). The lower percentage of type I fibers predisposes the diaphragm to fatigue (Keens et al., 1978). The intercostal muscles show a similar developmental pattern. Expression of various isoforms of the myosin heavy chains in muscle fibers of the diaphragm and the intercostal muscles of newborn and young infants may contribute to easier fatigability (Watchko and Sieck, 1993; Zhan et al., 1998). Less effective force-frequency, length-tension, and force-velocity relationships and a mismatch of energy supply and demand characterize diaphragmatic muscle and predisposes these newborns to fatigue, especially when there is widespread atelectasis (e.g., RDS) or poor chest wall compliance (e.g., anasarca) (Watchko et al., 1986; Watchko and Sieck, 1993). Methylxanthines improve neonatal diaphragmatic function (Maycock et al., 1992).

Healthy neonates breathe 30 to 60 times per minute to maintain normal oxygenation and to remove the increased amount of CO₂ produced by an oxygen consumption of 6 to 10 cc/kg per minute. This respiratory rate also helps maintain the FRC by reducing the amount of time available for expiration and by trapping gas within the lung. At normal respiratory rates, the time constant of the lungs (compliance of lungs × airway resistance [C_L × R_{aw}]) is, on average, 0.25 seconds. A slow respiratory rate, apnea, or bradypnea can reduce the FRC, especially in preterm neonates (Fig. 17-3). A low level of PEEP

■ **FIGURE 17-3.** The change in FRC of a 1550 g infant that occurred with decreasing ventilator rates without PEEP. A PEEP of 5 cm H₂O maintained the FRC at about 25 mL/kg even at 5 breaths per minute (not shown).

(5 to 7 cm H₂O) should always be added to maintain the FRC of infants and young children, especially when slow ventilatory rates are used.

Naturally occurring SAM or pulmonary surfactant is by far the most important mechanism for keeping alveoli of different sizes or diameters open. Initially, SAM appears in fetal lungs by 20 weeks' gestation, even though no functional alveoli exist (Clements, 1961). At about 35 to 36 weeks' gestation, the amount of SAM increases and is secreted onto the alveolar surface. The pulmonary surfactant monolayer creates a gas-liquid interface on the alveolar surface and drastically decreases surface tension during exhalation as the surface area decreases. During inspiration the monolayer is thinned, and the surface tension increases. SAM keeps the surface tension relatively constant regardless of the changes in the surface area and the radius of the alveoli. In neonates with RDS, there is loss of or inactivation of surfactant, and surface tension increases. The variability of surface tension normally occurring with changes in surface area is lost; alveoli develop higher pressures, collapse during exhalation, and remain collapsed (see Chapter 3, Respiratory Physiology in Infants and Children).

An additional mechanism that helps keep the alveoli open is the interdependence among alveoli, small airways, and lung parenchyma. Because the alveoli are attached to each other by connective tissues, the tendency of one alveolus to collapse during expiration pulls its neighbor open (Takishima and Mead, 1972). Millions of alveoli exerting this "pulling" effect help maintain FRC. Furthermore, blood-filled capillaries act as an exoskeleton for alveoli. If the pulmonary blood volume is inadequate, atelectasis develops. Increasing the blood volume increases FRC (Table 17-1) (Gregory, personal observation).

Thus, surfactant, intraalveolar forces, and pulmonary blood volume compensate for the lack of transpulmonary pressure at end expiration that is caused by the neonate's extremely compliant chest wall and are responsible for maintaining the infant's FRC, albeit smaller (30 cc/kg) than that of adults (50 cc/kg).

Surface Active Material

The demonstration by Avery and Mead (1959) that surfactant deficiency is the primary cause of RDS eventually led Phibbs et al. (1991) and Fujiwara et al. (1990) to use commercially

available surfactant prophylactically after birth or in the rescue mode after the symptoms of RDS were apparent. Intubated infants of fewer than 28 weeks' gestation often receive 1 or 2 doses of surfactant 12 hours apart. During preoperative evaluation of a newborn with RDS, it should be determined when the last dose of SAM was given and if an additional dose is required before surgery because of progressive atelectasis or worsening blood gases and oxygen requirement.

Pulmonary gas exchange is only possible after a significant portion of the lung fluid present in utero is removed from the airways and alveoli. Increased pulmonary lymphatic flow and surface-active phospholipids and proteins facilitate this process (Humphreys et al., 1967; King, 1982). Surfactant reduces the surface tension of the gas-liquid interface of the alveoli, keeping the air spaces open at end expiration. This reduction of surface tension is critical for the maintenance of FRC and gas exchange.

Type I pneumocytes account for more than 90% of the alveolar surface cells; type II pneumocytes, the SAM-storing cells, populate most of the remaining surface. The total weight of SAM consists of about 10% protein, 90% lipids, and 0.1% carbohydrates. The lipids lower the surface tension, but the proteins allow absorption and dispersion of the lipids in the air-liquid interface. Proteins are also necessary for reuptake of SAM by type II cells. Congenital absence of these proteins leads to a chronic RDS-like state (Yurdakök, 2004). During inspiration SAM is spread over the alveolar surface. During expiration it is compacted to lower the alveolar surface tension. SAM also stabilizes small airways and is important for pulmonary defense mechanisms (Jarstarand, 1984).

Respiratory Distress Syndrome

Neonatal RDS occurs when the quantity of SAM is insufficient or when there is delayed synthesis or release of surfactant (e.g., in infants of diabetic mothers). Giving betamethasone to the fetus, by way of the mother, before 36 weeks' gestation accelerates the production and release of SAM from the type II alveolar epithelial cells and reduces the incidence of RDS (Liggins and Howie, 1972). Typical clinical features of RDS include: early onset of tachypnea; intercostal, sternal, and suprasternal retractions; grunting respirations; oxygen desaturation; respiratory and metabolic acidosis; and death if not treated. A chest radiograph shows a diffuse reticulogranular pattern and air bronchograms (Fig. 17-4). Unless SAM is given, the natural course of RDS includes worsening symptoms for 2 to 3 days, resulting in either improvement or death. In some cases, respiratory function may deteriorate, rather than improve, because of a superinfection

■ **FIGURE 17-4.** RDS. Note the ground-glass appearance and the presence of air bronchograms. (From Brozanski BS, Bogen DL: *Neonatology*. In Zitelli BJ, Davis HW, editors: *Atlas of pediatric physical diagnosis*, ed 4, Philadelphia, 2002, Mosby.)

or complications of ventilatory support. RDS-associated death is often the result of severe lung injury induced by mechanical ventilation, sepsis, renal or hepatic failure, or CNS injury. This severe clinical pattern occurs less commonly when pulmonary surfactant is provided early. About 5% of all babies with RDS are born at term.

Before the development of commercially available surfactant, lung injury (e.g., pneumothorax, pulmonary interstitial emphysema, or BPD), blood loss from repeated blood sampling, and sepsis and its secondary effects (e.g., renal and hepatic dysfunction) were relatively common. Since 1990, exogenous SAM administration has significantly reduced the need for mechanical ventilation and oxygen therapy in preterm infants because of its effects on lung mechanics, including distensibility of the lung and end-expiratory volume stability (Morley et al., 2008). However, volutrauma (high tidal volume), and barotrauma (high airway pressure) persist in causing lung injury despite recent decreases in the incidence and severity of classic RDS and a reduction in the complications of pulmonary immaturity and supportive care. Despite all of these changes, the incidence of BPD has remained stable at about 20% (higher in ELBW infants) over the last 20 years (Bancalari and del Moral, 2001). But the BPD now seen in surfactant-treated lungs is different from classic BPD and is called *new BPD*. New BPD most commonly develops in ELBW infants, is characterized by a more uniform pattern of injury, and seems to represent an arrest of lung growth. Persistence of BPD, in spite of surfactant, suggests that other factors beside SAM deficiency contribute to BPD (Bancalari, 2001). Inflammatory and oxidative injury caused by infection, oxygen therapy, and “gentle” ventilation during periods of rapid lung growth and development, especially in the ELBW infants, seem to cause long-term pulmonary dysfunction (Kramer et al., 2009). The increased number of survivors has enlarged the number of patients (with and without BPD) requiring surgical treatment for coexisting long-term sequelae of prematurity.

Recent efforts to minimize lung injury caused by mechanical ventilation of premature infants have included introducing nasal CPAP (nCPAP) in the delivery room to prevent or treat RDS (Morley et al., 2008). This tactic avoids endotracheal intubation in patients and has markedly reduced the use of SAM. On the other hand, some infants with RDS (especially those weighing less than 1000 g) often fail a trial of nCPAP and require endotracheal intubation. They are usually treated with surfactant when their trachea are intubated.

Oxidative Injury in the Newborn

Although the role of oxygen in ROP is well established, oxygen toxicity of other organs, especially those of more mature newborns, is being increasingly recognized. Despite its widespread use for more than a century and the recognition that oxygen can be toxic for at least 50 years, the precise molecular mechanism of oxygen toxicity remains unknown (Tin, 2002). The severity of BPD has been correlated with oxygen exposure and with the oxygen saturation level used. In addition, greater oxidative injury to the heart, brain, and kidneys has been reported when neonatal resuscitation is accomplished with supplemental oxygen (Munkeby et al., 2004; Martín et al., 2007).

ROP is a multifactorial disease, but two main factors are associated with its development—prematurity and oxygen (see Chapter 27, Anesthesia for Ophthalmic Surgery). As stated, the neonate is exposed in utero to an oxygen tension of 20 to 30 mm Hg. Birth raises the P_{aO_2} to 55 to 85 mm Hg that may represent hyperoxia, especially for preterm neonates. The retinal vessels grow radially outward from the center of the optic disc from about 16 to 40 weeks’ gestation. Neonates born before term have incompletely developed retinal vessels (Roth, 1977). Two phases of ROP have been described. The initial phase, which occurs between 30 and 32 weeks’ gestation, is associated with inhibition of growth and loss of retinal vessels. Growth of the retina under these circumstances leads to retinal hypoxia. The second phase of ROP is associated with effusive retinal neovascularization and occurs between 32 and 34 weeks’ gestation. New vessels form in the avascular regions and send up fibrous bands to the vitreous gel and lens. These strands are responsible for retinal detachment in some premature infants (Chen and Smith, 2007). Vascular endothelial cell growth factor (VEGF) is required for new vessel growth in utero and afterwards. Administering oxygen after birth decreases VEGF during the first phase of ROP, which decreases vessel growth. In the second phase of ROP, retinal hypoxia increases VEGF expression, which causes exuberant vessel overgrowth. Insulin-like growth factor-1 (IGF-1) is required for VEGF to have its maximal effect. During gestation, serum concentrations of IGF-1 increase, and the severity of ROP is directly correlated with the level of IGF-1. In utero, IGF-1 is supplied by both the placenta and the amniotic fluid. This is withdrawn at birth, decreasing the effectiveness of VEGF, and vessel growth decreases. Excessive amounts of oxygen turn off VEGF. Thus, both VEGF and IGF-1, under appropriate circumstances, inhibit vessel growth and cause vessel regression. Because of the severe retinal hypoxia in phase I of ROP, VEGF and IGF-1 concentrations increase. Retinal vessels’ growth causes the severe problems seen in the later stages of ROP. Avoidance of excessive oxygen concentrations in the operating room is therefore necessary (Betts et al., 1977).

Because there is evidence that supplemental oxygen causes a significant amount of injury, the use of supplemental oxygen should be limited to that required to maintain the oxygen saturation between 85% and 93%, both during resuscitation at birth and during the entire neonatal period (Rabi et al., 2007).

BPD in the Surgical Patient

Infants with moderate to severe BPD often require supplemental oxygen beyond 36 weeks' postconceptual age and often have evidence of lower-airway obstruction. Chest x-rays usually show hyperinflation or atelectasis and, on occasion, bronchopneumonia. Recurrent upper airway infections are common. If BPD is severe, hypercarbia and treatment with diuretics (e.g., furosemide) may complicate management of fluids, electrolytes, and nutrition. Maintaining normal pulmonary gas exchange in infants with BPD during anesthesia and surgery may be difficult. Consequently, many infants require increased respiratory support (including PIP, PEEP, and oxygen) to maintain baseline oxygenation and ventilation; however, use of these modalities also increases the risk of lung injury. Analyzing the infant's current and recent ventilatory history, including severity and treatment of airway reactivity, is necessary to guide intraoperative care. Imitating the care established in the NICU can minimize exposure to excessive pressures, tidal volumes, and oxygen concentrations. To minimize the risk of a pneumothorax, pneumomediastinum, or interstitial emphysema, high peak airway pressures should be avoided, and adequate expiratory times should be allowed, especially if a patient has obstructive lung disease. All of these factors can cause sudden deterioration of hemodynamic and respiratory function. Hyperreactivity of the small airways is a common feature of BPD, and bronchodilation should be maximized preoperatively. Stimulation of the airways by tracheal intubation and surgical manipulation can induce severe bronchospasm, even at surgical planes of anesthesia.

Perioperative nutritional deficits and increased fluid requirements during surgery affect pulmonary function and ventilatory management, especially during and after major surgery (e.g., laparotomy for NEC). Assessing an infant's acid-base status ($Paco_2$, pH, base deficit) and preoperative hepatic and renal function is essential for determining what kind and how much fluid to administer during surgery. Vigorous intravenous crystalloid and colloid administration during anesthesia and surgery, as well as postoperative hemodynamic instability, can dramatically affect pulmonary function, especially if the lungs were injured by BPD.

Preoperative Evaluation of the Pulmonary System

Evaluation of the pulmonary system begins with a review of the gestation, birth, and neonatal course. Was the infant hypoxic or asphyxiated in utero or at birth? Did the infant require artificial ventilation or other resuscitation at birth? If so, are there residual, active pulmonary symptoms, signs, or laboratory abnormalities? Does the infant presently require mechanical ventilation? If so, what are the current requirements for FIO_2 , peak airway pressures, end-expiratory pressure, tidal volume, and ventilator rates? Have the ventilator settings increased or decreased over the previous 24 hours? What is the targeted oxygen saturation? What are the pH_a and $Paco_2$? If present, is hypercarbia chronic or acute, and is it intentional?

Physical Examination

Evaluating the chest movement and breathing pattern of patients from the foot of the bed often provides important information about ventilatory function. For example, do both sides of the chest move equally during inspiration? A difference in chest movement suggests a unilateral process, such as a pneumothorax, a pleural fluid collection, unilateral interstitial emphysema, or an endobroncheal intubation. Although auscultation of the chest may reveal decreased breath sounds on one side, it may not because breath sounds are readily transmitted from one side to the other in neonates. Consequently, the bilateral breath sounds of infants with a pneumothorax are often equal on each side. Percussing the chest or shining a high-intensity light through it may identify a pneumothorax when bilateral and equal breath sounds are present (Kuhns et al., 1975). Are intercostal, sternal, or suprasternal retractions present during spontaneous breathing? This is evidence of increased work of breathing and suggests collapse of lower airways (atelectasis), infiltration of air spaces (as with pneumonia, edema, meconium), pulmonary hypoplasia, or upper airway obstruction. Retractions are more prominent in preterm neonates because of the limited amount of fat and subcutaneous tissue surrounding their chests.

Does the nonintubated neonate grunt during expiration? Partial glottic closure during expiration (grunting) maintains a positive intrathoracic pressure, increases FRC, and improves oxygenation (Harrison et al., 1968). Grunting is common in patients who have reduced FRCs (as with HMD or pulmonary edema). Is expiration prolonged? Are the muscles of respiration actively used to expire? A prolonged expiratory phase of respiration suggests lower airway obstruction, for example, from secretions, masses (intrinsic or extrinsic to the airway), or bronchospasm. Additional details about treatment with bronchodilators (dose and frequency, response to various agents) and suctioning (frequency, quantity and quality of secretions, recent changes, results of cultures) are important for intraoperative planning for ventilatory care. An abnormal physical examination may suggest that further evaluation is required preoperatively (e.g., CT or magnetic resonance imaging [MRI] scan, fiber optic bronchoscopy, or pharmacologic intervention).

Stridor or a weak cry may be signs that the neonate has vocal cord injury (e.g., long-term intubation or congenital paralysis), subglottic stenosis, or subglottic granulomas (Hengerer et al., 1975). A smaller endotracheal tube may be required to prevent further laryngeal or tracheal injury, if tracheal intubation is planned in such patients. However, small endotracheal tubes are more easily occluded with secretions, and suctioning may be more difficult, especially during surgery. In addition, weaning patients from mechanical ventilation postoperatively may be difficult or impossible if the endotracheal tube is small for the infant's age. Mask or laryngeal mask airways (LMAs) or other airway devices may make the need for tracheal intubation unnecessary; however, LMAs increase dead space by adding large volumes above the glottis (Table 17-2). Most cases of neonatal stridor require the opinion of a pediatric pulmonologist, surgeon, or otolaryngologist to define the safest and most efficient means of providing adequate evaluation and treatment of the stridor (e.g., bronchoscopy, CT scan or MRI, or surgery). Clearly, planning for these evaluations must consider how to reduce the risk-to-benefit ratio of each diagnostic or therapeutic examination, especially if deep sedation or general anesthesia is

TABLE 17-2. The Dead Space of LMAs

Weight (Kg)	VT (mL)	VD (mL)	LMA (Size)	VD (Mask)	VD (Total)
1-5	1-35	2.5-11	1.0	6	8.3-17
6-10	42-70	18-21	1.5	7	25-28
11-20	77-140	23-42	2.0	10	33-52
21-30	147-210	44-63	2.5	13	57-76
30	221	65	3.0	22	87

LMAs and their connecting tubes were filled with water to determine the dead space. Tidal volume was assumed to be 7 mL/kg and the wasted ventilation (VD) to be 0.3. Based on these data, unless there is a leak around the mask, the PaCO₂ will be elevated, often above 60 mm Hg, in smaller patients. VT, Tidal volume; VD, dead space volume; LMA, laryngeal mask airway.

required. The need for and timing of tracheostomy should be considered early and discussed with the parents before surgery, especially when general anesthesia is required.

Blood Gas Analysis

Analysis of pH_a, Paco₂, and base deficit provides valuable information about the neonate's pulmonary function. Hypercarbia is the usual, normal physiologic compensation for metabolic alkalosis (e.g., from chronic furosemide administration). The level of Paco₂ alone does not tell whether the child has respiratory compensation for a metabolic acidosis or a metabolic compensation for respiratory acidosis. Acute hypercarbia produces acidosis, and the pH_a is appropriate for the level of Paco₂ (assuming there is no coexisting metabolic acidosis). Of course, mixed metabolic and respiratory abnormalities further complicate interpretation of the relationship between pH and Paco₂. If the Paco₂ is chronically elevated and the pH_a is relatively normal, acutely reducing the Paco₂ to normal will precipitate an acute respiratory alkalosis, which may significantly reduce cerebral blood flow. Every 1 mm Hg change in Paco₂ between 20 and 80 mm Hg Paco₂ causes a 2% change in cerebral blood flow. Thus, if the Paco₂ is 60 mm Hg, and is acutely reduced to 40 mm Hg, cerebral blood flow will decrease by as much as 40%. If this occurs in conjunction with hypotension, cerebral perfusion may well be inadequate. Hypocarbica and severe alkalosis should be avoided when possible, because it can result in poor neurologic outcomes (Curry et al., 2008).

Mechanical Ventilation

Infants who require mechanical ventilation before surgery often require increased support of ventilation during and after surgery, and patients who are spontaneously breathing and treated with nasal CPAP before surgery, usually require tracheal intubation and mechanical ventilation for variable periods after surgery. The lungs of neonates, especially premature neonates, are sensitive to oxidative damage, volutrauma (high volume trauma) as a result of overdistention of the lungs), and shear stress injury (low volume trauma) caused by repetitive opening and collapse of alveoli and terminal airways). In particular, lungs are easily overdistended during hand ventilation. Interestingly, neonates treated with CPAP alone have less evidence of pulmonary inflammation and CLD (Jobe et al., 2002). Small tidal volumes, rapid respiratory rates, and permissive hypercapnea

seem to reduce the amount and severity of neonatal lung injury, suggesting that intraoperative ventilation strategies should use the lowest effective tidal volumes (inspiratory and end-expiratory pressures) and inspired oxygen concentrations possible (Thomas and Speer, 2008). The Sao₂ should be maintained between 85% and 93% in preterm neonates, which may require the use of room air. Mild hypercapnea (Paco₂ of 45 to 55 mm Hg) is acceptable if there is no evidence of increased intracranial pressure, pulmonary hypertension, or severe metabolic acidosis. Aggressive hyperventilation should be avoided, and no attempt should be made to reduce the Paco₂ to 40 mm Hg or less without a very good clinical reason for doing so. Although knowledge of the ventilator settings used in the NICU is important for setting the initial respiratory rate and airway pressures in the operating room, the less sophisticated ventilators used during surgery are rarely as effective as the NICU's ventilators. Furthermore, the impact of positioning for surgery (e.g., lateral or prone), the procedure itself, retractors, surgeon's hands, fluid administered, anesthesia, and other factors all affect the effectiveness of mechanical ventilation in the operating room.

Infants treated preoperatively with high-frequency ventilation (HFV) usually fare better if they undergo surgery and anesthesia in the NICU and have their HFV continued throughout the surgery. High-dose narcotics and muscle paralysis provide adequate anesthesia in the NICU and are used because infants' ventilators cannot deliver inhaled anesthetics. Performing surgery in the NICU also eliminates the risks of transporting sick neonates to and from the operating room and allows easy access to the expertise of the NICU nurses and neonatologists.

The Cardiovascular System

Transitional Circulation

The fetal circulation is characterized by increased PVR, decreased pulmonary blood flow, decreased systemic vascular resistance, and right-to-left blood flow through a PDA and foramen ovale (Rudolph, 2007). At birth, the onset of ventilation and the elimination of the placental circulation have dramatic effects on systemic and PVRs (see Chapters 4, Cardiovascular Physiology, and 21, Congenital Cardiac Anesthesia: Non-Bypass Procedures). Pulmonary vascular resistance (PVR) decreases and pulmonary blood flow increases. Simultaneously, systemic vascular resistance increases, and the left atrial pressure rises. This functionally closes the foramen ovale and stops right-to-left shunting at this level. However, bidirectional shunting through the ductus arteriosus often continues for the first 24 hours of extrauterine life in healthy infants. If the ductus arteriosus fails to close, blood is shunted left-to-right into the pulmonary circulation as the PVR declines after birth. Anatomic closure of the ductus arteriosus occurs after several days, and shunting of blood through this structure ceases. The neonate now has the circulation of an adult.

If arterial hypoxemia or acidosis occurs during the first few days of life, the neonate's circulation may revert to the fetal pattern (i.e., pulmonary arterial vasoconstriction, pulmonary hypertension, and reduced pulmonary blood flow). The resultant increase in right atrial pressure reestablishes right-to-left shunting of deoxygenated blood through the foramen ovale and ductus arteriosus, producing arterial hypoxemia (Rudolph and Yuan, 1966). This return to the fetal circulatory pattern, called PFC or persistent pulmonary hypertension of the newborn

(PPHN), further exacerbates the hypoxemia and acidosis. Although numerous treatments for PPHN (e.g., hyperventilation or vasoactive agents) have been used, a selective and highly effective vasodilator of the pulmonary circulation has not been identified. PPHN may be an isolated phenomenon, or it may be associated with a variety of clinical conditions, including meconium aspiration, sepsis, polycythemia, diaphragmatic hernia, hypoxemia, acidosis, and severe hypotension. An echocardiogram should be performed to exclude structural cyanotic heart disease (Peckham and Fox, 1978; Murphy et al., 1981). The primary treatment of PPHN is aggressive hemodynamic support, including maintaining intravascular volume, initiating inotropic support (especially if PPHN is associated with sepsis or asphyxia), correcting acidosis and electrolyte disturbances, and administering antibiotics when appropriate. Ventilatory strategies have moved away from hyperventilation (pH greater than 7.5) and hyperoxia to more gentle approaches, including maintenance of normal oxygenation, $Paco_2$, and pH with either conventional or high-frequency mechanical ventilators. Vasodilatory agents such as NO are often used, but the protocols vary from institution to institution. NO has significantly reduced the need for extracorporeal membrane oxygenation to treat PPHN (Field et al., 2007).

Nitric Oxide

Control of the pulmonary circulation, especially during the transition from fetal to postnatal life, is complex and depends on the interaction of a variety of mediators and factors, receptors, and neurologic, endocrine, and vascular control mechanisms, both in endothelial and smooth muscle cells (Kinsella and Abman, 1995). For example, increased oxygen tension and expansion of the lungs with the onset of breathing decreases PVR directly. The rise in blood flow imparts shear stress to the vessels, which distends them, flattening the endothelium and the smooth muscle cells, and promotes the release of various mediators (Haworth, 2006). The balance between the effects of vasodilators (e.g., NO and prostacyclin) vs. vasoconstrictors (e.g., endothelin-1 [ET-1], leukotrienes) significantly affects pulmonary blood flow. As noted by Haworth (2006), "The pioneering studies of Dr. Dawes and his colleagues in Oxford in the 1960s on fetal sheep showed that mechanical ventilation reduced PVR and that the response was enhanced when the inspired gas was enriched with oxygen" (Dawes, 1968). Fifty years later, no single factor has yet been identified as being primarily responsible for the initiation of pulmonary vasodilation at birth. Nor do we know whether the endothelial cell or the smooth muscle cell is the prime target (Haworth, 2006).

NO is produced by the pulmonary vascular endothelial cells and is important for pulmonary vasodilation. NO is used to treat PPHN and, in a less well-defined role, to stimulate angiogenesis and promote lung growth, primarily in the ELBW infant. Inhaled NO has a rapid onset of action, is potent, and is a selective pulmonary vasodilator. Unfortunately, up to 40% of infants with PPHN do not respond to NO, and with the use of this drug there has been no positive effect on the incidence of BPD or neurodevelopmental deficits, mortality, or long-term outcome (Steinhorn, 2008).

Soluble guanylate cyclase in vascular smooth muscle converts guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). By stimulating guanylate cyclase, NO increases cGMP production, which decreases smooth muscle contractility and induces vasodilation.

Regulation of production and metabolism of NO occurs at multiple levels. First, NO production is subject to endothelial nitric-oxide synthetase activity (eNOS; lung eNOS is type III). eNOS has both reductase and oxygenase domains. When its substrate L-arginine is available, oxidation of NADPH and NO synthetase produce NO. On the other hand, when the concentration of substrates or cofactors (e.g., heat shock protein 90) is reduced, NOS is uncoupled and, instead of NO, reactive oxygen species such as peroxy-nitrate are produced. In fact, oxidative stress may contribute to the development of PPHN (Brennan et al., 2003). The balance between the vasodilating effects of oxygen and the injury caused by oxidative stress is a delicate one, and the injury may occur quickly. For example, ventilating the lungs of lambs with an F_{IO_2} of 1.0 for only 30 minutes blunted the subsequent response to NO (Lakshminrusimha et al., 2007). During high-dose NO administration, the deleterious effects of generating oxygen radicals must be balanced against its vasodilatory benefits.

Second, the activity of soluble guanylate cyclase and cyclic guanosine monophosphate (cGMP)-specific phosphodiesterase (PDE5) on smooth muscle cells contributes to NO's effectiveness in stimulating cGMP production. PDE5 hydrolyzes cGMP, which controls the duration and magnitude of cGMP's effect. Agents that inhibit PDE5, such as sildenafil, promote pulmonary vasodilation and have been used extensively to treat pulmonary hypertension in adults. There is less experience using these drugs in newborns with PPHN (Baquero et al., 2006; Martell et al., 2007). Development of a parenteral formula of these drugs may improve delivery of PDE5 antagonists for the treatment of PPHN (Mukherjee et al., 2009). Sildenafil has effectively diminished rebound pulmonary hypertension during weaning from NO (Atz and Wessel, 1999). Of note, both NO and sildenafil have been reported to stimulate lung growth. Ongoing trials of NO to minimize CLD may eventually define the role of this agent in the ELBW infant (Steinhorn and Porta, 2007). No agents are available that directly activate guanylate cyclase in patients.

The cyclic adenosine monophosphate (cAMP) pathway is another mechanism by which pulmonary vasodilation can be induced. Prostacyclin (PGL_2) stimulates adenylate cyclase and increases cAMP. However, intravenous infusion of this drug causes systemic hypotension, which often prevents the desired therapeutic effect from being achieved. Inhaled PGL_2 is a selective pulmonary vasodilator, but its efficacy in PPHN remains to be firmly established. Milrinone, on the other hand, inhibits cAMP metabolism by interfering with PDE3 and has been used clinically as adjunct therapy to NO (McNamara et al., 2006).

Antagonizing vasoconstriction is another strategy for treating PPHN. ET-1, a potent vasoconstrictor produced by the endothelium, and NO interact in a feedback loop. For example, NO decreases ET-1 production and ET-1 increases superoxide release, which impairs NO-induced vasodilation (Abman, 2007). In addition to directly antagonizing ET-1, other strategies to interrupt vasoconstriction offer promise. For example, a GTPase, RhoA, and its protein ρ -kinase are important for regulation of vascular tone, especially for maintaining the high PVR present in utero. Thus, inhibitors of both ET-1 and ρ -kinase may be useful for the treatment of PPHN. Finally, dysfunction of the signaling pathways of VEGF may be important in the pathogenesis of PPHN. For example, VEGF releases NO, and inhibition of VEGF receptors down-regulates eNOS. Reduced levels of VEGF have been reported in infants with PPHN (Lassus et al., 2001).

Myocardial Ultrastructure

The fetal and adult myocardia contract and relax using the same basic processes—increases in the cytosolic calcium concentration to cause force generation and decreases to cause relaxation (Crick et al., 1998). At all stages of maturation, the ventricle must develop force against a varying resistance or load (contraction and ejection) and then relax (filling). Membranes present in the adult myocardium that control both calcium flux and the contractile system are also present in the fetal heart; however, there are qualitative and quantitative age-related differences in these membranes. Progression toward adult myocardial function involves developmental changes in these structures associated with the mechanics of force generation (e.g., the sarcomere and myofibril), those involved with controlling calcium flux (e.g., the sarcoplasmic reticulum, receptors, channels, exchangers, transporters, and pumps), those related to myocardial compliance (e.g., extracellular matrix and cytoskeleton), and sympathetic innervation. In part, age-related differences in the response to calcium and various pharmacologic agents are the result of the developmental state of myocardial anatomy and function.

Force Generation

Sarcomere. The sarcomere is the functional unit of the myofilament. Sarcomeres consist of thick (myosin-containing) and thin (actin-containing) filaments and of regulatory proteins and a complex cytoskeletal matrix. All of these components undergo complex developmental changes during fetal and postnatal life.

The immature myocardium develops less force against a load than that of the adult (Anderson et al., 1984). For example, the premature and neonatal hearts are unable to maintain output against an arterial pressure that would be considered low in the adult. In part, this reflects a smaller myocardial mass and a thinner left-ventricular wall. In addition, the velocity and quantity of sarcomere shortening is less in isolated immature myocytes than it is in adult myocytes (Nassar et al., 1987).

Both the number and size of myocytes increase before and after birth. The shape of the myocyte changes from a smooth, spherical structure to a more irregular, rectangular one. With this change in shape, the surface area-to-volume ratio decreases. This process occurs more rapidly in the left ventricle than in the right. The neonatal period is characterized by significant development of the left ventricle and a shift from right-ventricular to left-ventricular predominance. There also is a marked increase in left-ventricular work that is the result of a higher stroke volume, systolic arterial pressure, and wall tension. Right-ventricular systolic pressure and work decrease. Relative to body weight, left-ventricular mass increases and right-ventricular mass decreases. The increase in the number (cell division) and size (hypertrophy) of the myocytes is more pronounced in the left ventricle than in the right. By the second month of life, increased cell size, rather than increased cell number, becomes the predominant developmental phenomenon. This has major implications for patients with CHD, especially those with lesions that obstruct outflow from either ventricle (Rudolph, 2000). Control of postnatal development is not completely understood, but α -agonist stimulation, cortisol, thyroid hormone, and a variety of growth factors seem to be important (Brown et al., 1985; Rudolph, 2000).

Myofibrils. The number of myofibrils per unit of intracellular volume increases, and their arrangement becomes more highly organized during myocyte maturation after birth. In the fetus, the myofibrils appear somewhat chaotic. In the adult they are in long, parallel rows that alternate with rows of mitochondria (and sarcoplasmic reticulum). In the immature myocardium, myofibrils are arranged in thin layers, and groups of nuclei and mitochondria reside in the center of the cell. In part, this difference in myofibril arrangement may be the anatomic basis for the differences in control of the intracellular calcium concentration and in sensitivity to calcium channel blockers in the neonate as compared with the adult (see Sarcoplasmic Reticulum, p. 526). That is, transsarcolemmal movement of calcium from the outside to the inside of the cell causes contraction of the immature myocardium, whereas intracellular release of calcium is responsible for contraction of the adult myocardium. The irregular arrangement of mitochondria in the immature myocardium is likely to prevent the organized contractile activity seen in the adult heart, where the mitochondria alternate regularly within sarcomeres.

Calcium Flux

Sarcolemma. The complex array of ion channels, pumps, exchangers, enzymes, and receptors of the plasma membrane (sarcolemma) of the sarcomere interact to maintain ionic homeostasis of the intracellular environment. Multiple age-related changes in the sarcolemma have been reported, and several of the most well-characterized and clinically important differences are included in the following list:

- Activity of the sodium-potassium adenosine triphosphatase (Na^+ , K^+ -ATPase) pump and expression of its subunits increases in number and activity with development. Digoxin binds to the α -subunit, and the reduced expression of this subunit is the reason digoxin has less inotropic effect in neonates.
- The sodium-calcium (Na^+ - Ca^+) exchanger also undergoes developmental changes. The function of this exchanger is primarily to move calcium from the intracellular to the extracellular compartment after contraction. This site is also important for the movement of calcium into the myocyte. The sarcolemmal Na^+ - Ca^+ exchanger apparently helps maintain intracellular calcium concentrations in some species of newborns (probably the human) but not adults. This exchanger may account in part for the sensitivity of the newborn myocardium to changes in extracellular calcium concentrations. For example, when blood is administered rapidly, serum calcium concentration can decrease and cause myocardial dysfunction (Sham et al., 1995). The higher density of the Na^+ - Ca^+ exchanger in the immature heart may also be linked to differences in contraction and relaxation rates. Also, when digoxin inhibits the Na^+ , K^+ ATPase pump, intracellular sodium increases, and it is the Na^+ - Ca^+ exchanger that extrudes sodium. When sodium is transported extracellularly in exchange for calcium, the intracellular calcium concentration increases, which may in part be responsible for the effect of cardiac glycosides on contractility.
- Activity of the sodium-hydrogen (Na^+ - H^+) exchanger is higher in the newborn myocardium and seems to be important for cell growth. In addition, this exchanger may be important for the well-described resistance of the newborn myocardium to acidosis.

- Developmental changes in structure and activity of the multiple types of potassium channels probably contribute to differences in the action potential (e.g., shortened action potential duration) measured in immature vs. mature myocytes.
- Density and distribution of the various types of calcium channels vary with maturation, but there is marked variability among species in the two general types of dihydropyridine-sensitive calcium channels (T [transient] type and L [long or slow] type).
- The T tubules are a network of invaginations of the sarcolemma into the center of the cell. These invaginations extend to the surface of the myocyte, thereby increasing its interaction with the extracellular environment (e.g., more rapid transmission of an action potential intracellularly). This system increases the ratio of cell surface-to-volume in the postnatal myocyte.

Sarcoplasmic reticulum. Various membranes surround the myofibrils and interact to control the intracellular calcium concentration. In the mature heart, the sarcoplasmic reticulum is the major intracellular organelle that controls cytosolic calcium concentrations during contraction; a small amount of extracellular calcium enters the myocyte and stimulates release of calcium from the sarcoplasmic reticulum (calcium-induced calcium release). The volume of sarcoplasmic reticulum, as well as its ability to pump calcium (i.e., uptake, longitudinal sarcoplasmic reticulum; storage and release, junctional sarcoplasmic reticulum), increases both before and after birth. The various subtypes of sarcoplasmic reticulum are less functionally differentiated in neonates.

Calcium flows through the calcium-release channel of the sarcoplasmic reticulum (i.e., ryanodine receptor) to initiate contraction. These channels form functional complexes with the L-type calcium channels of the sarcolemma and with various proteins (e.g., calsequestrin). Release channels interact with various immunosuppressive drugs (e.g., cyclosporine) and cause phosphorylation via the protein phospholamban during sympathetic stimulation. The concentration of phospholamban is reduced in the immature hearts of several species.

Caffeine, which releases calcium from the sarcoplasmic reticulum, has little effect on neonatal myocardial contractility. This suggests that extracellular, rather than intracellular, calcium controls contractility in the neonatal myocardium, probably through calcium entry via L-type channels of the sarcolemma. Also, extracellular calcium appears to more effectively activate myocardial contraction of the immature myocardium than of the adult myocardium. Compared with the adult heart, immature hearts are more sensitive to calcium-channel antagonists (Boucek et al., 1984). Furthermore, the newborn heart requires higher concentrations of extracellular calcium to achieve maximal contractility (Jarmakani et al., 1982). With maturation, the amount of sarcoplasmic reticulum and the number of specialized connections of sarcoplasmic reticulum with other membranes increases, as does the efficiency of pumping calcium. Finally, there is an increase in Ca⁺⁺-ATPase activity, which has been linked to improved sarcoplasmic-reticulum function with maturation (Mahony and Jones, 1986; Mahony, 1988). Age-related increases in the amount and organization of the sarcoplasmic reticulum improve systolic and diastolic myocardial function with age (see Cardiovascular Function in the Newborn, p. 527).

Contractile proteins. Contractile proteins are arranged into regular strands that account for the typical appearance of the sarcomere. Sarcomeres are divided into units that are bordered by I bands, which are bisected by Z discs and A bands with a dark M in the center. I bands consist of thin actin filaments, troponin, and tropomyosin. Thick filaments are made up of myosin. The A band is composed of overlapping thin and thick filaments plus other proteins. Multiple age-related changes in the contractile proteins of the sarcomere have been reported, and several of the best-characterized and clinically important ones are briefly discussed in this section. Although actin is a prominent contractile protein, the significance of the expression of its various isoforms during development remains unclear.

- Myosin is the most abundant contractile protein and consists of two heavy and four light chains. Isoforms of each undergo developmental changes, and several have been associated with ventricular growth and development.
- Troponin consists of three distinct proteins: troponins T, I, and C. The roles and expression of the various isoforms are complex and vary with the stage of development. Myocardial expression of cardiac vs. slow skeletal muscle isoforms of troponin appear to be important in the immature myocardium, because it may be important for the relative resistance of the immature heart to acidosis (Solaro et al., 1988). Expression of slow skeletal muscle troponin I in the fetal heart is linked to the newborn's ability to tolerate higher levels of respiratory acidosis without myocardial depression. In contrast, the adult myocardium expresses cardiac troponin I. Response of the immature myocardium to sympathetic stimulation is correlated with expression of slow skeletal troponin I. Cardiac, but not slow skeletal muscle troponin, is phosphorylated by β -stimulation. Phosphorylation decreases sensitivity to calcium, which facilitates myocardial relaxation during diastole. The slow skeletal muscle isoform found in the immature heart is not phosphorylated by β -agonists, which may be one reason for the newborn's difference in diastolic function (Solaro et al., 1988). Finally, expression of specific isoforms of troponin T has been correlated with myofilament responsiveness to calcium. If newborn and adult myocardia respond differently to calcium and calcium-channel-mediated pharmacologic agents, this may affect the choice of cardiotropic agents in the presence of disease (Anderson et al., 1984).

Myocardial Compliance

Cytoskeleton. The cytoskeleton includes the contractile proteins, titan and extramyofibrillar filaments (i.e., microfilaments, intermediate fibers, and microtubules). This intricate matrix provides the structural framework that organizes the complex intracellular compartments. This multi-level organization provides the mechanism for the intra- and extracellular communication required for the movement of the individual sarcomeres for translation into effective contraction and relaxation. The cytoskeleton provides the system for mechanical signaling. From the general appearance of the immature sarcomere, it is evident that dramatic changes in organization must occur during early development. A and I bands are more irregular in the immature myocyte; the

M band is absent; and the Z band is variable in width. Several of the most well-characterized and clinically important age-related changes in the cytoskeleton (extracellular matrix) are briefly discussed here:

- Titin is a large protein that extends from the end of the Z band (the end of the sarcomere) to the M band at the center. Isoforms of this protein are developmentally regulated. Fetal hearts seem to express the more compliant isoform.
- Proteins in the Z disc interact with adjacent sarcomeres to communicate tension along the myofibril. Various developmental changes in this complex array of proteins have been linked to growth and remodeling of the heart in response to adaptation of the circulation at birth. For example, desmin, a protein important for linking Z bands of myofibrils, is distributed throughout the subsarcolemmal area. As the myocardium develops, organization of this protein improves the connection of myofibrils with mitochondria, thus facilitating the mechanics of contraction. The distribution of various proteins in the cytoskeleton and in the extracellular matrix probably explains the irregular A- and I-band patterns, as well as the indistinct or absent M band. Integrins, which are important for linking cell surfaces to extracellular matrix proteins, are distributed differently in the immature heart. The amount and types of collagen present in the myocardium also follow a developmental pattern that is associated with changes in the expression of various collagen isoforms. These isoforms improve the resting load and passive state of the myocardium. Many of the cytoskeletal and extracellular matrix changes occur rapidly after birth (Robinson et al., 1983).
- The extracellular complex of microfilaments, intermediate fibers, and microtubules and their components undergo postnatal development and mediate various activities, such as cell growth, migration, and adhesion. For example, the collagen network becomes progressively more organized with maturation, and the population of Type III (more elastic) collagen eventually exceeds that of Type I.

Sympathetic Innervation

The sympathetic nervous system modulates a wide range of critical events in the developing myocardium, including cell growth and differentiation and distribution of and sensitivity to calcium. With maturation of adrenergic innervation, the quantity of neurotransmitters and the number of receptors increase. At birth, adaptation to postnatal hemodynamics is mostly mediated by the α -adrenergic system. That is, an early high level of α -adrenoreceptors may be critical for left-ventricular growth in the early postnatal period. In fact, α -1-blockade interrupts the increase in protein synthesis in cultured myocytes exposed to α -stimulation (Robinson, 1996). For example, the increase in adrenergic fibers innervating the myocardium modulates widespread development and expression of the various contractile systems (e.g., expression of the contractile proteins, efficiency of the calcium channel, and expression of myosin ATPase isoforms). Finally, the activity of adenylyl cyclase, an important enzyme involved in intracellular β -stimulation, increases in concert with the increase in catecholamine levels. The interaction of adrenergic innervation, catecholamine

concentrations, and functional changes in multiple proteins that regulate responses to various agonists is complex and difficult to accurately extrapolate to specific clinical scenarios.

Cardiovascular Function in the Newborn

In spite of the intense age-related changes in myocardial physiology and function, the qualitative characteristics of the fetal and neonatal heart are similar to those of the adult in that blood pressure is directly proportional to CO and systemic vascular resistance (Table 17-3). The primary determinants of CO are heart rate and stroke volume. Preload, afterload, and myocardial contractility interact to determine ventricular performance. At all times, oxygen delivery and oxygen demands are interdependent; oxygen delivery (CO) is regulated by oxygen consumption (metabolism).

The high collagen content and high ratio of Type I collagen to Type III collagen may be responsible for the relative noncompliance of the neonatal heart and its limited capacity to respond to volume loading (Klopfenstein and Rudolph, 1978). This non-distensible heart has limited capacity to increase stroke volume and augment CO when faced with an increased preload. Thus, the Frank-Starling response appears to have a limited role, and heart rate is the primary means of increasing CO in the newborn. Over the first months of life, myocardial contractility gradually increases, which allows CO to be maintained over a wider range of preloads and afterloads. Similarly, the increase in contractile proteins and the shift in the expression of various isoforms; the development of sarcoplasmic reticulum and T tubules, adrenergic innervation, calcium recruitment and transport; and the overall response of the myocardium to stress or increased demands all contribute to complex changes in force development.

The newborn's CO per unit weight is the highest of any age group (approximately 200 mL/kg per minute). Teitel (1985) hypothesized that the greater increase in myocardial performance with adrenergic stimulation in older lambs is to the result of a "lesser resting β -adrenergic tone" in the older animals. That is, the baseline state of the newborn myocardium is at higher level of " β -adrenergic tone," and the high resting CO of the newborn limits its ability to further increase CO in response to increased demand or to adapt to wide variations in preload or afterload. Because the newborn's normal heart rate is high, increasing the heart rate has limited effect on CO, but decreasing the heart rate dramatically decreases output.

Volume loading of the immature ventricle increases CO, but the effect is less than that that seen at older ages (Klopfenstein and Rudolph, 1978). Similarly, the tolerance of the immature myocardium to increases in afterload is less than it is at older ages. Thus, the impaired ventricular function of the fetus (i.e., preterm baby) and newborn are the result of fewer myofibrils;

TABLE 17-3. Comparison of Neonatal and Adult Myocardial Functions

	Neonate	Adult
Cardiac output	Rate dependent	Stroke volume and rate
Contractility	Reduced	Normal response
Starling response	Limited	Normal response
Catecholamine	Reduced	Normal response

decreased sympathetic innervation; decreased β -adrenoreceptor concentration; immaturity of the structure and function of the sarcoplasmic reticulum; maturation-specific mechanisms for calcium uptake, release, and storage; and a specific spectra of expression of various isoforms of contractile and noncontractile proteins, channels, exchangers, and enzymes.

Cardiovascular Evaluation

Preoperative evaluation of the newborn should focus on understanding “normal,” because infants of the same gestational age can vary significantly in their baseline heart rates and blood pressures (Fig. 17-5). Acid-base status (electrolytes, pH, P_{aCO_2}), urine output, and rates of fluid administration must be interpreted in the context of “normal” blood pressure and heart rate and the interventions required to maintain normalcy. Trends in these data over the hour, 6 hours, and 12 to 48 hours prior to examination help clarify the infant’s cardiac function. It is necessary to understand whether there were responses to fluid boluses and inotropic intervention, and if so, what those

responses were with respect to maintenance of cardiovascular stability. This critical insight is important when developing a rational anesthetic plan. Finally, evaluation of the current level of sedation and the response to various agents also helps determine which drugs (e.g., morphine, fentanyl) and the amounts of each drug that are required to achieve the desired effect. This knowledge will guide the anesthesiologist in determining which drugs may be most effective during surgery.

The Central Nervous System

During the third trimester, cortical gray and white matter volumes increase fourfold to fivefold. Growth and differentiation of dendrites and axons, proliferation of glia, synaptogenesis, and myelination characterize this dramatic process. The proliferation in the cerebellum is even more rapid than the cerebral cortex and is characterized by intense migration of various populations of cells (Allin et al., 2001; Limperopoulos et al., 2005b; Limperopoulos and du Plessis, 2006).

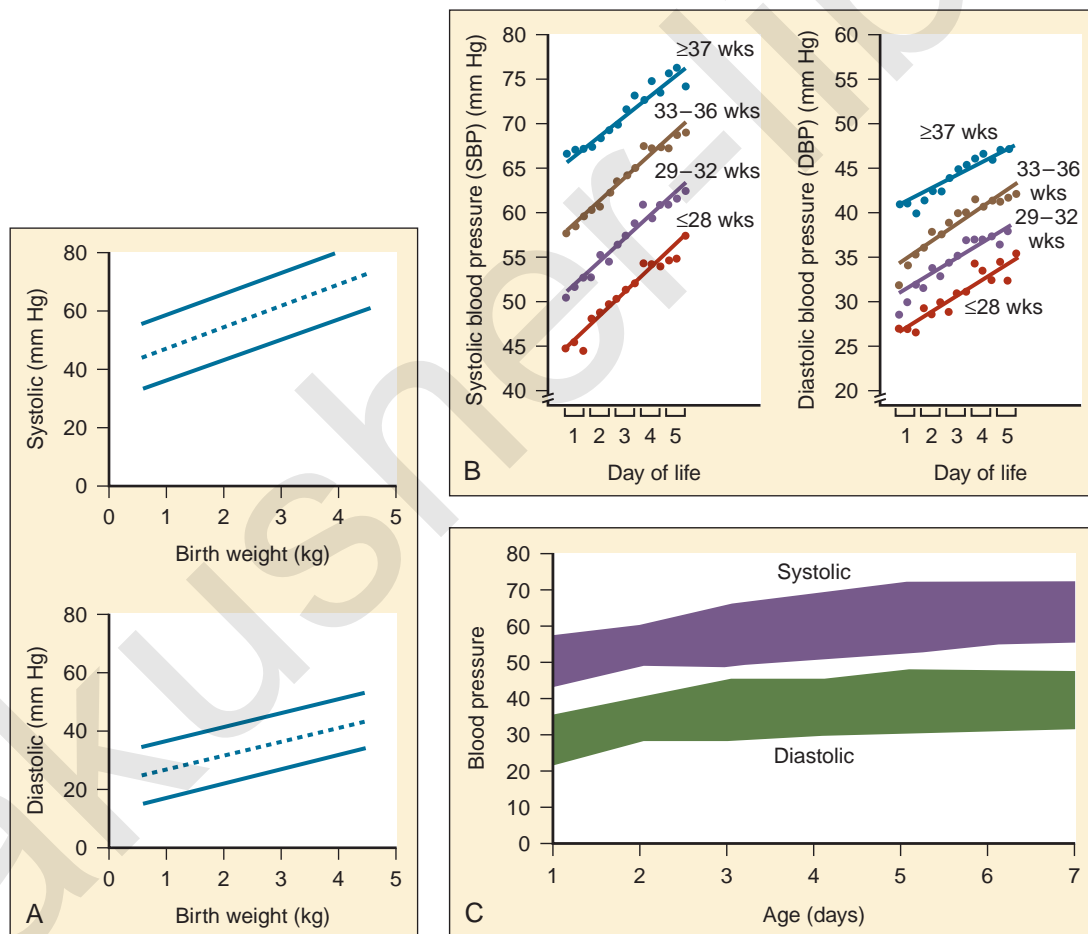

FIGURE 17-5. **A**, Linear regressions (broken lines) and 95% confidence limits (solid lines) of systolic (top) and diastolic (bottom) aortic blood pressures on birth weight in 61 healthy newborn infants during the first 12 hours after birth. For systolic pressure, $y = 7.13x + 40.45$; $r = 0.79$. For diastolic pressure, $y = 4.81x + 22.18$; $r = 0.71$. For both, $n = 413$ and $P < 0.001$. **B**, SBP and DBP are plotted for first 5 days of life with each day subdivided into 8-hour periods. Infants are categorized by gestational age into the following four groups: ≤ 28 weeks ($n = 33$); 29 to 32 weeks ($n = 73$); 33 to 36 weeks ($n = 100$); and ≥ 37 weeks ($n = 110$). **C**, Blood pressure ranges in premature infants during the first week of life, with a gestational age of 31.4 ± 2.6 weeks. (A From Versmold HT, et al.: Aortic blood pressure during the first 12 hours of life in infants with birth weight 610 to 4220 grams, *Pediatrics* 67:607, 1981; B From Zubrow AB, Hulman S, Kushner H, et al.: Determinants of blood pressure in infants admitted to neonatal intensive care units: a prospective multicenter study. *Philadelphia Neonatal Blood Pressure Study Group*, *J Perinatol* 15:470, 1995; C From Hegyi T, Anwar M, Carbone MT, et al.: Blood pressure ranges in premature infants: II. The first week of life, *Pediatrics* 97:336, 1996.)

In parallel with the intense growth of the parenchyma, the vascular network of the late-gestation brain also develops rapidly. The long and short penetrators lengthen and arborize, leading to a decrease in end- and border-zone blood flow. Despite this rapid growth, cerebral blood flow in late fetal life (8 to 15 mL/g per minute) is remarkably low compared with that of the adult. Blood flow to the white matter is even lower, approximately 25% of the flow to the cerebral cortex (Khwaja and Volpe, 2008). The presence of a pressure-passive cerebral blood flow may further predispose the newborn, especially the premature newborn, to ischemic injury (Greisen, 2005).

In addition to the overall patterns of intense brain growth in late gestation, the development of specific cellular elements defines the unique susceptibility of the preterm brain to hypoxic and ischemic insults. Microglia are macrophages that are prominent in the normal human brain during development and are concentrated in the cortical white matter. This population of cells peaks during the third trimester, the period of highest vulnerability to the white matter injury that is common in the premature infant. Although microglia have a critical function in normal development, activation of these cells precipitates release of cytokine and glutamate, producing reactive oxygen and nitrogen species. Preoligodendrocytes (precursors to myelinating oligodendrocytes) are especially susceptible to injury from oxidative and excitotoxic stress. Neuropathologic studies have documented that an intense inflammatory response in the white matter accompanies periventricular leukomalacia (PVL), and specifically, microgliosis characterizes diffuse, non-cystic PVL. Diffuse white matter injury on MRI correlates with neurodevelopmental delay in expremature infants (Woodward et al., 2006; Glass et al., 2008).

Another unique population of cells that is prominent during development is the so-called “subplate neuron” group. The subplate is three times thicker than the cortical plate between 22 and 36 weeks’ gestation, but it is absent at term (McQuillen and Ferriero, 2005). These neurons express neurotransmitters and growth factors that seem to be critical in orchestrating the migration of cells from the germinal neuroepithelium to distant sites (e.g., the corpus callosum or thalamus). This layer receives synapses and organizes connections with distant structures, produces axons, and serves as a waiting zone for cells and axons as their final ultimate location in the cortex is defined (Leviton and Gressens, 2007). Injury to the subplate may disrupt the critical interaction and feedback between the cortex and thalamus, leading to long-term functional consequences. The connectivity among various distant structures during a time of critical brain development has been postulated to correlate with deficits identified in the expremature infant in the specific areas of behavior, cognition, and other complicated higher cortical functions (e.g., executive function) (Limperopoulos et al., 2005b; Boardman et al., 2006; Kapellou et al., 2006; Counsell et al., 2007).

Derangements of early brain development correlate with abnormalities in the two major structures of embryogenesis: the neural tube (future brain and spinal cord) and the prosencephalon (future forebrain) (Volpe, 2001). Primary development of the neural tube (3 to 4 weeks’ gestation) and prosencephalon (2 to 3 months’ gestation) are complete early in gestation. The term *primary neural tube* includes embryogenesis of both the brain and the spinal cord. The prosencephalon develops shortly after closure of the anterior neural tube and is related to both the telencephalon (future cerebral hemispheres) and

the diencephalon (future thalamus and hypothalamus). Neural tube anomalies, such as anencephaly, craniorachischisis totalis, myeloschisis, and encephalocele, associated with these early events are dramatic and often fatal. Similarly, severe prosencephalic anomalies (holoprosencephalies) are often fatal, especially when they are associated with chromosomal abnormalities (e.g., trisomy 13-15 or trisomy/ring/deletion 18).

A less severe form of abnormal neural tube closure includes the lesions of spina bifida (incidence of 3 to 7 per 10,000 births). These neural tube anomalies are clinically important because affected infants often survive and have lifelong problems. The four primary types of spina bifida are categorized according to the severity of the defect. In the first type, spina bifida occulta, the divided vertebral arch, spinal cord, and meninges are covered with skin. Hair often protrudes from the skin overlying the defect, forming a sacral dimple. The presence of either hair or a dimple in this area should make anesthesiologists cautious of performing a caudal block without further information. In the second type, spina bifida cystica, neural tissue and its coverings protrude through the incompletely formed vertebral arch as a cystlike structure. In the third type, meningocele, the neural tube lies in its normal position but the meninges protrude through the defect; skin usually covers this lesion. In the fourth type, meningocele, both the spinal cord and the meninges protrude, often without skin. These lesions can occur at any level of the spine. Hydrocephalus is a common accompaniment of myelomeningocele—60% in occipital, cervical, thoracic, or sacral lesions and about 90% in thoracolumbar, lumbar, and lumbosacral lesions (Lorber, 1961). In most infants, hydrocephalus is not evident before the meningocele is closed, because cerebrospinal fluid leaks through the open lesion and decompresses the ventricles.

An Arnold-Chiari malformation is an abnormality of the hindbrain that occurs in most patients with meningocele (Fig. 17-6). The medulla oblongata is flattened and elongated and, along with the fourth ventricle, protrudes into the spinal

■ **FIGURE 17-6.** This MRI of Chiari’s malformation shows the brain stem being pushed down through the foramen magnum. (Courtesy Jim Barkovich, MD, University of California, San Francisco.)

canal through the foramen magnum. The downward position of the medulla also elongates the lower pons and upper medulla and may compress brainstem nuclei and cranial nerves. If the cerebellar tonsils are displaced through the foramen magnum, aqueductal stenosis and hydrocephalus can occur. Whether it becomes necessary to decompress the posterior fossa depends on the severity of the anatomic abnormalities and the symptoms. For example, anomalies that are severe enough to cause apnea, vocal cord paralysis, or central and obstructive ventilatory disturbances require early correction (Kirk et al., 1999). Up to 20% of infants with myelomeningocele have sleep-disordered breathing, and some of these patients require a tracheostomy (Kirk et al., 2000). The anesthesiologist should be aware that a wide range of abnormalities associated with myelomeningocele exists beyond infancy, because this group of patients commonly requires ventriculoperitoneal shunt revision or urologic or orthopedic procedures.

Other disorders, such as agenesis of the corpus callosum and septum pellucidum, are less commonly fatal, but they are often associated with abnormal neuronal migration and significant clinical abnormalities. Agenesis of the corpus callosum is usually associated with a syndrome (e.g., Aicardi's or Andermann's syndrome) or a chromosomal abnormality (e.g., 8, 11, 13, 15, or 18). As many as 80% of patients without a corpus callosum have other brain anomalies, as well as non-CNS malformations (Parrish et al., 1979; Jeret et al., 1987). Partial agenesis of the brain probably occurs later in development and is associated with clinical syndromes that have migrational and structural disorders. Agenesis of the septum pellucidum is never an isolated lesion. It is often occurs in conjunction with optic nerve hypoplasia (septo-optic dysplasia).

Once the structure of the neural tube and the prosencephalon are established (2 to 3 months of gestation), further development of the CNS is by proliferation and migration. Neurons proliferate from ventricular and subventricular regions at every level of the developing nervous system. From the second to the fourth month of gestation, some glia are formed, but most proliferating cells are neurons. From the fifth month of gestation into adulthood, glial multiplication is the primary process. Movement of cells from the ventricle to subventricular sites is important for our understanding of the pathophysiology of the preterm infant brain. For instance, the limited glial migration that occurs during early gestation is important for normal migration of other cells. Arterial and venous vessels develop at this same time. These developmental processes affect the prognosis of preterm infants, especially those born before 30 weeks' gestation (see Chapter 22, *Anesthesia for Neurosurgery*). The two diagnoses most commonly associated with CNS injury in preterm infants are periventricular hemorrhagic infarct (PVHI) and PVL.

Intraventricular/Periventricular Hemorrhage-Germinal Matrix/Intraventricular Hemorrhage

The pathophysiology of intraventricular hemorrhage (IVH) is related to the structure of the immature brain (Fig. 17-7) (Volpe, 2001). Proliferating ventricular and subventricular areas of the developing nervous system are very cellular and vascularized; neuroblasts (cerebral precursors for both gray and white matter) and glioblasts originate from these sites between 10 and 20 weeks' gestation. This region of the developing brain is gelatinous in midgestation, but the gelatinous nature of the area gradually decreases and is barely present in full-term infants.

■ **FIGURE 17-7.** This MRI is of IVH that occurred in a 980-g infant. The ventricles are filled with blood, and there is blood in the interstitium of the brain. (Courtesy Jim Barkovich, MD, University of California, San Francisco.)

The dense, well-developed vascular network present in midgestation (which arises from the middle and anterior cerebral and anterior choroidal arteries) drains into a venous system that receives blood from the entire brain and terminates near the head of the caudate nucleus, where the veins join the Galen vein. The primary bleeding site in the premature brain is where veins and capillaries join, rather than where capillaries join to arteries or arterioles. Between 25 and 32 weeks' gestation, the germinal matrix is most prominent at the head of the caudate nucleus, and this is the usual site of germinal matrix hemorrhage.

IVH has been divided into categories that correlate with the severity and extent of the initial injury and with the clinical outcome (Papile et al., 1978). Grade I is a subependymal hemorrhage with minimal or no IVH. Grade II is an IVH without distention of the ventricles. Grade III is IVH with enlargement of the ventricles by intraventricular blood. Grade IV, the worst category of all, includes IVH, ventricular dilation, and extension of the bleeding into the parenchyma of the brain. Volpe (2001) revised the grading as follows:

- Grade I: Germinal matrix hemorrhage is present, and ventricular enlargement is less than 10%.
- Grade II: 10% to 50% of the ventricle is affected with IVH.
- Grade III: More than 50% of the ventricle is involved, usually with enlargement of the lateral ventricles.

Echo density of the periventricular parenchyma falls into a separate classification.

The incidence and severity of IVH vary, but in general, they increase with decreasing gestational age and have an overall incidence of 7% to 23%. The incidence of grades III and IV IVH (10% to 12%) in VLBW infants has not changed during the last 10 to 15 years (Faranoff et al., 2003). In a group of ELBW

infants, grade I IVH was present in 13%, grade II in 7%, grade III in 7%, and grade IV in 6% of neonates. The 13% incidence of grades III and IV IVH is similar to that reported by Fanaroff (Adams-Chapman et al., 2008). Mortality is high in infants with grade IV bleeds (at approximately 50%), but it is not increased in those with grades I and II bleeds (Vohr et al., 2000). While grades I and II IVH are not associated with severe neurologic sequelae, about 35% of survivors of grade III and 90% of grade IV IVH have poor neurodevelopmental outcomes (Whitelaw, 2001). Furthermore, posthemorrhagic hydrocephalus that is severe enough to require a ventriculoperitoneal shunt has the highest incidence of severe neurocognitive impairment in early childhood (78% in the group with grade III lesions and 92% in those with a grade IV IVH) (Adams-Chapman et al., 2008). Even though there is less significant neurodevelopmental delay in near-term infants with uncomplicated grade I or II IVH, they are reported to have lower developmental functioning, and their grey matter volumes are 16% smaller by MRI than predicted (Vasileiadis et al., 2004; Patra et al., 2006),

Periventricular Leukomalacia

This bilaterally symmetric, nonhemorrhagic lesion is the result of white matter necrosis that occurs dorsally and laterally to the external angles of the lateral ventricles (Fig. 17-8). In the past, this lesion was cystic and easily visualized on ultrasound. More recently, the most common form of PVL seen in ELBW infants on MRI consists of diffuse cerebral white matter injury without cyst formation. PVL is sometimes inappropriately thought to be a consequence of IVH, because both are commonly present on the same scan. However, PVL is a postischemic lesion, not a venous infarction (Takashima et al., 1986). While focal and tissue necrosis may cause cavitation and cyst formation, eventually the loss of oligodendrocytes and abnormal myelination reduce the white-matter volume, causing ventriculomegaly. A consistent clinical correlate of PVL is spastic diplegia. More recently, a variety of neurodevelopmental and cognitive deficits have been associated with noncystic PVL in preterm infants.

■ **FIGURE 17-8.** MRI of cystic PVL. (Courtesy Jim Barkovich, MD, University of California, San Francisco.)

Autoregulation of Cerebral Blood Flow

Critically ill newborns often require mechanical ventilation, airway suctioning, and intravenous fluid boluses, all of which can affect blood pressure, CO, heart rate, and cerebral blood flow. Hypoglycemia, hypercarbia, hypocarbia, hypoxia, hypo- or hypernatremia, and hypocalcemia can also dramatically affect the neonate's hemodynamic status. Fluctuations in blood pressure and CO often affect the newborn's CNS, since cerebral blood flow may change as a result of absent or attenuated cerebrovascular autoregulation. Cerebral blood flow autoregulation is present in both preterm and full-term newborns, but it is tenuous (Fig. 17-9). Also, the range of pressures over which blood flow is regulated is narrower for preterm infants. Cerebrovascular autoregulation is easily disrupted in neonates, and the normal blood pressure of preterm infants is close to the lower autoregulatory limit (Lou et al., 1979; Versmold et al., 1981; Tweed et al., 1983; Lou 1998). With decreasing gestational age, the lower limit approaches normal blood pressure. Similarly, the upper range of autoregulation may be approached during later gestational development (Papile et al., 1985). Furthermore, the normal range of autoregulation can be disturbed or disrupted by hypoxia, acidosis, seizures, and by the low diastolic blood pressures of patients with a PDA (Lou et al., 1979; Tweed et al., 1983; Lou, 1998). Rapid increases in arterial blood pressure can rupture the fragile vessels of the immature brain, while hypotension and low perfusion pressures may cause ischemia.

Hypoxic Ischemic Injury

If the amount of cerebral blood-flow is insufficient for cerebral oxidative metabolic needs, severe, long-term neurologic injury may occur. Asphyxia has three biochemical features: hypoxemia, hypercapnia, and metabolic acidosis. Some authors have suggested that the normal events occurring during labor and delivery, including uterine contractions, cause a degree of asphyxia in all fetuses. Although severe asphyxia can cause hypoxic-ischemic encephalopathy (HIE) and injure other organs, HIE often develops without injury to other organs. HIE is defined as abnormal levels of consciousness, the presence of seizures, and a history of severe asphyxia (e.g., umbilical cord pH < 7.0, Apgar score of 0 to 3 for longer than 5 minutes, neurologic

■ **FIGURE 17-9.** Autoregulation of cerebral circulation in neonates (curve B) and adults (curve A). (Redrawn from Harris MM: *Pediatric neuroanesthesia*. In Berry FA, editor: *Anesthetic management of difficult and routine pediatric patients*, ed 2, New York, 1990, Churchill Livingstone. Data from Hernandez MJ, Brennan RW, Vannucci RC, Bowman GS: *Cerebral blood flow and oxygen consumption in the newborn dog*, *Am J Physiol* 234:R209, 1978).

dysfunction) (Leuthner and Das, 2004). Neurologic abnormalities caused by infections or metabolic causes should not be labeled HIE. HIE occurs in approximately 4 to 5 per 1000 live births. One study demonstrated a decrease in HIE between 1990 to 2000 (Wu et al., 2004a).

Hypoxic-ischemic injury is often multifactorial and can be traced to antepartum factors (e.g., infection, toxemia, or diabetes), intrapartum events (e.g., infection, abruption, or umbilical cord compression), and postpartum problems (e.g., CHD, diaphragmatic hernia, or sepsis). Regardless of its etiology, significant asphyxia results in depression at birth (e.g., apnea, bradycardia, or hypotonia) and a risk for HIE. Over the initial 24 hours of life, infants with HIE have depressed mental statuses and are difficult to arouse. They are often hypotonic and have temperature instability. In other cases, they may be “jittery.” Multifocal or focal seizures are common during the first 4 to 12 hours of life. At times the seizures can be simply repetitive eye movements, blinking, tongue movements, or apnea. The Moro reflex, suck, grasp, and the deep tendon reflexes may be depressed or absent. By 24 hours of life, the Moro reflex is usually hyperactive, the cry is high-pitched and shrill, and generalized seizures or apnea are present. The subsequent course for these patients during the neonatal period is enormously variable and depends on the severity and etiology of the initial events.

Unfortunately, no specific clinical or biochemical markers of asphyxia accurately predict later neurologic function. Isolated low 1-minute Apgar scores (see Apgar Score), transient moderate acidosis, or other metabolic abnormalities, in the absence of encephalopathy, do not correlate well with long-term outcome. Neurodevelopmental outcome is best predicted by severity of the encephalopathy. Sarnat and Sarnat related encephalopathy to neurologic outcome. In stage 1 (first 24 hours), the infant is hyperalert with unimpaired Moro and sympathetic reflexes and an electroencephalograph (EEG) reading that is abnormal. Stage 2 includes obtundation, hypotonia, hyperreflexia, and seizures. In stage 3, infants are stuporous, flaccid, and have abnormal brain stem and autonomic reflexes (Sarnat and Sarnat, 1976). These investigators reported normal outcome in infants who were in stage 2 for less than 5 days, but when the symptoms persisted for more than 7 days, severe neurologic injury occurred. The presence of stage 3 at any time during the clinical course was predictive of injury or death. Although variations on this scheme have been described, the general trends indicate that a severe neurologic syndrome in the neonatal period correlates with high mortality or significant functional impairment. Miller and associates (2004) developed a simple, quantifiable neonatal encephalopathy score based on the criteria identified by Sarnat and Sarnat (1976). Miller et al.’s (2004) encephalopathy score includes feeding, alertness, tone, respiratory status, reflexes, and seizure activity. The score obtained on day 1 and the maximum score from the first 3 days of life were correlated with outcomes of patients (who had neonatal encephalopathy) at 30 months of age. Similar to earlier reports, severe encephalopathy and seizures during the first 3 days of life predicted poorer outcomes.

Metabolic abnormalities associated with multiorgan system dysfunction after severe asphyxia (e.g., hypoglycemia, hypocalcemia, and hyponatremia) can precipitate or exacerbate seizures. Consequently, fluid intake and output and electrolyte concentrations after an asphyxial event must be corrected. Renal or hepatic injury or a period of *nil per os* (NPO) may contribute

to metabolic instability and to the development of secondary electrolyte abnormalities, such as the syndrome of inappropriate antidiuretic hormone (SIADH). Neuroimaging (e.g., cranial ultrasound and CT or MRI scans) are used to detect underlying CNS anomalies (e.g., arterial or venous malformations and masses) and extent of injury (e.g., stroke, hemorrhage, or ischemia), and it may suggest a specific intervention (e.g., surgery, interventional procedure for arteriovenous malformation [AVM]), or further evaluation (e.g., clotting studies). Aggressively treating seizures pharmacologically and providing supportive care are essential.

After an initial period of stabilization after neonatal resuscitation, searching for multiorgan dysfunction is a priority, especially if the neonate has HIE. For example, myocardial ischemia may manifest as tricuspid insufficiency or hypotension (decreased contractility). Pulmonary hypertension may evolve (at times associated with meconium aspiration) and require invasive monitoring and ventilator support. Clearly, inadequate cardiorespiratory function may exacerbate HIE if the CO is reduced or hypoxemia persists. Concern for gastrointestinal ischemia often delays feeding of premature infants for 3 to 7 days because it is thought that this reduces the risk of NEC. However, recent data suggest that this may not be true (Schurr and Perkins, 2008). Severe hepatic insults can cause clotting abnormalities or disseminated intravascular coagulation (DIC) and predispose the newborn to hemorrhage. Finally, renal insufficiency has been associated with CNS injury (67% of patients studied) and death (33%) if oliguria persists longer than 24 hours (Perlman and Tack, 1988).

Apgar Score

The Apgar score was initially proposed as a means of rapidly assessing the status of newborns at 1 minute after birth and as a means of determining whether a neonate required respiratory support (Apgar, 1953) (Table 17-4). As Casey and others (2001) recently suggested, “Every baby born in a modern hospital in the world is looked at first through the eyes of Virginia Apgar.” The Apgar score includes five variables with a range of scores from 0 to 2 (for a maximum of 10 points): heart rate, respiratory effort, muscle tone, reflex irritability, and color. Currently, the score is applied at 1 and 5 minutes, but in some cases the evaluation continues for as long as 20 minutes if continued resuscitative efforts are required.

The Apgar score has been demonstrated recently to be a predictor of mortality (Casey et al., 2001). In full-term infants,

TABLE 17-4. Apgar Score

Sign	0	1	2
Heart rate	Absent	Less than 100 beats per minute	More than 100 beats per minute
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Flaccid	Some flexion of extremities	Active motion
Reflex irritability	No response	Grimace	Vigorous cry
Color	Pale	Cyanotic	Completely pink

these authors found a mortality rate of 244 per 1000 (24.4%) for infants with 5-minute Apgar scores of 1 to 3, compared with 0.2 per 1000 (0.02%) for infants with 5-minute Apgar scores of 7 to 10. Similarly, in preterm infants of 26 to 36 weeks' gestation, the mortality rate was 315 per 1000 (31.5%) for infants with 5-minute Apgar scores of 0 to 3 and 5 per 1000 (0.5%) for infants with 5-minute Apgar scores of 7 to 10. Thus, the incidence of neonatal death was highest when the 5-minute Apgar scores were 3 or lower, independent of gestational age. Neonatal death most commonly occurred during the first day of life, with the majority of infants dying before 3 days of age. These data indicate that the Apgar score is a valid predictor of neonatal mortality. In fact, the Apgar score better predicted outcome than umbilical-artery pH of 7.0 or less. Combining a 5-minute Apgar of 0 to 3 with an umbilical artery blood pH of 7.0 or less increased the risk of death in both preterm and full-term infants. An Apgar score of 0 for longer than 10 minutes suggests that resuscitative efforts should be suspended (Jain et al., 1991). Papile (2001) stated, "At present, there is no single measure of the fetal or neonatal condition that accurately predicts later neurodevelopmental disability...but, few will deny [the Apgar score's] application at 1 minute of age accomplishes Dr. Apgar's goal of focusing attention on the condition of the infant immediately after birth." Although outcomes vary with gestational age, with the etiology of neonatal depression, and with other factors, effective resuscitation of infants with low Apgar scores resulted in survival of about 40% to 60% of the patients and, approximately two thirds of survivors had normal neurologic function (Leuthner and Das, 2004). In 1964, the Collaborative Study on Cerebral Palsy reported a stronger relationship between the 5-minute Apgar score and neonatal mortality than the 1-minute score (Drage et al., 1964). Controversy about the Apgar score arises when people try to use the Apgar score to predict neurologic outcome. Dr. Apgar did not intend that the score be used to establish the diagnosis of asphyxia, to measure the severity of perinatal asphyxia, or to predict long-term neurologic outcome. In fact, 75% of children with cerebral palsy had normal Apgar scores at 5 minutes (Nelson and Ellenberg, 1981).

Pathophysiology of Hypoxic-Ischemic Injury

Asphyxia-related insults follow a pattern of early energy depletion and failure of the Na⁺, K⁺-ATPase pump, which disrupts normal transmembrane ion gradients. This loss of these gradients causes the release of excitatory neurotransmitters, such as glutamate, dopamine, serotonin, and aspartate. Although glutamate is important for normal brain development, excessive excitation of glutamate receptors (e.g., *N*-methyl-D-aspartate [NMDA], α -3-amino-hydroxy-5-methyl-4-isoxazole propionic acid [AMPA], and kainite) leads to excessive intracellular calcium concentrations and activation of a variety of phospholipases and proteases that cause the release of arachidonic acid and other mediators. Downstream production of xanthine and prostaglandins generates free radicals, in part via the NO synthase system. Although this is a condensed and simplified version of some of the pathways for cellular injury, the basic schema of hypoxic-ischemic injury is clearly one of disruption of membrane and intracellular function (Volpe, 2001). The clinical correlates of this intense cellular injury include seizures, abnormal mental status, eventual cell death, and long-term CNS deficits.

Neuroprotection

Gonzalez and Ferriero (2008) emphasized that treatment of neonatal brain injury should focus on both neuroprotection and after injury treatment. Optimal therapy may require intervening at multiple pathways to both prevent cell death and to induce cell growth and differentiation (Gonzalez and Ferriero, 2008). In general, therapies under evaluation attempt to decrease oxidative stress (e.g., inhibition of NO, melatonin, allopurinol, or deferoxamine), inflammation (e.g., minocycline), and excitotoxicity pathways (e.g., magnesium, MK-801, topiramate, or memantine). Other strategies include administering various growth factors, such as erythropoietin, a glycoprotein that has diverse CNS functions. These include vasogenic and immune responses that may provide neuroprotection during hypoxia and ischemia and modulate neurogenesis and neural differentiation. Primarily studies of VEGF in animals have shown that VEGF regulates both angiogenesis and neurogenesis. Cortical neurons are the primary site of VEGF-A activity early in development, but later its primary effect is on glial cells. VEGF seems to enhance the survival of neurons after hypoxia and after exposure to glutamate. Generating new neurons could play a major role in recovery after injury that results from perinatal stroke or hypoxia and ischemia.

Hypothermia is being used more often as a method of treating brain injury. It is hypothesized that hypothermia modifies apoptosis and necrosis of injured neurons by reducing their metabolic demands and by decreasing the release of excitotoxic mediators. Several studies have shown a significant reduction in CNS injury with cooling to 33° to 34° C for about 72 hours. Preliminary results suggested decreased mortality and improved neurodevelopmental outcome, although the differences in neurodevelopment after cooling are not large (Shankaran et al., 2005; 2008). Hypothermia plus another form of therapy may have greater therapeutic effect than either treatment alone (Alkan et al., 2001).

Seizures

Seizures occur commonly in neonates, especially after asphyxia (Silverstein and Jensen, 2007). Neonates with encephalopathy, stroke, intracranial hemorrhage, CHD, inborn errors of metabolism, and some syndromes are prone to develop seizures. Without an EEG, it may be difficult to tell if a neonate is having a seizure, because non-seizure-induced, repetitive movements are common. Cerebral palsy, low intelligence quotient (IQ), and epilepsy often accompany seizures and receptor expression, and neonatal seizures alter synaptic plasticity (Holden et al., 1982; Mellits et al., 1982; Swann and Hablitz, 2000; Stafstrom et al., 2006). Phenobarbital, diazepam, phenytoin, and valproate are commonly used drugs for the treatment of seizures, but these drugs can increase apoptotic neuronal death (Pereira de Vasconcelos et al., 1990; Schroeder et al., 1995). Furthermore, they fail to block neonatal seizures in as many as 50% of patients (Sankar and Painter, 2005). Hypoglycemia and hypocalcemia are other causes of seizures, and correcting these abnormalities usually terminates the seizures. The neonate's PaCO₂ should be maintained within the normal preoperative range (not reduced), because alkalosis lowers the seizure threshold and may induce a seizure. Anesthesia obscures overt seizure activity, especially when paralytic drugs are used.

Perinatal Stroke

Perinatal stroke has been more commonly recognized during the past few years because of improved neuroimaging. The incidence is 1:2300 to 1:5000 infants born at term and 7:1000 in those born prematurely (Raju et al., 2007; Benders et al., 2008). Infants with CHD have significantly more ischemic perinatal strokes than other neonates (Sherlock et al., 2009). Approximately 40% of neonates with transposition of the great vessels (TGV) show evidence of preoperative stroke; an additional one third has evidence of a new stroke after cardiac surgery. Many of the patients who had a stroke before surgery underwent balloon septostomy to improve oxygen—the incidence of stroke is high after this procedure (McQuillen et al., 2006). Strokes are either detected in the first few days of life or after 28 days of age. Those detected early are found because patients have seizures or undergo an MRI. Despite the evidence of a stroke, many neonates have no signs of neurologic dysfunction. They may not show signs of focal lesions or encephalopathy (Miller, 2000). Perinatal strokes are classically located within the boundary of the area perfused by the middle cerebral artery, usually the left cerebral artery (Schulzke et al., 2005). The incidence of arterial perinatal stroke is similar in preterm neonates to that of term infants (de Veber et al., 1998). Cerebral venous thrombosis is another cause of perinatal strokes and is usually detected when the neonate develops seizures (Wu et al., 2003). Venous infarctions often become hemorrhagic.

Many infants with perinatal strokes show no evidence of injury in the neonatal period. The diagnosis is only made at 4 to 8 months of age when hemiplegia, seizures, or difficulty with locomotion or handedness are detected. Again, most of these injuries are the result of middle cerebral-artery occlusion.

The cause of a stroke in a given patient is almost never known. However, possible maternal factors include chorioamnionitis, prolonged rupture of the membranes, preeclampsia, and intrauterine growth retardation (Wu et al., 2004b). Twenty percent to 68% of infants with arterial ischemic stroke had prothrombotic states (Golomb et al., 2001). Polycythemia is also a cause of neonatal stroke, and suggested factors related to perinatal stroke include infection, inflammation, and hypoglycemia (Günther, et al., 2000; Benders et al., 2007).

Preoperative Neurologic Evaluation

Neurologically injured newborns often require surgery to treat CNS abnormalities (e.g., insertion of a ventriculoperitoneal shunt), to provide supportive care (e.g., insertion of a gastrostomy tube or central venous catheter for intravenous alimentation), or to treat associated anomalies and problems (e.g., repair of congenital diaphragmatic hernia [CDH], laparotomy to treat an intraabdominal crisis, repair of a meningomyelocele, or insertion of a ventriculoperitoneal shunt).

There are some important questions to answer as part of the preoperative evaluation of the nervous system of neonates. Does the neonate breathe spontaneously and is the heart rate relatively stable and normal (120 to 160 beats per minute)? Is the fontanel normal (i.e., skin even with the outer table of the skull), bulging (from increased intracranial pressure), or sunken (from dehydration or volume depletions)? Is the muscle tone normal for the infant's age? Differences in tone between the upper and lower extremities or between one side of the body or the other may suggest the presence of a neonatal stroke

(Ibrahim et al., 2008). Does the infant bring his hands and arms together in front of the chest (Moro reflex) when the arms are raised and suddenly released? Is the Moro reflex equal bilaterally? Does the infant grasp the examiner's finger when it is placed in a hand? When a finger is placed on the anterior sole of the foot, do the toes curl in a grasping motion? Is the Babinski reflex normal? Without experience it may be difficult to elicit deep tendon reflexes in neonates, especially preterm neonates. Do the eyes move normally when a flashlight is moved in different directions? The pupils should constrict to light, and there should be evidence of a gag reflex and a suck. A complete neurologic examination should be documented in the patient's chart to note neurologic abnormalities that predate surgery and anesthesia.

In addition to the above questions, infants with neurologic injury who are undergoing preoperative assessment are usually divided into three categories:

1. Stable infants with well-defined neurologic status who are scheduled for elective procedures,
2. Stable infants with evolving neurologic injuries, and
3. Acutely ill infants who require urgent surgery.

Preoperative evaluation of neurologically stable infants with no evidence of acute cardiorespiratory, hepatic, or renal problems and who require an elective surgical or diagnostic procedure should focus on determining what is normal for each patient. That is, what is the range of an infant's normal blood pressure, heart rate, respiratory rate, oxygen saturation (and FIO_2), urine output, and nutritional status. These variables should be kept within this normal range if possible. The neurologic status should be documented, including evidence for gastroesophageal reflux and its treatment, as well as the incidence of seizures (if any) and their treatment. If available, electrolyte and calcium concentrations and liver function studies should be reviewed. If the neonate's course is stable and the procedure proposed is noninvasive, the most relevant laboratory value is a hematocrit.

Infants whose condition is stable except for ongoing neurologic problems (e.g., encephalopathy or seizures) require review of their vital signs, laboratory values, and medications, and they must have an appropriate physical examination. The hemodynamic responses to sedatives and analgesics and to painful procedures should be reviewed so the anesthesiologist can develop an anesthetic plan that will minimize wide variations in blood pressure. It should be determined whether the intravascular volume is adequate. Rapid administration of intravenous fluid during induction of anesthesia should be avoided because doing this may suddenly increase arterial and intracranial pressures, which can cause intracranial hemorrhage, especially in preterm neonates. The intracranial hypertension and increased intracranial volumes occur because cerebrovascular autoregulation is abnormal or absent. Both hypertension and hypotension can exacerbate neurologic injury. If available, near-infrared spectroscopy (NIRS) or EEG data should be reviewed. Do feeding, suctioning the trachea, medications (e.g., sedation), and fluid therapy alter cerebral oxygenation (Baserga et al., 2003)? If the patient is mechanically ventilated, understanding how oxygenation and ventilation are affected by various interventions may provide clues to the best ventilatory strategy to employ during surgery.

Finally, if the surgery is urgent or emergent, the overwhelming focus must be on the lesion that is making the surgery

urgent, but the trends in cardiorespiratory and metabolic status must also be evaluated so that intraoperative management will have the least effect on the CNS injury and not make it worse.

Postanesthetic Apnea

Preterm and expremature infants undergoing elective surgery are prone to develop postoperative apnea (Steward, 1982; Gregory and Steward, 1983). Apnea is usually defined as cessation of breathing for 20 seconds or more. The likelihood of life-threatening postoperative apnea increases if the patient had apneic spells in the NICU (Liu et al., 1983). Twenty percent to 30% of preterm infants have apnea with cyanosis and bradycardia during the first month of extrauterine life. Steward (1982) reported the presence of apnea in 18% of preterm infants (with a gestational age of fewer than 38 weeks or a postnatal age of 3 to 28 weeks) during the first 12 hours after surgery.

A prospective study by Liu et al. (1983) found that a history of apnea and a postconceptual age of fewer than 44 weeks often resulted in apnea after surgery. Kurth and LeBard (1991) reported that postanesthetic apnea (defined as cessation of breathing for more than 15 seconds, not longer than 20 seconds) occurred commonly in expremature infants whose postconceptual ages varied from 32 to 55 weeks. The initial episode of apnea occurred as late as 12 hours after the termination of anesthesia. These authors recommended that infants who whose postconceptual age was younger than 60 weeks and who developed apnea after surgery be continuously monitored in the hospital until they were apnea free for at least 12 hours.

Welborn et al. (1986) found no evidence of apnea in a group of healthy premature infants who had a postconceptual age of 44 weeks or more at the time of surgery and who underwent general anesthesia for herniorrhaphy. Although many of these patients did not have apnea, 63.6% of the them had periodic breathing, a common finding in premature infants that is characterized by repetitive apneas of short duration (fewer than 5 to 10 seconds) without oxygen desaturation or cyanosis and is usually harmless. Malviya et al. (1993) noted that expremature infants younger than a postconceptual age of 44 weeks had significantly more apnea than older infants. Coté et al. (1995), using data from 255 patients garnered from previously published studies, found an incidence of apnea of 1% in infants of 55 to 56 weeks' postconceptual age. They also found an inverse relationship between postconceptual age and the incidence of apnea. Those who were 56 weeks' postconceptual age or younger had the greatest risk for apnea. Anemia (Hct < 30%) was also an important risk factor for apnea (Fig. 17-10).

Nearly all patients in these studies of postoperative apnea in prematurely born infants in the past were anesthetized with halothane or isoflurane, drugs that have higher blood-gas solubility coefficients than newer inhaled anesthetics such as sevoflurane and desflurane. These less soluble agents have been associated with a lower incidence of apnea in patients who do not have a history of preoperative apnea (William et al., 2001).

Other factors that predispose infants, especially premature infants, to apnea include hypoglycemia, hypoxia, hyperoxia, sepsis, anemia, hypocalcemia, and changes in the environmental temperature (Schulte, 1977). Postoperative apnea may also be the result of the interaction of general anesthesia with an immature CNS (including the respiratory center). For example, in low concentrations, halothane depressed the chemoreceptor

FIGURE 17-10. Predicted probability of apnea for all patients, by gestational age and weeks of postconceptual age. Patients with anemia are shown as the horizontal line. The bottom marks indicate the number of data points by postconceptual age. The shaded boxes represent the overall rates of apnea for infants within that range of gestational ages. The probability of apnea was the same regardless of postconceptual age or gestational age for infants with anemia. (Redrawn from Coté CJ, et al.: *Postoperative apnea in former preterm infants after inguinal herniorrhaphy: a combined analysis*, *Anesthesiology* 82:807, 1995.)

responses to hypoxia (Knill and Gelb, 1978). Inhaled anesthetics also depressed intercostal muscles function, thus reducing the FRC and increasing the risk of hypoxemia (Tusiewicz et al., 1977). These differences, coupled with an immature response to hypoxia and hypercarbia, predispose premature infants to erratic respiratory responses in the perioperative period (Rigatto et al., 1982).

Residual anesthesia in the postoperative period may also be an important factor in the development of apnea in preterm babies. This may be especially true when halothane, with its high lipid solubility, was the standard anesthetic in pediatric anesthesia. The cartilaginous upper airway of preterm infants may also predispose them to upper airway obstruction, and this obstruction may be made worse by the effects of residual anesthesia on pharyngeal muscles (Dransfield et al., 1983). Elective surgery should be delayed, if possible, until former preterm infants are beyond 44 weeks' postconceptual age (Gregory and Steward, 1983). Infants younger than 44 weeks' postconceptual age who require surgery must be individually evaluated. The type of surgery, the patient's gestational and postconceptual age, hematocrit, current cardiorespiratory function (i.e., oxygen or diuretic dependence, CLD, neurologic status) are all factors that must be taken into consideration when developing a perioperative plan for the expremature infant. These patients should be admitted to hospital for 24 to 36 hours for postoperative monitoring.

Thermoregulation

Newborns abruptly arrive into an environment that is approximately 20°C cooler than the one they just left. Living in this new, colder environment markedly increases the number of calories expended to regulate body temperature. Once born, neonates lose heat by evaporation, convection, conduction, and radiation. Extremely preterm infants can lose 15 times more heat by transdermal water loss than full-term babies (Hammarlund et al.,

1979). To compensate for increased heat losses, the sympathetic nervous system constricts skin blood vessels, which centralizes body heat (Asakura, 2004). Oxygen consumption and cell metabolism increase two- to threefold.

Many factors are responsible for heat loss, including cold environments (e.g., delivery rooms), a high ratio of surface area-to-body weight, reduced subcutaneous fat, and an underdeveloped ability to shiver in response to cold. Shivering is limited in part by the neonate's much smaller muscle mass (25% vs. 45% in the adult). The major compensatory mechanism for cold stress in neonates is nonshivering thermogenesis (NST). NST is the result of stimulation of triglyceride and fatty acid metabolism in energy-rich brown fat by norepinephrine and thyroid hormone (Stern et al., 1965). Brown fat, which is mostly deposited during the third trimester of pregnancy, is found between the scapulae and around major abdominal organs. Infants born before the third trimester have less ability to initiate NST and are prone to hypothermia. SGA neonates have NST but to a far lesser degree than AGA term infants.

Hypothermia (body temperature of less than 36° C) increases oxygen consumption, metabolic acidosis, and pulmonary and peripheral vascular resistance while reducing CO (Brady and Ceruti, 1966). Babies admitted to the NICU with a temperature of 35.5° C have a P_{aO_2} that is on average 18 mm Hg lower than neonates whose body temperatures are equal to 36.5° C. Warming cold infants to 36.5° C or higher increased P_{aO_2} (Stephenson et al., 1970). Neonates should reside in a neutral thermal environment (i.e., the environmental temperature at which their oxygen consumption is minimal). Normally, this occurs when the skin temperature is 36° C and the environment temperature is between 32° to 34° C (see Chapter 6, Thermoregulation: Physiology and Perioperative Disturbances, Fig. 6-2) (Adamson and Towell, 1965). Prematurity, hypoglycemia, and general anesthesia exaggerate the neonate's poor metabolic response to hypothermia (Swyer, 1975). Because preterm and asphyxiated or neurologically injured full-term neonates have limited ability to maintain normal body temperatures, their environmental temperature should be carefully controlled with overhead heaters, isolettes, and warm operating rooms.

Preoperative evaluation of temperature regulation should determine whether a neonate has difficulty maintaining body temperature. Preterm infants require servocontrolled devices to maintain normal body temperatures, whereas neurologically intact term infants usually require minimal assistance to maintain stable body temperatures (e.g., clothing and a blanket). AGA infants that have difficulty maintaining their body temperature should be evaluated for sepsis or neurologic injury. It is important to determine if the environmental temperature was increased or decreased to maintain a normal body temperature; having to do so is an indication of temperature instability and possible sepsis.

There are several methods of maintaining a neonate's body temperature, including covering the body with clear plastic, covering the head with a hat, placing a warming pad under the infant, increasing the environmental temperature, and wrapping the infant in warm blankets (see Chapter 6, Thermoregulation: Physiology and Perioperative Disturbances).

Maintenance of a normal body temperature is crucial, because hypothermia increases PVR, decreases pulmonary blood flow and causes right-to-left shunting of blood through the foramen ovale or PDA (see Transitional Circulation, p. 523, and Chapter 6, Thermoregulation: Physiology and Perioperative Disturbances, Fig. 6-8) (Brady and Ceruti, 1966; Stephenson et al., 1970).

Prolonged exposure to a hypothermic environment places demands on neonates that may exceed their ability compensate for these demands. If they cannot do so, hypoventilation, inadequate oxygen delivery, tissue acidosis, and cardiovascular collapse may occur (Adamsons et al., 1965).

The neonate's temperature can be maintained by wrapping the trunk and extremities with plastic wrap, using stockinet caps, and caring for the child in incubators and overhead heaters (Roberts, 1981; Vora et al., 1999). Other than a cap, it is difficult to use any of these devices in the operating room because their use makes it difficult or impossible to do the operation.

Overhead heaters allow access to the patient and are commonly used during the first few days of life and in the operating room before the surgical drapes are applied. Beside allowing access to the patient, these devices effectively maintain the baby's body temperature. Compared with incubators, overhead warmers increase insensible water loss by about 0.94 mL/kg per hour or 22.6 mL/kg per day (Flenady and Woodgate, 2003). More overhead warmer-treated patients had a serum sodium of greater than 150 mEq/L, compared with incubator-treated infants (Meyer et al., 2001). This increases the daily fluid requirements. The oxygen and energy consumption and the incidence of bradycardia are increased in overhead warmer-treated neonates (Long, 1980; Gorski et al., 1990; Hutchison, 1994). Nurses interact more often with infants who have been cared for in an overhead warmer than with those who were cared for in an incubator, which increases the opportunity for infections (Davenport, 1992). There are no reported differences in the rate of NEC, IVH, PVL, or death associated with overhead warmers and incubators.

Infants cared for in incubators have less insensible fluid loss, lower fluid intake, and lower body temperatures on the first 2 days of life. However, no difference in weight gain, maximum serum sodium, or serious complications (e.g., NEC, PVL, or ROP) was found in infants treated in the incubator vs. the overhead warmer (Meyer et al., 2001). More infants in the overhead-warmer group required phototherapy for hyperbilirubinemia. When evaluating neonates for surgery, anesthesiologists must be aware that patients cared for in overhead warmers may be hypovolemic more often than patients cared for in incubators and require correction of their intravascular volume preoperatively.

Liver

During the third to fourth week of gestation, epithelium of the posterior foregut forms an outpouching (liver bud) that invades the mesenchymal cells of the septum transversum of the diaphragm. Cells from both structures form hepatocellular tissue that is separated by sinusoids. The blood supply of the developing liver originates from the yolk sac. These vessels eventually become the hepatic and portal venous systems (Mitchell and Sharma, 2009). A connection between the hepatic bud and the duodenum forms the common bile duct, and an outgrowth from the common bile duct forms the gallbladder and the cystic duct. Endodermal cells occlude the extrahepatic bile ducts for the first 3 months of gestation. Failure to recannulate the ducts around this time results in extrahepatic biliary obstruction (i.e., biliary atresia), a common cause of liver failure during the first year of life. By the fourth week of gestation, hepatocytes produce and secrete some proteins, including α -fetoprotein

and α_1 -antitrypsin (Diehl-Jones and Askin, 2002). By the fifth week of gestation, hematopoietic stem cells are present in the liver, and these cells are the primary source of hematopoiesis throughout the first two thirds of gestation; the bone marrow assumes this role during the third trimester. To accomplish hematopoiesis, the liver mass increases fortyfold, and in early gestation, hematopoietic cells outnumber hepatocytes. Early in gestation hepatic cells differentiate into type II hepatocytes and intrahepatic bile ducts. Failure to develop intrahepatic ducts is another major cause of liver failure during infancy. Formation of the Golgi apparatus permits synthesis and secretion of albumin and other proteins. By the second month of gestation, bile is secreted. Glycogen synthesis occurs by the tenth week of gestation, and acini are present by the third gestational month. The umbilical vein, not the portal vein, supplies most of the blood flow to the left (90%) and the right (60%) lobes of the liver in utero (Bloom and Fawcett, 1975).

The liver serves a critical role in carbohydrate, protein, and lipid metabolism. It also synthesizes a wide array of compounds essential for coagulation; it stores iron (ferritin), and biotransforms a large number of endogenous (e.g., thyroxine and steroid hormones) and exogenous (e.g., drugs and toxins) substances. This discussion focuses on those aspects of liver function most relevant to the anesthetic care of the newborn: glucose metabolism, coagulation, and biotransformation of drugs. Because of its high incidence, hyperbilirubinemia is also discussed.

Glucose Metabolism

The fetal supply of glucose is abruptly interrupted at birth, requiring neonates to meet their glucose needs by glucose intake, by converting glycogen (which is stored in the liver and heart during the third trimester of pregnancy) to glucose, and by glycogenolysis. Glycogen breakdown is under the control of catecholamines and glucagon. The liver of infants born at term has a greater store of glycogen than the adult (Kalhan and Parimi, 2000). Glycogenolysis allows full-term infants to maintain normal serum glucose concentrations during a 10 to 12 hour fast. Since glycogen storage and the capacity for degradation mostly occur during the last trimester of pregnancy, preterm infants are predisposed to hypoglycemia. Gluconeogenesis is not active in fetal liver, but a variety of hepatic enzymes that are important in gluconeogenesis (e.g., glucose-6-phosphatase) undergo rapid development after birth (Kalhan and Parimi, 2000; Kalhan et al., 2001).

Preoperatively, most newborns receive an intravenous infusion containing 5% to 10% dextrose. In general, an infusion rate for dextrose of 4 to 7 mg/kg per minute (e.g., 10% dextrose at 4 mL/kg per hour equals 6.6 mg/kg per minute of dextrose) maintains normoglycemia in both full-term and preterm infants. Normal glucose levels are between 40 and 60 mg/dL. A blood sugar concentration of less than 40 mg/dL is defined as hypoglycemia. The symptoms of hypoglycemia are nonspecific and include jitteriness, cyanosis, apnea, lethargy, seizures, and hypotonia. The common causes of hypoglycemia include hypoxemia, sepsis, and high levels of circulating insulin. During a preoperative visit, the serum glucose concentration achieved with the current rate of intravenous glucose administration should provide the information needed to determine what glucose infusion rate is required during surgery. Occasionally administering this amount of glucose produces hyperglycemia, and the infused concentration of glucose must be reduced, usually to 2.5% dextrose.

Biotransformation

The liver is the primary site for metabolism of drugs and other xenobiotics, as well as for detoxification of nontherapeutic and environmental compounds. Because of this vital function, the liver is vulnerable to the toxic effects of these compounds. Because degradation pathways are immature, infants (especially newborns) may metabolize drugs and toxins less efficiently than older patients. Three main categories of hepatic-drug metabolizing systems include phase I (oxidation-reduction and hydrolysis), phase II (conjugation with glucuronic acid, glycine, acetate, or sulfate), and phase III (transport from liver) reactions. In general, the neonatal liver has less capacity to metabolize and excrete drugs because there are deficiencies of many of the enzymes involved in oxidation, reduction, hydrolysis, and conjugation.

Cytochrome P450 (CYP) enzymes are responsible for phase I processes. More than 50 CYP enzymes have been identified, and they are classified according to their nucleotide sequence (Wilkinson, 2005). Although the full clinical relevance of the relative expression of these enzymes in fetus and neonates is yet to be defined, their primary expression is in the liver, and their developmental expression has a major role in the pharmacokinetics and pharmacodynamics of drugs, including those used during anesthesia. The CYP3A family is responsible for metabolism of about 50% of all drugs (Hines and McCarver, 2002). Multiple patterns of developmental expression have been reported (Figs. 17-11 and 17-12). For example, although CYP3A7 is present in utero, its expression is negligible 1 week after birth. On the other hand, the concentration of CYP3A4 is low during fetal life but is about 50% of adult levels by 6 months of age. CYP2D6 has a multitude of polymorphisms and may be of particular relevance in the metabolism of psychotropic (and anesthetic) drugs (Blake et al., 2005). Clearly, as the ontogeny of metabolizing enzymes and transporters is understood, the dosing of drugs will be better adjusted for age-related differences, toxicity may be avoided, and clinical effectiveness will be improved.

Fewer data are available concerning the ontogeny of phases II and III. However, the uridine glucuronosyltransferases (UGTs) function at much lower levels in neonates than they do in adults. For example, glucuronidation of morphine reaches adult levels only at 2 to 6 months of age (de Wildt et al., 1999). Other conjugating enzymes with major roles in drug metabolism have been less well characterized (glutathione S-transferases, N-acetyltransferases, glucuronosyl transferases), but they are likely to play important roles in the unique drug handling commonly seen in the newborn.

Although the clinical implications of the genetic variability and developmental changes of hepatic metabolizing processes are not clearly identified, examples of age-related differences in drug responses are well documented. For example, the age-related pharmacokinetics of various muscle relaxants and narcotics were described more than 20 years ago (Cook, 1981; Fisher et al., 1982; Gauntlett et al., 1988). Caffeine and theophylline are metabolized by CYP1A2, which is expressed at low levels in the newborn and requires age-related considerations for therapeutic dosing (Hakkola et al., 1994). More recently, both postnatal age and postconceptual age were correlated with decreased and variable propofol clearance in preterm and full-term infants. Of note, multiple cytochrome P450 enzymes are required for metabolism of this drug. Consequently, altered expression of phases I and II hepatic metabolic enzymes may be responsible for these pharmacokinetic findings (Allegaert et al., 2007).

■ **FIGURE 17-11.** Changes in metabolic capacity. The activity of many cytochrome P-450 (CYP) isoforms and a single glucuronosyltransferase (UGT) isoform is markedly diminished during the first 2 months of life. In addition, the acquisition of adult activity over time is enzyme- and isoform-specific. (From Kearns GL, et al.: *Developmental pharmacology-drug disposition, action, and therapy in infants and children*, N Engl J Med 349:1157, 2003.)

■ **FIGURE 17-12.** Ontogeny of cytochrome P450 (CYP) 3A4 and 3A7 activity expressed as activity measured using isoform-specific probes in human liver microsomes. (From de Wildt SN, et al.: *Cytochrome P450 3A: ontogeny and drug disposition*, Clin Pharmacokinet 37:485, 1999.)

The preoperative evaluation of a newborn should include a review of current medications and determination of unexpected durations of action, toxicity, or side effects. In general, prolonged effects of these drugs can be expected in neonates because the enzymes of metabolism and elimination are immature.

Coagulation

The fetus produces coagulation factors because they inefficiently cross the placenta. Plasma levels of some coagulation proteins and factors and laboratory tests of clotting function (e.g., prothrombin time [PT] and activated partial thromboplastin time [APTT]) are markedly different in healthy full-term and preterm infants than in adults (Table 17-5).

Plasma concentrations of vitamin K-dependent proteins (e.g., factors II, VII, IX, and X), as well as factors XI and XII, prekallikrein, and kininogen, are about 50% lower than those of adults, but the concentrations of fibrinogen, factor V, and factor VIII are similar to those of adults (Andrew et al., 1987; 1988).

TABLE 17-5. Normal Values for Clotting Tests Appropriate for Gestational Age (AGA), Small for Gestational Age (SGA), and Premature Infants During the First Day of Life

Test	AGA	SGA	Premature
INR	1.3 ± 0.15	1.3 ± 0.2	1.3
Range	1.00-1.9	1.05-2.0	1.3
PT (Sec)	15.5 ± 1.4	16.2 ± 2.4	13
Range	13.4-19	13.3-23.6	10.6-16.2
aPTT (Sec)	42 ± 6.6	44 ± 8	53.5
Range	30-57	33-68	27.5-79.4
Fibrinogen g/l	2.83 ± 0.58	1.55	2.43
Range	1.25-3.0	0.2-2.2	1.5-3.73

Data from *Biol Neonate* 83:177-181, 2003; *Blood* 70:165-172, 1987; and *Blood* 72:1651-1657, 1988.

Disturbances in clotting caused by liver dysfunction correlate with decreased synthesis of both clotting and fibrinolytic factors and with abnormal platelet function. Hepatocytes synthesize factors I (fibrinogen), II (prothrombin), V, VII, IX, and X, and abnormal production of these factors is reflected in a prolonged PT. The PT mostly reflects availability of factor VII. Thrombin levels of newborns are about 50% those of adults. APTT primarily reflects the amount of thrombin generated (Green et al., 1976).

In spite of differences between newborn and adult liver function, clinically significant bleeding is uncommon in normal neonates who have adequate vitamin K levels. The association of vitamin K deficiency and hemorrhage in the newborn was initially described in 1894, is secondary to inadequate activity of vitamin K-dependent coagulation factors (i.e., II, VII, IX, and X), and is corrected by vitamin K replacement (Sutor et al., 1999). On the other hand, the newborn is predisposed to bleeding by infections and asphyxia, which may cause DIC. DIC is associated with prolonged PT and APTT that are caused by depletion of certain coagulation factors (e.g., fibrinogen and factors V and VIII), with increased fibrin degradation products, and thrombocytopenia.

Preoperative evaluation should initially focus on whether or not there is a history of bleeding. If no clinical bleeding has been noted and the PT and PTT are normal for age, no further preoperative evaluation or treatment is indicated. Since many infants requiring surgery have significant physiologic derangements and nutritional deficiencies, laboratory studies, including a PT and APTT and a platelet count, should be obtained. If bleeding has occurred or if the laboratory studies are abnormal and there is clinical instability (e.g., sepsis or NEC), aggressive treatment is indicated. Preoperatively, interpretation of responses to fresh frozen plasma (FFP) (which contains adult levels of all coagulation proteins) or cryoprecipitate (which contains high levels of fibrinogen and factor VIII) will aid in planning to maintain intraoperative hemostasis. FFP is used sometimes for intraoperative volume repletion if hemostasis is also abnormal. However, rapid administration of FFP can cause hypotension because of the high concentrations of histamine present in some FFP and because of decreased ionized calcium concentrations caused by citrate. If large volumes of intravenous fluids are not needed, cryoprecipitate may be used to correct the fibrinogen and factor VIII deficiencies associated with DIC. Cryoprecipitate does not correct other clotting deficiencies.

Hyperbilirubinemia

Increased serum bilirubin concentrations are almost universal during the first postnatal week. (Kahlan and Parini, 2000). In most cases, hyperbilirubinemia is transient and has been labeled *physiologic*. The primary source of bilirubin is hemoglobin, but other heme-containing proteins (e.g., cytochromes, catalases, and myoglobin) also contribute. Infants produce more bilirubin per kg of body mass than older patients because they have higher red cell masses and their red blood cells have shorter life spans. Bilirubin is the end product of hemoglobin breakdown and has also been reported to be an antioxidant and a free-radical scavenger (Sedlak and Snyder, 2004).

Because of its large nonpolar structure, bilirubin is lipophilic and requires biotransformation for excretion. Binding of bilirubin to albumin facilitates its delivery to the liver, and uptake of bilirubin into hepatocytes for conjugation requires glucuronic acid (i.e., organic anion transporter, [OATP2]) (Cui et al., 2001). Uridine diphosphate glucuronic acid provides the glucuronic acid. Most bilirubin is excreted in bile as bilirubin diglucuronides. Upon entry into the intestinal lumen, a variety of pathways exist for further disposal of bilirubin. As occurs in adults, bacteria metabolize bilirubin to urobilinogens for excretion in feces. Since the neonatal gastrointestinal tract lacks the same bacterial flora as adults, bilirubin may be reabsorbed and raise the serum bilirubin concentration. Beta-glucuronidase is also important for bilirubin metabolism, because it deconjugates bilirubin. Although this enzyme clears unconjugated bilirubin from the placenta, it increases bilirubin reabsorption from the gut after birth. Breast milk contains high level of β -glucuronidase and is partly responsible for “breast-milk jaundice” (Gourley and Arend, 1986).

Even if significant hemolysis occurs in utero, the normal placenta efficiently clears the bilirubin, and the newborn is seldom jaundiced. However, after birth the same bilirubin production would cause jaundice in most infants. With increasing bilirubin concentrations, the skin becomes progressively yellow (icteric) in a cephalocaudal pattern (Knudsen, 1990). The term *physiologic jaundice* refers to the common, transient, indirect

(unconjugated) hyperbilirubinemia in normal newborns. However, jaundice should be considered abnormal if it is present in the first 36 hours of life, persists beyond 10 days of life, is greater than 12 mg/dL, and the direct (conjugated) bilirubin is greater than 2 mg/dL or more than 30% of the total bilirubin concentration. Multiple disorders of increased bilirubin production (e.g., hemolysis secondary to maternal-fetal blood group incompatibility, other hemoglobinopathies, reabsorption of red blood cells from a hematoma, and polycythemia) or decreased excretion (e.g., as with genetic diseases, hypothyroidism, or infants of diabetic mothers) are recognized. Preterm infants more commonly develop elevated levels of bilirubin and are more vulnerable to bilirubin-induced CNS toxicity. CNS toxicity, or kernicterus, results from hyperbilirubinemia. Neuronal necrosis is the predominant feature and occurs mostly in the basal ganglia, brainstem, oculomotor nuclei, and cochlear nuclei.

During the preoperative visit, levels of total and direct bilirubin and their trends should be determined, as these levels and trends may reflect either normal postnatal development or sepsis and other anomalies. Hyperbilirubinemia, in association of other laboratory values, may provide an estimate of possible hepatic dysfunction and suggest the need for additional laboratory studies. Various tests evaluate direct injury to the liver; alanine aminotransferase (ALT), aspartate aminotransferase (AST), lactate dehydrogenase (LDH), and bilirubin concentrations may be increased as a result of asphyxia-ischemia-hypoxia (“shock liver”), sepsis, toxin-induced injury, or hepatitis. Direct bilirubin concentrations contribute to the hyperbilirubinemia that occurs with sepsis. Abnormalities in alkaline phosphatase, γ -glutamyltransferase (GGT), and 5-nucleotidase (5-NT) are more often the result of impaired bile flow or cholestasis. Specific clearances of substances, such as indocyanine green and paraaminobenzoic acid (PABA), are measures of hepatic excretory function. While albumin is synthesized only in the liver, abnormal serum albumin levels may also result from protein lost in the gastrointestinal track or kidney or from chronic infection. Finally, abnormal ammonia concentrations should suggest the presence of specific urea-cycle defects. During preoperative assessment, the goal is to understand the functional status of the liver and to estimate the effect of current liver function on drug metabolism, blood loss, surgical trauma, and the need for coagulation factors.

Renal Function

Metabolic stability and electrolyte homeostasis are maintained in utero by the placenta; renal growth and development appear not to be linked or regulated by function during this time. Permanent kidneys appear during the fifth week of gestation, and nephrons appear during the eighth week, initially in the juxtamedullary region and cortex. A complex interaction of genes, such as Wilms' tumor gene 1 (WT1), and growth factors such as neurotrophic factor, (GDNF) orchestrate this process (Taeusch et al., 2005; Dziarmaga et al., 2006). By 20 weeks' gestation, one third of the final number of nephrons is present, and by 35 to 36 weeks' gestation, the adult number of nephrons is present (see Chapter 5, Regulation of Fluids and Electrolytes) (McDonald and Emery, 1959). During the second half of gestation, kidney growth is in direct proportion to gestational age. Infants born prematurely develop new nephrons until about 34 to 35 weeks'

postconceptual age. Once the full complement of nephrons is present, further maturation of the kidneys occurs by increases in both glomerular and tubular size. Vascular growth and development parallel nephrogenesis. Anesthesiologists must understand renal development because of the kidneys' importance in maintaining acid-base homeostasis and fluid and electrolyte balance (see Chapter 5, Regulation of Fluids and Electrolytes).

Among healthy full-term infants, the number of nephrons varies up to fivefold (Merlet-Bénichou et al., 1999). Recent studies suggest that having fewer nephrons at birth correlates with hypertension later in life (Brenner et al., 1988; Keller et al., 2003). These authors suggest that hypertrophied, overworked nephrons slowly sclerose, leading to progressive renal dysfunction. The reduced number of nephrons is thought to result from both genetic and environmental factors (Lelièvre-Pégorier and Merlet-Bénichou, 2000). Recently, polymorphism of the RET gene was shown to reduce the number of nephrons (Zhang et al., 2008). A common variant of another gene, PAX2, is also associated with having smaller kidneys at birth (Quinlan et al., 2007). Both prematurity and fetal growth retardation have negative effects on postnatal renal growth (Huang et al., 2007; Rakow et al., 2008). Finally, oxidative injury during the neonatal period has been associated with decreased capillary density and fewer nephrons in adult rats (Zydzorczyk et al., 2008).

Urine is formed by 10 weeks' gestation, and urine production increases from about 2 to 5 mL/hour at 20 weeks' gestation to 10 to 12 mL/hr at 30 weeks', 12 to 16 mL/hr at 35 weeks', and to 35 to 50 mL/hr at 40 weeks' gestation (Rabinowitz et al., 1989). Because the fetal kidneys process large volumes of fluid, large quantities of hypotonic urine are produced. Fetal urine production is essential for the maintenance of normal amniotic fluid volumes, especially after 18 weeks' gestation. Oliguria causes oligohydramnios, which is associated with a specific facies, clubfeet, limb contractures, and in some cases, pulmonary hypoplasia. In essence, high fetal urine volumes are necessary for normal development of organs besides the urinary tract.

Fetal urine is initially hypotonic (100 to 250 mOsm/kg). Its tonicity decreases throughout gestation. For example, urinary sodium is 120 mEq/L at midgestation and decreases to 50 mEq/L by 32 to 35 weeks' gestation (Spitzer, 1996). Fetal and neonatal renal function is characterized by low renal blood flow, glomerular filtration rate (GFR), solid excretion, and concentrating power. Renal blood flow is low in utero because renal vascular resistance is high. After birth, renal blood flow increases markedly as a result of an increase in the arterial blood pressure and a decrease in renal vascular resistance. These changes allow more of the CO to be distributed to the kidneys (2% to 4% in utero, 10% at 1 week of age, 25% in the adult). Renal blood flow is about 20 mL/min per 1.73 m² at 30 weeks' gestation, 45 mL/min per 1.73 m² at 35 weeks' gestation, about 80 mL/kg per 1.73 m² at term, 250 mL/min per 1.73 m² at 8 days after birth, and 770 mL/min per 1.73 m² at 5 months of age (Heisler, 1993). Similarly, fetal GFR increases rapidly in utero as the number of nephrons increases. Because fetal kidney growth begins deep in the medulla, the juxtamedullary nephrons are more mature than other nephrons at birth and have greater tubular length than outer and inner cortical nephrons. Since the glomerulus is uniform, a "tubular-glomerular" imbalance exists. This imbalance explains, at least in part, why more of the solids presented to the proximal tubules of newborns are not reabsorbed.

The GFR of preterm infants is a function of both gestational and postnatal age. During the first 24 hours of extrauterine life, the GFR of infants born before 25 weeks' gestation may be as low as 2 mL/min per 1.73 m². Infants born between 25 and 28 weeks' gestation have a GFR of 10 to 13 mL/min per 1.73 m², and those born after 34 weeks' gestation have one of 20 to 25 mL/min per 1.73 m², which is similar to that of full-term infants (Svenningsen and Aronson, 1974). Although GFR increases at a slower rate in ELBW infants, all neonates without acquired renal insufficiency double their GFR by 2 weeks of age and triple it by 3 months of age. Thereafter, GFR increases more slowly. Adult values for GFR are reached by 12 to 24 months of age. Because there is rapid renal maturation after birth, a 3-week old infant with 27 weeks' gestation may have significantly more mature renal function than a healthy 6-hour-old full-term infant. Renal maturation apparently occurs in response to demand (separation from the placenta plus solute exposure). Renal filtration and concentrating ability increase when the kidneys are challenged.

The serum creatinine concentration is commonly used as a measure of glomerular function. At birth, it reflects maternal values and is higher than that of normal 1- to 2-week-old full-term neonates (0.4 mg/dL). For the first 4 weeks of life, the plasma creatinine concentration of preterm infants exceeds that of full-term infants (Bueva and Guignard, 1994). Interestingly, the serum creatinine concentration was the same at birth in infants born before 27 weeks' gestation as it was in those born at 31 to 32 weeks' gestation. Serum creatinine concentrations increased in all groups over the first 3 days of life and then gradually decreased to less than 0.5 mg/dL (Gallini et al., 2000). However, the maximum creatinine concentration reported was higher and occurred later (day 3.5 vs. day 1) in the most immature neonates. Creatinine clearance increased in all groups, but it increased more slowly in the infants who had fewer than 27 weeks' gestation. The variability in GFR and creatinine clearance, as a function of gestational and postnatal age, means that drugs primarily eliminated by the kidneys may be eliminated differently in different neonates.

Renal Tubular Function

Maintenance of normal extracellular fluid volume, water balance, sodium, and other electrolyte concentrations are interrelated and undergo significant postnatal changes. In addition to the marked changes in nephron number, glomerular function, and renal blood flow, developmental changes occur in the renal tubules throughout fetal and postnatal life. Coupled with tubular immaturity, metabolic demands of rapid growth and illnesses make managing fluids and providing nutritional support complicated in the newborn. The following factors should be considered:

1. Neonates, especially premature neonates, are less able to reabsorb and to excrete sodium (Fig. 17-13). Reabsorption of sodium by the proximal tubule increases with gestational age; 5% of the filtered sodium is excreted in the urine of infants with more than 30 weeks' gestation, but only 0.2% is excreted in full-term infants (Vanpeé et al., 1988). Hypoxia, respiratory distress, and hyperbilirubinemia may increase fractional sodium excretion.
2. Newborns have limited ability to concentrate their urine (245 to 450 mOsm/L in premature infants vs. 600 to 800 mOsm/L in full-term infants vs. 1200 to 1400 mOsm/L in adults).

■ **FIGURE 17-13.** Scattergram demonstrating the inversion correlation between fractional sodium excretion and gestational age. (From Siegel SR, et al.: *Renal function as a marker of human renal fetal maturation*, Acta Paediatr Scand 65:481, 1976.)

- Newborns of more than 35 weeks' gestation can dilute their urine to adult levels, about 50 mOsm/L. Infants born before 35 weeks' gestation can dilute it to about 70 mOsm/L. The maximum urinary osmolality attained after a dose of desmopressin (DDAVP) was about 520 mOsm/kg in infants with 30- to 35-weeks' gestation and 570 mOsm/kg in 4- to 6-week-old infants born at term. A 1- to 2-year-old child concentrates his urine to 1300 to 1400 mOsm/kg after a dose of DDAVP (Svenningsen and Aronson, 1974). The majority of infants still do not concentrate their urine that well at 6 to 12 months of life.
- Newborns commonly have low serum bicarbonate concentrations (12 to 16 mEq/L in ELBW infants, 18 to 20 mEq/L in infants with 30 to 35 weeks' gestation, 20 to 22 mEq/L in term infants, and 25 to 28 mEq/L in adults) (Schwartz et al., 1979). The loss of bicarbonate increases urine pH.
- The transport maximum (T_m) and the tubular reabsorption of glucose are both decreased (150 mg/dL in term neonates, 180 mg/dL in older children and adults). Glucosuria may occur in preterm infants at serum glucose concentrations below 100 mg/dL.
- Calcium absorption occurs in the proximal tubules of the kidneys, primarily by passive diffusion. High renal sodium losses increase calcium loss. Sick neonates, especially premature neonates, require supplemental intravenous calcium to maintain normal ionized calcium concentrations.
- Serum potassium concentrations that exceed 5.0 mmol/L are relatively common in newborns, particularly premature newborns that have a mild metabolic acidosis. Nonoliguric hyperkalemia, characterized by a rapid

rise of serum potassium during the first 1 to 3 days of life, also occurs in ELBW infants, probably as the result of rapid shifts of potassium from intra- to extracellular compartments (Mildenberger et al., 2003). Treatment of this disorder includes insulin/glucose, calcium/bicarbonate, diuretics, and binding resins.

All renal tubular cells are polarized. The apical membrane faces the lumen of the tubule, and the basal membrane faces the capillaries. Sodium is actively reabsorbed along the entire tubular system. Most sodium-coupled transporters required to salvage amino acids, glucose, phosphate, and lactate are located on the apical membrane of the proximal tubules. The Na^+ , K^+ -ATPase pump, which is responsible for approximately 70% of renal oxygen consumption, is located on the basolateral membrane and is important for active transport of sodium. About 60% to 80% of sodium reabsorption occurs in the proximal tubules. Another 10% to 15% occurs in the distal (i.e., aldosterone responsive) and collecting tubules (antidiuretic hormone [ADH] determines water permeability). The amount of sodium in fluid presented to the distal tubules depends in part on the efficiency of the proximal tubules.

After birth, reabsorption of sodium in the proximal tubules increases five- to tenfold in response to increased Na^+ , K^+ -ATPase activity (Holtbäck and Aperia, 2003). Glucocorticoid hormones increase messenger ribonucleic acid (mRNA) for both subunits of this enzyme, and prenatal administration of betamethasone to mature the lungs may also mature renal function. Similarly, developmental changes in the Na^+ - H^+ exchanger (NHE) may be responsible for differences in acid-base balance among newborns, older children, and adults. The kidneys both reabsorb bicarbonate and excrete fixed acids. Bicarbonate reabsorption occurs primarily in the proximal tubules, but it also occurs in the loop of Henle and the collecting ducts. Hydrogen is actively secreted, and the secreted hydrogen reacts with bicarbonate to produce carbonic acid and carbon dioxide. These substances enter the tubular cells through the action of carbonic anhydrase. Bicarbonate again forms and exits the cell via another transport mechanism. Several isoforms of NHE have been identified, and impaired function of this transporter has been described (Rodríguez-Soriano, 2000; Holtbäck and Aperia, 2003). Immature carbonic anhydrase activity and impaired NHE function explain in part the normal metabolic acidosis found in newborns.

Distribution of total body water changes throughout fetal life (Friis-Hansen, 1983; Brans, 1986). At 16 weeks' gestation, the total body water makes up 94% of the fetus' weight; at about 32 weeks' gestation it is 82%, and at term it is approximately 75%. The size of the extracellular compartment decreases from 65% at 16 weeks' gestation to about 60% at 24 to 25 weeks' gestation, to about 50% at term. At the same time the intracellular compartment increases from 34% in early gestation to 50% at term. Of note, most extracellular water is in the interstitial space (i.e., an extracellular compartment). This is exaggerated in preterm neonates, especially ELBW neonates, whose extracellular water compartments are very large.

During the first 3 to 7 days of extrauterine life, healthy term infants lose about 5% to 10% of their body weight, primarily through contraction of the extracellular water space (Fig. 17-14). Preterm infants follow a similar pattern, but they may lose more than 15% of their body weight; premature infants also take longer to establish steady growth than full-term infants do.

■ **FIGURE 17-14.** Extrauterine growth chart according to gestational age in weeks. (Data from Schaffer SG, Quimiro CL, Anderson JR, Hall RT: Postnatal weight changes in low-birth-weight infants, *Pediatrics* 79:702, 1987; Gleason CA, Taeusch HW, Ballard RA, editors: *Avery's diseases of the newborn*, ed 8, Philadelphia, 2005, Saunders, p. 1575.)

Cardiorespiratory abnormalities and their treatment, infections and their side effects, and pharmacologic interventions so alter growth patterns that it is difficult to define normal growth patterns in preterm neonates.

Hormonal control of neonatal fluid and electrolyte homeostasis is complex, and some of its features are unique. The renin-angiotensin-aldosterone, atrial natriuretic peptide (ANP), vasopressin, and catecholamine (i.e., dopamine and noradrenalin) systems affect regulation of electrolytes and water balance. However, the overall effectiveness of each of these systems is less than it is later in development. For example:

1. Aldosterone, angiotensin, and plasma renin activity are elevated in both term and preterm infants and are inversely related to gestational age. Immature kidneys are less responsive to the sodium- and water-conserving effects of these hormones. The roles of these hormones in neonatal adaptation are not well established, but their concentrations are high for several weeks, especially in critically ill patients. Prostaglandins counterbalance the vasoconstrictive effects of these hormones. The high concentrations of these hormones cause vasoconstriction and may be responsible, at least in part, for the renal failure seen after a dose of indomethacin is given to close a PDA.
2. The plasma vasopressin (ADH) concentration is higher in newborns than it is later in life, especially after vaginal delivery, and it is thought to be responsible, at least in part, for low urine output during the first 24 hours of life. Vasopressin may also participate in the postnatal contraction of the extracellular volume immediately after birth. It may also be responsible for indomethacin-induced renal failure in premature infants. Hypoxia, atelectasis, IVH, and BPD increase urine ADH concentrations in both preterm and term infants, and this nonosmotic secretion of ADH partly accounts for the dilutional hyponatremia of newborns, especially premature newborns (Wiriathian et al., 1986). Thus, the limited ability of fetuses and newborns to concentrate their urine is correlated with an immature concentrating ability of the medullary system, decreased response to ADH, and an immaturity of their aldosterone system.
3. ANP inhibits the production and action of both renin and aldosterone. High circulating concentrations of this peptide, plus prostaglandins and progesterone, are partly responsible for the negative sodium balance (Tulassay et al., 1986). Although few documented developmentally important actions of this compound have been reported, PEEP-induced oliguria can occur because less ANP is released.

TABLE 17-6. Maintenance Fluid Requirements During the First Month of Life

Birth Weight (g)	Insensible Water Loss (mL/kg/day)	Water Requirements (mL/kg/day) by Age		
		Day 1-2	Day 3-7	Day 8-30
<750	100-200	100-200+	150-200+	120-180
750-1000	60-70	80-150	100-150	120-180
1001-1500	30-65	60-100	80-150	120-180
>1500	15-30	60-80	100-150	120-180

Adapted from Veille JC: AGA infants in a thermoneutral environment during the first week of life, *Clin Perinatol* 15:863, 1988; Tausch W, et al.: *Schaffer and Avery's diseases of the newborn*, ed 6, Philadelphia, 1991, Saunders; and Lorenz J, et al.: Phases of fluid and electrolyte homeostasis in extremely low birth weight infants, *Pediatrics* 96:484, 1995.

Based on the complex interactions of renal development, illness, prematurity, and therapy, fluid and electrolyte management in the newborn should take the following factors into account:

1. Postnatal diuresis contracts the extracellular space, and the amount of contraction is greater in preterm infants. During the first few days after birth, clinicians should allow the normal negative fluid and electrolyte balancing process of nonsurgical patients to take place while maintaining cardiorespiratory stability and providing sufficient fluid intake to keep up with transepidermal fluid losses (Table 17-6).
2. Transepidermal fluid loss is related to gestational age and can be as much as 60 to 100 mL/kg per day in ELBW infants. Over the first 5 days of life, fluid losses decrease dramatically from 45 to about 19 g/m² per hour in infants with 25 to 27 weeks of gestation (Fig. 17-15) (Sedin et al., 1983). During the first few postnatal days, naked preterm infants lose up to 15 times more water through evaporation than naked full-term infants (Hammarlund et al., 1983). Consequently, naked VLBW infants may lose as much as 10% of their body weight through evaporation during the first 24 hours of life. Premature neonates have increased respiration, which further increases water loss. Evaporation accounts for about 40% of total baseline water losses in children and adolescents. The insensible evaporative water loss is several magnitudes greater in premature neonates than it is in older patients, because preterm neonates have increased epidermal permeability for water and because they have a larger surface area-to-volume ratio. The larger relative surface area provides a larger surface from which preterm neonates can lose water. To maintain normal water and electrolyte balance, meticulous attention must be paid to intake and output of fluid, body weight, urine output, and electrolyte concentrations (especially in ELBW infants) during the first 3 to 5 days of life.
3. Providing a warm, humidified environment and inspired gases or using plastic shields reduces transepidermal fluid loss, especially in ELBW infants, but these methods are difficult or impossible to use during surgery.
4. Measurement of serum and urine electrolytes, serum glucose concentrations, hematocrit, body weight, and intake and output of fluids help guide fluid therapy. It has been suggested that PDA, NEC, and CLD are caused by overhydration or by hyper- or hyponatremia, but there is no conclusive evidence to support this contention.
5. An intravenous calcium infusion is usually required in preterm, asphyxiated, or LGA and SGA infants until they can take in adequate enteral nutrition.

The high anabolic rate associated with growth makes the neonate's limited ability to excrete solute a problem. Moreover, this increased solute load occurs at a time when the therapeutic index for fluid and electrolytes is narrow (especially in VLBW infants), when insensible water losses are enormous, when there is renal immaturity or insufficiency, and when multiorgan effects of prematurity and infection are common.

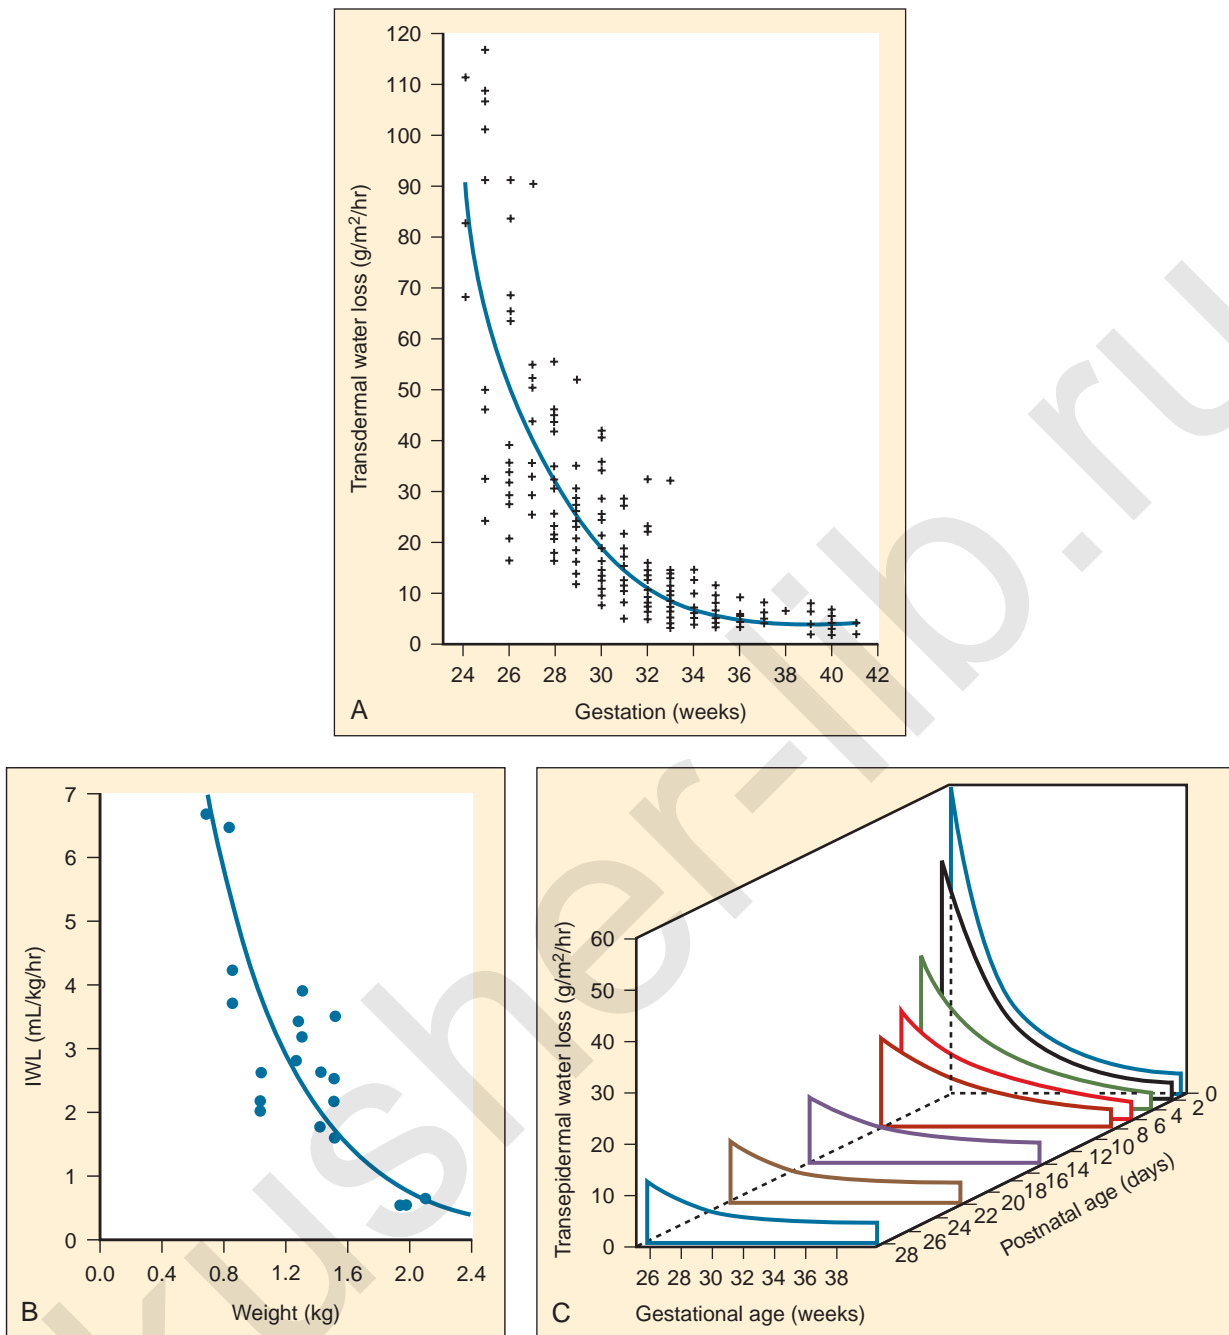

Hematology

Developmental hematopoiesis occurs in three stages and locations—the embryonic yolk sac, the fetal liver, and the bone marrow (Sacher and McPherson, 1986; Rappaport, 1997). Each stage is critical to survival.

Embryonic hematopoiesis begins at about 14 days' gestation when the mesodermal pluripotential stem cells of the ventral yolk sac form primitive megaloblastic nucleated red cells (mean corpuscular volume [MCV] 400), primitive macrophages, and megakaryocytes. At 5 weeks' gestation, pluripotential hematopoietic stem cells migrate from the aorta-gonad-mesonephros (AGM) region to populate the liver and spleen, the temporary sites of hematopoiesis. These uncommitted stem cells divide and produce progeny that either replenish the stem cell pool or mature to committed cell lines and then produce erythrocytes, macrophages, and myeloid and lymphoid cells. By 9 weeks, lymphopoiesis is present in the lymphoid plexuses and the thymus.

At 8 weeks' gestation, AGM stem cells begin to populate bone marrow, and the complex regulatory hematopoietic interactions that are sustained over a lifetime are initiated. As progenitor cells populate the maturing extracellular bone-marrow matrix, adhesion molecules such as integrins, selectins, and CD 14+ cells promote progenitor cell-stromal binding, creating protected microenvironments. The microenvironments allow the selective influence of growth factors (e.g., cytokines, colony stimulating factors, and interleukins) to promote cell growth and maturation. Generally, progenitor cells account for fewer than 1% of marrow cells, but at birth a much larger percentage of umbilical cord cells are progenitors. At term, hematopoietic capacity is comparable with that of adults.

Embryonic erythrocytes contain hemoglobin Gower-1 (unpaired globin chains, many forming tetramers), are nucleated, macrocytic (MCV 400), and not controlled by erythropoietin. Fetal erythrocytes are present and sensitive to erythropoietin.

■ **FIGURE 17-15.** **A**, The effects of gestation on transepidermal water loss. Measurements were made from abdominal skin and carried out in the first few days of life. **B**, Insensible water loss (IWL) as a function of birth weight in premature infants nursed under radiant warmers. **C**, Transepidermal water evaporation from the skin of premature neonates with gestational ages of 25 to 40 weeks, followed longitudinally from birth over the first month of life. Dehydration is the most dangerous in the first week of life for the most immature babies of less than 28 weeks' gestation, before skin keratinization occurs. (**A**, From Hammarlund K, et al.: *Transepidermal water loss in newborn infants, III: relation to gestational age*, *Acta Paediatr Scand* 68:795, 1979. **B**, Adapted from Costarino AT, Baumgart S: *Controversies in fluid and electrolyte therapy for the premature infant*, *Clin Perinatol* 15:863, 1988. **C**, From Sedin G, et al.: *Measurements of transepidermal water loss in newborn infants*, *Clin Perinatol* 12:79, 1985.)

by the sixth week of gestation. They contain mostly fetal hemoglobin ($\alpha 2\gamma 2$) with small amounts of hemoglobin A ($\alpha 2\beta 2$). At birth, erythrocytes are macrocytic (MCV 110) and contain primarily fetal hemoglobin (60% to 80%), which less effectively binds 2,3-diphosphoglycerate (2,3-DPG) and shifts the oxygen dissociation curve to the left, making it less difficult to take up oxygen but more difficult to release it to the tissues. Anti-A and anti-B isoagglutinins develop during the first 6 months of

life. Alloimmunization to red cell antigens is rare in neonates after transfusion. Myelopoiesis is active at 5 months' gestation, but granulocytopoiesis is half of that in adults and gradually increases to adult levels at term. Most of the increase in granulocytes occurs in the last trimester of pregnancy. The absolute number of granulocytes present at birth usually exceeds that of older children but decreases in the first few days after birth. Lymphocytes then become more numerous and remain more

numerous for the first 4 years of life. Megakaryocytes are present in bone marrow, and platelets are present in blood by 11 weeks' gestation. At birth, the platelet counts of term and preterm infants are comparable to those of adults, but the newborn's ability to regulate thrombopoiesis and myelopoiesis is immature, causing inadequate cell production during severe stress.

Jopling et al. (2009) reported an increase in hemoglobin concentration from 14 g at 25 weeks' gestation, 16 g at 30 weeks, 17 g at 35 weeks, to 18 g at term in AGA neonates. A similar increase occurred in the hematocrit. The increases of hemoglobin and hematocrit were linear and not affected by gender. SGA infants have higher hemoglobin concentrations than full-term babies 3 hours after birth, and the concentration decreases about 10% over the first week of life. The higher hemoglobin concentration of SGA neonates is thought to be compensation for intrauterine hypoxia and elevated levels of erythropoietin (Snijders et al., 1993). Preterm infants have lower hemoglobin concentrations at birth than SGA or AGA infants, and the decrease in hemoglobin concentration is greater in premature infants after birth (Table 17-7) (Obladen et al., 2000).

The true hemoglobin of preterm infants may be difficult to determine, because many of these infants have intrauterine hypoxia before birth. This may stimulate hemoglobin production, as may steroid administration to the mother. The production of new erythrocytes decreased after birth as a result of lower concentrations of erythropoietin and fewer reticulocytes. Many preterm infants fail to respond to erythropoietin, because they have iron deficiency (Obladen et al., 2000). However, low iron concentrations may protect them from free-radical injury (Khawaja and Volpe, 2008).

The white blood count of neonates is variable at birth, especially in neonates who receive betamethasone or are infected in utero (Table 17-7) (Cohen et al., 1993). Some healthy infants have white blood cell (WBC) counts of 25,000 at birth. On the other hand, 21% of SGA neonates are neutropenic at birth but have normal cell counts by 7 days after birth (Ozyürek et al., 2006).

One third of SGA infants are thrombocytopenic on the first day of life, possibly because of consumption of platelets by placental infarcts. These infarcts may also be responsible for the polycythemia of SGA neonates. The platelet count of normal SGA infants is 102 to 292×10^9 , and is usually greater than 250×10^9 after a few days (Table 17-7).

Preoperative Hematologic Evaluation

Several important questions must be answered during the preoperative evaluation. Is there evidence of bleeding? Are there petechiae or skin hemorrhages? Is there, or has there been, recent active bleeding into the bowels, lungs, or the brain? What is the platelet count, and has it decreased over the previous 24 hours? Were platelet transfusions required to maintain the desired platelet count, usually greater than $100,000/\text{mm}^3$? Are PT and PTT normal? If not, has the patient been treated with FFP? How many times? How much did FFP improve the PT, PTT, and international normalized ratio (INR)? For how long does it remain improved (normal)? When was FFP last administered? What is the WBC count? Is it increased or decreased from normal? Does an increase or decrease in the WBC count occur with sepsis? What are the patient's hemoglobin concentration and hematocrit value? Are they high? If so, is this because of overtransfusion or dehydration? Is the hematocrit value low? If so, is the low hematocrit value caused by bleeding or by excessive blood drawing? Is blood available for the patient in the blood bank? How many units have been cross-matched against the child? How old is the blood? Blood that has been in the blood bank for more than a few days has an elevated potassium concentration, often in excess of 10 mEq/L. If this blood is administered rapidly to replace blood loss in neonates, a potassium-induced cardiac arrest may occur, which may be difficult to treat (Brown et al., 1990). Because many infants have potassium concentrations of 5 mEq/L or more, rapid addition of potassium during blood transfusion may be disastrous or lethal.

TABLE 17-7. Normal Hematologic Values for Appropriate for Gestational Age (AGA), Small for Gestational Age (SGA), and Premature Infants

Test	AGA		SGA		Premature

OUTCOMES

Survival

Precisely comparing data about preterm infants from various reports remains challenging because of factors such as differences in cohorts, single vs. multiple hospitals, differences in attitudes about survivability of ELBW infants, differing levels of available intensive care, and variable needs to transport mothers or infants. Infant mortality rates vary among and within countries and among ethnic and racial groups. Nevertheless, no doubt remains that gestational age imparts the most significant impact on both short- and long-term outcomes after preterm birth, although other factors must be considered. Tyson et al. (2008) noted that female gender, exposure to antenatal corticosteroid therapy, singleton birth, and increased birth weight (per 100-g increment) each showed improved outcomes similar to those associated with an increase in gestational age of approximately 1 week.

Comparing outcomes data across various decades continues to challenge experts. A “graduate” of the NICU in 1972 was exposed to a remarkably different set of standards than the infant who was a NICU patient in 2005 or later. The impact of prenatal steroids and postnatal surfactant on survival and morbidity is widely recognized and has been clearly documented since the 1990s (Hack et al., 1991, 1995; Stevenson et al., 1998; Horbar et al., 2002). In addition, definitions of diseases (e.g., CLD or BPD) and stratification of severity (e.g., IVH or NEC) evolve as outcomes are defined, but interpreting and comparing data among various decades is

challenging. Finally, the lag in understanding the impact of various therapies on long-term outcome requires years of analyzing serial evaluations of survivors that have been stratified according to birth weight and gestational age.

In spite of these challenges, certain patterns have emerged, and two of them deserve comment. First, no significant improvement in survival without neonatal and long-term morbidity has been measured between 1997 and 2002 (Fig. 17-16). Second, incurring three or more major morbidities (e.g., BPD, brain injury, ROP, and to a lesser degree, infection) predicts risk for death or survival with neurodevelopmental impairment (Bassler et al., 2009). Overall, 85% of inborn VLBW infants survive to be discharged from the NICU. Most deaths occur within the first week of life, and 87% of deaths happen within 28 days of extrauterine life (Fanaroff et al., 2007). Survival for an entire group of VLBW infants (501 to 1500 g) differed by only 1% when a cohort from 1995 to 1996 was compared with one from 1997 to 2002. In contrast, mortality decreased from 59% to 45% in a group of infants weighing between 501 and 750 g (1990 to 1991 vs. 1997 to 2002). As expected, mortality is strongly correlated with birth weight and gestational age, and less dramatic differences were noted when comparing the same time frames for other groups: 19% to 12% (751 to 1000 g), 7.7% to 6% (1001 to 1250 g), and 5% to 3% (1251 to 1500 g). Of greater significance, survival without major neonatal or long-term morbidity (e.g., BPD, IVH, or NEC) remained stable but differed as a function of gestational age (500 to 750 g, ~20%; 751 to 1000 g, 50%; 1001 to 1250 g, 85%; 1251 to 1500 g, 90%) (Fanaroff et al., 2007; Eichenwald

FIGURE 17-16. Short-term outcomes of VLBW according to birth-weight group. (From Eichenwald E, Stark A: *Management and outcomes of very low birth weight*, N Engl J Med 358:1700, 2008.)

and Stark, 2008). Data from other sources reveal similar findings and reinforce the concept that outcome of preterm infants must be meticulously analyzed within narrow ranges of gestational age (Costeloe et al., 2000; Wood et al., 2000; Fanaroff et al., 2003; Lucey et al., 2004; Markestad et al., 2005; Tommiska et al., 2007).

Although patterns of long-term outcome emerge with intense follow up of the expremature infant, accurately predicting outcome in the NICU during the first few days or weeks of life remains elusive. This is in part because the prolonged NICU course, especially for the ELBW infant, subjects the premature infant to repeated insults, including infection, PDA, and side effects of and complications from supportive therapy (e.g., oxygen toxicity, barotrauma, NEC, or drug effects). The cumulative impact of various morbidities has been reported, revealing that incurring just one of three common morbidities (i.e., BPD, brain injury, or ROP) doubled the incidence of death or neurosensory abnormality at 18 months. Identifying two of these morbidities tripled the incidence (Schmidt et al., 2003). Although less dramatic, the same investigators (as well as other groups), using the same cohort, reported that infection (e.g., sepsis, meningitis, or NEC) impacts death and neurodevelopmental outcome at the 18-month mark, although less dramatically (Glass et al., 2008; Bassler et al., 2009). The association of poor neurodevelopmental outcome with surgically treated NEC has been repeatedly noted (see *The Expremature Infant: Neurologic Function*, p. 552).

The perinatal factors that seem to dominate long-term pulmonary and neurologic outcomes seemed to be linked via the pathways of infection or inflammatory mediators and oxidative stress. Attempts to interrupt the injurious effects of inflammation and oxidative stress are challenging, because the injury is often an exaggeration of a normal process. For example, a variety of cellular damage is associated with production of reactive oxygen (ROS) and reactive nitrogen species (RNS) during hypoxic-ischemic events and reperfusion (e.g., peroxidation of membranes, structural proteins, and enzymes). However, these molecules have a critical role in regulating normal cellular function, immunity, circulation, and growth (Maltepe and Saugstad, 2008). Similarly, administering NO may have a role in preventing BPD in the ELBW infant, but results are controversial (Barrington and Finer, 2007; Arul and Konduri, 2009).

Chronic Lung Disease and Bronchopulmonary Dysplasia

Childhood CLD evolves from a variety of congenital and anatomic lesions (e.g., CDH, cystic adenomatoid malformation, and cardiac malformations) and acquired disorders (e.g., sepsis or meconium aspiration), but the overwhelming majority of infants and children acquire the disorder as a result of preterm birth and its supportive care, including oxygen and ventilatory support. BPD refers to CLD associated with prematurity. Although routine surfactant therapy has dramatically decreased the overall impact of BPD both in and after discharge from the NICU, residual lung disease persists as a critical factor that defines mortality and life-long morbidity associated with preterm birth. In fact, the incidence of BPD has remained steady over the last 20 years, recognized in approximately 20% of VLBW infants (Bancalari and del Moral, 2001). Additionally, BPD might be considered a systemic disease, because the retinitis and neurodevelopmental delay commonly coexist with this disorder.

The diagnostic criteria for CLD have been revised as the survival of preterm infants has improved. Northway et al. (1967) first described BPD as a CLD that developed in some preterm infants exposed to oxygen and positive pressure ventilation. In this original group of infants, none had fewer than 31 weeks' gestation, and only one weighed less than 1500 g.

Initially, the definition of BPD was based on the following clinical and radiographic criteria proposed by Bancalari et al. (1979):

1. Mechanical ventilation for more than 3 days in the first week of life.
2. Persistence of oxygen dependence after 28 days.
3. Radiographic abnormalities characterized by patchy density with areas of hyperlucency.

In 1988, CLD was redefined as oxygen dependence at 36 weeks' postconceptual age (rather than 28 days) (Shennan et al., 1988). More recently, pulmonary insufficiency after prematurity was defined as BPD rather than CLD, in order to distinguish it from other sources of neonatal respiratory disease. In addition, the definition of BPD has been revised as follows to include a system for grading its severity (Jobe and Bancalari, 2001):

1. Oxygen dependence for at least 28 postnatal days
2. Grading at 36 postmenstrual weeks for infants born with fewer than 32 weeks' gestation or at 56 days of life for infants born with more than 32 weeks' gestation.

Mild- F_{IO_2} , 0.21

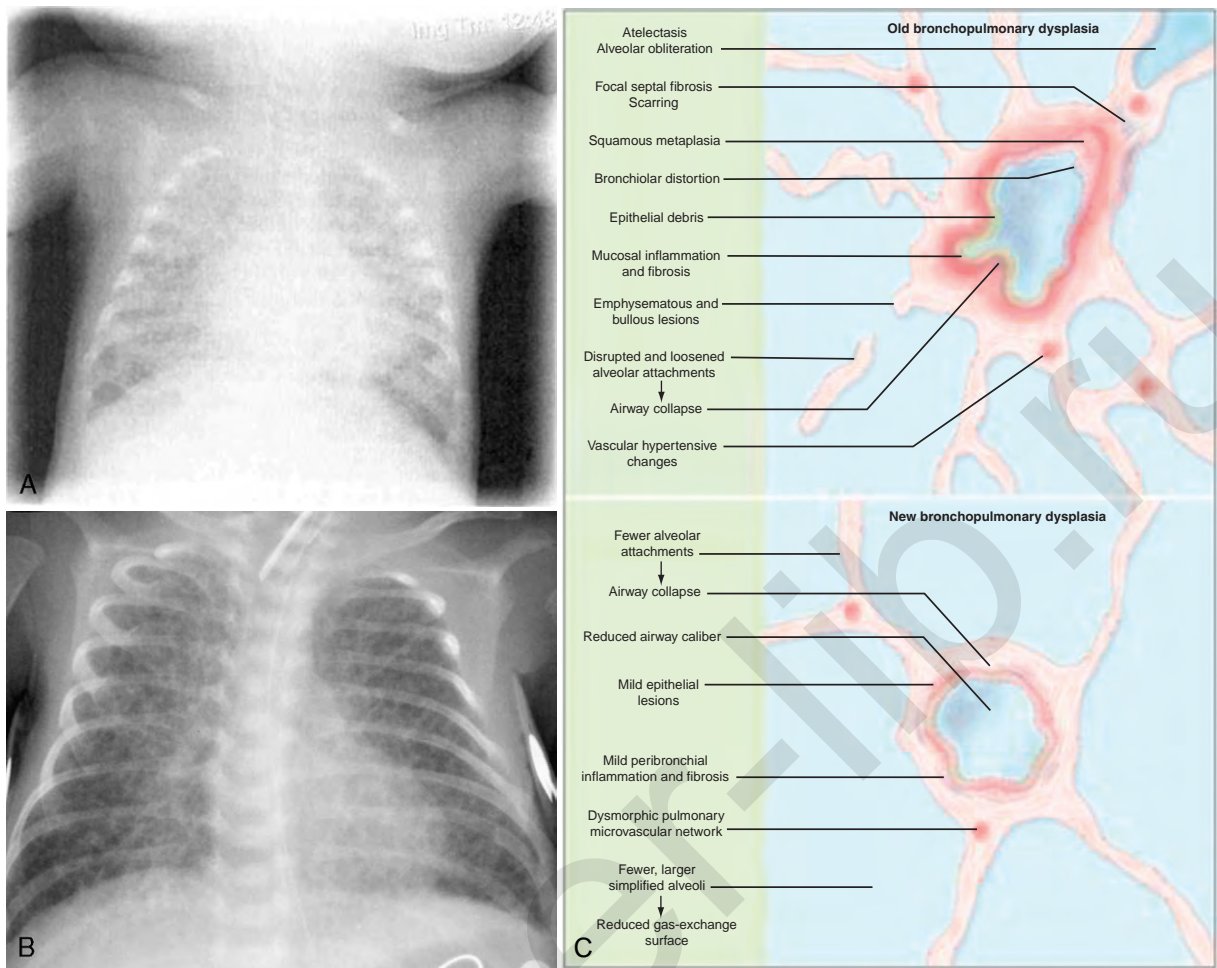

Moderate- F_{IO_2} , 0.22-0.29

Severe- F_{IO_2} , >0.30, CPAP, or mechanical ventilation

The definition of BPD continues to evolve as the mortality of infants of 28 weeks' gestation improves, and as the physiology and pathology of the new BPD is understood. The definition of BPD in the ELBW infant is likely to further change, as guidelines for oxygen administration and the target for oxygen saturation during resuscitation and in the NICU are standardized, ventilatory strategies are redefined, and effective or preventive pharmacologic interventions are identified for the premature and expremature infant.

CLD of infancy is simply defined as abnormal lung function, with an abnormal chest radiograph in the first 3 to 4 months after birth; abnormal function results from injury and repair with consequent maldevelopment of the lungs and respiratory dysfunction. This definition includes BPD. Initially, Northway et al. (1967) considered BPD to be caused by RDS, to evolve as a consequence of the repair process, and to lead to parenchymal fibrosis, chronic inflammation, airway epithelial metaplasia, injury to the large airways, and smooth muscle hypertrophy. Chest radiographs typically showed areas of overinflation as well as areas of volume loss consistent with fibrosis (Fig. 17-17, A,C).

Several factors, including increased survival rates and the possible unique susceptibility of the ELBW infant to lung injury, improved perinatal care to include the use of antenatal glucocorticoids and postnatal surfactant. Less aggressive ventilatory support and oxygen delivery also contribute to the current definition of BPD (Fig. 17-17, B,C) (Hussain et al., 1998). This "new" BPD is characterized by negligible epithelial lesions, injury to the large airways, fewer and larger alveoli, decreased and dysmorphic capillaries, and a variable amount of fibroproliferation. The characteristic fibroproliferative pattern of BPD is usually absent in the surfactant-treated lungs. Instead, the pathology is one of abnormal growth of both alveoli and vasculature (Hussain et al., 1998; Jobe and Bancalari, 2001).

■ **FIGURE 17-17.** **A**, The pathologic description of classic chronic disease or "old BPD" is a fibroproliferative process with epithelial metaplasia, interstitial fibrosis, and air space obliteration from the fibrosis. This correlates with the radiologic findings of nonhomogeneity of the lung parenchyma with densities secondary to volume loss from fibrosis extending to the periphery coexisting with cystic emphysema (note cysts in both lung bases, right > left) and hyperinflation (note the flattened diaphragms). This is a pattern of repair of a response to injury. **B**, The abnormal pathology in the new BPD is abnormal growth of alveoli and vasculature, dilation of distal sites of gas exchange (alveolar ducts), but no prominent fibrosis. This correlates with a fine, hazy, uniform parenchymal pattern with modest hyperinflation but no cysts. This is a pattern of arrested development. **C**, Picture representation showing differences between old bronchopulmonary dysplasia and new bronchopulmonary dysplasia. (See text for specifics.)

Developmental delay and arrested growth, rather than severe epithelial injury with severe fibrosis and smooth muscle hyperplasia, characterize the lungs of the ELBW infant with new BPD (Fig. 17-17, C). As survival of ELBW infants has increased, the term *expremature* has evolved to refer to an infant who was born midgestation, with lungs in the canalicular stage of development (24 to 27 weeks' gestation), rather than in the saccular stage (31 to 34 weeks' gestation). Because of prenatal glucocorticoids and postnatal surfactant therapy, the expremature infant has less severe acute lung injury and requires less aggressive interventions.

Birth during the canalicular stage of lung development rather than the saccular stage seems to predispose ELBW infants to growth retardation of the lungs, perhaps secondary to interference with a variety of cell-signaling pathways that are essential for lung development. These signaling pathways can be affected by genetics, inflammation, infection, mechani-

cal ventilation, and oxygen toxicity. The role of genetics has not been clearly defined, but fibroblast growth factor-10, transforming growth factor- β (TGF- β), surfactant proteins, tumor necrosis factor α (TNF- α) converting enzyme, Hoxa-5-gene, epithelial sodium specific channel (ENaC), cytochrome P450 1A2, and glucocorticoid receptors have all been associated with the disease (Nogee et al., 1994; Ramet et al., 2000; Copland and Post, 2002; Hallman and Haataja, 2003; Kunzman et al., 2007; McDevitt et al., 2007; Kramer, 2008). Additional risks include sepsis or inflammation and the effects pharmacologic agents.

Some infants who have never had classic RDS develop BPD after minimal exposure to oxygen, ventilation, or infection. In these cases, despite seemingly minimal insult, the normal processes of alveolarization and microvascular development seem to be impaired. These infants are usually ELBW, develop oxygen dependency in the second or third (or later)

week of life, may progress to requiring CPAP or mechanical ventilatory support, and subsequently develop BPD. Since 2000, approximately two thirds of infants with BPD were ELBW with fewer than 28 weeks' gestation (Baraldi and Filippone, 2007). A large number have long-term pulmonary insufficiency, are often hospitalized (especially during the first year of life), and have a higher incidence of developmental abnormalities than preterm infants without BPD (Short et al., 2003, 2007; Lamarche-Vadel et al., 2004; Vrijandt et al., 2007). Currently, no specific marker has been identified that predicts the development, course, or severity of BPD. Current evidence confirms that a variety of factors interact synergistically to disrupt normal lung growth and development. These factors include genetics, hypoxia, hyperoxia, mechanical ventilation, steroids, and inflammation (Baraldi and Filippone, 2007; Eichenwald and Stark, 2008).

Inflammation and BPD

Infection and inflammation play critical roles in the etiology of preterm delivery and subsequent BPD. Chorioamnionitis has been associated with preterm delivery, and several reports have suggested that an in utero inflammatory trigger initiates a cascade of injury that is sustained postnatally with the introduction of oxygen and positive pressure ventilation and by repeated bouts of infection (Yoon et al., 1999; Goldenberg et al., 2000; Schmidt et al., 2001; Speer, 2004, 2006; Kramer, 2008; Kramer et al., 2009).

TGF-1 has also been identified as a critical modulator in the development of BPD. TGF-1 regulates lung development, plays a role in inflammation and repair processes, and has been proposed as a key factor in inducing lung maturation associated with glucocorticoid administration (McDevitt et al., 2007).

Proinflammatory cytokines also appear critical in the initial postnatal response to lung injury in the preterm infant (Groneck et al., 1994; Tullus et al., 1996; Jonsson et al., 1997).

Mechanical Ventilation and BPD

The fluid-filled fetal lung must be inflated at birth to successfully transition to exchanging oxygen and carbon dioxide. Because of mechanical disadvantages (e.g., high chest wall compliance or inadequate surfactant), neurologic immaturity (e.g., immature control of breathing), and weakness of respiratory muscles, the preterm infant commonly requires ventilatory assistance (e.g., CPAP, mechanical ventilation, or supplemental oxygen) to achieve effective transition to breathing. In one report, 60% to 70% of newborns with fewer than 26 to 28 weeks gestation and all infants with fewer than 25 weeks' gestation were treated with positive pressure ventilation after intubation of the trachea (Morley et al., 2008). The premature lung has less collagen, so the chest wall is more compliant, and the airways are distensible; therefore, the response to stretch caused by the inflation pressure may be significant. Even after surfactant administration, mechanical ventilation initiates and sustains an inflammatory reaction (Ferreira et al., 2000). Lung neutrophils release cytokines and initiate an inflammatory cascade that is associated with a higher incidence of BPD. A recent report noted that ventilation at birth might initiate a systemic inflammatory response in addition to the local response in the lung (Hillman et al., 2007). Of

note, PEEP does not seem to protect the preterm lung from this rapid injury (Hillman et al., 2008).

CPAP may be associated with less lung injury compared with positive pressure ventilation (Avery et al., 1987; Morley et al., 2008). However, many ELBW infants may not sustain adequate oxygenation or ventilation during CPAP and require mechanical ventilation.

Oxygen Therapy/Toxicity

The oxygen saturation of the fetus at term is approximately 50% to 60%, decreasing to as low as 30% intermittently during labor (East and Colditz, 2007). Immediately after birth, the full-term infant's oxygen saturation is approximately 60%, and 5 minutes after birth the lower limit of normal is approximately 70%. The healthy full-term infant may have oxygen saturation less than 90% for as long as 5 to 10 minutes after vaginal birth and longer after cesarean section (Kamlin et al., 2006; Rabi et al., 2006; Dawson et al., 2007). With these data in mind, oxygen treatment must be titrated to achieve what has been defined as normal in the first hour of life to avoid needless exposure to excess oxygen.

Pulse oximetry provides a constant, accurate reading of heart rate and oxygen saturation.

The Term Infant

Multiple studies and metaanalyses have provided evidence for revising recommendations for delivery of oxygen during resuscitation of the full-term infant, comparing short-term outcome as well as mortality after resuscitation with room air or 100% oxygen (Davis et al., 2004; Saugstad et al., 2005, 2008). Regardless of the specific physiologic mechanisms, infants who were resuscitated using room air recovered more quickly as assessed by Apgar score, time to first cry, heart rate at 90 seconds, and sustained pattern of respiration (Saugstad, 2005; Saugstad et al., 2008). Of importance, Davis and colleagues (2004) reported lower mortality at 1 and 4 weeks with no difference in the incidence of hypoxic-ischemic encephalopathy between the two groups.

Some published guidelines continue to recommend an F_{iO_2} of 1.0 during initial resuscitation (de Caen and Singhal, 2006). However, Canada and Australia have incorporated these data into their clinical practice by revising standards for resuscitation of the newborn, moving away from the tradition of administering an F_{iO_2} of 1.0 (de Caen and Singhal, 2006; Morley et al., 2008).

The Preterm Infant

Most experts will agree that oxygen plays a role in the most severe long-term consequences of preterm birth: BPD, ROP, and neurodevelopmental abnormalities. The question remains as to what oxygen saturation should be targeted during resuscitation and in the NICU (Tin and Gupta, 2007).

Hyperoxia produces lung injury at any stage of development, but it may be particularly damaging to the immature lung because of insufficiency of several systems that are important in protecting tissues from oxygen toxicity. This oxygen load may produce an excess of free radicals that induce inflammation and damage cellular lipids, proteins, and carbohydrates (Maltepe and

Saugstad, 2008). Antioxidant enzymes (e.g., superoxide dismutase [SOD], catalase, glutathione peroxidase, and glutathione reductase) develop on a time scale similar to surfactant, so that the level of these antioxidants normally rises rapidly just before birth (Frank and Sosenko, 1987). In addition to its effects on antioxidant systems, hyperoxia inhibits surfactant synthesis, normal protein synthesis, and DNA synthesis, as well as producing pulmonary vascular reactivity (Newman et al., 1983; Clement et al., 1985; Jornot et al., 1987).

Studies reported that targeting higher oxygen saturation was associated with higher incidence of CLD (STOP-ROP Multicenter Study Group, 2000; Askie et al., 2003).

The Expremature Infant: Pulmonary Function

Despite the vast amount of literature regarding pulmonary outcome after preterm birth, gestational age exerts the most critical influence on eventual pulmonary function. Nevertheless, the following generalizations can be made:

- BPD is common in ELBW infants, occurring in approximately 60% to 90% of infants at 23 weeks' gestation and approximately 50% to 70% of infants at 25 weeks' gestation. BPD is less common in infants with more than 30 weeks' gestation or who weigh more than 1500 g. Arrest of lung growth is the characteristic pattern of lung injury in the ELBW infant.
- Pulmonary dysfunction occurs in premature infants without BPD. This group often has spirometric findings that lie between those for healthy full-term infants and premature infants with BPD (Pelkonen et al., 1997).
- CLD commonly coexists with poor feeding and growth and prolonged neonatal hospitalization.
- Hospitalizations over the first year of life are common. Pulmonary function seems to improve over the first 6 to 8 years of life, but residual airflow abnormalities have been noted in expremature adolescents and adults.
- Routine surfactant therapy has not changed the incidence of BPD, especially in ELBW infants. New BPD is often milder in the neonatal period and later, but the ultimate pulmonary function in adult life remains unknown.
- Neurodevelopmental abnormalities are common in infants with BPD.

Prematurity with or without RDS and with or without BPD is associated with long-term pulmonary sequelae (Saigal and Doyle, 2008; Smith et al., 2008). In spite of recent dramatic changes to clinical care throughout the perinatal period, BPD persists as a major long-term health problem, especially for the ex-ELBW infant. As noted in the recent reports of the clinical trials of inspired NO in preterm infants, birth weight persists as the most predictive variable of outcome (e.g., death and BPD), although other factors (e.g., higher oxygen concentration, outborn status, or male gender) contributed to later pulmonary function (Arul and Konduri, 2009). In general, premature infants with BPD encounter the most severe long-term respiratory abnormalities compared to both gestationally matched expremature infants without BPD and control-group infants who were born at term. That is, expremature infants with BPD have more severe abnormalities of pulmonary function, especially those reflecting airflow, air-trapping, and hyper-responsiveness, than their counterparts without BPD, but even

this latter group has spirometric values below those of full-term infants. As noted by Doyle et al. (2006), "Tinier or more immature survivors have worse respiratory function than those who are more mature or larger at birth, whether they have BPD or not." Surprisingly, this general pattern has not changed since the introduction of surfactant (Halvorsen et al., 2004; Korhonen et al., 2004; Doyle et al., 2006).

In addition to spirometric pulmonary assessments, exercise tolerance and diffusion of gases during exercise have helped define the functional impact of residual respiratory abnormalities in the expremature infant (Jacob et al., 1997). Children aged 7 to 8 years old who had BPD after preterm birth had lower gas transfer compared with children who were born at term or were born prematurely but had no CLD (Mitchell et al., 1998). During exercise, only BPD survivors had wheezing or oxygen desaturation. In a study by Jacob et al. (1997), expremature infants with a history of severe BPD, expremature infants who had RDS but no BPD, and healthy term infants were studied at ages 9 to 12 years. The BPD group used a greater percentage of their ventilatory reserve ($V_{eMAX}/40 FEV_1$) during exercise, especially those children with the lowest forced expiratory volume at 1 second (FEV_1) (Jacob et al., 1997). Similar findings were noted in a group of 9- to 15-year-old ex-ELBW infants. In this study, in addition to having lower forced expiratory flow (FEF) rates and lower FEV_1 , oxygen consumption was noted to be low in formerly ELBW infants. Of note, the values for the ELBW infants who had not had BPD were lower than infants of normal birth weight but better than those who had had BPD. Postexercise arterial oxygen saturation for both groups of ELBW infants was lower than in infants of normal birth weight (Kilbride et al., 2003).

Similarly, Smith et al. (2008) recently documented spirometric abnormalities (e.g., FEV_1 , $FEF_{25\%-75\%}$, or peak expiratory flow rates [PEFR] values) in a group of 10-year old ex-ELBW infants as compared with a group of children born at term between 1992 and 1994. For example, 28.5% of the preterm group, compared with 11.8% of the controls, had an FEV_1 of less than 80% predicted; 41.5% of the preterm group had a $FEF_{25\%-75\%}$ of less than 67% predicted, but none in the control group did. The most striking results included the lower exercise capacity (44% of the control group) and lower predicted peak oxygen consumption. Other studies have suggested that children with a history of mild BPD do not have decreased exercise capacity compared with other survivors of neonatal mechanical respiratory support, but the BPD groups did have a greater incidence of oxygen desaturation during exercise (Bader et al., 1987; Parat et al., 1995; Santuz et al., 1995).

Postmortem assessment of morphometric lung development has documented the drastic restriction in the number of alveoli in survivors of BPD compared with that of normal infants. The total numbers of alveoli in a 22-month-old child (31.1 million) and in a 28-month-old child (40.4 million) were less than that in a healthy 1-week-old infant (67.2 million) (Margarf et al., 1991). Of course, infants who die from CLD may have more dramatic morphometric abnormalities than the less severely affected survivors.

These postmortem studies of infants with CLD also documented an abnormal architecture of elastic fibers, the framework on which new alveoli develop. Elastic fiber damage is primarily linked to oxygen damage and an increased activity of elastase (Bruce et al., 1985). With damage to the cellular matrix, further deposition of collagen and elastin is erratic. Although the effects of prematurity on the molecular mechanisms of lung

growth are not clearly defined, the consequences of decreased alveolar surface area and airway hyperreactivity have significant clinical implications.

The First 6 Years

Chronic lung injury secondary to prematurity characteristically includes decreased vital capacity (VC), obstruction of small airways, chest hyperinflation, and reactive airways disease. Infants with BPD are more severely affected than those without BPD, and both have worse function than healthy infants born at term. Over the first 1 to 2 years of life, the expremature infant often has significant respiratory symptoms. Reactive airways disease is common and is exacerbated by a high incidence of infections (Greenough et al., 1990; Parat et al., 1995; Smyth et al., 1995; Tarpay and Celi, 1995; Walther et al., 1995; Tait et al., 2001). Oxygen therapy may be necessary for months to years in order to maintain oxygen saturation between 90% and 95%. Bronchodilators and diuretics are often mainstays of therapy. Significant hypoxemia often accompanies respiratory infections, and hospital admission and readjustment of medications are repeatedly needed. Finally, aspiration associated with gastroesophageal reflux can lead to acute or recurrent pulmonary deterioration (Greenough et al., 1990; Radford et al., 1996). These trends persist in the postsurfactant era, and similar data have been recently reported in ELBW infants (Baraldi and Filippone, 2007). Especially in the first 3 years of life, expremature infants with a history of BPD are more likely to wheeze, cough, and require hospitalization for respiratory illness. (Hack and Fanaroff, 2000; Lamarche-Vadel et al., 2004; Greenough et al., 2005; Hennessy et al., 2008).

Some have noted that the conditions of patients with BPD may worsen over the first year, especially in the setting of acute viral infections, particularly respiratory syncytial virus (RSV). Preterm infants with BPD are at high risk for RSV infection because of the severity of their illness, their greater risk for respiratory failure, and the need for mechanical ventilation (Simon et al., 2007; Simoes, 2008). The impaired parenchymal and vascular development in the setting of new BPD may predispose this population to the inflammatory consequences of RSV that result in alveolar overinflation and pulmonary edema (Carpenter and Stenmark, 2004). Thus, expremature infants, even those without BPD, have been targeted to receive immunization with palivizumab (Lanctot et al., 2008).

After the First 6 Years—Adolescents and Adults

In 1990, Northway presented a follow-up study of 26 patients (ages 14 to 23 years) from his original cohort (Northway et al., 1967, 1990). Only one of the patients in the initial cohort had weighed less than 1500 g and was born at fewer than 30 weeks' gestation. On follow up, 76% of patients had pulmonary dysfunction (e.g., abnormalities on pulmonary function tests, reactive airways disease, or both). Airway obstruction was noted in 68% of patients, with 24% having fixed airway obstruction. Although all were leading normal lives and were usually asymptomatic, the former BPD patients had more incidences of wheezing and pneumonia, limitation of exercise, and long-term medication use.

Almost 20 years after the introduction of surfactant and with revised approaches to ventilation and oxygen therapy, studies have examined the pulmonary function of school-aged and older expremature infants. These infants can be divided into two groups: expremature infants who were treated with surfactant and expremature infants who were not. In one study, the pulmonary function of school-aged expremature infants with CLD who did not receive surfactant at birth was measured serially when the children were between 6 and 10 years of age and again between 11 and 18 years of age. At the final testing, pulmonary function tests revealed normal total lung capacity (TLC) and normal VC, but these values had improved over the course of the repeated pulmonary function studies. RV and RV/TLC decreased over time, suggesting gradual improvement in air trapping (Koumbourlis et al., 1996). The PEF_r, FEV₁, and the ratio of FEV₁ to forced vital capacity (FVC) remained at or above the normal range in all patients. FEF_{25%-75%}, FEF_{50%}, and FEF_{75%} were decreased in 50% of these patients. The lower values are suggestive of obstruction of relatively small airways. Regardless, most children in both groups responded to inhaled bronchodilator treatment.

Doyle (2006) has reported outcomes for patients at ages 8, 11, 14, and 19 years as part of a prospective longitudinal research study of VLBW survivors. Although the data in late adolescence reflect different neonatal practices than those currently followed, the report is notable in that it documents that airflow abnormalities at younger ages persisted into adulthood. Most subjects in the non-BPD group had normal lung function. In contrast, some variables reflecting airflow were lower in those with BPD compared with the non-BPD group. That is, 33% of the BPD group but only 8% of the non-BPD group had an FEV₁ greater than 75% predicted. Similarly, 42% and 16% of the BPD and non-BPD groups, respectively, had an FEV₁/FVC of less than 75%. However, when the non-BPD group was compared with a control group of normal birth weight, only 94% met their predicted FEV₁, compared with 99% of the control subjects. Similarly, FEV₁/FVC predicted values were met in 83% vs. 89% of the non-BPD group vs. controls. A significant finding in this study was that between 8 and 19 years of age, the BPD subjects had a greater decrease in the FEV₁/FVC ratio than the non-BPD group, and this difference was greater if the subjects were smokers. Similarly, Halvorsen et al. (2004) reported that in 17-year-old subjects, both FEV₁ and FEF were decreased in proportion to the severity of BPD. Those with moderate to severe BPD had greater decreases in FEV₁ and FEF than those with mild BPD, who in turn showed greater decreases than preterm infants without BPD. Those in the control group experienced the smallest amount of decrease in rates.

Lung volume abnormalities tend to gradually normalize in groups of expremature infants with BPD, and the process of recovery continues well into adolescence. Chronic airflow obstruction is common but not present in all expremature infants who had BPD (Fig. 17-17). Of particular significance, expremature infants who had no BPD in the newborn period may actually suffer from obstructive airway disease that persists into adolescence and early adulthood.

The pulmonary function tests in school-aged expremature infants who received surfactant at birth reveal that FVC, FEV₁, and FRC are within normal limits (and similar to values obtained in a group who had not received surfactant) but lower than values in a control group of children born at term.

Airway resistance (R_{aw}) was slightly elevated and maximum expiratory flow (MEF_{25}) was slightly decreased, suggestive of mild lower-airway obstruction. In addition, similar to studies in VLBW infants who were not treated with surfactant, exercise challenge elicited bronchial reactivity. Thus, these data reveal little effect of surfactant on VLBW infants (of 25 to 30 weeks' gestation) from the viewpoint of long-term pulmonary function at 6 to 7 years of age. Of note, surfactant has not dramatically altered respiratory function in ELBW infants (Pelkonen et al., 1998; Gappa et al., 1999).

The following observations can be made in summary:

- More than 90% of children diagnosed with BPD at 36 weeks' postconceptual age had documented airway obstruction in follow-up studies.
- The incidence of β -agonist responsive airway obstruction in ex-premature infants is striking—45% in those treated with surfactant and 67% in the placebo group, compared with 0% in those who were born at full term.
- The incidence of CLD did not differ after surfactant treatment.
- The duration of tracheal intubation and oxygen therapy, with or without surfactant therapy, correlated with pulmonary outcome (Pelkonen et al., 1998).

BPD and Neurologic Outcome

BPD is a well-recognized risk factor for adverse neurodevelopmental outcome in both the initial few years and at school age. For example, even with the changes in practices in the 1990s, rates of Mental Developmental Index (MDI) scores of less than 70 (severe disability) and overall developmental impairment at about 20 months of age in infants with BPD did not improve when a cohort from 1996 to 1999 was compared with one from 2000 to 2003 (Kobaly et al., 2008). In each group, 42% had an MDI of less than 70 and about 50% of each group had an overall developmental impairment. In another report, the incidences of enrollment in special education classes and scores lower than 70 on full-scale IQ tests (in the mental retardation range) were higher in a group of 8-year-old children who had been VLBW and had BPD (Short et al., 2003). In particular, speech and language problems and the need for occupational and physical therapy, as well as function on applied problems and motor skills, were all affected in the BPD group. Difficulty with mathematics seemed to be most pronounced.

In addition, Thompson et al. (2007), identified a uniform reduction in various cerebral volumes in premature infants with BPD. The common finding of arrested growth in both the brain and the lungs may eventually be linked via a specific molecular or physiologic pathway, extending understanding beyond the observational and shifting therapy toward prevention, rather than treatment, of complications.

The Ex-premature Infant: Neurologic Function

Injury to the brain in the perinatal period often can be linked to lifelong complications, including a higher risk for motor disorders, learning or developmental delays, seizures, and death. No specific therapy has been identified for long-term cognitive, sensory, and motor deficits. Minimizing or preventing neurologic complications from perinatal injury requires extensive knowl-

edge of the precise cellular and molecular mechanisms of the developing brain's response to asphyxia, hypoxia, and inflammation. Such mechanisms have not been definitively mapped and cannot be definitely correlated with specific clinical scenarios, except in a very general way. Most agree that injury to the developing brain involves an initial insult from hypoxia or ischemia, followed by secondary damage from reperfusion that results in excitotoxicity and release of various cytokines; however, precisely connecting this principle to clinical care is often impossible (Perlman, 2006).

Schmidt et al. (2003) studied the rate of neurodevelopmental disability associated with a history of having between one and three of the following conditions: BPD, an abnormality visible on a head ultrasound, and severe ROP. The incidence of disability was 18%, 42%, 63%, and 88% with 0, 1, 2, or 3 of these complications, respectively.

Of significance, neonatal events associated with sepsis seem to be associated with a particularly high incidence of adverse neurodevelopment in preterm infants. The group with sepsis or NEC was noted to have delayed cognitive and motor development at 2 years (Shah et al., 2008).

Advances in neuroimaging techniques (e.g., diffusion-weighted MRI and spectroscopy) have dramatically advanced our knowledge about patterns of injury at various gestational and postnatal ages and allowed these to be correlated with the severity and nature of clinical events. Vulnerability to injury varies in different areas of the brain and for different cell populations at various maturational stages. For example, hypoxic-ischemic injury is most commonly associated with white-matter injury in premature infants but is associated with cortical or subcortical damage in term infants. In both groups, injury tends to evolve over days to weeks. The early, rapid necrotic death of cells is followed by the delayed neurodegeneration secondary to energy failure and membrane dysfunction, edema, massive neurotransmitter release, effects of oxygen free radicals and calcium release, and other complex cellular and molecular derangements. Thus, gestational and postnatal ages and severity of insult interact to define the neuropathology (e.g., region and extent of injury) of prenatal and neonatal brain injury and developmental outcome.

Brain Injury in the Preterm Infant

For simplicity, white-matter injury in the preterm infant can be divided into two main categories: PVHI and PVL. The effects of each are often difficult to separate, since they commonly coexist. In the past, cranial ultrasounds of the preterm infant identified focal necrotic lesions that evolved into cysts. These lesions seemed to correlate with the development of cerebral palsy (10% to 15% of VLBW infants). Although such severe lesions obviously define significant risk for abnormal development, most cases of abnormal neurologic outcome could not be correlated with the presence of cystic PVL or PVHI (Miller et al., 2003). Developmental deficits beyond what would be expected from focal white-matter injury are common in follow-up care of the ELBW infant. For example, the high incidence of cognitive deficits without prominent motor deficits among survivors of prematurity (approximately 50%) is more commonly attributed to neuronal abnormalities rather than white-matter abnormalities (Volpe, 2003).

Over the last decade, the nature of brain injury associated with prematurity has been identified as a more diffuse, noncystic

white-matter injury and has been described in at least 50% of ELBW patients. Of major significance, studies using quantitative MRI have linked gray-matter injury to this diffuse white-matter injury (Volpe, 2003). That is, neuronal loss parallels the white-matter injury. Although the specific link between white- and gray-matter injury has not been clarified, the concept that prematurity disrupts the coordinated growth of the entire brain seems well accepted (Kepellou et al., 2006; Counsell et al., 2007).

Clinical Outcome

At least 50% of VLBW infants are diagnosed with white-matter injury based on MRI findings (Volpe, 2003; Dyet et al., 2006). Of significance, abnormalities persist and are seen in MRIs performed in late childhood and adolescence (Constable et al., 2008; Ment et al., 2009). Most studies of VLBW and ELBW infants note that although neurosensory deficits (e.g., hearing loss or blindness) have decreased, problems with cognitive and academic function and behavior (e.g., attention disorders, emotional control issues, or problems with social interaction) have increased. In addition, a higher incidence of anxiety and depressive disorders has been reported in expremature infants (Rickards et al., 2001; Saigal et al., 2003; Anderson and Doyle, 2004; Wilson-Costello et al., 2007; Constable et al., 2008; Kobaly et al., 2008; Ment and Vohr, 2008). In several reports, these problems have been noted to persist into adolescence and adulthood (Hack et al., 2004; Farooqi et al., 2006). Even with the pervasive incidence of intellectual, emotional, and academic disorders in expremature infants, lower rates of risky behaviors have been reported in young adults (Hack et al., 2004). Saigal et al. (2006) also reported that, in spite of lower levels of educational achievements, expremature infants display a high level of adapting and functioning as adults.

Cerebral Palsy

Cerebral palsy (CP) refers to a group of nonprogressive motor dysfunction syndromes related to CNS lesions encountered early in development, but they are usually without a clear-cut etiology. Cerebral palsy is diagnosed in approximately 1 infant per 1000 live births (Wu et al., 2006). The increase in motor tone observed with CP includes spasticity, rigidity, and dystonia; some patients have choreoathetosis. About half of the cases of CP are diagnosed in full-term infants.

A variety of lesions in neuroimaging studies accompany the clinical diagnosis. For example, Wu et al. (2006) noted a wide range of findings in a series of 273 patients (227 MRI; 46 CT), including focal infarction (22%), malformation (14%), periventricular white-matter abnormalities (12%), generalized brain atrophy (7%), hypoxic-ischemic brain injury (5%), and intracranial hemorrhage (5%). On closer examination, 45% of patients with spastic hemiparesis had evidence of focal arterial infarction. The brain malformations were diverse (e.g., schizencephaly, agenesis of the corpus callosum, polymicrogyria, septooptic dysplasia, and others). Of significance was the low incidence of

findings consistent with hypoxic-ischemic injury (5%) and the high incidence of a normal brain (31%).

SUMMARY

The medical and surgical history of the expremature infant is often characterized by a complicated medical and surgical history, often with superimposed persistent chronic disease. Preoperative assessment and integration of these chronic problems into the acute surgical and anesthetic setting require careful review of records and communication with multiple caregivers. As patients grow and develop, the relevance of their perinatal and neonatal course diminishes. Nonetheless, many of the events of early life can manifest as life-long disabilities, such as chronic pulmonary problems and developmental delay.

Reactive airways disease of the expremature has been reported to be less responsive to antiinflammatory agents and more prone to serious complications from RSV.

Developmental delay (and associated medical problems) is common in premature infants. Patients with neurologic disorders have a high incidence of autonomic neuropathy, which delays esophagogastric transit and gastric emptying. Neurologically impaired children are at high risk for symptomatic gastroesophageal reflux, especially when the patient is fed via nasogastric tube or gastrostomy. In addition, delayed gastric emptying has been documented in infants and children with neurologic disorders and symptoms of gastroesophageal reflux.

In addition to the medical issues of the expremature, parents of expremature infants are often over protective, have extensive experience with health care providers, and can provide encyclopedic data about their child's history (Wightman et al., 2007). Effectively interacting with parents of an expremature infant may require greater sensitivity and take more time than usual. Preoperative anxiety may be great in any child who requires repeated interaction with the operating room, but the challenge may be even greater in the setting of the patient with developmental delay and a variety of significant coexisting problems.

Various personality traits have also been associated with some older expremature patients, including anxiety and social isolation (Rickards et al., 2001; Allin et al., 2006; Wightman et al., 2007). Although evaluation of and attention to such traits in the preoperative setting are similar to others with a similar history, in the context of the expremature infant, focusing on the multitude of complex medical problems may allow the psychological concerns to be underappreciated.

Surgical procedures during the neonatal period impose significant physiologic perturbations on the infant. With increasing regularity, diseases of adult life have been linked to events in early development (in utero, newborn, infancy, or childhood). For example, intrauterine growth retardation has been linked to an increased risk for a variety of adult disorders, including coronary heart disease, stroke, hypertension, type II diabetes, and even psychiatric illness (Barker and Osmond, 1986a; Barker, 1995, 2006; Ravelli et al., 1998; Singhal et al., 2003, 2004; Barker et al., 2005; Mittendorfer-Rutz et al., 2007). In addition, early postnatal and childhood nutrition and obesity have been associated with metabolic disorders such as dyslipidemia and glucose intolerance, growth abnormalities, and cardiovascular disease in adults (Huang et al., 2007; Mikkola et al., 2007; Rakow et al., 2008). These adult disorders with pediatric foundations were initially based on Barker and Osmond's epidemiologic study (1986b). However, subsequent research has expanded his original "thrifty-phenotype" hypothesis (i.e., survival of the undernourished fetus demands that nutrition be directed to vital organs such as the brain, resulting in insulin resistance in other tissues such as muscle and the pancreas) to include a "developmental plasticity" theory (Hales and Barker, 2001; Gluckman et al., 2005; McMillen and Robinson, 2005). These initial reports have spawned an entire focal point for research and a model termed the *developmental origins of health and disease* (Gluckman et al., 2005; Gillman et al., 2007; Silveira et al., 2007). Recently, the increased risk for cardiovascular and metabolic disease has been extended to include

preterm infants, both those who are appropriate for gestational age (AGA) and those who are small for gestational age (SGA) (Hofman et al., 2004a, 2004b; Mikkola et al., 2007).

Perhaps the most obvious and irrefutable link between early events and adult diseases exists in the settings of major congenital anomalies and preterm birth. The full impact of the synergistic roles of the thrifty phenotype and developmental plasticity theories remains to be defined, but the critical long-term effects (from early postnatal development and beyond) of disease processes encountered after preterm birth and associated with congenital anomalies is already appreciated. This chapter addresses anesthetic pharmacology for the neonate, approaches to intraoperative monitoring of the neonate, and the more common neonatal general surgical procedures with respect to perioperative management, embryology, and long-term outcome.

ANESTHETIC PHARMACOLOGY IN THE NEONATE

Increasing evidence indicates that the physiologic response of neonates to painful stimuli is similar to that of adults (see Chapter 15, Pain Management). The response of the sympathetic nervous system to noxious stimulation includes tachycardia and hypertension, which in the setting of abnormal cerebral autoregulation predisposes the infant with a low birth weight (LBW) to intraventricular hemorrhage and possibly pulmonary hypertension. The goal during anesthesia is to avoid pain and its cardiovascular and neurologic consequences. The response

of newborns to opioids and potent inhalation agents is variable, and meticulous titration is critical for neonates undergoing surgery, both to avoid cardiovascular collapse and to maintain acid-base balance and also to eliminate awareness and pain.

Pharmacokinetics and Pharmacodynamics

Pharmacokinetics and pharmacodynamics of drugs are affected by anatomic factors relating to body composition and distribution of water, as well as physiologic factors such as metabolism (i.e., hepatic biotransformation); protein binding; and pathologic factors (e.g., disease, anesthesia, and surgery) (see Chapter 7, Pharmacology of Pediatric Anesthesia). Maturation changes in distribution of total body water, tissue composition, and organ function contribute to the unique response of the newborn and young infant to various drugs. In early fetal development, water constitutes approximately 94% of body weight. As gestation continues, the total body water decreases so that at 32 weeks, 80% to 90% of body weight is water, and at term, total body water is approximately 70% to 75% of body weight. Adult proportions of fluid to body weight (55%) are reached between the ages of 9 months and 2 years. The distribution of water between the extracellular and intracellular compartments also changes during fetal growth. Extracellular water (interstitial fluid plus plasma volume) decreases from 60% of body weight at the fifth month of fetal life to approximately 45% at term. Intracellular water increases from 25% in the fifth month of fetal life to 33% at birth; therefore, the extracellular fluid compartment of the newborn is equal to or greater than the intracellular fluid space. In adults, the intracellular and extracellular fluid compartments are approximately 40% and 20% of body weight, respectively. Because the plasma component of the extracellular fluid compartment remains at approximately 5% of body weight throughout life, it is the interstitial water that is greater in infancy (40%) and declines to 10% to 15% in the adult (Friis-Hansen, 1971).

Age-dependent changes in body composition also occur. At term, fat constitutes 11% of body weight. Fat content doubles by 6 months of age and is approximately 30% at 1 year. Teenage girls remain with approximately 20% to 30% fat, whereas fat in teenage boys decreases to 10% to 15% fat. Moreover, the composition of fat tissue changes with age. Fat of the newborn may contain as much as 57% water and 35% lipids; adults have 26% water and 71% lipids (Friis-Hansen, 1971). Skeletal muscle comprises 25% of total body mass in a full-term newborn compared with 43% in an adult.

The binding of drugs to serum proteins depends on several factors, including the concentration of protein, the number of binding sites on these proteins, and the affinity of the binding sites. The concentration of total serum protein, albumin, and α_1 -acid glycoprotein is lower in early infancy and reaches adult levels by approximately 1 year of age (Pacifica et al., 1986). Albumin primarily binds acidic drugs; α_1 -acid glycoprotein binds basic drugs. The concentration of these two proteins and their binding affinities are deficient in the newborn (Piafsky and Woolner, 1982).

The primary organ for drug biotransformation is the liver, but the kidneys, intestines, lungs, and skin also have minor roles. Hepatic oxidation, reduction, and hydrolysis (nonsynthetic, phase I reactions) mature rapidly, achieving adult rates by 6 months (Niems et al., 1976). Drugs metabolized via this cytochrome P450-dependent monooxygenase system include phenobarbital and phenytoin. Conjugation reactions (synthetic, phase II

reactions) convert drugs into more polar compounds to facilitate renal excretion. These systems also mature postnatally.

The renal excretion of drugs is a function of glomerular filtration rate (GFR), active secretion, and passive reabsorption. GFR and secretion increase in an age-dependent manner. Renal blood flow and GFR increase dramatically during the first postnatal week and more gradually during the next several months, and adult performance is achieved at approximately 6 to 12 months of age (Arant, 1978; Hook and Bailie, 1979). Tubular secretory and reabsorptive capacity also mature postnatally (Fetterman et al., 1965).

Cardiac output and its distribution to various organs contribute to drug elimination. The perinatal adaptation to extrauterine life demands rapid changes in the circulation. This process may be inhibited as a result of congenital heart disease or acid-base problems. Drug metabolism and elimination may be drastically affected when cardiovascular function is abnormal.

Inhaled Anesthetic Agents

Infants have a higher incidence of cardiovascular instability and cardiac arrest during induction of inhalational anesthesia than do older persons (Rackow et al., 1961; Friesen and Lichtor, 1982, 1983; Morray, 2000, 2002; Murat et al., 2004). This untoward effect of potent inhalational agents can be attributed to several factors, including faster equilibration, rapid myocardial uptake in infants, the increased anesthetic requirement, and sensitivity of the neonatal myocardium. Infants attain a higher concentration of inhaled anesthetic agents in the heart and brain than do adults at the same inspired concentration. Moreover, the neonatal myocardium has a smaller fraction of contractile mass, and the magnitude and velocity of fiber shortening are less than in the adult myocardium. These factors and the increased anesthetic requirement, which is inversely related to age, all produce a higher incidence of adverse cardiovascular effects in infants.

The rate of rise of the alveolar concentration of an inhaled anesthetic depends on several factors: the inspired concentration, alveolar ventilation, and uptake. The greater the alveolar ventilation, the faster is the rate of rise of the alveolar concentration. This effect of alveolar ventilation is affected by the size of the functional residual capacity (FRC). Infants and children have an FRC similar to that of the adult, 30 mL/kg per minute. In contrast, alveolar ventilation is much higher in the infant (100 to 150 mL/kg per minute) compared with the adult (60 mL/kg per minute). This difference parallels the greater oxygen consumption of the infant. Thus, in the normal term newborn who weighs 3.0 kg, the ratio of alveolar ventilation to FRC is approximately 5:1, compared with the adult, in whom the same ratio is 1.5:1. As a result of this difference, the time constant of the inhaled anesthetic equilibrium for infants is much shorter than for the adult. Consequently, changes in concentrations of inspired gas are reflected rapidly in alveolar levels. In fact, it has been demonstrated that alveolar levels of inhalational anesthetic agents reach equilibrium faster in infants than in adults (see Chapter 7, Pharmacology of Pediatric Anesthesia).

The rise of the alveolar concentration of an inhaled anesthetic is opposed by uptake of the agent into lung tissue and more importantly, blood. Three factors determine inhaled anesthetic uptake: cardiac output, the alveolar-to-mixed venous anesthetic partial pressure difference, and solubility. Each of these factors has unique aspects in the infant, compared with in the adult, and consequently affects the pharmacology of the uptake of inhaled agents.

The greater the cardiac output, the greater is the anesthetic uptake. The cardiac output of the newborn is 250 to 300 mL/kg per minute; by 8 weeks of age, the cardiac output has decreased to 150 mL/kg per minute. The cardiac output of young infants is approximately 3 to 6 times that of the normal adult (70 mL/kg per minute). By itself, this high cardiac output should significantly decrease the rate of rise of the alveolar concentration of the soluble anesthetic agents. However, the newborn distributes a greater proportion of this cardiac output to the vessel-rich group of organs and a smaller proportion to the muscle and fat group. The equilibrium between the inspired and alveolar concentrations of inhaled agent occurs more rapidly, because uptake decreases faster.

Because the cardiac output is predominantly distributed to the vessel-rich group and because the muscle group is small, the arterial-venous partial pressure difference narrows quickly in the young and thereby decreases uptake.

Both left-to-right and right-to-left shunting occurs in infants. A left-to-right shunt results in an increase in total cardiac output. However, the shunted blood does not lose anesthetic to tissue; instead it returns to the lung with the same anesthetic partial pressure. This recycled blood cannot accept more anesthetic agent unless the alveolar partial pressure has risen. Thus, a left-to-right shunt has no effect on anesthetic uptake. A right-to-left shunt slows the rate of rise of the alveolar concentration of an inhaled anesthetic. The anesthetic-deficient, shunted blood dilutes the concentration of the anesthetic in the blood, decreasing the partial pressure of anesthetic in the arterial circulation. This slows the rate of rise of the anesthetic by slowing tissue uptake and equilibration.

Blood-gas partition coefficients of isoflurane, halothane, and sevoflurane did not differ in preterm infants compared with full-term infants but were lower than in adults. Only serum cholesterol correlated with the blood-gas partition coefficients (Malviya and Lerman, 1990). The blood-gas partition coefficient is an important determinant of solubility and therefore the rate of rise of the alveolar concentration of an inhaled agent.

The effect of age on the solubility of the inhaled agents in tissue is also important in determining the rate of rise of the alveolar concentration of the agent—the rate of anesthetic induction. Data by Lerman et al. (1986) are consistent with earlier work documenting that anesthetic solubility in brain, heart, liver, and muscle increases with age. An increase in solubility may prolong uptake, delay equilibration of the tissue partial pressure of anesthetic, and prolong the time of induction. Lerman and others found that the rate of increase in tissue anesthetic partial pressure, and therefore alveolar anesthetic partial pressure, is approximately 30% more rapid in newborns than in adults.

Minimal alveolar concentration (MAC) is an estimate of anesthetic requirement and changes with age (Fig. 18-1) (Kato and Ikeda, 1987, 1992; LeDez and Lerman, 1987). In the original study, Gregory et al. (1969) reported that infants in the first 6 months of life had the highest MAC. In a later study, newborns were noted to require approximately 25% less halothane at MAC compared with infants who are between 1 and 6 months of age (Lerman et al., 1983) (see Chapter 7, Pharmacology of Pediatric Anesthesia).

Intravenous Anesthetics and Analgesics

Several studies have shown an increased sensitivity to and more prolonged effects of barbiturates and morphine in the neonate and young infant (Kupferberg and Way, 1963; Way et al., 1965).

■ **FIGURE 18-1.** Effect of age on MAC of anesthetic gases. The MAC of anesthetic gases is dependent on age. MAC is higher at birth than in adults and increases until peaking at 3 to 6 months. The values at 1 year of age are closer to the adult values. (From Greeley WJ: *Pediatric anesthesia*, In Miller RD, editor: *Atlas of anesthesia*, vol 7, Philadelphia, 1999, Churchill Livingstone.)

These features have been attributed in part to the immaturity of the blood-brain barrier, allowing faster and greater penetration and therefore higher concentration of these drugs in the brain.

In 1981, Robinson and Gregory reported that after a 10 mL/kg bolus of lactated Ringer's solution, 30 to 50 mcg/kg of fentanyl was a safe anesthetic for premature infants undergoing ligation of a patent ductus arteriosus (PDA). Several years later, evidence was presented that infants who received fentanyl in combination with d-tubocurarine and nitrous oxide in oxygen had an improved perioperative course compared with those infants who did not receive analgesics (Anand et al., 1987).

Plasma levels of fentanyl are lower in infants vs. children vs. adults (newborns were not studied) after similar intravenous doses (Singleton et al., 1987). Gauntlett and others (1988) noted that clearance of fentanyl in newborns increased during the first few weeks of life. Elimination half-life and volume of distribution did not change. In a study of newborns who were administered continuous fentanyl infusions, Saarenmaa and others (2000) noted that plasma clearance correlated with maturity (gestational age) and weight, whereas Santeiro and others (1997) noted a correlation of clearance with postnatal age (Fig. 18-2). Koehntop et al. (1986) have shown a highly variable disposition and elimination of fentanyl in neonates. In addition, infants with increased intraabdominal pressure (e.g., omphalocele, gastroschisis, or septic ileus) appeared to have a further increase in the elimination half-life compared with infants undergoing repair of a PDA or myelomeningocele. Davis and others (1989) noted that the clearance of alfentanil in newborn premature infants was markedly reduced compared with older children (Fig. 18-3).

Koren and others (1985) have shown that the elimination half-life for morphine (13.9 hours) in human neonates is markedly prolonged compared with that in older children and adults (2 hours). They also showed reduced clearance and higher

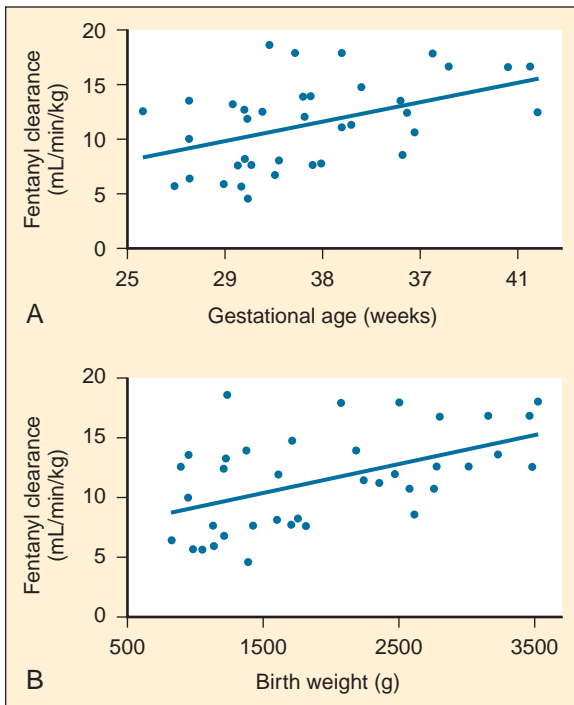

FIGURE 18-2. Plasma clearance of fentanyl correlates with **A**, gestational age ($r = 0.46$, $P < 0.01$), and **B**, birth weight ($r = 0.48$, $P < 0.01$). (From Saarenmaa et al.: Gestational age and birth weight effects of plasma clearance of fentanyl in newborn infants, *J Pediatr* 136:767, 2000.)

serum concentration in neonates compared with those seen in older children after morphine infusion. Because of the large variability in clearance among neonates of different ages, the dose of opioids needs to be carefully titrated for each patient and each clinical setting.

Remifentanyl is an ultrashort-acting opioid. Remifentanyl is metabolized by plasma and tissue esterases, and its metabolism

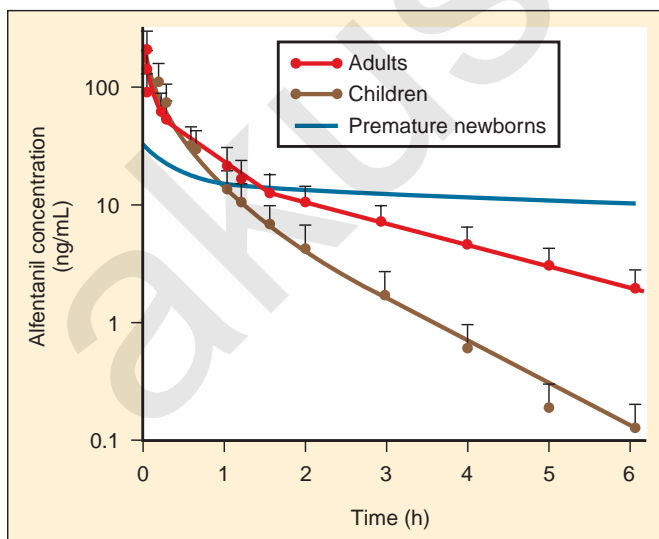

FIGURE 18-3. Age-related changes in alfentanil pharmacokinetics for premature infants, children, and adults. (From Davis CM, Brando M: *Pediatric pharmacology*. In Greeley W, editor: Atlas of anesthesiology, vol 7, Philadelphia, 1999, Churchill Livingstone.)

is independent of organ elimination. As a result, in neonates its pharmacokinetic profile is different from any other opioid. The remifentanyl clearance rate in neonates is greater than in any other age group. Although its volume of distribution is large, its terminal elimination half-life does not change with age (Ross et al., 2001). Because remifentanyl is metabolized in tissues and plasma, it does not accumulate, and consequently its context-sensitive half-time is flat (i.e., the time for 50% reduction at the effect site is independent of drug duration). Thus, remifentanyl may be an ideal drug for anesthetic use in neonates.

Animal studies have shown a decreased median effective dose (ED_{50}) for thiopental in the early weeks of life. Also, arousal in newborn rats occurred at lower brain levels of thiopental than in adult rats (Mirkin, 1975). Although this may suggest that lower doses of thiopental are needed in young neonates, studies by Jonmarker and others (1987) suggest the contrary. Similarly, ketamine requirements are greater (mg per kg of body weight) in infants than in older children (Lockhart and Nelson, 1974). Ketamine has been shown to produce apnea in infants with increased intracranial pressure (Lockhart and Jenkins, 1972). Ketamine produces hypertension and tachycardia, which some anesthesiologists have taken advantage of in caring for infants and children with congenital heart disease, cardiovascular instability, or both.

Propofol is commonly administered to infants. Propofol clearance is dependent on hepatic blood flow (high extraction coefficient) with subsequent metabolism and glucuronidation. In population pharmacokinetic analysis, Allegaert et al. (2007) noted that postmenstrual age and postnatal age were predictive covariants for clearance and that developmental maturation occurs within the first two weeks of life (Fig. 18-4).

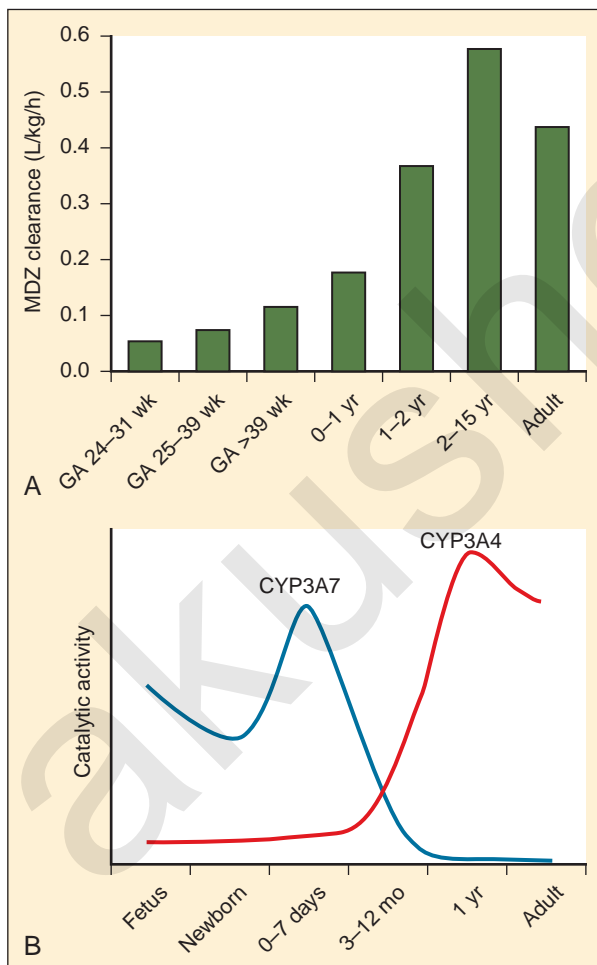

FIGURE 18-4. Simulated population propofol concentrations (line) in neonates aged 27, 38, and 43 weeks' gestation, with a postnatal age (PNA) of 10 days or less, after a bolus dose of 9 mg in 10 seconds. (From Allegaert et al.: Interindividual variability in propofol pharmacokinetics in preterm and term neonates, *Br J Anaesth* 99:864, 2007.)

Midazolam is an extensively used drug in both full-term and preterm infants and is metabolized by the P450 3A subfamily. Midazolam clearance in preterm infants is less than in children and older infants, and it may reflect the pattern of CYP3A4 ontogeny (Fig. 18-5). DeWildt et al. (2001), in a study of 24 preterm infants, found no relationship between age (postconceptional, gestational, or postnatal) and midazolam clearance. Of note was that in infants exposed postnatally to indomethacin, plasma clearance was higher and the volume of distribution was larger than in those infants not exposed to indomethacin. Because CYP3A4 expression is actuated during the first week after birth regardless of gestational age at birth, the decrease in midazolam clearance probably represents a decrease in CYP3A activity.

Muscle Relaxants

Developmental pharmacologic changes influence the requirements for muscle relaxants in infants and older children. Synaptic transmission is slow at birth, the rate at which acetylcholine is released during repetitive stimulation is limited, and neuromuscular reserve is reduced (Fig. 18-6). In addition, the reported sensitivity of infants to the effects of neuromuscular blocking

■ **FIGURE 18-5.** Developmental aspects of CYP3A activity. **A**, Clearance of the CYP3A4 probe midazolam. **B**, CYP3A7 and CYP3A4 expression. GA, Gestational age; MDZ, midazolam. (From de Wildt SN et al.: *Cytochrome P450 3A: ontogeny and drug disposition*, Clin Pharmacokinet 37:485, 1999.)

■ **FIGURE 18-6.** Tracings of the frequency sweep electromyogram (FS-EMG). (From Crumrine RS, Yodkowski EH: *Assessment of neuromuscular function in infants*, Anesthesiology 54:29, 1981.)

agents has differed depending on whether drug administration was indexed to body weight or to body surface area. Because most neuromuscular blocking agents are distributed in the extracellular space and the extracellular space is related to the body surface area, dosage requirements for neuromuscular blocking agents often correlate with surface area rather than with body weight. Neonates and infants have a higher sensitivity (lower ED_{50} and ED_{95}) for most nondepolarizing blocking agents.

Fisher et al. (1982) studied infants' sensitivity to nondepolarizing muscle relaxants using the pharmacodynamic and pharmacokinetic properties of d-tubocurarine. These investigators determined the steady-state plasma concentration associated with 50% neuromuscular blockade (CP_{ss50}) and noted that infants had a lower CP_{ss50} than older children. Because the volume of distribution of d-tubocurarine in infants is significantly larger than that in older children, the dose (mg per kg of body weight) required to achieve the same degree of neuromuscular blockade appeared the same for infants and older children. Although the pharmacokinetic data reveal similar clearance values for infants and older children, the infant's larger volume of distribution and consequently longer elimination half-life suggest that infants need less frequent and smaller supplemental doses for continued neuromuscular relaxation. Although these data are specific for d-tubocurarine, the general principles can be extrapolated to other hydrophilic compounds that are primarily distributed to the "central compartment" (i.e., small volume of distribution).

Studies of rocuronium in infants and children have shown that onset time in small infants is faster, and the occurrence of 100% block at lower doses compared with older children suggests a greater potency in infants. In addition, rocuronium has an age-dependent difference in duration of action and in recovery following 0.45 mg/kg and 0.6 mg/kg doses (Fig. 18-7) (Driessen et al., 2000; Rapp et al., 2004).

GENERAL APPROACH TO INTRAOPERATIVE MONITORING OF THE NEONATE

Safe and effective intraoperative management of the newborn depends on understanding basic principles of physiology and pharmacology, as well as understanding the technical aspects of monitoring and the anesthesia equipment.

■ **FIGURE 18-7.** Recovery of twitch to 10%, 25%, 50%, and 75% of baseline value (*min*) in infants after single-dose relaxation with rocuronium bromide ($n=61$, mean \pm SE). Note significant differences between 0 and 1 month and between 5 and 12 months. $P = 0.05$ ($0.45 \text{ mg} \cdot \text{kg}^{-1}$) and $P = 0.05$ ($0.6 \text{ mg} \cdot \text{kg}^{-1}$). (From Rapp et al.: Neuromuscular recovery following rocuronium bromide single dose in infants, *Pediatr Anesth* 14:329, 2004.)

Thermal Protection

As already described, the newborn infant loses thermal protection after birth, so measures must be taken to protect against heat loss during surgery (Box 18-1):

Attention must be paid to fine, seemingly insignificant details in the care of a sick neonate because the margin of safety is narrow. Although advanced electronic monitoring has contributed significantly to the safety of these babies, the anesthesiologists' clinical skills, judgment, and evaluation remain indispensable.

Monitoring in the Operating Room

General Observation

Color (e.g., cyanosis and pallor), chest mobility (e.g., bilateral expansion, respiratory pattern, and chest compliance), and palpation (e.g., warmth, pulses, and peripheral perfusion) are often difficult to assess because of the patient's position and draping on the operating room (OR) bed. The use of specific monitors depends on the planned surgical intervention and the underlying disease state.

Circulatory Monitoring

A precordial stethoscope is a simple and effective means to assess the quality of heart sounds, rate, and rhythm, as well as breath sounds. A change in the intensity of heart sounds

indicates a decrease in blood pressure and possibly cardiac output. Depending on the surgical procedure and the method of airway management (mask vs. laryngeal mask airway [LMA] vs. endotracheal tube), an esophageal stethoscope is an alternative monitor for noninvasive beat-to-beat cardiovascular monitoring. Although the sensitivity of the stethoscope has been discussed, the simplicity and accuracy of the precordial and esophageal devices to monitor heart tones and breath sounds during surgery involving pediatric patients cannot be denied (Hubmayr, 2004).

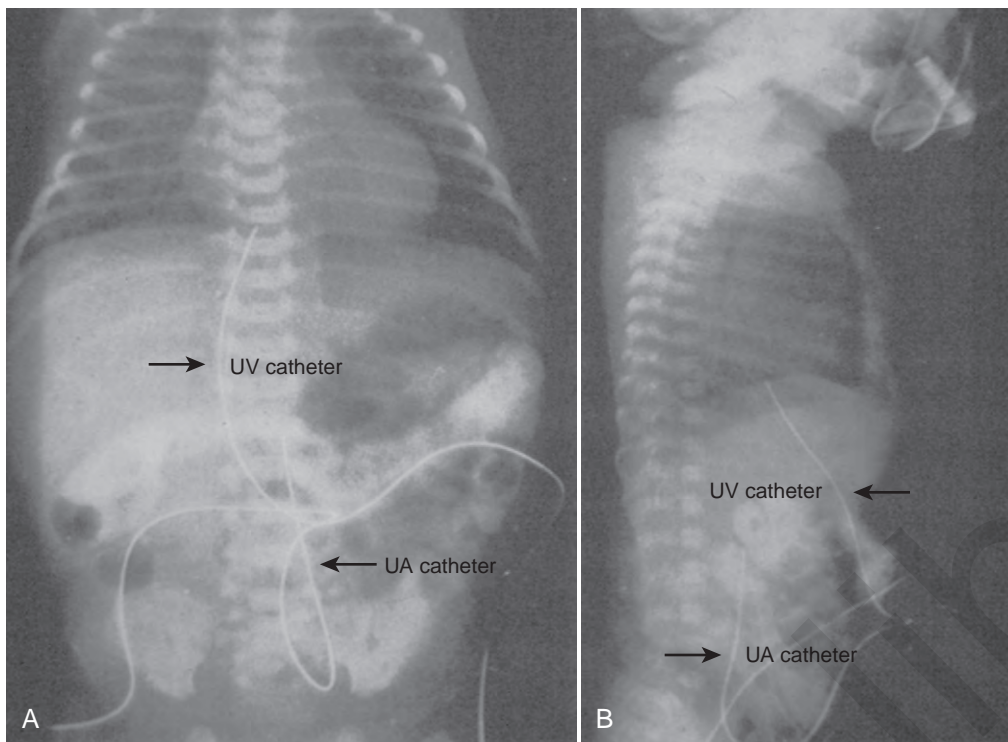

The primary role for continuous electrocardiography during anesthesia for the newborn is to detect arrhythmias, especially in the setting of electrolyte disturbance or as evidence of adverse effects of various drugs. Simple monitoring of heart rate is available via the pulse oximeter, now a routine monitor for all patients in the OR.

In most cases, the blood pressure can be accurately monitored with an automated device based on oscillometry (e.g., Dinamap) or ultrasonic flow (e.g., Arteriosonde) if the appropriate-sized cuff is available. Cuff inflation of the automatic devices should cycle no more frequently than every 3 to 4 minutes to avoid ischemia to the arm (Waugh and Johnson, 1984). Systolic blood pressure measurements correlate with the circulating blood volume and therefore are essential to monitor and guide fluid and blood replacement. Another alternative system is a Doppler ultrasonic transducer, which has a characteristic sound that decreases in intensity with a decrease in blood pressure.

An indwelling arterial cannula allows repeated blood sampling for cardiopulmonary and biochemical evaluation. A 22- or 24-gauge cannula can be inserted percutaneously or by cut-down into a variety of sites, including the radial, dorsalis pedis, or posterior tibial arteries. Before the insertion of the catheter, the adequacy of circulation to the hand should be assessed by applying a modified Allen's test (Brodsky, 1975). The axillary artery is rarely cannulated. In general, the umbilical artery can be cannulated in the first 4 to 7 days of life, but this is usually avoided after the first 2 days of life because of the risks of infection and vascular emboli. The umbilical catheter tip can be placed high (T10 to T12) or low, above the bifurcation of the aorta and below the level of the renal arteries (L4, L5). The placement of the catheter must be confirmed by a radiograph (Fig. 18-8).

Box 18-1 Protection Against Heat Loss During Surgery

- Transport the baby in a heated isolette
- Warm the operating room to more than 27° C (80° F)
- Use a warming mattress (water temperature of 40° C)
- Heat and humidify gases to 36° C (at the trachea)
- Use a radiant heat warmer with a servocontrol mechanism
- Wrap noninvolved areas with plastic
- Warm intravenous fluids and blood
- Warm scrubbing and irrigation solutions
- Monitor the temperature in the operating room

■ **FIGURE 18-8.** Umbilical artery-vein x-ray image. **A**, AP view. **B**, Lateral view. UA and UV catheters have different courses on plain films. The UV catheter goes directly up to the right atrium from the umbilicus, whereas the UA catheter goes down into the external iliac artery and up into the aorta.

The risk for retinopathy of prematurity necessitates meticulous monitoring of oxygen saturation in the neonate, especially the very low–birth-weight (VLBW) infant. Most neonatologists recommend adjusting the inspired oxygen to maintain oxygen saturation between 90% and 95%, depending on the underlying medical status, gestational age, hemoglobin, and postnatal age (i.e., quantity of HgF). Of importance, if blood is shunting right-to-left through a PDA, the oxygen saturation measured in the lower extremities or umbilical artery (postductal site) does not reflect the oxygen saturation in the retinal vessels (preductal site). To enable simultaneous monitoring of both preductal and postductal oxygen saturation, two pulse oximeters are placed—one on the right hand (preductal) and one on a lower extremity (postductal). During right-to-left shunting through the PDA, the preductal oxygen saturation is higher than the postductal value, and the difference depends on the amount of shunting. If blood is shunting right-to-left only via the foramen ovale or other intracardiac sites (e.g., ventriculoseptal defect), the preductal and postductal oxygen saturation are equal (see Chapters 3, 4, and 23, *Respiratory Physiology in Infants and Children, Cardiovascular Physiology, and Anesthesia for General Abdominal, Thoracic, Urologic, and Bariatric Surgery*).

An arterial cannula must be connected to a pressure transducer and slowly and continuously infused with a small volume of diluted heparin solution (0.1 to 1 units/mL) at the rate of 0.5 to 1 mL/hr. In the extremely low–birth-weight (ELBW) infant, the flush volume should be measured and included in calculating the total daily fluid intake. In addition, extreme caution is critical while flushing an arterial cannula, because retrograde embolization into the cerebral circulation is possible in the small infant, especially with a patent foramen ovale or PDA.

A central venous catheter may be indicated to administer blood, fluid, total parenteral nutrition (TPN) and medications, and to monitor central venous pressure (CVP). Using the Seldinger technique, a catheter can be inserted percutaneously into the

subclavian, internal jugular, external jugular, or femoral veins. In emergencies or situations of difficult venous access, the umbilical catheter can be inserted and passed into the right atrium (Fig. 18-8). Its location must be verified by x-ray or by a CVP tracing. Umbilical vein catheters have been associated with portal vein thrombosis. All central venous catheters are associated with significant morbidity, including thrombosis, emboli, and infection. Central venous catheters in the LBW infant have additional risks, from malpositioning and from the disruption of venous flow (ratio of the size of vessel to the size of the catheter is low).

Ventilatory Monitoring

The combination of immature and fragile central nervous and cardiorespiratory systems coupled with unstable chest wall mechanics and variable responses to anesthetic agents are often indications for mechanical ventilatory support both during and after surgery for the newborn. For each patient and for each procedure, the anesthesiologist must evaluate the needs and the requirements for mechanical ventilation. For some infants, the ventilatory status might be so precarious that using a more advanced ventilator from the neonatal intensive care unit intraoperatively might offer additional options for responding to intraoperative events affecting ventilatory status. Of note, if an infant requires a specific mode of ventilatory support, such as high-frequency oscillation, the OR ventilatory strategy should be coordinated with the critical care team.

Manual ventilation has been proposed as a technique to allow the anesthesiologist to continuously sense changes in compliance of the chest and airways. However, Spears and others (1991) noted that manual ventilation can be extremely unreliable for sensing changes in airway compliance. In addition to monitoring heart sounds, the precordial or esophageal stethoscope is a simple system to monitor ventilation and quality of breath sounds. Peak airway and end-expiratory pressures

should also be measured. End-tidal carbon dioxide devices (mass spectrometers or infrared analyzers) are now the “standard of care” to continuously monitor the adequacy of respiratory exchange. These devices provide a breath-to-breath level of carbon dioxide tension, and the waveform of this measurement can provide information about rebreathing, ventilator disconnection, suspected air embolism, and hypermetabolic states (see Chapter 10, Equipment).

The pulse oximeter provides a precise, continuous readout of the hemoglobin oxygen saturation. During the first 1 to 2 weeks of life and without transfusion of autologous blood, the oxygen dissociation curve of HgF is shifted to the left of the adult curve so that hemoglobin saturation of 95% to 97% corresponds to an arterial oxygen tension (P_{aO_2}) of 52 to 77 mm Hg, assuming a P_{aO_2} at 50% hemoglobin saturation (P_{50}) of 19 mm Hg. The hemoglobin saturation should be correlated with an arterial partial pressure of oxygen (P_{O_2}) measurement to ensure valid interpretation of oxygen saturation data in the OR (see Chapter 3, Respiratory Physiology in Infants and Children).

Monitoring of the Neuromuscular Junction

Neuromuscular blockade can be monitored with a battery-operated nerve stimulator. The simple twitch and train-of-four are elicited by stimulating the ulnar nerve at the wrist or the posterior tibial nerve at the ankle. The neonate’s neuromuscular response to nerve stimulation allows the anesthesiologist to titrate further doses of a muscle relaxant and avoid excessive neuromuscular blockade. However, neuromuscular monitoring is technically challenging for VLBW infants because of the small size of their muscles. Accurate data from the transcutaneous devices are often impossible to obtain. Inserting needles into a tiny infant’s extremity should be justified because such trauma may cause bleeding or infection. Furthermore, even with needles in place, obtaining a reliable response using the standard battery-operated devices is unpredictable. Of significance, most of these infants require mechanical ventilation postoperatively, so that documenting full recovery to neuromuscular blockade is often unnecessary immediately after surgery.

Monitoring Urine Output

Devices that collect urine during surgery (specifically, Foley catheters or modifications) are helpful, because in the absence of glycosuria, urine output is a good indicator of hydration, circulating volume, and renal function. The desirable range of

urine output in the neonate under anesthesia is 0.5 to 2.0 mL/kg per hour. Note that for a 1-kg infant, 0.5 to 2 mL of urine per hour is difficult to reliably collect in the setting of surgical drapes, lack of direct access to the patient, and easy kinking of drainage tubing secondary to pressure and positioning. Thus, in actual practice, accurately assessing urine output is difficult.

MINIMAL-ACCESS SURGERY IN THE NEONATE

The development and refinement of endoscopic tools, optical technology, and surgical skills have allowed even the most complex neonatal procedures, such as congenital diaphragmatic hernia (CDH), tracheoesophageal fistula (TEF), congenital cystic adenomatoid malformation, and lobar emphysema, to be routinely accomplished with minimal-access surgery (Georgeson, 2003; Al-Qahtani and Almaramhi, 2006; Ponsky and Rothenberg, 2008). The field of minimal-access surgery continues to evolve and expand into other arenas such as robotic techniques, “stealth surgery” (or “scarless surgery”), and natural orifice transluminal endoscopic surgery (NOTES) (Dutta and Albanese 2008; Dutta et al., 2008; Isaza et al., 2008).

Endoscopic surgical techniques improve surgical conditions and produce better outcomes for patients. Improved technology has created endoscopic tools and video equipment that produce a magnified image and consequently better visualization of the surgical field. In patients with TEF the thoracoscopic approach improves the surgeon’s view, because the fistula is seen perpendicular to its connection to the membranous trachea; consequently the surgeon may more easily identify the exact site for ligation (Fig. 18-9) (Holcomb et al., 2005; Rothenberg, 2005b).

In addition to better visualization, minimally invasive surgery has also been associated with shorter postoperative recovery periods and decreased pain, inflammation, and scarring (Fujimoto et al., 1999). With less trauma to tissues, fluid therapy may be reduced as well. In some specific procedures, such as repair of a TEF, the avoidance of a posterior-lateral thoracotomy may prevent thoracic nerve damage, winged scapula, shoulder girdle weakness, fused ribs, chest wall asymmetry and muscular/soft tissue developmental abnormalities, and scoliosis (Jaureguizar et al., 1985; Rothenberg, 2005a;). In abdominal surgery, the use of minimally invasive techniques may decrease the incidence of adhesive injury after laparoscopy. This may be especially relevant in the newborn, in whom adhesive bowel obstruction after laparotomy ranges between 1% to 2% per year (Ponsky and Rothenberg, 2008).

■ **FIGURE 18-9.** **A**, Thoracoscopic and **B**, bronchoscopic views of a TEF. In the bronchoscopic view the TEF is posterior (*bottom*), and the carina is more anterior (*top*). (*B* From Barksdale EM, Jr: *Surgery*. In Zitelli BJ, Davis HW, editors: *Atlas of pediatric physical diagnosis*, ed 4, St. Louis, 2002, Mosby, p 562.)

Minimal-access surgery in neonates also presents challenges and limitations. The small working space and small size of the newborn, coupled with the unique aspects of neonatal physiology, make thoracoscopic surgery and one-lung ventilation difficult. There is a learning curve to minimally invasive surgery. Procedure times, operative morbidity, and conversion rates to open procedures vary among centers and surgeons (Ponsky and Rothenberg, 2008).

Efficient and safe endoscopic surgery requires both surgical and biotechnical expertise, as well as highly skilled OR and anesthesia teams (Kalfa et al., 2007). Because of these technical challenges, the OR times in the early learning phase may be markedly prolonged compared with operating times for the open procedures (Rothenberg, 2005a; Tsao and Lee, 2005; Nguyen et al., 2006; Kalfa et al., 2007).

The newborn's small size, combined with the unique physiology of transitional and neonatal circulation, forces the pediatric anesthesiologist to analyze the risks of minimal access surgery. In particular, insufflation with carbon dioxide (CO₂) leads to increased pressure in either the thorax or the abdomen, as well as hypercarbia, and it may profoundly affect neonatal pulmonary physiology. In order to minimize complications, clear preoperative planning requires that both the surgeon and anesthesiologist ask the following questions as part of their assessment:

1. What contraindications exist to a laparoscopic approach? For example, weight less than 2 kg, long-gap esophageal atresia, severe lung disease, hemodynamic instability and pulmonary hypertension.
2. What intraoperative indications would occur to cause conversion to an open procedure? For example, a range of time limits and defining cardiorespiratory and blood-loss indications for converting to an open procedure should be at least tentatively established preoperatively.
3. What intraoperative access, monitoring, and anesthetic techniques are required? For example, some surgeons do not use routine bronchoscopic evaluation before TEF repair, whereas others would not proceed without it. In addition, the approach toward attempting one-lung ventilation should be addressed (i.e., bronchial blocker or mainstem intubation).
4. As with any surgery, informed consent, including risks and alternatives must be obtained. In this case, what should parents be told about the expertise of the surgeons, anesthesiologists, and OR team?

Minimal access surgery creates a unique set of operative conditions that may impose significant cardiorespiratory effects: positioning, insufflation, prolonged pneumoperitoneum or pneumothorax, and hypercarbia. The insufflation of any substance into the peritoneum or the thorax must be controlled to avoid excessive pressure in the cavity. The simple increase in pressure can dramatically affect hemodynamic and respiratory function. The development of low-flow devices and valved trocars has allowed surgeons to adopt specific approaches for the newborn or small infant (intrathoracic pressure greater than 10 mm Hg and intraabdominal pressure less than 15 mm Hg). CO₂ has become the most commonly used agent for insufflation because of its high solubility, low expense, and noncombustible nature. On the other hand, CO₂ is readily absorbed from both the peritoneum and the thoracic cavity. The cardiorespiratory effects of insufflation with CO₂ during laparoscopy and

thoracoscopy have been well documented in adults but not in children, infants, and newborns. Although the hemodynamic and pulmonary effects of insufflation may be similar during laparoscopy and thoracoscopy, most of the data reported for thoracoscopy are derived during one-lung ventilation. However, one-lung ventilation in the newborn cannot be achieved with the same techniques used in the adult (e.g., double-lumen tubes or endobronchial blockers).

Laparoscopy Background

The cardiorespiratory effects of laparoscopy are often difficult to separate from those of anesthesia, surgery, and intraoperative positioning (e.g., Trendelenberg or reverse Trendelenberg). Although the enormous amount of data accumulated for adults, children, and older infants cannot be directly extrapolated to newborns, some of the trends noted in these studies are worth considering in the context of neonatal surgery and anesthesia.

In adults, intraoperative pulmonary catheter monitoring determined the hemodynamic effects of general anesthesia, the reverse Trendelenberg position, peritoneal insufflation, and their combined effects during laparoscopic cholecystectomy. After induction of anesthesia, mean arterial pressure and cardiac index decreased from baseline. Adding the reverse Trendelenberg position further decreased right atrial and pulmonary capillary wedge pressures, cardiac index, and mean arterial pressure. After peritoneal insufflation with CO₂ while in the reverse Trendelenberg position, mean arterial pressure increased as systemic and pulmonary vascular resistances increased. Right atrial and pulmonary capillary wedge pressures increased, and cardiac index decreased beyond the level associated with positioning.

These hemodynamic changes from insufflation, positioning, and hypercarbia are of minimal significance in a euvolemic, healthy adult, but the risks may become significant in patients with underlying cardiac disease (Grabowski and Talamini, 2009). Data documenting cardiorespiratory responses to laparoscopy in infants have been reported, but only about studies involving the use of noninvasive tools, and they differ from some of the results reported in healthy adults.

Using a transesophageal ultrasonic probe inserted after induction of general anesthesia in 12 healthy boys (23 ± 5 months of age), Gueugniaud et al. (1998) noted that pneumoperitoneum (10 mm Hg) decreased aortic blood flow and stroke volume and increased systemic vascular resistance. No effects on mean arterial pressure or end-tidal CO₂ were noted. Of importance, these patients remained supine (no reverse Trendelenberg positioning).

Manner et al. (1998) reported the pulmonary effects of pneumoperitoneum in 10 patients between the ages of 1 and 15 years who were undergoing a variety of laparoscopic procedures (intraperitoneal pressure, 12 mm Hg). In this study, the patients' pulmonary compliance decreased (17% with the reverse Trendelenberg position, 28% with the reverse Trendelenberg position plus insufflation); peak inspiratory pressure increased (25% with the reverse Trendelenberg position, 30% with the reverse Trendelenberg position plus insufflation) and end-tidal CO₂ tension (PETCO₂) concentration increased from 33 to 42 mm Hg at maximum insufflation pressure. In 17 infants (younger than 10 months) who were undergoing a variety of procedures that required at least 30 minutes of laparoscopy but experienced

no change in position, Bannister et al. (2003) reported similar findings. Patients were divided into two groups: those weighing less than 5 kg (intraabdominal pressure less than 12 mm Hg), and those weighing more than 5 kg (intraabdominal pressure, less than 15 mm Hg). Again, peak inspiratory pressure increased (18%) and correlated with insufflation pressure, and dynamic compliance decreased (48%). Tidal volume decreased 33% and oxygen saturation fell 2% to 11% in 41% of the patients. Ventilation was adjusted to maintain P_{ETCO_2} within 10% of baseline, and 20 adjustments were reported. Neither heart rate nor blood pressure changed with insufflation or ventilatory adjustments, and significant changes from baseline status were noted at insufflation pressures of 10 mm Hg and greater but not at pressures of 5 mm Hg. Similar minimal hemodynamic effects of low-pressure pneumoperitoneum have been documented in young children elsewhere (DeWaal and Kalkman, 2003).

Of note, inducing a pneumoperitoneum in the Tredelenburg position during gynecologic surgery in adults decreases the distance between the endotracheal tip and the carina as well as the tracheal length (Kim et al., 2007). Because the distance between the larynx and the carina is markedly less in the infant, this phenomenon may be of critical importance in the newborn undergoing laparoscopy.

Renal function is affected by pneumoperitoneum. However, data have primarily been acquired in the adult population. In adults, decreased urine production has been attributed to the decreased glomerular filtration rate and renal perfusion from the direct effects of pneumoperitoneum (e.g., compression of the renal artery, the inferior vena cava, or the parenchyma) or from secondary effects (e.g., decreased cardiac output and release of mediators) (Rosin et al., 2002). Renal blood flow and renal function decrease during pneumoperitoneum; the effects on blood flow are pressure dependent and exacerbated in the head-up position, but they return to normal after deflation (Demyttenaere et al., 2007).

The effect of pneumoperitoneum on intracranial pressure has been studied in adults. Although the newborn's cerebrovascular physiology and autoregulatory responses differ from those of the adult, newborns with limited autoregulatory responses may have more profound cerebral vascular responses from increased intraabdominal pressure. In adult animals, intraabdominal pressures of 15 and 25 mm Hg—but not 5 mm Hg—affected intracranial pressure, similar to findings by Rosenthal et al. (1998) (Rosin et al., 2002). Bloomfield et al. (1997) created models that linked intraabdominal, intrathoracic, and intracranial pressures. As with other studies, pleural, peak inspiratory, right atrial, and pulmonary arterial pressures increased as intraabdominal pressure increased above 10 mm Hg. The increases became especially significant at intraabdominal pressures of 25 mm Hg. At the same time cardiac index decreased, but systemic vascular resistance increased and blood pressure remained stable. Increased intracranial pressure accompanied the rise in intraabdominal pressure; however, these changes reversed when the abdomen was decompressed. Of significance, the increase in pleural and intracranial pressures with increased intraabdominal pressure was prevented in a group of swine with the chest opened (e.g., median sternotomy and pleuropericardotomy). However, in spite of the open chest, cardiac index decreased and systemic vascular resistance increased. The investigators suggested that the acuity of the increase in intrathoracic pressure secondary to an abrupt rise in intraabdominal pressure acutely increased central venous pressure,

preventing cerebral venous outflow. When they prevented the effect of intraabdominal pressure on the pleural pressure (open chest), venous and intracranial pressures did not change.

The absence of predictable autoregulation of cerebral perfusion in the newborn combined with the significant risk of injury secondary to oxygen and positive pressure ventilation may have unique implications for the anesthetic management of the newborn during either laparoscopy or thoracoscopy. Although indirect monitoring of cerebral blood flow is available (e.g., near-infrared spectroscopy, or *NIRS*), ideally a reliable, continuous method to accurately monitor cerebral perfusion pressure would be of critical benefit in this setting (Brady et al., 2007).

In summary, pneumoperitoneum in infants affects ventilation as well as cardiovascular, renal, and cerebrovascular function. With pneumoperitoneum, the upward displacement of the diaphragm affects intrathoracic pressure and lung volumes, ultimately affecting compliance, peak airway pressure, tidal volume, and effective minute ventilation. All of these changes result in a decrease in functional residual capacity, which can promote atelectasis and worsen the ventilation/perfusion mismatch abnormalities.

Laparoscopy and Thoracoscopy in the Newborn

The effects of insufflation during both laparoscopy and thoracoscopy are dramatic in the newborn. The impact of increased intrathoracic pressure and hypercarbia can profoundly influence the transitional circulation. Changes in patient oxygen saturation, hypotension, interruption of the procedure, and hypercarbia are common in the newborn (Kalfa et al., 2005, 2007; Krosnar and Baxter, 2005).

Insufflation in the newborn also decreases core body temperature. In 50% of newborns, the postoperative core temperature was less than 36° C. A long operative time (insufflation for more than 100 minutes) was associated with lower postoperative core body temperature (Kalfa et al., 2005).

Inaccurate end-tidal CO_2 values are common during laparoscopy, especially in the setting of cyanotic heart disease (Laffon et al., 1998; Wulkan and Vasudevan, 2001). At the same time, absorption of CO_2 from the peritoneum seems to be age-dependent (McHoney et al., 2003). The total amount of insufflated CO_2 and elimination of CO_2 correlated with age. Younger patients also demonstrated a short period of increased CO_2 elimination after desufflation, which may be related to increased venous return after the decrease in intraabdominal pressure.

Because one-lung ventilation is challenging to achieve and at times is not tolerated by a newborn, many pediatric surgeons suggest that insufflation of the chest with low flow of CO_2 (1 to 2 L/min, peak pressure of 4 to 6 mm Hg) in the 30- to 45-degree prone position induces adequate lung collapse (Rothenberg, 2002; 2005b; Holcomb et al., 2005).

Because many of the strategies to affect one-lung ventilation are not available for the newborn, adequate surgical exposure for thoracoscopy relies heavily on insufflation to collapse the lung. Lungs with abnormal distribution of ventilation impede uniform collapse with insufflation, so the newborn with abnormal lung function may not be eligible for thoracoscopic surgery. The effect of pneumoperitoneum on tracheal length implies that the risk for inadvertent endobronchial intubation may be increased in the newborn.

In spite of the myriad of critical physiologic challenges, endoscopic procedures have been conducted successfully in high-risk infants with conditions such as hypoplastic left heart syndrome, complex cyanotic heart disease, and patients with single ventricle physiology (Mariano et al., 2005; Rice-Townsend et al., 2007; Slater et al., 2007).

SPECIFIC NEONATAL SURGICAL LESIONS

Abdominal Wall Defects: Gastroschisis and Omphalocele

Gastroschisis and omphaloceles are the most common abdominal wall defects (ectopia cordis and cloacal and bladder extrophy are less common), but they are still rare, with an incidence of approximately 1:10,000 and 1:4000 to 7000 births (Paidas et al., 1994). Some have suggested that both ethnic and geographic origins affect the incidence, but overall the lesions seem sporadic (Mann et al., 2008).

Currently, fetal ultrasounds are routinely conducted to screen for high-risk conditions. For example, nuchal translucency and biochemical markers (free β -subunit of human chorionic gonadotropin and pregnancy-associated plasma protein A) are now measured to screen for aneuploidy or cardiac and other anomalies (Souter and Nyberg, 2001; Weiner et al., 2007). An abnormal value on screening prompts an evaluation that includes a detailed fetal ultrasound; in the case of abdominal wall defects, ultrasound confirms the presence of a lesion in approximately 95% of cases after as few as 10 to 14 weeks' gestation (Mann et al., 2008). The in utero diagnosis allows planned delivery at a medical center with resources for high-risk obstetric, surgical and anesthetic, and neonatal care.

Although omphalocele and gastroschisis appear to be similar in gross physical appearance, these lesions are distinct from each other. An omphalocele is a central defect of the umbilical ring; the abdominal contents herniate into the intact umbilical sac unless the sac ruptures in utero (Fig. 18-10). The umbilical cord is also inserted into the sac, which contains an internal peritoneal membrane and external amniotic membrane. The lesion has a fascial defect of more than 4 cm (fewer than 4 cm is often considered an umbilical hernia) and often as large as 10 to 12 cm. The sac often contains the stomach, loops of the

■ **FIGURE 18-10.** Newborn with large omphalocele, sac intact. Umbilical cord is seen emerging from mass. The major problem will be replacing the viscera in the small abdominal cavity.

small and large intestines, and in about 30% to 50% of cases, the liver. A gastroschisis, on the other hand, is an abdominal wall defect that usually occurs to the right of the umbilical cord, with visceration of bowel through the defect (Fig. 18-11). This lesion is usually 2 to 5 cm in diameter, and in most cases there are only small and large bowel present. In rare cases the liver may exit through the abdominal wall defect as well. The bowel is exposed to the intrauterine environment with no sac, causing its loops to become matted, thickened, and often covered with an inflammatory coating or peel. Whether this exudative peel is secondary to a specific inflammatory pathway or just an effect of amniotic fluid is unclear. The umbilical cord is normal and separate from the defect. When the testes exit along with the bowel, cryptorchidism occurs with gastroschisis (Lawson and de La Hunt, 2001; Weber et al., 2002).

Embryology

Although experimental models have been described, the embryologic etiology of these lesions is not completely understood (Correia-Pinto et al., 2001). Omphalocele has been described as a failure of the cephalic, lateral, and caudal folds to fuse (closure of the exocoelomic space) and as abnormal fusion and differentiation of myotomes to form abdominal wall musculature (7 to 12 weeks of gestation). That is, the abdominal cavity is primarily underdeveloped. During weeks 7 to 12 of development, the midgut elongates and herniates into the umbilical cord. By week 12, the abdominal cavity is large enough for the developing gut to exit the cord and reenter the abdomen. Some believe that the simple failure of this return to the abdomen is a developmental arrest that results in an omphalocele and a small abdominal cavity. The abdominal cavity is small only because the gut remains in the umbilical sac.

Gastroschisis is considered to be an earlier embryologic event, resulting from an abnormality of the development of the right omphalomesenteric artery or right umbilical vein, which in turn results in ischemia to the right paraumbilical area. More recently, abdominal wall defects have been ascribed to an

■ **FIGURE 18-11.** Gastroschisis, sometimes called ruptured omphalocele, with umbilical cord intact. Heat loss, rapid dehydration, and infection are added to problems of omphalocele.

abnormal relationship between cell proliferation and planned cell death (apoptosis) at the critical embryonic folding period (Robinson and Abuhamad, 2000). Inadequate mesoderm development may contribute to dysplastic abdominal wall growth. This underdeveloped site is commonly found just to the right of the umbilicus and ruptures with increased pressure of the growing intraabdominal organs. Similar defects in other areas may produce other lesions, such as extrophy of the bladder.

Gastroschisis is usually an isolated lesion, but recent reports raise the possibility of familial occurrence (Yang et al., 1992; Torfs et al., 1994). In utero exposure to acetaminophen, aspirin, and pseudoephedrine has been associated with an increased incidence of gastroschisis (Werler et al., 2002; Baerg et al., 2003). In the case of either an omphalocele or gastroschisis, rotation of the gut is incomplete in utero, resulting in various “malrotation” phenotypes. Intestinal atresias are common, especially in patients with gastroschisis.

Although neither gastroschisis nor omphalocele is considered to be familial, 50% to 75% of infants with an omphalocele have other anomalies, and 20% to 30% have chromosomal abnormalities (Robinson and Abuhamad, 2000; Weber et al., 2002; Mann et al., 2008). Only 15% to 20% of infants with gastroschisis have associated malformations, and only rarely is there a complex pattern of malformation (Stoll et al., 2008). For example, Beckwith-Wiedemann, Rieger’s, and prune belly (Eagle-Barrett) syndromes are associated with omphaloceles, as are trisomies 13, 15, 18, and 21. If the omphalocele contains only bowel and if oligo- or polyhydramnios are present, the likelihood of an associated chromosomal abnormality increases. Others have noted that omphaloceles that contain liver and other viscera are more likely to have cardiac, renal, or limb anomalies, whereas the smaller omphaloceles are more likely to have gastrointestinal or central nervous system malformations (Mann et al., 2008). Syndromes of midline defects often include an omphalocele, and the lesion has been noted in the nonsyndromic multiple congenital anomalies (MCA) complex.

Single-gene mutations have been identified in omphaloceles with multiple anomalies, such as the filamin A, alpha (*FLNA*) gene in the otopalatodigital syndrome, which is characterized by abnormalities in the axial and appendicular skeleton plus extraskeletal anomalies such as omphalocele (Robertson, 2007). One syndrome, Pentalogy of Cantrell, includes an omphalocele, diaphragmatic hernia, sternal abnormalities, an ectopic and anomalous heart, and gene abnormalities at Xq25 to Xq26.1. Another syndrome (OEIS Complex) involving the lower abdomen includes omphalocele, bladder or cloacal extrophy, imperforate anus, colonic atresia, sacrovertebral anomalies, and meningomyelocele. No environmental or teratogenic associations have been proposed as etiologic causes. Allen et al. (2006) reported an association with assisted reproductive technology. Thus, identifying an abdominal wall defect in utero demands an intense evaluation for associated anomalies, which may be isolated, part of a recognizable malformation syndrome, or chromosomal. In addition, serial ultrasounds should be conducted to evaluate fetal growth and well being, as well as amniotic fluid volume. Of note, after 20 to 32 weeks’ gestation, a higher incidence of fetal demise has been reported. The mode of delivery for infants with abdominal wall defects remains controversial, but recent studies have shown that in gastroschisis and nongiant omphaloceles (i.e., liver extracorporeal), outcome after vaginal delivery is no different than with caesarean section (Henrich et al., 2008). The controversy centers on delivery

with gastroschisis because of the unprotected viscera, but no advantages of cesarean section are consistently apparent when survival and incidence of complications are evaluated (Weber et al., 2002).

Preoperative Management

The preoperative management of abdominal wall defects is concerned primarily with fluid resuscitation, minimizing heat loss, treating sepsis, and avoiding direct trauma to the herniated organs. Rather than “rushing” to close the defect, careful assessment of associated defects, establishing smooth cardiorespiratory transition, and ensuring adequate intravascular volume comprise the critical aspects of preoperative management.

Normothermia should be maintained or achieved by preventing heat loss from the exposed viscera. A bowel bag may be used for this purpose (Towne et al., 1980). Emphasis should be placed on covering the lesion with gauze, nonadherent dressing, and a plastic cover rather than moist (saline-soaked) material, as moisture tends to exacerbate heat loss (Mann et al., 2008). It is critical to avoid distorting the sac or twisting at the base. Decompressing the stomach with an orogastric or nasogastric tube minimizes regurgitation, aspiration pneumonia, and further bowel distention. Broad-spectrum antibiotics are started and intravenous fluid therapy (e.g., lactated Ringer’s solution) at as much as 3 to 4 times (150 to 300 mL/kg per day) the usual maintenance rate (80 to 100 mL/kg per day) is infused to provide adequate hydration and to compensate for a combination of peritonitis, edema, ischemia, protein loss, and significant third-space loss. Without such vigorous fluid resuscitation, hypovolemic shock, hemoconcentration, and metabolic acidosis may develop. A urine output of 1 to 2 mL/kg per hour suggests adequate hydration. Because of the large fluid requirements, acid-base status and electrolyte levels should be monitored carefully by serial arterial or venous blood-gas measurements. Rarely, severe metabolic acidosis develops in spite of aggressive fluid delivery (e.g., coexisting sepsis), and sodium bicarbonate (infusion or bolus) or sodium acetate infusion may be required to maintain the pH at greater than 7.20. In general, delivery of crystalloid and colloid provides adequate support.

Intraoperative Management

Surgical management aims to repair the abdominal wall defect and reduce the protruded viscera. If primary closure is not possible, a staged repair is planned, including the use of the silo chimney or the silastic silo prosthesis (Schuster, 1967). The “silo” consists of a silastic or Teflon mesh that is sutured to the fascia of the defect. The synthetic material used to cover the lesion and the specific mechanism for placing the organs into the abdomen (e.g., umbilical tapes or umbilical cord clamps) vary from center to center. After the silo is in place, the extraabdominal organs are gradually returned to the peritoneal cavity over 3 to 10 days (Fig. 18-12). Improved outcome using the delayed-repair approach after the nonoperative placement of a spring-loaded silo has been described by Schlatter et al. (2003). These authors state that this procedure is accomplished in the neonatal intensive care unit (NICU) or delivery room and requires no anesthesia. The prosthesis is then removed, the lesion is reduced under general anesthesia, and eventually the defect is closed. The authors also claim that the time to both first and full feeds was shorter in infants who underwent

■ **FIGURE 18-12.** A silo is used to aid in the reduction of the abdominal contents when the abdominal cavity is too small. Over time, the intestinal contents are gradually reduced back into the abdominal cavity.

delayed closure. Similarly, Pastor et al. (2008) performed a prospective multicenter study of infants with gastroschisis. They noted that the routine use of a preformed silo was associated with similar outcomes as primary closure for infants; however, this method has not gained widespread acceptance.

Forcing the viscera into an underdeveloped abdominal cavity that cannot accommodate the herniated bowel and tight closure of the defect can restrict diaphragmatic excursion, possibly compress the lungs, and may produce abdominal compartment syndrome (ACS). ACS not only impairs respiratory function, but the high intraabdominal pressure can diminish blood flow to the kidneys and other viscera, impair venous return, and even increase intracranial pressure via effects on intrathoracic pressure (Rosenthal et al., 1998). Thus, during abdominal closure, the anesthesiologist must monitor airway pressures to identify decreased pulmonary compliance, as well as observe for evidence of decreased perfusion to the lower extremities (evidence of ACS). The surgeon and the anesthesiologist should cooperate to assess the feasibility of a primary closure. Yaster et al. (1988) noted that an increase in intragastric pressure of greater than 20 mm Hg and CVP of more than 4 mm Hg above baseline were often associated with reductions in venous return and cardiac index, requiring surgical decompression of the abdomen. The impact of ACS on hemodynamic function and its treatment with percutaneous drainage of the peritoneal cavity has been described in adults and older children, especially in the setting of trauma, and recently in a low-birth-weight infant with a sepsis and an intestinal perforation (Hunter and Damani, 2004; Hunter, 2008, Rasner et al., 2008).

An arterial catheter facilitates blood sampling and continuous monitoring of blood pressure. However, a CVP catheter might be equally valuable for evaluating changes in blood volume and the degree of visceral compression during abdominal closure, and to allow metabolic monitoring (e.g., serial intraoperative glucose levels in infants with Beckwith-Wiedemann syndrome) (Yaster et al., 1988). Intravenous fluids often consist of 5% to 10% dextrose in 0.2% saline to deliver the maintenance therapy and lactated Ringer's solution (8 to 15 mL/kg, or more, per hour) for third-space loss. Vigilant efforts at preventing heat loss should be sustained (see Chapter 6, Thermoregulation: Physiology and Perioperative Disturbances).

After decompression of the stomach, anesthesia may be induced with inhalation or intravenous agents. Because it distends the bowel, nitrous oxide is avoided. In most cases, neuromuscular blockade facilitates the abdominal decompression or closure. Ventilation with an air (or nitrogen) and oxygen mixture with low concentrations of an inhalation anesthetic plus intravenous opioids are titrated in response to the hemodynamic status. In neonates who have received transfusions of adult blood, the inspired oxygen concentration must be adjusted to maintain oxygen saturation between 85% and 95% and lower in the preterm infant (See Chapter 17, Neonatology for Anesthesiologists). In infants who have not received adult hemoglobin transfusions, the oxygen saturation should be maintained at 90% to 97%, and in preterm infants it should be kept at between 90% and 95%. In the infant who has had no transfusion, this assumes a P_{50} of 19 mm Hg, and an O_2 saturation between 90% and 97% results in a P_{aO_2} of 40 to 64 mm Hg. In the preterm infant, an O_2 saturation of 90% to 95% results in a P_{aO_2} of 40 to 52 mm Hg (See Chapter 3, Respiratory Physiology, Table 3-3). Vane et al. (1994) demonstrated that spinal anesthesia can be an effective anesthetic for the repair of gastroschisis in selected patients. Evaluating for associated intraabdominal anomalies (e.g., atresia) is worthwhile, but especially in the setting of gastroschisis the "matted" bowel is difficult to examine thoroughly for other malformations.

Postoperative Care

Postoperatively, after an uncomplicated primary closure of an abdominal wall defect, mechanical ventilation is usually required for 24 to 48 hours or longer; thereafter, respiratory compliance usually improves dramatically (Nakayama et al., 1991, 1992). Clearly, infants undergoing a gradual reduction after placement of a silo or similar device should be mechanically ventilated during this process. Infants with a small defect can sometimes be extubated at the conclusion of surgery. All patients must be carefully monitored for respiratory and infectious complications in an intensive care unit after closure of an abdominal wall defect. Inferior vena caval compression (evident by blueish lower limbs) or bowel ischemia (necrotizing enterocolitis) can occur as a result of increased abdominal pressure and may require surgical decompression.

The onset of peristalsis after repair of omphalocele or gastroschisis is usually delayed, and the resulting ileus may be prolonged so that total parenteral nutrition is generally required for days to weeks postoperatively (O'Neil and Grosfeld, 1974). Bowel hypomotility is most common in infants with gastroschisis. In anticipation of this, most infants with large lesions and especially gastroschisis should have appropriate intravenous access established in the OR to facilitate early postoperative nutritional support, which is essential for healing and recovery. Prolonged feeding intolerance should precipitate an evaluation for an associated intestinal atresia or other intestinal lesion.

Outcome

Survival of infants born with anterior abdominal wall defects has improved dramatically as a result of prenatal diagnosis; improved surgical, anesthetic, and perioperative intensive care; and nutritional support. The advent of accurate prenatal imaging has allowed termination of a pregnancy when a fetus with multiple anomalies, chromosomal lesions, or a huge defect

is identified. When the defect exists in isolation from other anomalies or malformations, 95% to 97% survival is expected. Mortality and long-term outcome are related to associated anomalies (e.g., cardiac malfunction or intestinal atresia); complications of treatment (e.g., bowel perforation, necrotizing enterocolitis, sepsis, or short bowel syndrome); and the side effects of intravenous alimentation (e.g., liver failure or sepsis). In a single institutional report by Phillips et al. (2008), of the patients with gastroschisis and intestinal atresia about one third have significant intestinal dysmotility without short bowel syndrome or obstruction. Although specific data have been collected to stratify and predict outcomes of patients with abdominal wall defects, an obvious observation is that infants with a simple defect (i.e., no atresias, no extraintestinal anomalies, and defect smaller than 5 or 6 cm) and no postoperative complications (e.g., obstruction, necrotizing enterocolitis, or short gut syndrome) have a better prognosis than those with a complex lesion or difficult postoperative course (Molik et al., 2001; Henrich et al., 2008). Of course, outcomes in the setting of a giant omphalocele (i.e., a liver-containing lesion through an abdominal defect wider than 5 cm) are overshadowed by a significant incidence of long-term respiratory insufficiency that may be related to sequelae of abnormal chest wall development (Tsakayannis et al., 1996; Biard et al., 2004).

In a follow-up study of 23 infants born with gastroschisis between 1972 and 1984 and who survived more than 1 year (older than 16 years of age at the time of study), Davies and Stringer (1997) reported that 22 of these 23 infants were in good health and that their overall growth was normal. About one third of the patients with gastroschisis had undergone additional surgery for adhesions, bowel obstruction, or scar complications related to their defect. In a 30-year review of morbidity related to adhesions after an abdominal wall defect in the neonatal period, van Eijck et al. (2008) reported an incidence of small bowel obstruction of 25% in the gastroschisis group, but only 13% in the patients who had had an omphalocele. Of all the patients, 88% required a laparotomy, and 85% occurred in the first year of life. A history of sepsis or wound dehiscence was a factor for predicting the development of a small bowel obstruction. The authors suggest that pediatric surgeons should evaluate the relevance of adhesion-prevention techniques and materials at the time of the initial surgical treatment of abdominal wall defects (e.g., component separation technique or hyaluronate-based barrier) (van Eijck et al., 2008).

Of note, in 25% to 60% of patients with anterior wall defects, the absence of an umbilicus was a distressing physical sign, especially during adolescence (Tunell et al., 1995; Davies and Stringer, 1997). Studies involving shorter follow-up periods have noted patients with chronic abdominal pain and gastroesophageal reflux (Fasching et al., 1996). Recently, economic analysis of care of infants with gastroschisis emphasized that the cost of care is high and that on average 47 days of hospitalization were needed in order to establish full feeds (Sydorak et al., 2002).

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) is a defect in the diaphragm that develops early in gestation and is associated with extrusion of intraabdominal organs into the thoracic cavity (Fig. 18-13). The incidence of CDH ranges between 1:2500 and 1:3000 live births. CDH may be an isolated lesion, or it may

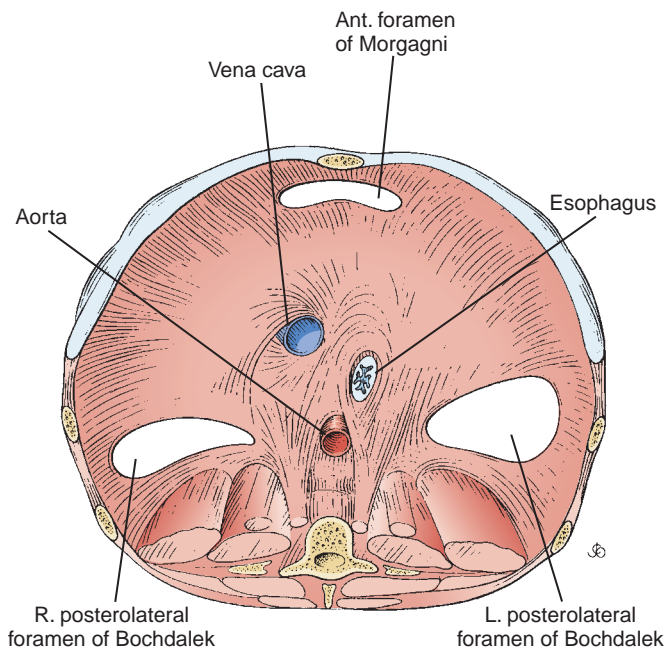

■ **FIGURE 18-13.** Diaphragmatic hernia at postmortem examination showing obliteration of left pleural cavity and severe compression of the heart and right lung. (Courtesy of Dr. Arnold Colodny, Boston, Mass.)

be associated with other anomalies. Although most cases are considered sporadic rather than part of a genetic syndrome, the nonisolated CDH has been linked to specific chromosomal anomalies including duplication of 1q24 to q31.2 and deletion of a portion of 6q, 8p23.1, and 15q26 (Holder et al., 2007; Clugston et al., 2008). In addition, CDH is a key feature of syndromes such as Beckwith-Wiedemann; coloboma, heart, atresia choanae, retardation, genital, and ear (CHARGE); Cornelia de Lange's; and Denys-Drash. Trisomies 13, 18, and 21 and 45 are the most common aneuploidies associated with CDH. Multiple examples of familial cases have been reported, but recurrence rates are low.

The most common defect is posterolateral (Bochdalek's hernia), occurring in 90% of cases, of which 75% are left sided. Morgagni (anteromedial) and paraesophageal hernias and eventrations make up the remainder (Fig. 18-14). This anomaly is much more than a hole in the diaphragm. CDH is also associated with the following conditions:

- Varying degrees of bilateral lung hypoplasia
- Pulmonary hypertension and arteriolar reactivity
- Congenital anomalies (e.g., cardiac, gastrointestinal, genitourinary, skeletal, neural, and trisomic)
- Significant morbidity and mortality

Since the 1980s, the survival of neonates with CDH has improved dramatically from 40% to 60% in the 1980s to 70% to 80% in the 1990s. The drastic improvement in the operative mortality rate of CDH has apparently resulted from the new strategy of delaying surgery, neonatal stabilization, and the adaptation of new a lung-protective, or "gentle ventilator," strategy with a small tidal volume, a higher and adequate positive end-expiratory pressure (PEEP) to keep the airways open, and

■ **FIGURE 18-14.** Diagram, with view from below, showing sites of congenital diaphragmatic hernia.

the acceptance of the resultant rise in P_{CO_2} (permissive hypercapnea) (Nakayama et al., 1991; Boloker et al., 2002; Harrison et al., 2003). The development of the lung-protective approach is based on the findings that the traditional ventilatory strategy of maintaining “normal” P_{CO_2} levels with large tidal volumes results in further damage to the lung tissues and exacerbates acute respiratory distress syndrome (ARDS) (Wada et al., 1997; Björklund et al., 1997) (see *Timing of Surgery*, p. 570).

CDH persists as a lesion with many unanswered questions; however, the impact of pulmonary hypoplasia and pulmonary hypertension on pathophysiology and clinical outcome is well recognized. For example, Dillon et al. (2004) correlated pulmonary artery pressure (measured via echocardiogram) with survival in a cohort of 47 full-term infants treated with delayed surgery and gentle ventilatory approaches such as high-frequency oscillatory ventilation (HFOV), permissive hypercapnia, nitric oxide (NO), or extracorporeal membrane oxygenation (ECMO). All 23 infants with estimated normal pulmonary artery pressure within the first 3 weeks of life (49% of study) survived. In contrast, none of the 8 patients with persistent systemic (or higher) pulmonary artery pressure survived. Of the remaining 16 patients with pulmonary artery pressure between these two extremes, 12 (75% of the 16) survived. Both in utero and postnatal optimum management strategies for these infants remains unclear (de Buys Roessingh and Dinh-Xuan, 2009).

Survival of inborn patients is lower (62.6%) than outborn patients (83.3%), suggesting that surviving transport to a tertiary care center occurs at a higher rate for those with less severe lesions. Since 2000, survival rates of patients who receive care at a NICU are at least 60% to 70% (Migliazza et al., 2007). Thus, institution-based reports that only include data about live-born infants cared for in a NICU may underestimate the total mortality of CDH and the incidence and severity of associated anomalies. Survival rates associated with an isolated congenital diaphragmatic hernia approaches 80% in those who do

not require ECMO (Sigalet et al., 1995; Reickert et al., 1998). Harrison first noted in the 1970s that mortality may be “hidden” when in utero deaths and early postnatal deaths are not included in calculating mortality associated with CDH (Harrison et al., 1978, 1994).

A population-based study of CDH in western Australia that included complete outcome data (i.e., miscarriages, stillbirths, and terminations of pregnancies) noted that of the 116 CDH cases studied, 61% of infants were born alive (Colvin et al., 2005). Of those born alive, 35% died before transport, and 52% survived beyond the age of 1 year. However, if the denominator includes all cases, only 32% survived past 1 year. Of these infants, only 16% of all prenatally-diagnosed and 33% of live-born, prenatally-diagnosed infants with CDH survived beyond the age of 1 year, whereas 92% of infants who had surgery and 80% of those who reached the referral center survived beyond 1 year of age. A major anomaly was identified in 47% of this cohort, and mortality reached 78% in this subgroup. In those pregnancies that were terminated, 71% had a major anomaly in addition to CDH. Similar to other reports, 53% of CDH cases were identified in utero; 49% of these were terminated. Of the 47% diagnosed postnatally, 74% were liveborn. Most deaths occurred in the first week of life. Eighty-eight percent of those with a preoperative pneumothorax died. Low birth weight and low Apgar scores at 1 and 5 minutes were also predictive of increased mortality. Thus, high mortality associated with this lesion persists, and prenatal termination dramatically confounds the accurate overall estimate of the outcome of CDH.

Similar findings have been reported from the United Kingdom’s northern health region on all cases of CDH from 1991 to 2001, which included antenatal diagnoses and termination, associated anomalies, therapy, and outcome. Stege et al. (2003) claimed that in the era of gentle ventilation, various newer therapies (e.g., ECMO, HFOV, and NO) have had minimal impact on mortality when complete case ascertainment is included. The authors noted that the two factors that distort postnatal mortality include the rate of termination and the presence of other anomalies. Stege also reported that the mortality rate before ECMO was available was 68% total (57% of live births) and after ECMO was available, the mortality rate was 58% total (45% of live births). However, since discontinuing ECMO as a therapeutic option, mortality has remained at 58% overall (40% of live births). Similar patterns evolved for data about NO and HFOV. That is, changes in ventilator supportive care (i.e., gentle ventilation) of infants with CDH probably account for the decreased mortality and survival for CDH. The authors emphasize that only about 50% of CDH cases are identified on antenatal surveillance, leading to persistence of births of infants with this life-threatening lesion who are without the advantages of a tertiary level nursery care that has pediatric surgical and medical expertise.

Stillborn babies with CDH have a 95% incidence of other anomalies. A severe cardiac malformation combined with CDH implies a lethal outcome (Fauza and Wilson, 1994; Migliazza et al., 2007). Although various series’ rank the incidence of associated malformations differently, Stege et al. (2003) reported that cardiovascular lesions were most common, followed by chromosomal, skeletal, facial dysmorphism (cleft palate, ear deformity), gastrointestinal, and syndromal. Rarely, CDH is a part of a complex set of anomalies called *Pentalogy of Cantrell*, which consists of omphalocele, sternal cleft, ectopia cordis, and an intracardiac defect (ventricular septal defect or diverticulum

of the left ventricle) (Wesselhoeft and DeLuca, 1984). Although uncommon, CDH has been associated with several other syndromes including, Fryns' syndrome, Goldenhar's syndrome, Brachmann-deLange syndrome, and Beckwith-Weidemann syndrome (Thornburn et al., 1970; Fryns et al., 1979; Rollnick and Kaye, 1983; Jelsema et al., 1993).

Embryology

The diaphragm, lungs, and gastrointestinal tract develop synchronously. The lungs begin as a ventral bud of the foregut. Airway development and branching begin between the fourth and fifth weeks of gestation and progress until the terminal bronchioles are formed by the seventeenth week. The ventral (membranous) component of the diaphragm is formed between the third and fourth weeks of gestation. At about the eighth week of gestation, this portion envelops the esophagus, inferior vena cava, and aorta and fuses with the foregut mesentery to form the posterior and medial (membranous) portions of the diaphragm. The lateral margins of the diaphragm are considered to be derived from the muscular components of the body wall (recent investigations in rats have questioned the contribution of the body wall). The pleuroperitoneal canals close when all the membranous portions of the diaphragm fuse together, and by the ninth week of gestation, diaphragmatic closure is usually complete (Wells, 1954). If the closure (obliteration) of the pleuroperitoneal canals is delayed beyond the ninth to tenth weeks of development, or if the normal rotation and settling of the midgut occur before the tenth week or before the obliteration of the pleuroperitoneal canals, the midgut (abdominal viscera) herniates into the thoracic (pleural) cavity.

In the past, this defect has been attributed to an abnormal closure of the pleuroperitoneal canal, but investigations using the nitrofen-induced CDH model in the rat have used an innovative approach to reexamining the etiology of this lesion. CDH seems to be linked to a disordered formation of the pleuroperitoneal fold—a much earlier event (fourth week of gestation). An abnormal formation of the framework of mesenchyme, which inhibits muscular development of the diaphragm, has been linked to abnormalities in the retinoid signaling pathway. This suggests that vitamin A may play a role in the pathophysiology of CDH (Greer et al., 2003; Holder et al., 2007). CDH was found in 20% to 40% of offspring of rodents (dams) deficient in vitamin A, suggesting a critical role of the retinoid pathway. In addition, exposure to nitrofen (inhibitor of a key enzyme responsible for conversion of retinal to retinoic acid) was associated with development of CDH.

Preoperative Management

Pathophysiology

In the most common presentation, the herniated abdominal viscera (which includes the midgut but may also include the stomach, parts of the descending colon, the left kidney, and the left lobe of the liver) occupies the left thoracic cavity and interferes with the development of the lungs. In most cases, depending on the severity of the hernia, some degree of pulmonary hypoplasia exists, the severity of which depends on when the herniation and compression occurred during fetal development. The herniation of abdominal contents shifts the mediastinum to the right, compresses the contralateral lung and, in part, contributes to

abnormal development of that lung. On the other hand, simple compression of the ipsilateral and contralateral lungs fails to explain the severe morphologic derangements in lung development, such as fewer alveoli with thickened walls, smaller alveolar and gas exchange surface area, decreased vasculature with medial hyperplasia, and extension of the muscle layer into intraacinar arterioles (Done et al., 2008).

The structural abnormalities of the pulmonary vasculature correlate with the pathophysiology, mortality, and morbidity of CDH. The low number of airways, the simple arterial branching pattern, the increase in smooth muscle mass at the level of the resistance vessels, and left ventricular abnormalities add to the severity of cardiorespiratory dysfunction produced by the hernia itself (Schwartz et al., 1994). Alveolar development does occur postnatally, but growth at the preacinar level is limited in that the number of airway generations remains constant after midgestation (Geggel and Reid, 1984). Postnatal vascular remodeling provides larger and less muscular arteries, so the pathology present at birth in the setting of CDH has been documented to reverse to some degree (Beals et al., 1992). Nonetheless, the degree of pulmonary hypoplasia and hypertension is predictive not only of mortality but of the development of long term sequelae in the survivor.

The anatomic abnormalities in the pulmonary vasculature of CDH imply that persistent pulmonary hypertension will commonly accompany this anomaly. The most consistent findings include a fewer number of pulmonary arteries per unit of lung volume and peripheral muscularization of small arteries leading to thickening of the medial and adventitial layers (Geggel et al., 1985). Although small arteries (equal to 200 μm) predominantly determine pulmonary vascular resistance (PVR), other factors also influence the pulmonary circulation of the newborn.

The fall in PVR (approximately 80%, which normally occurs in the first 24 hours of life) and rise in pulmonary blood flow that is essential for the transition from placental circulation to the postnatal pattern is dependent on adequate function of the endothelial cell (see Chapters 3 and 4, Respiratory Physiology in Infants and Children and Cardiovascular Physiology). Imbalance in the production, release, and circulating levels of vasoconstrictors (leukotrienes C₄ and D₄, thromboxane A₂, platelet activating factor) and vasodilators (NO, prostacyclin) seems to be central to the right-to-left shunting observed with pulmonary hypertension associated with CDH (Furchgott and Zawadzki, 1980; Haworth, 2006). Endothelins are also involved in the persistence of high pulmonary vascular resistance. Persistently elevated levels of endothelin 1 (ET-1) have been described in infants with CDH (Rosenberg et al., 1993; Kobayashi and Puri, 1994). In utero, ET-1 contributes significantly to maintaining normal high PVR. Postnatally, various endothelially-derived vasoconstrictive peptides are produced in response to inflammation, ischemia, and other stimuli. Multiple receptors, both in the vascular smooth muscle and in the vascular endothelial cell, mediate response to these molecules. In part, the release of these vasoactive agents is also in response to ventilator-induced epithelial and endothelial damage from hyperinflation of the hypoplastic lungs. Active remodeling of the pulmonary vascular bed continues gradually over the first 2 to 4 weeks of life.

Diagnosis and Treatment

Diagnostic and therapeutic modalities have been developed for both the prenatal and postnatal periods.

Prenatal Diagnosis and Treatment

Prenatal diagnosis of CDH has increased from approximately 10% in 1985 to near 60% at present (Dillon et al., 2000). The most common findings include displacement of the heart and a fluid-filled bowel in the thorax. Both stomach and small bowel are often present (Garne et al., 2002). Ultrasound diagnosis of a large defect (e.g., dilated intrathoracic stomach, herniated left lobe of the liver, or polyhydramnios) suggests a severe lesion; however, prenatal ultrasounds can have a high incidence of false negatives (Lewis et al., 1997).

A variety of indices including lung-to-head circumference ratio (LHR), diameter of the proximal pulmonary artery indexed to the descending aorta, and others have been developed to estimate prognosis by evaluating the pulmonary circulation to estimate risk for severe pulmonary hypoplasia. Jani et al. (2009) noted that an LHR and intrathoracic position of the liver independently predicted poor outcome. In a study by Ruano et al. (2006), survival was estimated to be approximately 50% when the liver was herniated into the thorax. The LHR can also define extreme lung hypoplasia and predict 100% mortality (Albanese et al. 1998; Desfrere et al. 2000; Sbragia et al., 2000; Cacciari et al. 2001; Muratore et al. 2001; Boloker et al. 2002; Stege et al. 2003). However, differences in the specific method to generate the index may lead to confusion when interpreting results among various institutions. In addition to these indices, in utero magnetic resonance imaging (MRI) has been proposed as a method to define anatomy (e.g., position of the liver or volume of the lungs) and identify associated anomalies (Cannie et al., 2008).

Because the fundamental pathophysiology of CDH is pulmonary hypoplasia, various fetal surgical techniques to improve the growth of hypoplastic lungs in utero have been developed (Harrison et al., 1990, 1993, 1997). Starting with animal models in the 1980s, Harrison and colleagues gradually perfected some open fetal surgical procedures and introduced the ex utero intrapartum treatment (EXIT) procedure. The procedure was eventually abandoned in favor of a minimally invasive technique using fetoscopy to surgically occlude the trachea. Tracheal occlusion is aimed to manipulate the physiology of fetal lung development; that is, the fetal lung development is physiologically accelerated by the airway expansion that results from accumulation of lung fluid while the glottis is occluded. In a group of fetuses with moderate hypoplasia enrolled in a trial sponsored by the National Institutes of Health (NIH), the tracheal occlusion technique marginally improved the survival of the affected fetus. However, the procedure was associated with significant complications, including premature labor and delivery. At the same time, the survival of the infants with CDH with conventional postnatal managements improved (Harrison et al., 2003; de Buys Roessingh and Dinh-Xuan, 2009). Further studies of fetal endoscopic tracheal occlusion (FETO), in which the time of tracheal occlusion and release is adjusted, continue; however, the procedure remains investigational (Done et al., 2008).

Postnatal Diagnosis and Treatment

Clinical Presentation. Infants who are born with bilateral lung hypoplasia or severe unilateral hypoplasia exhibit symptoms immediately at birth. In the setting of a prenatal diagnosis, the delivery is deferred to a high-risk center with access to pediatric surgeons, NO, extracorporeal oxygenation, HFOV, and other advanced neonatal therapies.

The classic triad of CDH consists of cyanosis, dyspnea, and apparent dextrocardia. Physical examination reveals a scaphoid abdomen, bulging chest, decreased breath sounds, distant or right-displaced heart sounds, and bowel sounds in the chest. Radiographic examination of the chest shows a bowel gas pattern in the chest, mediastinal shift, and little lung tissue at the right costophrenic sulcus (Fig. 18-15).

Infants who weigh 1000 g, are born before 33 weeks' gestation, or who have an alveolar-to-arterial oxygen gradient ($P[A-a]O_2$) of more than 500 seldom survive (Raphaely and Downes, 1973). On the other hand, over the last two decades, antenatal diagnosis, neonatal stabilization and delayed surgery, and (most importantly) the avoidance of ventilator-induced lung injury have resulted in significant improvement in morbidity and mortality of infants with severe CDH.

Timing of Surgery. In the past, CDH was considered a neonatal emergency, and surgery to reduce the hernia was performed urgently. The infant's lungs were hyperventilated with 100% oxygen in an attempt to produce pulmonary vasodilation with hyperoxia and respiratory alkalosis. Although the combination of hyperoxia and respiratory alkalosis may produce transient pulmonary vasodilation, mechanical ventilation results in overdistension and damage to the alveolar and capillary membranes (volutrauma, previously called *barotrauma*), which induces an inflammatory reaction and the associated release of vasoactive mediators. Eventually, pulmonary vasoconstriction and hypertension occur, as the balance between vasodilation (oxygen plus alkalosis) and vasoconstriction (inflammatory mediators) shifts and secondary lung injury increases.

The goal of the initial management of CDH is to avoid a surgical intervention when the infant is hypoxic and acidotic and the cardiorespiratory status is labile. Optimizing hemodynamic and respiratory support rather than the specific timing of surgery contributes to improving outcome (Migliazza et al., 2007). Thus, medical management is directed to stabilizing the cardiorespiratory function by improving oxygenation to achieve a preductal saturation more than 90%, correcting any metabolic acidosis, reducing right-to-left shunting and increasing pulmonary perfusion using the least aggressive ventilation possible (Hazebroek et al., 1988). These goals underlie the rationale for some centers initiating HFOV immediately and introducing ECMO to allow pulmonary rest. Unfortunately, these maneuvers have not been predictably effective.

Surgery affects the respiratory system's compliance. Sakai et al. (1987) reported that the postoperative compliance of the respiratory system (CRs), as measured with a noninvasive, passive mechanic's technique, immediately decreased 10% to 77% from the preoperative value, suggesting that pulmonary dynamics often deteriorate after surgical repair of the hernia (Lesouef et al., 1984). These observations prompted a reevaluation of the practice of urgent surgery. Instead, surgery is delayed to allow transition to a stable postnatal cardiorespiratory status.

Nakayama and others (1991) evaluated pulmonary function and outcome of 22 infants with severe CDH treated either with traditional emergency repair or with preoperative stabilization for 2 to 11 days. Of 13 infants who underwent immediate repair of CDH, nine received ECMO support postoperatively, and six of the 13 infants (two after ECMO) survived (46% survival). Of nine infants whose surgery was delayed for preoperative stabilization, six immediately received ECMO support for 4 to 10 days;

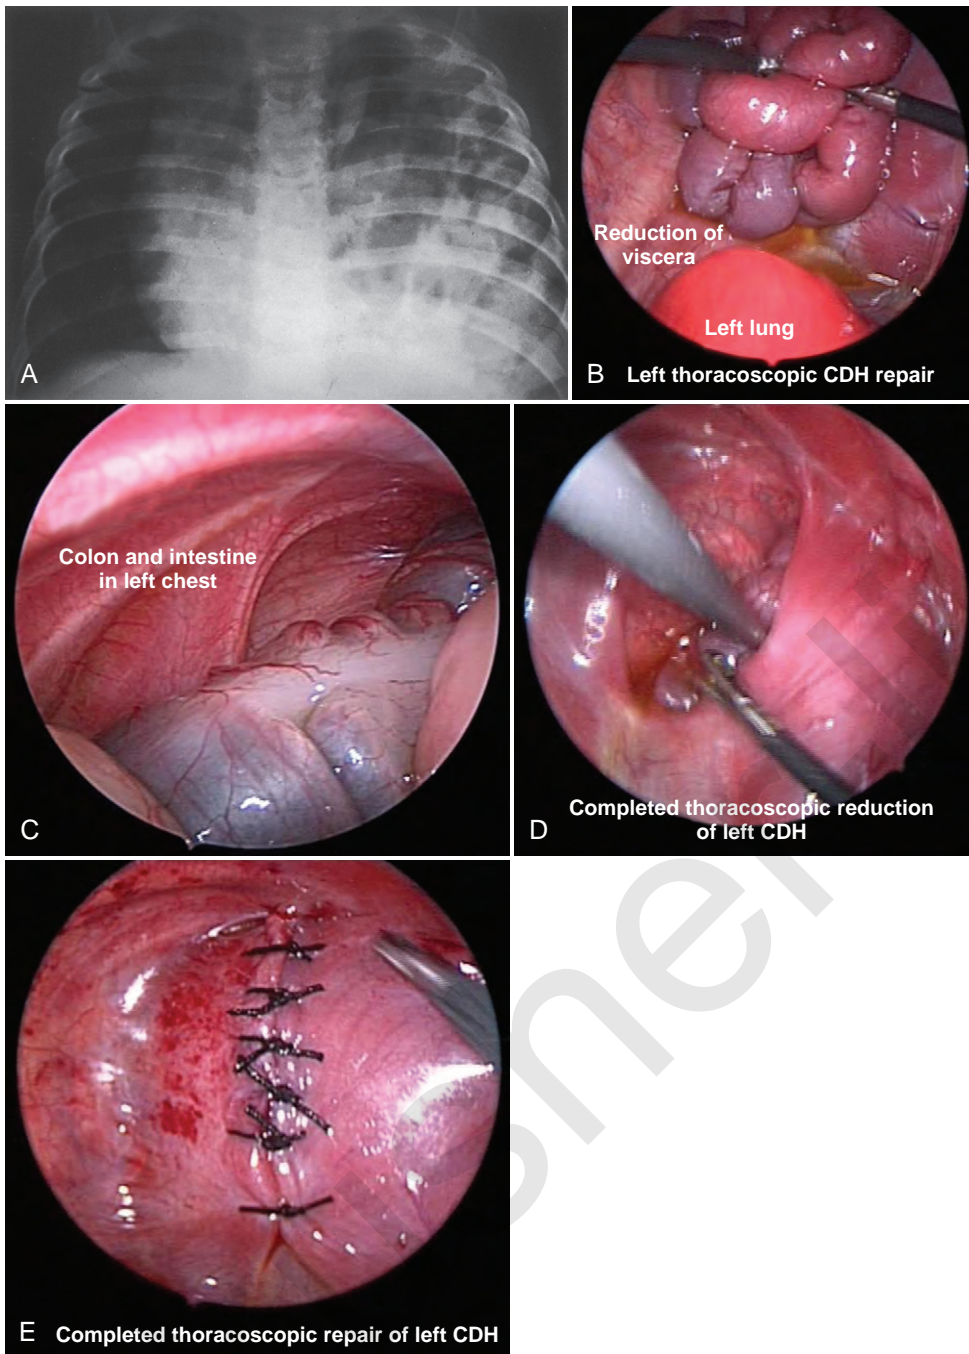

FIGURE 18-15. CDH. **A**, Chest x-ray showing small bowel. **B**, Laparoscopic view of herniated small bowel. **C**, Laparoscopic view of colon and intestine. **D**, Laparoscopic view of reduced abdominal contents. **E**, Laparoscopic view with completed repair.

one with extreme lung hypoplasia died before surgery after an intraventricular hemorrhage. The other eight infants survived after surgery (89% survival). Seven days after surgery, CRS of infants in the immediate repair group did not improve from the preoperative values. In contrast, CRS increased more than 60% from their baseline values in the infants who underwent preoperative stabilization. Although the duration of mechanical ventilation was similar in the survivors of the two groups, the preoperative stabilization group had higher postductal P_{aO_2} , lower respiratory rates, lower peak and mean airway pressures, and lower fraction of inspired oxygen values (F_{iO_2}). Based on the physiologic and clinical evidence, these researchers concluded that preoperative stabilization is beneficial before the repair of CDH. Surgery should be delayed as long as 5 to 15 days until

PVR has decreased and ventilation can be maintained with a low peak inspiratory pressure (less than 25 cm H_2O) and F_{iO_2} (about 0.50).

Preoperative care of an infant with severe CDH should start in the delivery room. Positive pressure ventilation by mask and bag has risks, because attempting to expand the noncompliant lungs may damage the hypoplastic lung by overdistention, as well as distend the stomach and intestines (which are in the left hemithorax), further decreasing chest compliance (Wada et al., 1997; Björklund et al., 1997). If spontaneous ventilatory efforts are inadequate, early intubation of the trachea and decompression of the stomach are important initial steps to prevent further distension of and pulmonary compression by the displaced abdominal viscera.

However, after intubation of the trachea, minimizing the trauma from positive pressure ventilation is an important ventilatory intervention. Björklund et al. (1997) found that six manual inflations with a tidal volume of 35 to 40 mL/kg in preterm lambs resulted in persistent respiratory failure and pneumothorax despite surfactant treatment. Wada and colleagues (1997) also found that ventilation of premature lambs at birth with a tidal volume of 20 mL/kg for only 30 minutes resulted in marked decreases in CR_s , along with the development of poor gas exchange. In comparison, premature lambs ventilated with 5 or 10 mL/kg of tidal volumes maintained high CR_s and normal gas exchange. Although most infants with CDH are born at term or near term, these data may be relevant in CHD where the pulmonary development is abnormal.

Animal studies suggest that ventilatory strategies that employ small tidal volumes maintain high CR_s and better gas exchange (Björklund et al., 1997; Wada et al., 1997). Thus, current ventilatory strategies for an infant with CDH incorporate lower peak and end expiratory airway pressures and accept hypercapnea (Wung et al., 1985, 1995; Boloker et al., 2002). In general, HFOV serves as a rescue therapy; however, others advocate respiratory support with HFOV immediately at birth (Migliazza et al., 2007). Ventilation and F_{IO_2} are adjusted to maintain a preductal saturation of 90% to 95%. The P_{aCO_2} is allowed to remain as high as 60 to 65 mm Hg (permissive hypercapnea). Crystalloid and blood products are administered to maintain intravascular volume and red-blood-cell mass. Adequate sedation is administered in efforts to minimize increase in PVR. Periods of right-to-left shunting are tolerated if the patient's underlying hemodynamic status is stable, and vasopressors (e.g., dopamine or milrinone) are infused to maintain hemodynamic stability. In the immediate postnatal period, some infants initially respond to stabilizing maneuvers (e.g., gentle ventilation or hemodynamic support), but in some cases this early stability represents a "honeymoon period" that is followed by a sudden, often unexplained return to a state of persistent pulmonary hypertension and clinical deterioration (e.g., acidosis, hypoxemia, severe hypercapnia, pulmonary hypertension, and right-to-left shunting through the foramen ovale, and patent ductus arteriosus). If a reversion to a state of persistent pulmonary hypertension occurs, then trials of NO and HFOV are initiated and ECMO is considered.

Nitric Oxide. NO is a free radical with a short half-life, produced endogenously but often administered as an inhaled agent to take advantage of its effects as a selective pulmonary vasodilator. Although a role for NO in the treatment of pulmonary hypertension with CDH is a logical extension from its effectiveness in infants with pulmonary hypertension associated with meconium aspiration, sepsis, or congenital heart disease, clear cut effectiveness in the setting of CDH has not been demonstrated (Kinsella et al., 1992; Roberts et al., 1992; Bloch et al., 2007).

NO diffuses across the alveolar capillary membranes and binds to and thereby stimulates enzymes with transition metal centers (e.g., heme), such as cyclic guanylate cyclase. This increases cyclic GMP, activates protein kinase, and causes vascular smooth muscle to relax (see Chapters 3, 4, and 17, Respiratory Physiology in Infants and Children, Cardiovascular Physiology, and Neonatology for Anesthesiologists). Phosphodiesterases quickly metabolize NO, thereby limiting its half-life. In addition to cyclic guanosine monophosphate (cGMP)-mediated action, NO also has non-cGMP actions. For example, NO interacts directly with proteins

with active thiol groups, such as those in the heart. NO's modification of various myocardial proteins has been linked to regulation of contractility, but this action has not been well defined in the setting of CDH and neonatal pulmonary hypertension (Zimmet and Hare, 2006).

Toxic effects of NO are primarily attributed to its interaction with superoxide and the production of the highly reactive oxidant peroxynitrite. In addition, NO reacts with oxygenated hemoglobin to form methemoglobin. Although monitoring the concentration of methemoglobin is recommended if NO is administered for prolonged periods, significant methemoglobinemia is not commonly encountered during common clinical scenarios.

In a small series, Shah et al. (1994) noted that patients with CDH may be more resistant to the effects of inhaled NO, whereas Karamanoukian et al. (1994) noted that NO was effective in patients with hypoplastic lungs only after extracorporeal membrane oxygenation. In a study of patients treated with HFOV from birth, only 28% of those with severe pulmonary hypertension achieved reversal after NO. In general, most patients with intractable pulmonary hypertension plus lung hypoplasia do not have a predictable, dramatic response to NO. Nonetheless, because some patients do respond and the drug has limited toxicity in lower doses, NO is often used in infants with CDH who require therapy beyond gentle conventional ventilatory support (e.g., HFOV).

Even in the setting of respiratory failure without CDH, the long-term benefits of NO compared with other therapeutic interventions remain controversial. In a follow-up study of infants (with fewer and more than 34 weeks' gestation, treated and not treated with NO) who had been enrolled in the INNOVA trial (15 neonatal units in the United Kingdom, Republic of Ireland, Finland, and Belgium), respiratory morbidity was similar when the impact of NO was analyzed. For example, wheezing and rehospitalization were common in both term and preterm infants who received and did not receive NO (Hoo et al., 2009). Clearly, neonates with severe respiratory compromise are at high risk for long-term pulmonary dysfunction.

Extracorporeal Membrane Oxygenation. A notable series of 400 patients were reported in two manuscripts by Azarow et al. (1997) in Toronto and Wilson et al. (1997) in Boston. ECMO was used as rescue therapy in Boston, and HFOV was used in Toronto. Survival in the two cities was nearly identical (53% and 55%). A 2008 Cochrane review concluded that in spite of short-term efficacy, improved long-term survival without major sequelae was not apparent with ECMO (Mugford et al., 2008). Thus, many centers now reserve ECMO as a rescue therapy for infants who have persistent preductal hypoxemia in spite of inotropic and ventilatory support (including HFOV and NO) (Bohn, 2002, 2006).

A common set-up for ECMO is a venoarterial circuit where the patient's internal jugular vein and common carotid artery are cannulated. In this system, blood is drained by gravity from the right atrium, oxygenated through the membrane oxygenator, and returned to the patient through the arterial cannulae. During venovenous bypass, the patient's blood returns to the membrane oxygenator by gravity, is oxygenated in the membrane oxygenator, and is then returned to the venous system. Thus, in venovenous ECMO, adequate systemic oxygen delivery depends on an effective cardiac output, whereas in infants undergoing venoarterial ECMO the bypass system can compensate

for both pulmonary and myocardial dysfunction. Significant risks are associated with ECMO, including bleeding at surgical or chest tube insertion sites, intracranial hemorrhage, sepsis, hypertension, and brain death. Clearly, the underlying disease (e.g., meconium aspiration without pulmonary hypoplasia vs. CDH with pulmonary hypoplasia) influences the success rates of ECMO (Dalton and Thompson, 1992). In general, because the mortality and the likelihood of intracranial hemorrhage are higher in low-birth-weight infants, ECMO is limited to infants weighing more than 2 kg and with more than 35 weeks' gestation, and to infants who have no evidence of prior intracranial hemorrhage.

The criteria for instituting ECMO vary, but guidelines generally include $P(A-a)O_2$ of greater than 600 mm Hg for more than 6 to 8 hours or an oxygen index ($FiO_2 \times \text{mean airway pressure}/Pao_2$) of 51 for 5 hours. Nonetheless, no selection criteria appear to be accurate in predicting survival (Newman et al., 1990; Van Meurs, 1990; Steimle et al., 1994; Bohn, 2006; Mugford et al., 2008). In view of the improved survival with gentle ventilation (including HFOV), coupled with the significant morbidity associated with ECMO, ECMO intervention has been relegated a less central role in the setting of CDH.

Intraoperative and Postoperative Management: Open Repair

Although many centers now approach repair of CDH via minimal access techniques, open repair still remains common (Guner et al., 2008a). Severe pulmonary dysfunction limits the tolerance of thoracoscopy and one-lung ventilation, making minimal access surgery difficult or impossible (see Minimal-Access Surgery in the Neonate, p. 561).

In most cases, open surgical repair is approached through an abdominal incision, but a transthoracic or thoracoabdominal approach may be taken. Infants with large defects may not tolerate primary closure of the abdomen after the hernia is reduced. In such a case, a patch closure is attempted. In rare cases, a chimney prosthesis or silastic pouch is placed. In these infants, venous access in the lower extremities should be avoided because the inferior vena cava may be compressed after reduction of the hernia, limiting venous return. In all cases, an internal jugular cannula provides reliable access, allows CVP monitoring both intraoperatively and postoperatively, and may be essential to deliver TPN postoperatively.

With rare exceptions, infants with a moderate or large CDH require ventilatory support and sedation preoperatively, and many receive neuromuscular blockade. The goals of ventilation and oxygen delivery in the operating room are the same as the preoperative. Avoiding volutrauma includes a small tidal volume, appropriate PEEP (5 to 7 cm H_2O) to avoid atelectasis and shear stress trauma (low volume injury), adequate oxygenation without hyperoxia (oxygen saturation of hemoglobin, measured with pulse oximetry [SpO_2] 90% to 95%) and permissive hypercapnea as needed, while maintaining adequate pH (>7.25). In many cases, vigorously maintaining intravascular volume with crystalloid or colloid may be effective in minimizing right-to-left shunting. If a sudden deterioration occurs in ventilation or hemodynamic status, pulmonary hypertension must be quickly differentiated from a contralateral pneumothorax, because the treatment for a pneumothorax is needle thoracostomy and chest tube placement, and hyperventilation should be avoided to prevent air leak into a pneumothorax. NO treatment (10 to 20 ppm in inspired gas mixture) should be initiated if pulmonary

hypertension with arterial desaturation is suspected, while ventilation with permissive hypercapnea and PEEP is maintained.

All newborns deserve meticulous attention to temperature stability in the operating room, but infants with a CDH have dramatic risks associated with hypothermia related to its effect on increasing PVR, which may increase right-to-left shunting through a PDA or the foramen ovale (see Chapter 6, Thermoregulation Physiology and Perioperative Disturbances). Hypothermia increases oxygen consumption, and in the setting of marginal cardiorespiratory function, may result in inadequate oxygen delivery and acidosis, which then further increases pulmonary vasoconstriction and worsens oxygen saturation.

The selection of specific anesthetic agents must be based on cardiorespiratory status, the location of the surgery (NICU or operating room), and the plans for intraoperative ventilatory support. Nitrous oxide is avoided in infants with CDH because many require high-inspired oxygen concentration and also because nitrous oxide can diffuse into the viscera and exaggerate lung compression. If an anesthesia machine is available, low concentrations of inhalation anesthetics (sevoflurane or isoflurane) may be advantageous in producing pulmonary vasodilation, but if effects on SVR are greater than PVR, right-to-left shunting may actually worsen. In most cases, high-dose opioids (usually fentanyl) are administered and the narcotic infusion continues into the postoperative period (Hickey et al., 1985; Hickey and Retzack, 1993).

Outcomes

The prolonged and complicated neonatal course of infants with CDH implies that these infants are at high risk for long-term pulmonary, gastrointestinal or nutritional, and neurocognitive disorders. Muratore et al. (2001) noted that therapy with ECMO and the need for a patch correlated with later significant pulmonary disease. However, non-ECMO survivors also required repeated treatment for respiratory problems secondary to ventilator-induced lung injury and the onset of reactive airways disease. For example, 52% of all CDH survivors required therapy with bronchodilators, and 41% received inhaled steroids. Approximately 25% of survivors had evidence of obstructive lung disease. Jaillard et al. (2003) noted significant long-term pulmonary complications, reporting a 22% incidence of chronic lung disease at two years of age, and the use of ECMO and need for patch repair predicted later respiratory illness. Others report higher incidence of chronic lung disease that seemed to improve over time. Nonetheless, exercise performance was described as abnormal in some survivors, and approximately 50% of adults in one study had abnormal pulmonary function (Vanamo et al., 1996). Finally, approximately 4% of survivors require tracheostomy (Muratore et al., 2001; Jaillard et al., 2003).

Growth failure, oral aversion, and gastroesophageal reflux occur in 45% to 90% of infants with CDH, and the incidence correlates with the size of the defect and need for patch repair (Committee on Fetus and Newborn, 2008). At least one third of these infants require nutritional supplements via gastrostomy or nasogastric tube. In these infants, reflux is often exacerbated by the presence of these devices.

Neurocognitive delay and behavioral disorders have been documented in the survivors of CDH, especially in those who had been supported with ECMO, with developmental delay noted in more than one third of some cohorts (Nobuhara et al., 1996).

In particular, motor and language problems are common and have been detected in 60% to 70% of patients with CDH at age 3 years (Friedman et al., 2008). In these and other series, the infants treated with ECMO may have a higher incidence of significant neurodevelopmental delays (Bernbaum et al., 1995). Sensorineural hearing loss has been described in as many as 50% of patients with CDH in later infancy, even after normal screening was documented in the NICU. Recurrent or prolonged hypoxemia, exposure to ototoxic drugs (e.g., lasix, aminoglycosides), and ECMO have been suggested as causative factors (Robertson et al., 2002; Fligor et al., 2005; Erikson et al., 2009).

In addition to neurologic, pulmonary, and gastrointestinal disorders, survivors of CDH often develop chest-wall deformities and scoliosis. The incidence is higher in those with large defects that required patching. Similarly, recurrence of a hernia is most common among those with large defects with a patch in place. Because survivors of CDH have undergone major invasive care in the NICU and multiple surgical interventions, long-term, structured, multidisciplinary follow-up care is essential to the future care of these patients.

Tracheoesophageal Fistula and Esophageal Atresia

The incidence of TEF and esophageal atresia (EA) ranges between 1:3000 and 1:4000 births (Sparey et al., 2000). Approximately 20% to 25% of these infants have additional congenital defects. The incidence of associated defects is particularly high (50% to 70%) in the group with isolated EA but least common in infants with the H-type fistula. The most common anomalies include congenital heart disease (approximately 35%, including ventricular septal defect, atrial septal defect, tetralogy of Fallot, atrioventricular canal, and coarctation of the aorta), genitourinary disorders (about 24%); gastrointestinal disorders (approximately 24%, including duodenal or ileal atresia, malrotation, and imperforate anus); skeletal anomalies (approximately 13%); and central nervous system disorders (about 10%) (Dave et al., 1999). The term *VACTERL* (*vertebral, anal, cardiac, tracheoesophageal, renal, limb*) association refers to these anomalies, because they commonly coexist in various combinations with TEF/EA. As many as 20% to 25% of infants with esophageal atresia have at least three of the lesions included in VACTERL (Rittler et al., 1996).

Recently, a significant incidence of non-VACTERL anomalies (single umbilical artery, 20%; genital defects, 23%; and respiratory tract anomalies, 13%) were retrospectively identified from two pediatric centers in the Netherlands (de Jong et al., 2008). In spite of the significant incidence of multiple anomalies, the risk of recurrence is less than 1% in nonsyndromal TEF/EA (Goyal et al., 2006; Ioannides and Copp, 2009). However, TEF and EA are known to be common in Trisomy 18 (about 25%), Trisomy 13, and to a lesser degree, Trisomy 21. As with CDH, the wide mining of databases and adaptation of techniques such as fluorescent in situ hybridization (FISH) and whole genome arrays have allowed identification of rare and small chromosomal abnormalities (e.g., partial trisomy 3p, partial deletion 5p, distal 13q deletion, interstitial deletions of 17q) in some cases of TEF/EA, but no specific regions have been consistently linked to these anomalies (Felix et al., 2007). Thus, at this point, the etiology seems to be multifactorial and sporadic in the nonsyndromic version. Familial and syndromic patterns

occur in fewer than 1% of the cases. Finally, exposure to various teratogens has not correlated consistently with TEF/EA.

A variety of other lung anomalies (e.g., lobar agenesis, pulmonary hypoplasia, horseshoe lung, and absence of a bronchus to the right upper lobe) have been reported in the context of TEF/EA, and some experts have proposed that the lesion should be termed “general foregut malformation” (Kovesi and Rubin, 2004). In addition, TEF/EA has been identified in the setting of DiGeorge’s and Down syndromes as well as with CHARGE association.

Mortality associated with TEF/EA generally depends on the severity of the associated heart disease and birth weight. In 1994, Spitz linked survival rates to the following three categories:

Group 1: Birth weight more than 1500 g without a major cardiac anomaly (97% survival).

Group 2: Birth weight less than 1500 g or major cardiac anomaly (59% survival).

Group 3: Birth weight less than 1500 g and major cardiac anomaly (22% survival).

More recently, within the same three groups, survival rates improved to 98%, 82%, and 50%, respectively (Lopez et al., 2006). Clearly, the spectrum of presentation from an isolated TEF/EA to a multisystem or chromosomal disorder has major implications for mortality and morbidity, as well as for treatment options and surgical and anesthetic management.

Embryology

The embryogenesis of TEF/EA remains incompletely defined, but several theories have been proposed (Ioannides and Copp, 2009). It is known that the trachea and esophagus develop from the foregut in the first 4 to 5 weeks of gestation. One theory suggests that the respiratory system results from a rapid outgrowth from the foregut. That is, the tracheal primordium buds off the foregut and remains a separate structure during subsequent development. Another theory focuses on active growth of mesenchymal septum that divides the foregut into ventral (respiratory) and dorsal (gastrointestinal) structures. The septum has been considered to begin at the distal site (bronchopulmonary buds), but in fact such a structure has not been clearly identified in studies of tracheoesophageal development. Other theories seem to combine segments of each of these two theories, proposing that the trachea and esophagus separate as a result of foregut folds. Ioannides et al. (2002) suggested that the physical separation of the original foregut is a critical component of the organogenesis of the esophagus and trachea. On the other hand, differentiation of both respiratory and esophageal components usually does not occur in the setting of TEF/EA.

At the molecular level, aberrant signaling in the sonic hedgehog pathways and other regulatory genes has been linked to TEF/EA in several studies (Veraksa et al., 2000).

Hedgehog proteins are signaling glycoproteins involved in many processes of early development, including embryogenesis of the foregut as well as development of the craniofacial structures, heart, and great vessels. Of the multiple hedgehog proteins, only sonic hedgehog (Shh) is expressed in mammalian gut and lung. Mutants for Shh and for the Gli proteins (transcription factors) have been noted with tracheoesophageal malformations and various other well-described associated anomalies (e.g., VACTERL) (Kim et al., 2001).

In studies examining the expression of thyroid-transcription factor-1 (TTF-1) known to be specific to the respiratory tract, the distal esophagus in TEF/EA was proposed to be of tracheal origin. TTF-1 expression localizes to the lung bud but not to the esophagus early in gestation. TTF-1 is expressed in the fistula tract throughout gestation. Based on this work, the distal “esophagus” might be of embryonic lung origin. This finding, in part, could explain the pathophysiology and clinical findings of TEF/EA: poor esophageal motility, gastroesophageal reflux, esophageal stenosis, and pseudostratified columnar (respiratory epithelium) rather than squamous epithelium (esophageal epithelium) (Crisera et al., 1999a, 1999b). Other explanations for abnormal esophageal motor function in TEF/EA focus on the abnormal innervation of the esophagus. For example, dysplasia of both Meissner’s plexus (submucosal nerves) and Auerbach’s plexus (myenteric) occur along with an abnormal distribution of mitochondria, and high levels of vasoactive intestinal polypeptide and NO synthase (NOS) (Li et al., 2007).

Anatomy of TEF

The anatomic variations of TEF have been well described and, in most cases TEF and EA occur together (Types B, C, E) (Fig. 18-16). The most common lesion (more than 90% of cases) is type C, in which a fistula exists between the trachea and the lower esophageal segment at a point slightly above the carina, and the upper esophageal segment ends blindly in the mediastinum at the level of the second or third thoracic vertebra.

Prenatal Diagnosis and Clinical Presentation

TEF should be suspected in the presence of maternal polyhydramnios, which may result from esophageal obstruction that prevents the swallowing of amniotic fluid. Preterm labor may then develop as a result of the excessive intrauterine volume. However, in most cases polyhydramnios is a nonspecific sign and develops idiopathically; congenital anomalies account for only 10% to 20% of cases (Dashe et al., 2002). For example, polyhydramnios can develop secondary to impaired fetal swallowing because of abnormal central nervous system function, including weakness associated with neuromuscular dysfunction. Unfortunately, polyhydramnios and small or absent fetal stomach bubble are the most common ultrasound findings associated with TEF/EA. These have a low positive predictive value, and false positives are common (Houben and Curry, 2008). Similarly, when TEF accompanies EA, amniotic fluid can pass into the stomach from the trachea, usually enough to form

a stomach bubble but not enough to prevent polyhydramnios. In addition, polyhydramnios is rarely identified before about 24 weeks’ gestation (Pretorius et al., 1987). A dilated blindly ending upper pouch of the esophagus (upper pouch sign) has been described on ultrasound, but as with MRI studies, it has not been deemed an accurate prenatal method for diagnosing TEF/EA (Houben and Curry, 2008). Overall, the prenatal detection rate is 40% to 50%. The significant incidence of coexisting abnormalities and syndromes (e.g., Trisomy 18) implies that an in utero diagnosis should precipitate karyotyping and an intense search for other structural anomalies. As with other severe congenital anomalies, prenatal diagnosis of TEF/EA may improve outcome by allowing optimal prenatal counseling and postnatal treatment. Unlike with CDH, supportive interventions for TEF/EA are less urgent and the implications of birth outside a major medical center are less risky, so prenatal diagnosis, although ideal, is of somewhat less critical significance.

Postnatal diagnosis depends on the specific anatomy of the TEF/EA, except in the case of an H-fistula, when the newborn infant exhibits excessive salivation, drooling, cyanotic spells, swallowing problems, and coughing, which is relieved to some extent by suctioning. The diagnosis of EA can be confirmed in the delivery room by the inability to pass a catheter down the esophagus into the stomach. When a radiopaque catheter is used, a radiograph reveals the catheter in the blind upper pouch. If a TEF is present, a plain radiograph of the chest and abdomen reveals air or gas bubbles in the stomach and intestines that have entered through the fistula (Fig. 18-17).

■ **FIGURE 18-17.** Gastric distention in type C lesion, may require prompt relief. Note blindly ending esophagus on lateral view. (Courtesy of Dr. Arnold Colodny, Boston, Mass.)

■ **FIGURE 18-16.** Types of congenital abnormalities of the esophagus. **A**, EA, no esophageal communication with the trachea. **B**, EA, upper segment communicating with the trachea. **C**, EA, lower segment communicating with the back of the trachea. More than 90% of all esophageal malformations fall into this group. **D**, EA, both segments communicating with the trachea. **E**, Esophagus has no disruption of its continuity but has a TEF. **F**, Esophageal stenosis. (From Gross RE: The surgery of infancy and childhood, Philadelphia, 1953, WB Saunders.)

Ultrasonography is important in the diagnosis of any associated cardiac, renal, or genitourinary abnormalities. Often, H-type fistulas escape diagnosis until an infant, child, or adult is evaluated for recurrent pneumonia.

Preoperative Management

The ligation of a TEF is urgent, but not emergent, except in the setting of respiratory insufficiency severe enough to require ventilatory support. In that setting, the presence of a TEF and poor lung compliance often prevent delivery of adequate tidal volumes (ventilation escapes into the esophagus and stomach via the fistula). In such cases, the dilation of the stomach may add to the respiratory compromise by elevating the diaphragm and worsening pulmonary compliance. Preoperatively, several interventions are undertaken promptly to protect the lungs from aspiration pneumonia, including:

- Avoiding feeding
- Upright positioning of the infant to minimize gastroesophageal reflux
- Intermittent suctioning of the upper pouch
- Administration of antibiotic therapy to treat sepsis or aspiration pneumonia

Intraoperative Management

Surgical Technique

Although thoracoscopic approaches have been adopted and are now the initial surgical approach at many centers, many infants with TEF/EA require the traditional open technique. Preoperative considerations are the same for either approach. Meticulous evaluation of pulmonary status helps determine whether one-lung ventilation will be tolerated and whether an intraoperative ventilator other than the device associated with the anesthesia machine should be available. Although considered routine by some surgeons, others may elect to reserve preoperative bronchoscopy only for infants with a confusing clinical picture. Along with careful consideration of the pulmonary status, assessment of the hemodynamic status and a search for associated anomalies dominate the preoperative evaluation.

Optimally, a total repair can be accomplished as a one-stage procedure, in which the fistula is ligated and the esophagus is primarily anastomosed. In infants with significant associated anomalies or sepsis, thoracotomy may be considered too risky, and instead a palliative procedure such as a gastrostomy may be performed. Because a gastrostomy would only be undertaken in the event that the infant is not able to tolerate a more definitive surgery, many of these infants receive preoperative mechanical ventilation. In many cases, a more definitive surgery can be performed within 24 to 72 hours, when the extent of other anomalies is defined, cardiovascular stability is established, and a clear surgical plan has been defined. The gastrostomy is kept patent to decompress the stomach and minimize regurgitation into the lungs, and in cases in which definitive surgery is delayed, it allows enteral feeds.

Unless the aortic arch is right-sided, the surgical approach for open repair is through a right thoracotomy using a posterolateral extrapleural approach. On occasion, the distal portion of the esophagus is either absent or too short to reach the proximal segment. Type C (EA with a TEF between the distal esophagus

and the trachea) is most commonly associated with a gap short enough to allow a primary repair, and Type A (EA) is least commonly associated with such a gap. Usually, at some point preoperatively, the gap between the proximal and distal esophagus is measured. However, the methods to assess the gap range from simple radiographic contrast studies (“unstressed”) to images with metal dilators inside the proximal and distal pouches (if a gastrostomy is present). In any case, the measurement only serves as an estimate for operative approach. In general, a gap smaller than two vertebral bodies is considered appropriate for a primary repair. If the gap is between two and six vertebral bodies, a delayed anastomosis might be considered, and if it is greater than six vertebral bodies, some would suggest that primary anastomosis is impossible. Others propose various methods to induce growth. In some series, EA with a long gap is defined in terms of centimeters between the ends. A gap of longer than 2.5 cm is sometimes considered the starting point for the category of long-gap EA (Foker et al., 2005). Thus, comparing approaches and results among series remains challenging because definitions and methods to measure the gap vary.

In cases in which a delayed surgery is planned, surgeons have traditionally ligated the fistula and inserted a gastrostomy, and some have also exteriorized the upper pouch through an esophagostomy. The baby can receive nutrition via the gastrostomy until surgery. In most cases, definitive repair is undertaken between 3 and 6 months of age, depending on the infant’s status (e.g., growth and cardiorespiratory status) and the opinion of the surgeon. At that time, the two esophageal segments are either directly anastomosed or surgically bridged with an interposed bowel segment or gastric tube graft. In many centers, these traditional approaches have been replaced with those focused on inducing growth of the esophagus or simply waiting for spontaneous growth. The goal is to accomplish a primary anastomosis within the first few months of life, aiming to avoid the high incidence of reflux, dysmotility, and other associated complications using nonesophageal tissue to close the gap (see Outcomes, p. 578).

Techniques to lengthen the native esophagus in order to shorten the distance between the proximal and distal ends have remained controversial, but in some cases they have allowed primary anastomosis (Foker et al., 2009). Foker et al. (2005) described inducing esophageal lengthening by placing external or internal traction sutures to induce rapid growth, creating an anastomosis of the esophageal ends without disruption of the wall by myotomies, and placing the esophageal junction below the diaphragm. In most cases, normal growth of the esophagus has been induced, with traction allowing increases in width as well as length. Often at least two thoracotomies are required in this approach; the same small incision (3 cm) is used, thus sparing the serratus anterior muscle, minimizing the incidence of rib fusion, and decreasing both short- and long-term complications (Foker et al., 2009). Other techniques to induce growth of the esophagus have been proposed, and recently thoracoscopic elongation of the esophagus has been reported (van der Zee et al., 2007). In some cases, simply delaying the primary closures for several weeks or months allows adequate growth (i.e., no tension either internally or externally).

Airway Management

The awake intubation technique is considered by some to be the safest approach to secure the airway in infants with TEF. It allows appropriate positioning of the endotracheal tube without

positive pressure ventilation, as well as minimizes the risk of gastric distention from inspired gases passing through the fistula. Often, titrating small doses of fentanyl (0.2 to 0.5 mcg/kg) or morphine (0.02 to 0.05 mg/kg) allows intubation of the trachea without excessive hemodynamic stimulation or depression. An alternative induction technique includes an inhalation anesthetic with or without muscle relaxation and with cautious, gentle positive pressure ventilation as needed.

Evaluating the upper airway via rigid or fiberoptic bronchoscopy remains integral to the presurgical planning of TEF/EA repair. Although some surgeons and anesthesiologists consider the procedure a fundamental part of the preoperative or intraoperative assessment (e.g., ensure that only one fistula is present, assess for tracheomalacia and other anomalies, and position the endotracheal tube), others reserve bronchoscopy for cases where the clinical status suggests that anatomy must be further defined. In fact, fistulas may be difficult to identify via bronchoscopy. In addition, if the bronchoscopy is conducted to ensure a precise positioning of an endotracheal tube, this goal may be difficult to sustain after the bronchoscopy (even with careful marking of the endotracheal tube, attention to flexion and extension of the neck, and other precautions) because of subsequent repositioning for surgery and normal movement of the endotracheal tube during positive pressure ventilation and repeated suctioning during surgery. Furthermore, the TEF is often located close to the carina, and attempts to position the endotracheal tube below the fistula may precipitate one-lung ventilation (intentional or unintentional).

A key decision for the surgeon and anesthesiologist involves whether one-lung ventilation would facilitate the surgical procedure, and if so, appropriately select those patients who are likely to tolerate the technique (see *Minimal-Access Surgery in the Neonate*, p. 561). If tolerated, collapse of the lung may improve surgical exposure, but in some cases an unacceptable fall in oxygen saturation (in spite of high F_{iO_2} and continuous positive airway pressure [CPAP] to the nonventilated lung) requires a return to two-lung ventilation. Thus, it may be illogical to commit significant time to bronchoscopy, and in some cases doing so may needlessly prolong the operative time. Finally, even with initial ideal positioning of the endotracheal tube, in some patients ventilation through the fistula still occurs, especially if high peak airway pressures are required.

After the endotracheal tube is in its "assigned" position (i.e., one- or two-lung ventilation), end-tidal carbon dioxide and oxygen saturation should be monitored, and the stomach and chest should be auscultated to ensure that the lung(s) are adequately ventilated. Ideally, the stomach is not distended with inspired gases (i.e., ventilation does not enter the stomach via the fistula, or the fistula itself has not been intubated). Salem et al. (1973) suggested distal positioning of the endotracheal tube, with the bevel facing anteriorly and the posterior wall of the endotracheal tube occluding the fistula, but this maneuver is challenging to achieve and maintain.

Although precordial stethoscopes have been relegated to secondary rank because monitoring oxygen saturation and end-tidal carbon dioxide have become standards of care, a precordial stethoscope can contribute importantly to intraoperative care during repair of TEF. The precordial stethoscope can be positioned in the left axilla (i.e., during a right thoracotomy) to allow breath-to-breath monitoring of adequate ventilation to the dependent lung. Ideally, in infants with unstable cardiorespiratory status or congenital heart disease, an arterial

catheter (umbilical or radial) should be available. In the setting of right-to-left shunting via a patent ductus arteriosus, pre- and postductal oxygen saturation monitoring with two pulse oximeters may provide critical data about shunting and pulmonary hypertension (see *Congenital Diaphragmatic Hernia*, p. 567).

Few patients have a gastrostomy at the time of presentation for surgery for EA/TEF, but if one is present, the gastrostomy tube could be submerged in a container of water after the trachea is intubated to observe for gas bubbles, which would be evident during ventilation of the fistula. If bubbling occurs, the endotracheal tube should be repositioned. Alternatively, the gastrostomy tube can be connected to a capnograph. When the endotracheal tube is proximal to the fistula, carbon dioxide might be detected. When the endotracheal tube is distal to the fistula, no expiratory gases would be detected.

A gastrostomy may serve as a low-resistance vent through which some of the tidal volume escapes, especially if high peak airway pressures are needed to ventilate noncompliant lungs and the chest wall. Although inserting a Fogarty catheter (or other ballooned device) retrograde via the gastrostomy or via a bronchoscope into the TEF has been reported, this technique is often impractical in the setting of small infants (Filston et al., 1982; Karl, 1985). Precise positioning of a catheter so that the balloon is occluding only the fistula is difficult to achieve, and even if the positioning is perfect on initial attempt, maintaining this precise position of the catheter for any length of time is almost impossible. Furthermore, displacement of the balloon can be disastrous (e.g., occluding the trachea). Finally, a high-pressure balloon may impinge on small pulmonary vessels or airways, compromising pulmonary blood flow or ventilation.

Once satisfactory ventilation is assured, the chest is opened and the lungs are retracted. Lung retraction (or one-lung ventilation) may dramatically change oxygenation and ventilation, especially in infants with respiratory dysfunction from immature lungs, pneumonia, or congenital heart disease. Intermittent release of pressure by the surgeon to allow reinflation of the lungs often improves oxygenation and ventilation. Blood clots or secretions may block the endotracheal tube, and repeated endotracheal suctioning may be required. Because the trachea is a soft structure in the newborn, surgical manipulation may kink the airway and further obstruct the airway. Thus, interference with adequate oxygenation and ventilation can occur as a result of the patient's anatomy, operative positioning, and surgical manipulations. In many cases, the inspired concentration of oxygen and mechanical ventilation (sometimes manual ventilation) must be adjusted often, balancing the risks of oxygen toxicity and barotrauma with those of hypoxia. Of course, the surgeon and anesthesiologist must constantly communicate to minimize avoidable events.

Diaz et al. (2005) reported the incidence of intraoperative critical events (as well as overall survival) in open-surgical TEF/EA repair in patients with and without congenital heart disease (excluding patent ductus and or patent foramen ovale). In this report, all patients with ductus-dependent lesions were mechanically ventilated preoperatively, and the incidence of clinically important events was higher in this group, even when compared with infants who had less significant heart anomalies. Difficulty with intubation and oxygen saturation secondary to lung retraction, plugging of the endotracheal tube, and hypotension dominated the events. Perioperative mortality in the highest risk group was 23%, consistent with the survival rates (82% survival, even with a major cardiac lesion) as reported by Lopez et al. (2006), using a three-tiered risk assignment.

After the TEF is ligated and if primary esophageal anastomosis is planned, the anesthesiologist passes a catheter through the nose or mouth into the blind upper pouch to identify the upper esophageal structure. The surgeon passes a catheter into the lower part of the esophagus, and the anastomosis is made over the catheter. When the anastomosis is complete, the catheter is withdrawn just above the suture line, and the proximal end of the catheter is marked at the mouth. The distance from the mouth to the distal tip is noted to guide suctioning in the postoperative period.

Postoperative Management

Some full-term infants are extubated after simple ligation of a TEF, but this is rare. Tracheomalacia or a defective tracheal wall at the site of the fistula can cause collapse of the airway and preoperative aspiration may compromise pulmonary function. Treatment of postoperative pain, when combined with the host of other cardiorespiratory problems of the newborn, often requires a period of postoperative ventilation for at least 24 to 48 hours. Opioid infusions and regional anesthetic techniques have been successfully used for pain management. Most surgeons request that ventilation with a mask and bag be avoided for at least several days postoperatively, especially if the esophagus has been anastomosed. Infants who have had a “long-gap” atresia repaired often have tension at the anastomotic site that may be better protected with postoperative ventilatory support for 5 to 7 days. Deep sedation or neuromuscular blockade to eliminate spontaneous ventilation (i.e., eliminate negative intrapleural pressure transmitted to the anastomosis) are maintained as a function of the status of the infant, as well as bias of the surgeon or neonatologist. Babies whose lungs were contaminated preoperatively or intraoperatively, whose intraoperative course was complicated (e.g., trachea perforation), or whose underlying lung disease is associated with prematurity or other lesions are also mechanically ventilated postoperatively. In these cases, the approach to postoperative ventilatory support is often defined more by the pulmonary status than the surgical events. In part, the intraoperative anesthetic plan is tailored to meet the postoperative ventilatory requirements.

Outcomes

TEF/EA cannot be considered a simple anatomic problem that is easily cured by a surgical intervention. After surgery, structural and functional abnormalities commonly persist long term, even into adulthood. The design of the initial neonatal surgery must focus on the goal of achieving physiologically normal function, but this is difficult. To avoid the psychological overlay of “chronic disease,” early repair is obviously ideal. In reality, multiple significant long-term problems should be anticipated in survivors of TEF/EA.

Early complications primarily consist of anastomotic leaks and strictures. Some anastomotic leaks spontaneously seal; others may require intensive medical or even surgical treatment. Strictures at the site of esophageal anastomosis or the fistula may develop in as many as 30% to 40% of infants, but early lesions often respond to two or three dilations. More significant strictures often develop in response to gastroesophageal reflux (GER) and are associated with a history of significant anastomotic leaks in the immediate postoperative period and after repair of long-gap lesions.

GER is probably the most common and significant long-term problem after TEF/EA. GER is recognized in at least 40% of patients (35% to 58%), and is more common after anastomosis under tension, after gastrostomy, and after delayed primary repair (Kovesi and Rubin, 2004; Spitz, 2006). GER seems to correlate with many of the long-term problems associated with TEF/EA: strictures; pulmonary disease (e.g., recurrent aspiration pneumonia, reactive airways disease, and parenchymal disease); feeding problems and oral aversion; and poor growth. Follow up and evaluation of GER are critical for all survivors of TEF/EA.

Esophageal dysmotility/disordered peristalsis and abnormal lower esophageal sphincter function is recognized in at least 75% of patients with EA and in all children who have undergone delayed repair with interposition procedures. In childhood, choking episodes are common. Many children eat slowly and often compensate by drinking water and other liquids during meals. Choking episodes may be associated with apnea and cyanotic spells. Esophageal obstruction may develop, and some patients require removal of impacted material. Although dysphagia may persist into adulthood in 10% to 30% of patients, symptoms seem to dissipate after the first decade of life (Kovesi and Rubin, 2004).

Symptoms of dysmotility correlate with reduced intrinsic innervation (e.g., myenteric plexus or Auerbach's plexus), disorganized muscle layers in the esophagus, tracheobronchial remnants, and a shortened intraabdominal segment of the esophagus (secondary to anastomosis). Feeding aversion develops more commonly in those with pure EA and in those who are exclusively fed via gastrostomy early in life. Feeding aversion, esophageal dysmotility, and GER may lead to growth failure. Furthermore, without aggressive medical or surgical therapy, esophagitis and eventually Barrett's esophagus, a precancerous lesion, may develop. Approaches toward performing antireflux surgery (e.g., Nissen fundoplication) vary from center to center, but surgery clearly plays a role in treating severe GER. Some surgeons recommend aggressive surgical intervention within the first 6 to 24 months of life to minimize the secondary complications of severe GER.

Tracheomalacia and other abnormalities of the trachea also define long-term outcome after TEF/EA. Although common, tracheomalacia appears to be clinically significant in only about 10% of patients (Spitz, 2007). Tracheomalacia tends to improve after the first 3 to 5 years of life, and is rare in isolated EA. Tracheomalacia is generally identified at or just above the site of the TEF, and therefore is most prominent in the lower one third of the trachea. The trachea seems to have an excessive membranous portion that is prone to instability. A brassy cough (“TEF cough”) is common in infants and children but rarely persists into adulthood. When symptoms are severe, stridor may develop. Treatment for tracheomalacia is required only in patients with severe symptoms (e.g., apnea, recurrent pneumonia, or worsening stridor) and usually involves an aortopexy (i.e., suturing the aorta to the posterior surface of the sternum), which draws the anterior trachea forward as the posterior aspect of the aorta adheres to the trachea. Recently, a stenting procedure has been effective in treating tracheomalacia and may be less invasive than aortopexy (Kovesi and Rubin, 2004).

In addition to the major structural abnormalities, the epithelium at the site of the TEF (but at times in all the major airways) can be abnormal, lacking both cilia and goblet cells, and thereby decreasing mucociliary clearance (Goyal et al., 2006).

This lesion may be exacerbated by or be secondary to GER. Rarely, secretions may be retained to the point of inducing tracheal metaplasia. A blind pouch at the site of the former TEF can be a nidus for trapping secretions.

Recurrent upper and lower respiratory infections occur in 35% to 75% of infants and children, especially throughout the first 3 to 4 years of life, and they may be related to GER or impaired mucociliary clearance secondary to the abnormal tracheal epithelia (Dudley and Phelan, 1976; Spitz, 2007). Wheezing commonly accompanies these infections (Chetcuti and Phelan, 1993). Even with decreased symptoms over time, pulmonary function studies 6 to 37 years after repair show a high incidence of obstructive and restrictive forms of lung disease (Chetcuti et al., 1992; Robertson et al., 1995). Specifically, abnormal expiratory flow rates (e.g., low forced expiratory volume at 1 second [FEV₁] in 25%, low forced expiratory flow 25%-75% [FEF_{25%-75%}] in 14%), reduced lung volume (e.g., low vital capacity in 15%), and airway hyperreactivity have been documented in survivors.

Open posterolateral thoracostomy in infants has been associated with musculoskeletal malformations, including “winged” scapula and chest-wall asymmetry (see *Minimal-Access Surgery in the Neonate*, p. 561). Scoliosis has been attributed to both the thoracostomy and associated vertebral anomalies. Scoliosis would predictably reduce total lung capacity, so in survivors of TEF/EA, compromise may be exaggerated when a structural chest-wall deformity is added to other sources of pulmonary dysfunction.

As with other congenital anomalies, survivors of TEF/EA encounter lifelong disorders that require multidisciplinary, long-term supportive care and meticulous follow-up care to minimize complications induced by and secondary to their primary lesions.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) persists as a major source of perinatal and life-long morbidity and mortality, primarily affecting premature infants with a gestational age of fewer than 36 weeks (usually fewer than 32 weeks), and particularly virulent in ELBW infants. In its acute and severe phase, NEC is a gastrointestinal emergency. Although centered in the gastrointestinal tract, NEC is a systemic process primarily related to the sepsis that accompanies intestinal necrosis and increased mucosal permeability. Isolated intestinal perforation (IP) refers to a clinical scenario that some suggest is distinct from NEC (Pumberger et al., 2002). Of note, IP seems to occur earlier and with lower incidence of pneumatosis and pneumoperitoneum, and in the ELBW infant it may have a lower mortality (38.3%)

compared with that of NEC (55.2%) (Blakely et al., 2005). Others have reported that early exposure to indomethacin (but not prenatal steroids) plays a role in the etiology of IP (Attridge et al., 2006). The two entities are difficult to accurately differentiate preoperatively, so they are treated similarly—both medically and surgically. This discussion centers on “classic NEC.”

In spite of intense basic, clinical, and epidemiologic research, the precise etiology of this life-threatening and common disease is unknown and considered to be multifactorial. The only clear-cut risk factor is prematurity. At least 90% of infants diagnosed with NEC are premature, and severity of symptoms, complications, and mortality are inversely related to gestational age (Hsueh et al., 2002). Of note, 11.5% of infants weighing 401 to 750 g, 9% of those between 751 and 1000 g, 6% of those between 1001 and 1250 g, and 4% of those between 1251 and 1500 g are affected (Guillet et al., 2006). As the survival rate of premature infants, especially ELBW infants, has improved, the incidence of NEC has increased in some populations. Although enormous progress in the delivery of neonatal care is apparent, estimates of incidence (10% to 20% in infants weighing less than 1500 g), requirement for surgery, and mortality associated with NEC have remained remarkably static. In part, the increased number of susceptible infants may explain the lack of improved overall survival in infants with NEC. Recent data note that 1 to 5 of every 1000 live births in the United States are diagnosed with NEC, and 1% to 7% of all patients admitted to the NICU and approximately 10% of VLBW infants are affected (Hsueh et al., 2002; Guillet et al. 2006; Holman et al., 2006; Lin and Stoll, 2006; Hunter et al., 2008; Lin et al., 2008b). Mortality ranges from 15% to 30% and is highest among the most immature and those treated surgically (30% to 50%). Between 20% and 40% of patients are treated surgically.

Bell et al. (1978) described three stages of NEC. Stage I refers to mild disease, with the infant having only nonspecific symptoms (e.g., vomiting, gastric residuals, apnea, bradycardia, and guaiac-positive stools). There is no definitive radiologic evidence for NEC, and the state of the bowel is completely unknown. Stage II includes infants with definitive NEC. They have clinical symptoms similar to the infants in Stage I, but radiographs show that they have pneumatosis intestinalis or portal venous air (Figs. 18-18 and 18-19). Stage II infants are suitable candidates for medical management. Stage III includes infants with advanced disease. These infants have evidence of intestinal necrosis or perforation along with clinical signs of hemodynamic, respiratory, and hematologic instability. Although these three stages are not distinct and represent a continuum of clinical disease, the three-stage concept helps define management strategies. Walsh and

■ **FIGURE 18-18.** Air pattern in the portal venous system of the liver in an infant with NEC. (From Rowe MI: *Necrotizing enterocolitis*. In Welch KJ et al., editors: *Pediatric surgery*, ed 4, Chicago, 1986, Year Book.)

■ **FIGURE 18-19.** NEC at time of laparotomy. Patchy areas of small bowel involvement.

Kleigman (1986) expanded the classification, but the primary framework of suspected, definite, and advanced disease persists. Nonetheless, some have recommended abandoning Bell's criteria in favor of new guidelines, because NEC is not a uniform disease entity (i.e., does not have a specific etiology) and the pathophysiology remains incompletely defined (Table 18-1) (Gordon et al., 2007).

Pathophysiology

NEC is a paradoxical disease. Infants with milder disease usually recover with outcomes similar to those of other infants of the same gestational age, but severely affected infants who require surgery have high mortality, and those who survive usually develop significant gastrointestinal and neurodevelopmental morbidity. Although miniepidemics do occur, most cases of NEC are sporadic and cannot be correlated with any specific infectious agent. The disease only occurs postnatally (not in stillborns), and it is rare in full-term infants and infants who have never been fed (Hsueh et al., 2002). The full-term infant who does develop NEC tends to display symptoms and

signs in the first 1 to 3 days of life, sometimes before feeding has been initiated. There is usually a history of a hypoxic and ischemic events such as perinatal asphyxia, respiratory distress, or congenital heart disease. In contrast, the preterm infant tends to develop symptoms and signs after 2 to 3 weeks of life after feeding has been initiated, often without any preceding dramatic cardiorespiratory event.

Intestinal mucosal injury from ischemia caused by reduced mesenteric blood flow is commonly proposed as a physiologic mechanism for NEC. Mesenteric blood flow may be compromised by a decreased cardiac output in the presence of fetal asphyxia, a patent ductus arteriosus, apnea or bradycardia, heart failure, arrhythmia, severe cardiorespiratory instability, or hypoxemia. Immature regulation and autoregulation of the mesenteric circulation in response to a primary event (e.g., apnea, or patent ductus arteriosus) probably factors into the pathogenesis of NEC. Specific clinical events that seem to contribute to the pathogenesis of NEC include enteral feeding of small preterm infants, use of a hyperosmolar formula, bacterial infection, intestinal dysfunction (e.g., feeding intolerance or slow transit), infection, polycythemia, congenital heart disease, and a history of umbilical arterial catheterization or exchange transfusion.

The most common anatomic site for NEC is the ileocolic region. However, NEC is often discontinuous, with patchy distribution in both the small and large intestines in as many as 50% of cases (Fig. 18-19). Large bowel involvement is most common in the full-term infant. Perforations often are multiple and although commonly identified at the junction of a necrotic and normal bowel, perforations are also found within the affected areas.

The primary pathologic findings in NEC are coagulative or ischemic necrosis, as well as inflammation. The inflammatory response seems to be unique in that abscesses do not form, as seen in inflammatory bowel disease, infectious colitis, or acute arterial occlusion (Hsueh et al., 2002). The combination of ischemia and bacteremia seems to underline the pathophysiology of the disease. For example, NEC does not evolve after an episode of vascular injury in utero, when the bowel is sterile (Mussemche et al., 1986). Instead, an intestinal atresia or stenosis may develop. The formation of gas bubbles (pneumatosis intestinalis) reflects fermentation of an intraluminal substrate

TABLE 18-1. Modified Bell's Staging for NEC

Review of Bell's Stages	Clinical Findings	Radiographic Findings	Gastrointestinal Findings
Stage I	Apnea and bradycardia, temperature instability	Normal gas pattern or mild ileus	Gastric residuals, occult blood in stool, mild abdominal distention
Stage II A	Apnea and bradycardia, temperature instability	Ileus gas pattern with one or more dilated loops and focal pneumatosis	Grossly bloody stools, prominent abdominal distention, absent bowel sounds
Stage II B	Thrombocytopenia and mild metabolic acidosis	Widespread pneumatosis, ascites, portal-venous gas	Abdominal wall edema with palpable loops and tenderness
Stage III A	Mixed acidosis, oliguria, hypotension, coagulopathy	Prominent bowel loops, worsening ascites, no free air	Worsening wall edema, erythema and induration
Stage III B	Shock, deterioration in laboratory values and vital signs	Pneumoperitoneum	Perforated bowel

Adapted from Kleigman RM, Walsh MC: Neonatal necrotizing enterocolitis: pathogenesis, classification, and spectrum of disease, *Curr Probl Pediatr* 17(4):243-288, 1987; Gordon PV, Swanson JR, Attridge JT, Clark R: Emerging trends in acquired neonatal intestinal disease: is it time to abandon Bell's criteria? *J Perinatol* 27:661-671, 2007.

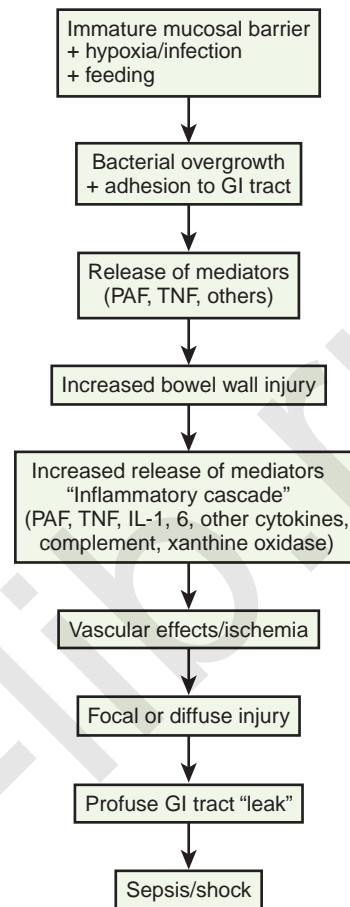

by bacteria; however, NEC is not associated with a specific organism or with particularly virulent bacteria. A wide range of organisms have been identified in the stool of infants with NEC, some who also have a bacteremia with the same organism: *Escherichia coli*; various strains of *Enterobacter*, *Klebsiella*, and *Pseudomonas*; coagulase-negative *Staphylococci*; and others. Viral agents have been associated with NEC but are not considered a major infectious etiology.

Classically, although the hypothesis for the etiology of NEC has focused on circulatory insufficiency or infection, the pathophysiology of NEC in the preterm infant also involves an exaggerated inflammatory response in the setting of abnormal bacterial colonization, an inadequate epithelial barrier (e.g., defects in mucus or immature tight junctions), an immature intestinal motility (e.g., disordered peristalsis), and an immature gastrointestinal immunity (Hunter et al., 2008). In fact, the immature gastrointestinal tract is characterized by inadequate secretion and production of mucin, which may predispose it to increased permeability to and adherence of bacteria. The immature immunity of the preterm intestine increases the susceptibility of an inadequate barrier to injury from uncontrolled inflammatory responses.

Activation of inflammatory and apoptotic pathways and antiapoptotic mechanisms relies on the interaction of systems in the invading organism with specific receptors in the host. So-called microbial-associated molecular patterns (MAMPs) interact with a specific pattern-recognition receptor (PRR) on host cells. A well-known PRR is the human toll-like receptor 4 (TLR4), a receptor for lipopolysaccharide (LPS), a substance in the cell walls of some bacteria. Of relevance to the preterm infant, hypoxia and exposure to infant formula may exaggerate expression of this receptor. Adult human intestine is characterized by minimal TLR4 expression, but expression in fetal intestine is high. The overexpression of the normal TLR4 receptor may predispose the immature intestine to enhanced proinflammatory injury; interaction with MAMPs of pathogenic bacteria leads to apoptosis and inhibition of healing from injury (Leaphart et al., 2007). Apoptosis of the intestinal epithelia has been noted in human infants with NEC (Ford et al., 1997). Thus the preterm infant may be predisposed to NEC via an inability to maintain adequate inflammatory responses while avoiding overactivation of proinflammatory responses (e.g., via TLR4 receptors), which lead to injury.

Although multiple inflammatory markers and various cytokines (IL-8, IL-10, liver and intestine fatty acid binding protein) have been associated with NEC, no single marker has been identified that allows early diagnosis and management of NEC (Young et al., 2009). Several “models” of NEC, emphasizing the role of inflammatory and vasoactive mediators, platelet-activating factor (PAF), and tumor necrosis factor- α (TNF α) have been developed (Fong et al., 1990; Sun and Hsueh, 1991; Sun et al., 1996; Wand et al., 1997; Tan et al., 2000). However, no experimental approach has been ideal, because models for this disease do not exactly mimic the clinical disease (Sodhi et al., 2008).

Nonetheless, by correlating clinical studies to experimental models, it appears that similar to sepsis, NEC is driven by the pathway of activation of cytokines, prostaglandins, and NO, which interact to initially induce intestinal injury via polymorphonuclear neutrophil (PMN) activation and PMN adhesion (Fig. 18-20). PAF and TNF α seem to play a central role in inducing intestinal injury.

■ **FIGURE 18-20.** Schematic representation of the pathophysiology of NEC. *GI*, Gastrointestinal; *IL-1*, interleukin 1; *PAF*, platelet-activating factor; *TNF*, tumor necrosis factor.

One theory is that PAF induces cell injury after inducing production of various reactive oxygen species (ROS), but the precise mechanism is unclear. Of note, the xanthine dehydrogenase/xanthine oxidase system is abundant in the intestine and seems to generate superoxide during ischemia. Elevated levels of PAF have been measured in infants with NEC (Rabinowitz et al., 2001). In addition, premature infants have low levels of the PAF-degrading enzyme acetylhydrolase (Caplan et al., 1990). Exactly how other mechanisms included in the pathogenesis of NEC (e.g., immature immunologic mechanisms, abnormal patterns of bacterial overgrowth, and deficient mesenteric blood flow regulation) interact with the intense inflammatory response is not completely understood. Finally, differences in the content of sialic acid and N-acetylglucosamine residues of the mucosa may affect anatomy and function of the microvilli, leading to certain types of bacterial colonization, bacterial adhesion, and eventually, permeation of the gastrointestinal tract (Claud and Walker, 2001).

Another pathway that plays a critical role in the pathophysiology of NEC centers on the interaction of NO, prostaglandins, and epidermal growth factor (EGF) in regulating epithelial function. Prostaglandins function in maintaining tight junctions. Normal low levels of NO regulated by endothelial nitric oxide synthase (NOS) activity enhance blood flow to the mucosa and maintain microvascular flow. However, high levels of NO

in response to stimulation of inducible NOS may cause cytotoxicity as a result of damage to the epithelial barrier (disrupting epithelial tight junctions) and excessive apoptosis, as seen in early NEC (Ford et al., 1997; Chokshi et al., 2008). Thus, although NO seems to be critical in maintaining mucosal blood flow, high levels may have injurious effects, disrupting the tight junctions of the epithelium and inducing abnormal apoptosis. In addition, endothelin (a vasoconstrictor) is released in response to various pathologic conditions, such as NEC. EGF seems to induce migration and proliferation of epithelial cells in response to injury, but levels of this mediator are low in some preterm infants, specifically those with NEC. The cytoprotective effect of EGF, which is found in high levels in breast milk, may eventually be incorporated into nutritional strategies to prevent and treat NEC (Guner et al., 2008b; Nair et al., 2008).

Finally, various genetic factors (i.e., prematurity, respiratory distress syndrome, and periventricular leukomalacia) may interact either directly or indirectly in the development of NEC. For example, recent analyses of preterm twins uncovered a familial origin for NEC, as well as for intraventricular hemorrhage (IVH) and bronchopulmonary dysplasia (BPD) (Bhandari et al., 2006). That is, 52% of the variance for NEC could be explained by genetic and shared environmental factors. The *TLR4* gene and its products have been reported to be higher in an animal model of NEC, and the risk for NEC has been associated with a specific genotype of interleukin (CPS1 T1405N polymorphism, IL-18[607]) (Jilling et al., 2006). The incidence of the genotype was significantly higher in those with stage III compared with those who had stage I or II NEC (Moonen et al., 2007).

The observation that inflammation is the result of NEC, rather than the cause, has prompted a variety of interventions aimed at enhancing epithelial integrity, such as human milk feeds, various amino acid supplementations, and various probiotics, prebiotics, and postbiotics (Lin et al., 2008a). Although a specific role for any agents other than human milk remains unclear, any introduction of pharmacologic agents may have dramatic effects on other therapeutic agents used in the NICU and the operating room.

Preoperative Management

A typical infant with NEC is a preterm baby weighing less than 1500 g and often less than 1000 g. Some infants have had perinatal asphyxia or other respiratory complications in the early postnatal period. Prenatal complications associated with NEC may include events that are associated with asphyxia or prematurity, such as premature rupture of the membrane, placenta previa, maternal sepsis, toxemia, breech delivery, or cesarean section for fetal distress.

In “classic NEC,” gastrointestinal signs appear between the first and tenth days of life in more than 90% of cases, and they include abdominal distention, retained gastric secretions and high gastric residuals after feeding (may be bile-tinged), vomiting, bloody or mucoid diarrhea, and occult blood in stools. Figure 18-21 shows the probability of a patient experiencing intramural gas, bloody stools, or portal venous gas when diagnosed with NEC vs. gestational age. In some cases, these signs are preceded by nonspecific abnormalities such as apnea, bradycardia, thermal instability, or lethargy, with a gradual development of gastrointestinal problems. In other infants, the course is fulminant with rapid onset of abdominal signs with acidosis, hemodynamic instability, and disseminated intravascular coagulation (i.e., septic shock), often with bowel perforation. In infants with acute onset of advanced NEC, surgical intervention is emergent. Many infants with obvious NEC have decreased platelet counts (50,000 to 75,000/mm³ or lower) and prolonged prothrombin and partial thromboplastin times. Some infants have leukocytosis with a high percentage of bands, but others develop profound leukopenia and neutropenia. Early in the disease process, abdominal radiographs may reveal dilated, fixed (adynamic ileus) loops of bowel, but in advanced NEC, pneumatosis (intramural air in the intestine), gas in the portal venous system, and pneumoperitoneum develop.

Without evidence of intestinal necrosis or perforation, the initial treatment for NEC is nonoperative. Decompressing the stomach with an orogastric tube, no feeding, administering fluid and electrolyte therapy (including parenteral nutrition),

■ **FIGURE 18-21.** Probability curves for symptoms of bloody stools, intramural gas, or portal venous air in babies with NEC. (From Sharma R et al.: *Clinical manifestations of rotavirus infection in the neonatal intensive care unit*, *Pediatr Infect Dis J* 21:1099, 2002.)

delivering broad-spectrum antibiotics after obtaining cultures of blood and urine, and correcting hematologic abnormalities are the main components of medical therapy. Supportive hemodynamic therapy, including inotropic agents and steroids, may be needed to treat septic shock. Bowel perforation is the only generally accepted indication for surgery, but relative indications may include peritonitis, air in the portal system, bowel wall edema, ascites, and a progressively deteriorating cardiorespiratory status (Box 18-2).

The role of primary peritoneal drainage in the surgical treatment of NEC and IP has been scrutinized. Peritoneal drainage was initially proposed as a method to treat the most unstable infants with NEC, usually ELBW infants (Ein et al., 1977). Some have reported that this intervention provides advantages in the ELBW infants but not in those weighing more than 1500 g (Azarow et al., 1997). Theoretically the ELBW infant may benefit from such a temporizing procedure that would allow resuscitation and stabilization. However, the effectiveness of peritoneal lavage in “buying time” for an infant to achieve hemodynamic, acid/base, and hematologic stability is actively debated.

In a prospective cohort of 16 NICUs (NICHD Neonatal Research Network), the overall in-hospital mortality associated with NEC in this group of ELBW infants was 49%. Poor prognosis was associated with lower gestational age and birth weight, preoperative vasopressors, and HFOV support. Mortality was 55% for patients with NEC and 38% for those with IP. However, in this study, initial treatment with a peritoneal drain vs. laparotomy was at the discretion of the surgeon (i.e., subject to bias), therefore mortality could not be accurately correlated with surgical management (Blakely et al., 2005). Subsequently, a multicentered randomized trial compared outcome of primary peritoneal drainage with laparotomy in another group of preterm infants. In this study, the infants were lighter than 1500 g and had fewer than 34 weeks’ gestation (compared with a weight of less than 1000 g in the earlier study), who had free intraperitoneal air either on abdominal radiograph or by clinical examination (by both the surgeon and neonatologist),

or had stool, bile, or pus on paracentesis. Because of clinical deterioration, 5 of the 55 (9%) in the peritoneal drainage group underwent laparotomy. Because of stricture, obstruction, or feeding intolerance, another 16 (29%) underwent laparotomy. Mortality at 90 days was similar (peritoneal drainage, 34.5%; laparotomy, 35.5%), as was dependence on intravenous nutrition (peritoneal drainage, 47.2%; laparotomy, 40%). Length of hospitalization did not differ between the groups. Of note, the investigators did not uncover a difference in mortality when outcome was stratified according to gestational age subsets (younger than 24, 25 to 26, 27 to 30, and 30 to 34 weeks’ gestation) (Moss et al., 2006).

In a multicenter randomized trial including 31 NICUs in 13 European countries, ELBW infants with pneumoperitoneum on radiograph either underwent laparotomy or placement of an intraperitoneal drain. Survival at 6 months was similar (51.4%, intraperitoneal drain; 63.6%, laparotomy). In contrast to Moss et al.’s (2006) study, 74% of infants underwent laparotomy between 0.4 and 21 days. These investigators suggest that peritoneal drainage is ineffective as a temporizing measure or as a definitive treatment. That is, if a drain is placed, a laparotomy should be performed soon afterward (Rees et al., 2008).

The preoperative assessment of infants with NEC focuses on evaluating and correcting the respiratory, circulatory, metabolic, and hematologic disorders. Trends in blood gases, glucose, electrolytes, hematocrit, and coagulation status (including platelet count) should be noted. Increased colloid and crystalloid therapy may be needed in hypovolemic infants with massive third-space fluid losses, bleeding, and disseminated intravascular coagulation. Electrolyte disturbances (including acidosis) are exaggerated in the setting of acute renal failure, which may evolve secondary to shock or abdominal compartment syndrome.

Respiratory support often must be increased as abdominal distention or metabolic and respiratory acidosis worsen. Thus, the anesthesiologist must decide whether a ventilator from the NICU would provide advantages, whether manual ventilation is necessary (possible need for more personnel), or whether the ventilator associated with the anesthesia machine is adequate. If the infant’s status is so unstable that transport to the operating room seems too risky, a surgical procedure in the NICU should be considered.

Box 18-2. Indications for Surgery

ABSOLUTE INDICATIONS

Pneumoperitoneum
Intestinal gangrene (positive results of paracentesis)

RELATIVE INDICATIONS

Clinical deterioration
Metabolic acidosis
Ventilatory failure
Oliguria, hypovolemia
Thrombocytopenia
Leukopenia, leukocytosis
Portal vein gas
Erythema of abdominal wall
Fixed abdominal mass
Persistently dilated loop

NONINDICATIONS

Severe gastrointestinal hemorrhage
Abdominal tenderness
Intestinal obstruction
Gasless abdomen with ascites

Intraoperative Management

Intraoperative monitoring ideally includes arterial and central venous cannulae for continuous monitoring and blood gas and metabolic analysis. Fresh frozen plasma, platelets, and red blood cells may be administered early in surgery in response to clinical and laboratory evidence of coagulopathy. Inspired oxygen concentration should be adjusted to produce an arterial oxygen saturation of 85% to 90%. Nitrous oxide must be avoided, especially in the presence of free air in the gastrointestinal and portal venous systems.

Potent inhalation agents are often poorly tolerated and often are only introduced in low concentrations to supplement narcotics. High doses of fentanyl (e.g., 50 mcg/kg) or other narcotic can be slowly delivered, as tolerated hemodynamically, or delivered as an infusion to provide infants with analgesia and amnesia. Neuromuscular blocking agents facilitate surgical interventions. Inotropic agents are often needed to support the cardiovascular system when fluid therapy alone fails to maintain adequate perfusion. Glucose intolerance is common

in septic infants. In all cases, fluid that does not contain glucose should be delivered to provide crystalloid resuscitation. Of note, the high glucose content of red blood cell products may eliminate any need for other glucose delivery. Ideally, glucose can be measured intraoperatively, especially in procedures longer than 45 to 60 minutes that require large quantities of blood, and in infants with major glucose instability preoperatively.

Because of the large fluid requirements, hypothermia is a common intraoperative complication. The operating room and infused fluids are warmed to assist in maintaining adequate body temperature. In the surgical treatment of NEC, necrotic bowel is resected, and usually, the marginally viable ends are exteriorized. The cardinal principles of surgery for NEC are to excise all necrotic bowel but preserve as much bowel length as possible by leaving “marginal” appearing bowel in place, decompressing the bowel, and removing pus, stool, and necrotic debris from the peritoneal cavity. Preserving the bowel may require multiple segmental resections and second-look operations to reassess bowel viability. Select patients may tolerate resection and primary reanastomosis. Bowel strictures may develop within days to months after the initial surgery, often necessitating further surgical intervention. Often enterostomies are closed within 4 weeks to 6 months after the initial surgery.

Postoperative Management

Postoperatively, mechanical ventilation and cardiovascular support are universally required in these infants. Central venous parenteral nutrition is essential after sepsis is controlled and metabolic stability is established.

Outcome

Mortality from NEC is high, ranging between 10% and 30% (or higher in surgically treated ELBW infants). Regardless of treatment (medical or surgical), approximately 30% of patients develop strictures. Recurrence of NEC is rare. Infants who initially respond to placement of an intraperitoneal drain may eventually require surgery, but some do not. Infants who develop an isolated intestinal perforation may be distinct from those with NEC and have a more benign course. The hospital course for preterm infants with NEC can be prolonged and characterized by repeated episodes of sepsis and long-term requirements for intravenous alimentation as enteral feedings are introduced slowly.

A devastating complication in survivors of NEC is short bowel syndrome, which develops in as many as 20% to 25% of surgically treated patients (Rees et al., 2008). In these cases, the bowel resection is so extensive that the infant is unable to establish enteral feedings, implying a need for long-term intravenous alimentation despite its high-risk morbidity (e.g., sepsis and hepatic failure). Although site and amount of resection seem to correlate with the development of short bowel syndrome, diffuse mucosal injury may persist in areas of bowel injured by NEC but not resected. Current interventions include intestinal lengthening procedures or even bowel transplantation. The use of tissue-engineered small intestine is under intense investigation (Guner et al., 2008b). Evidence suggests that breast milk decreases the incidence of NEC and its complications. The roles for treatment with probiotics, nonspecific (steroids, indomethacin, magnesium, copper) and specific antiinflammatory agents (PAF receptor blockers), growth factors (erythropoietin), or antibiotics remain speculative (Millar et al., 2003).

Beyond the gastrointestinal outcome, the risk for long-term neurodevelopmental problems was first reported in 50% of survivors almost three decades ago (Stevenson et al., 1980). Deficits in psychomotor and mental development have been confirmed in the VLBW survivors of NEC, especially those who have undergone surgery (Vohr et al., 2000; Stoll et al., 2004; Hintz et al., 2005; Rees et al., 2007; Schulzke et al., 2007). The risk for those treated surgically is approximately twice that of those treated medically. In fact, those treated medically have outcomes similar to those of the same gestational age without a history of NEC (see Chapter 17, Neonatology for Anesthesiologists).

Prevention strategies are now focused on feeding techniques and manipulating gut flora. However, definitive approaches for introducing probiotics, various amino acids, or agents such as epidermal growth factor have not been established. Clearly, identifying infants at risk to prevent progression to a disease that requires surgery may be critical in minimizing gastrointestinal and neurodevelopmental complications from NEC.

Imperforate Anus (Anal Atresia)

The incidence of anorectal malformations is 1:5000 live births. Miller et al. (2009) reported an association of anorectal atresia with caffeine intake, cigarette smoking, and environmental tobacco smoke. Imperforate anus can range from a mild stenosis to a complex syndrome with other associated congenital anomalies. The higher the anatomic relation of the terminal bowel to the puborectalis sling of the levator musculature, the greater is the incidence of associated anomalies. The incidence of additional genitourinary abnormalities is 48%, but it ranges from 14% in infants with perineal fistulas to 90% in infants with bladder fistulas. Twenty-four percent of infants have a tethered spinal cord (Levitt et al., 1997). Male infants with imperforate anus may require an operation soon after birth for relief of obstruction. In female infants, a rectovaginal fistula usually prevents total bowel obstruction so that surgical treatment is not an emergency.

Intraoperative Management

Anesthetic requirements vary depending on the severity of the abdominal distention and complexity of the surgery: a simple perineal anoplasty, a temporary colostomy, or an extensive abdominoperineal repair. Anorectal malformation can be classified by the presence or absence of a fistula and by the fistula's location (Pena and Hong, 2000) (Box 18-3). Perineal fistulas in both male and female infants represent the simplest defect, and treatment generally consists of an anoplasty performed in the neonatal period. Imperforate anus with no fistula is the least common presentation, whereas rectourethral fistulas are the most common, with the exception of the perineal fistula. The standard surgical approach has generally involved the following three steps:

1. A diverting colostomy performed in the neonatal period,
2. The main repair done during infancy, and
3. A take-down colostomy performed later in infancy.

Surgical trends, however, have been aimed at performing the primary repair without a colostomy. The primary repair involves a posterior surgical approach. Laparoscopic techniques have been used to assist in the pull-through technique (Georgeson, 2000).

Box 18-3. Therapeutic Classification of Anorectal Malformations

MALES

Cutaneous fistula, no colostomy required
 Anal stenosis
 Anal membrane
 Rectourethral fistula, colostomy required
 Bulbar
 Prostatic
 Rectovesical fistula
 Anorectal agenesis without fistula
 Rectal atresia

FEMALES

Cutaneous (perineal), no colostomy required
 Fistula
 Vestibular fistula, colostomy required
 Vaginal fistula
 Anorectal agenesis without fistula
 Rectal atresia
 Persistent cloaca

Anesthetic considerations for neonates with intestinal obstruction from any etiology include airway management of a full stomach, assessment of fluid status, correction of electrolyte disturbances, treatment of sepsis, and cardiorespiratory evaluation. Marked abdominal distention secondary to intestinal obstruction can impede diaphragmatic excursion and impair ventilation. Gastric (or lower intestinal) contents often are incompletely emptied with nasogastric suction, so that the risk of aspiration is significant, especially during induction of general anesthesia.

Intubation of the trachea of infants with an apparently normal upper airway can be accomplished with an awake or rapid-sequence technique. If the anesthesiologist suspects that the upper airway will be difficult to visualize, the usual airway precautions should be observed. That is, neuromuscular blocking agents, deep sedation, and general anesthesia are avoided and an awake technique is attempted. Supplemental support systems for the difficult airway (e.g., neonatal bronchoscopes, light wand, and LMA) should be available (see Chapter 10, Equipment).

Anesthesia during the surgery can include potent inhalation anesthetics, narcotics, or both. In general, nitrous oxide is avoided because of the risk for increasing bowel distention. Intermediate-acting or long-acting nondepolarizing muscle relaxants often improve surgical conditions at lower inhaled anesthetic concentrations. If early postoperative extubation is planned, narcotics should be judiciously administered, but in many cases postoperative mechanical ventilation is required.

Imperforate anus is usually recognized early in the postnatal period, and massive distention may not develop in the group of infants without total bowel obstruction. Therefore the complications associated with intestinal obstruction are minimized, as are the complications from bowel ischemia, third-space fluid loss, electrolyte disturbances, and sepsis. Imperforate anus without a fistula can be associated with the development of total intestinal obstruction in utero, leading to severe abdominal distention, bowel perforation, sepsis, or a combination.

In addition, other congenital anomalies often have a dramatic effect on the management of these infants. For example, imperforate anus is associated with TEF, renal anomalies, and heart disease (VACTERL Association).

During surgery, the management of fluids, blood replacement, and electrolyte delivery are similar to the principles discussed for NEC and for intestinal obstruction. As with any intraabdominal surgery in the newborn, a major challenge is maintaining an adequate intravascular volume. The presence of radiopaque contrast agents, bowel manipulation, and peritonitis increases third-space fluid requirements. In such cases, 10 mL/kg per hour (or more) of isotonic saline solution or colloid is generally needed intraoperatively. Monitoring urine output, quality of heart tones, heart rate, and blood pressure is a basic requirement to assess continuing fluid needs. Invasive monitors such as an arterial catheter and a CVP catheter generally are reserved for those with marked cardiorespiratory instability.

Postoperative Management

The preoperative and intraoperative courses and the effects of associated congenital anomalies set the stage for the postoperative course. Many infants require postoperative ventilatory support, total parenteral alimentation, cardiovascular support, and treatment of sepsis. The function and recovery of the gastrointestinal system vary enormously among infants with imperforate anus and seem to be related to whether the lesion is isolated and whether the complications of total bowel obstruction have developed.

Outcome

Intestinal obstruction has historically been one of the major causes of death after neonatal surgery. With more skilled pediatric management and the development of parenteral alimentation, mortality is now limited primarily to infants whose condition is diagnosed late and who require extensive excision of the small and large bowels. Long-term complications from anorectal malformations, especially a high imperforate anus, can be lifelong and involve sequelae related to fecal soiling, constipation, and sexual inadequacy.

Intestinal Obstruction

Intestinal obstruction is a surgical emergency in the newborn, requiring swift intervention after diagnosis. Bowel obstruction has symptoms and signs similar to those seen at other ages, such as vomiting, abdominal distention, decreased bowel sounds, and radiologic evidence of gas-filled loops of bowel. However, in the newborn the list of etiologies includes a unique set of congenital anomalies.

Delay in the diagnosis and treatment of such lesions may lead to various complications that can increase morbidity and mortality. As described for the infant with imperforate anus, delay in diagnosis leads to disturbance of fluid and electrolyte balance and increased abdominal distention, with subsequent respiratory embarrassment and high risk for aspiration pneumonia. Intestinal perforation, necrosis of the bowel, and septicemia are other secondary consequences if intestinal obstruction is not managed promptly.

Distended bowel forces the diaphragm into a high, fixed position, limiting excursion, causing severe ventilatory compromise, and increasing the risk of aspiration. Although prompt surgical repair is imperative, optimizing the patient's metabolic status is critical before surgery. Initiation of corrective fluid and electrolyte therapy should precede the induction of anesthesia. Nasogastric suction may decrease gastric distention and the risk for aspiration, but if the site of obstruction is below the duodenum, the abdominal distention is not drastically affected.

Although the underlying etiologies of intestinal obstruction are variable (annular pancreas, intestinal atresia or stenosis, duplication of intestine, meconium ileus, tumors, enterocolitis), the problems of anesthetic management for surgical correction of these lesions are similar.

Duodenal Obstruction

The incidence of duodenal obstruction in the neonate is 1:10,000 to 1:40,000 births and is often associated with other congenital anomalies such as Down syndrome, cystic fibrosis, renal anomalies, intestinal malrotation, and especially midline defects such as esophageal atresia and imperforate anus. An intraluminal diaphragm, a membranous web, or an annular pancreas can also be associated with obstruction of the duodenum. The degree of obstruction varies from severe or complete atresia to incomplete obstruction or stenosis (Mustafawi and Hassan, 2008). Air contrast films reveal a dilated stomach and a dilated proximal duodenum, resulting in the "double-bubble" appearance (Fig. 18-22).

Infants with complete obstruction exhibit copious vomiting of bile or bile-stained gastric contents and minimal abdominal distention. The infant may or may not pass meconium in the first day of life. Infants who have incomplete obstruction have intermittent bile-stained vomiting and usually pass meconium. A delay in the treatment of this condition can result in dehydration, weight loss, and hypochloremic alkalosis.

Jejunioleal Atresia

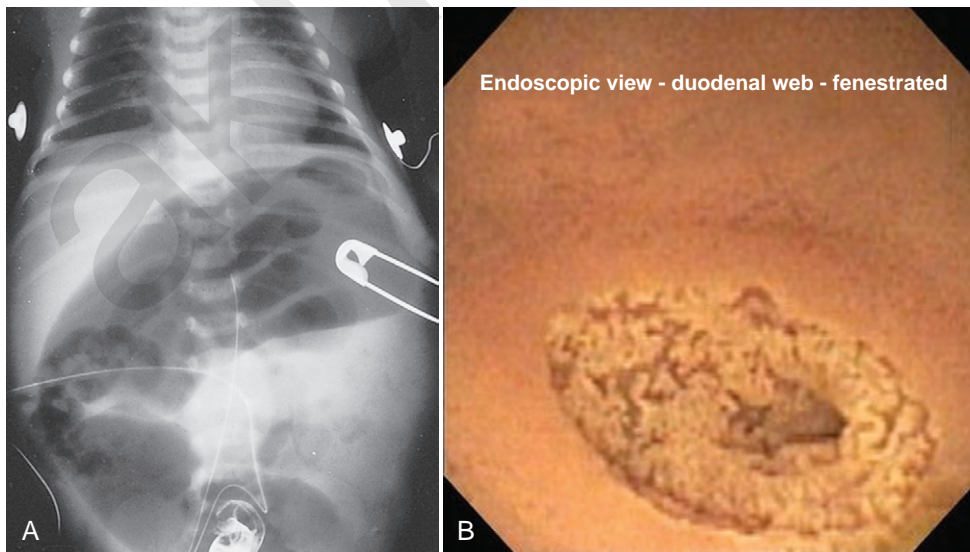

Jejunioleal atresia causes complete obstruction in 1:5000 live births. In contrast to duodenal atresias, jejunioleal atresias are

associated with few other anomalies. Prematurity is associated with 50% of cases, polyhydramnios with 25%, and cystic fibrosis with 20%.

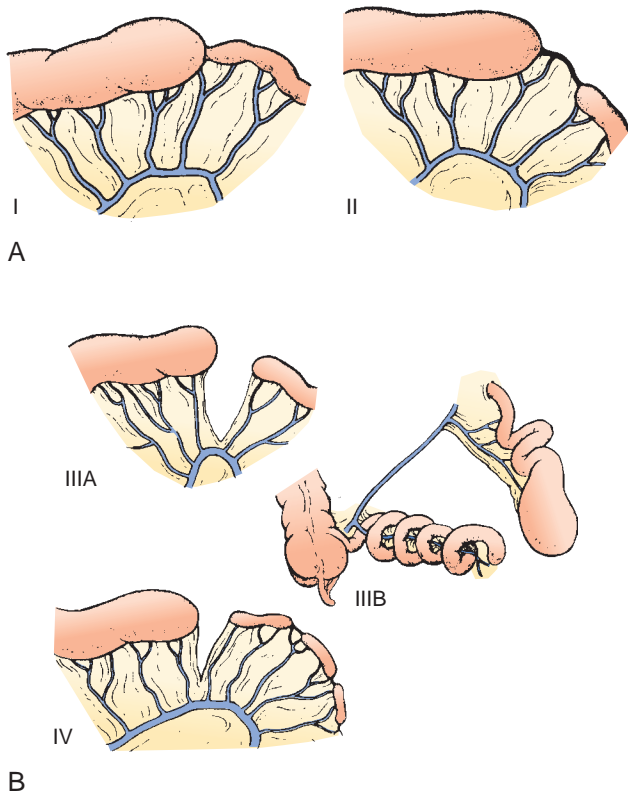

The etiology of jejunioleal atresia is uncertain but is thought to involve intrauterine vascular accidents. Four types of atresia have been identified (Fig. 18-23). Type I is not a true atresia but actually is a membranous obstruction of the lumen in an intestine of otherwise normal length and diameter. Type II, a true atresia, consists of two blind ends that are often connected by a fibrous strand with slightly shortened intestinal length. Type IIIA lesions have blind ends separated by a mesenteric defect. The type IIIB lesion is also called "apple peel" or "Christmas tree" deformity and consists of a long jejunal atresia with a very short remaining ileum. The superior mesenteric artery is missing, and the blood supply to the ileum is by retrograde flow via a branch of the ileocolic artery. Type IIIB lesions are rare but have a very high mortality rate. Type IV lesions involve multiple intestinal atresias.

Meconium Ileus

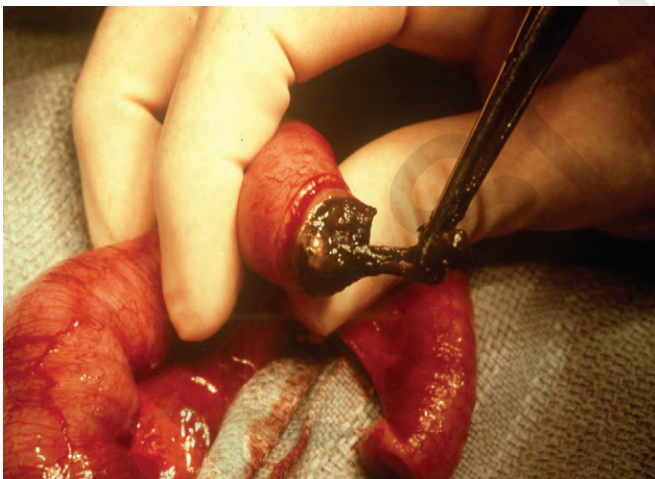

Meconium ileus is a luminal obstruction of the distal small bowel by abnormal meconium. Meconium ileus is found almost exclusively in patients with cystic fibrosis, but only 20% of patients with cystic fibrosis have meconium ileus. Because meconium ileus manifests in the neonatal period, respiratory symptoms of cystic fibrosis generally are not present. Both surgical and nonsurgical therapies are used to relieve the obstruction. The nonsurgical approach involves diatrizoate meglumine enemas, which can be both diagnostic and therapeutic. Diatrizoate meglumine, a water-soluble contrast agent, loosens and softens the meconium, thereby facilitating its evacuation. When medical management does not succeed, surgery is performed. After the peritoneal cavity is entered and the obstruction is located, diatrizoate meglumine or acetylcysteine is injected into the bowel lumen and allowed to mix with the meconium. When the meconium has loosened, it is massaged into the colon. If this is unsuccessful, an enterostomy is performed, and the sterile meconium is evacuated from the small bowel (Fig. 18-24).

■ **FIGURE 18-24.** Thick tenacious meconium in a patient with meconium ileus.

Malrotations and Volvulus

Malrotations are rare and generally result from abnormalities in the rotation of the bowel, which usually occur during the tenth to twelfth weeks of gestation. Consequently, areas of ischemia and atresia develop, along with volvulus, resulting in strangulation of bowel, bloody stools, abdominal distention, peritonitis, and hypovolemic shock (Fig. 18-25). Nonrotation or malrotation is twice as common in boys as in girls and often produces symptoms of intestinal obstruction in the first 1 to 2 months after birth. In

■ **FIGURE 18-25.** Malrotation with midgut volvulus without ischemia (A) and with infarction (B). (From Barksdale EM, Jr: *Surgery*. In Zitelli BJ, Davis HW, editors: *Atlas of pediatric physical diagnosis*, ed 4, St. Louis, 2002, Mosby, p 572.)

other cases, symptoms do not appear until later, even adulthood. The diagnosis of malrotation cannot be excluded if diarrhea is present, if clinical symptoms are mild, or if x-rays are normal (Miller et al., 2003). In patients with intestinal malrotation without volvulus, surgery often involves Ladd's procedure, which can be performed either open or laparoscopically (Draus et al., 2007). Malrotations are often associated with duodenal stenosis or atresia or small intestinal atresia, as well as with cardiac, esophageal, urinary, and anal anomalies. Major anatomic defects of the abdominal wall (e.g., gastroschisis and omphalocele) and CDH universally have intestinal malrotation or nonrotation.

The operative procedure for a nonrotation complicated by volvulus consists of untwisting the intestine and then a short intraoperative period of observation to evaluate recovery of vascular perfusion to the involved intestine. Areas of frank necrosis are excised, and a primary anastomosis is performed. If the patient has peritonitis or poor perfusion of the remaining bowel, proximal and distal enteral stomas are formed. The surgical operation, Ladd's procedure, involves the following five steps: eviscerating the midgut, derotating the volvulus in a counterclockwise direction, lysis of Ladd's peritoneal band, appendectomy, and placing the caecum in the left lower quadrant.

Children with less than 30 to 40 cm of small bowel generally develop short-gut syndrome and ultimately require TPN. If marginal areas of intestinal viability are present at the operation, they may be left unresected in the hope that postoperative resuscitation

improves the perfusion. Under these circumstances, a “second-look” operation usually is performed 24 to 48 hours later.

Sacroccocygeal Teratoma

Sacroccocygeal teratomas are the most common congenital neoplasm, occurring in 1:40,000 infants. Approximately 95% of infants are female.

Embryology and Diagnosis

The tumor is derived from pluripotential cell lines and contains components consisting of all three germ layers. Perinatal mortality is high when the tumor is diagnosed antenatally. Postulated causes of death include high output cardiac failure, preterm delivery secondary to polyhydramnios, anemia from hemorrhage into the tumor, dystocia, and tumor rupture.

Sacroccocygeal teratomas receive their blood supply from the middle sacral artery and branches of the internal iliac artery. A steal syndrome can shunt blood from the placenta and lead to high output cardiac failure and hydrops. Approximately 2% to 10% of sacroccocygeal tumors are malignant before the infant reaches 2 months of age, and 50% are malignant by 1 year of age. Serum α -fetoprotein levels are elevated in 70% of children with malignant tumors.

Sacroccocygeal tumors generally arise from the tip of the coccyx and vary with the amount of internal and external extension. These tumors are classified into four types according to their locations (Box 18-4; Fig. 18-26).

Intraoperative Management

Surgical treatment involves complete resection of both the tumor and coccyx. Failure to remove the coccyx completely can result in local recurrence. In utero treatment options include open fetal surgery, endoscopic laser ablation, and radiofrequency ablation (Bullard and Harrison, 1995; Hecher and Hackeloer, 1996; Paek et al., 2001) (see Chapter 19, Anesthesia for Fetal Surgery).

Box 18-4 Sacroccocygeal Tumor Types

- Type I: External with minimal pressure component
- Type II: External with considerable intrapelvic extension
- Type III: External with pelvic and intraabdominal extensions
- Type IV: Presacral with no external presentation

Anesthetic management for removal of tumors in the neonatal period requires an understanding of neonatal physiology and an appreciation for the possibility of cardiovascular instability, massive blood transfusion requirements, hypothermia, and coagulation dysfunction. Death during resection is often related to hemorrhage, hypothermia, coagulopathy, and the inability to provide adequate cardiopulmonary support during the intraoperative manipulation of the tumor. For large tumors, adequate venous access, central venous access, and invasive arterial pressure monitoring are essential.

Outcome

Predictors of poor outcome have been associated with diagnosis before 20 weeks' gestation, delivery before 30 weeks' gestation, development of hydrops, low birth weight, and a 5-minute Apgar score of less than 7 (Chisholm et al., 1999). Long-term issues involve urologic complications, urinary incontinence, problems with defecation, and cosmetically unacceptable scars (Derix et al., 2007; Taylor et al., 2009). Associated congenital anomalies are common in patients with congenital anorectal malformations (Stoll et al., 2007).

SUMMARY

For newborns to survive the transition from fetal to extrauterine life, critical multisystem developmental adaptation must occur. Congenital anomalies and acquired disease states requiring anesthetic and surgical intervention may deter this orderly physiologic transition. Those involved with anesthetic care of neonates must acquire and maintain an in-depth knowledge of developmental physiology as well as an understanding of the effects of immaturity on anesthetic and monitoring requirements. The pediatric anesthesiologist must assimilate this information and thoughtfully apply it to the practice of neonatal anesthesia.

Fetal interventions present a unique therapeutic opportunity. With advances in medical imaging technology, fetuses can be screened for anatomic congenital defects early in the course of a pregnancy. Although postnatal therapy is adequate for many fetuses, some congenital defects will not allow a successful transition to extrauterine life. Other birth defects may result in death in utero or serious disability after birth (Harrison, 1996). The logistics of fetal interventions can be quite challenging, but the ideas behind many of the treatments are conceptually quite simple. Some examples of interventions include bypass of fetal airway obstruction that would be fatal at birth, resection of a lung lesion causing hydrops fetalis, and repair of a myelomeningocele to minimize long-term disability (Table 19-1). Prenatal therapy opens new territory by making the fetus an active recipient of a given intervention. While the fetus is actively treated, the mother, by necessity, also receives medical care. Because of the high risk of these procedures, patient selection is an important consideration. The mothers must be at a sufficiently low anesthesia risk, and they must be highly motivated to comply with frequent follow-up and activity restrictions. Providing anesthesia for these patients requires a thorough understanding of maternal, fetal, and placental physiology. Familiarity with minimally invasive and open procedures and an understanding of the diseases amenable to fetal therapy are important. A list of key terms and acronyms is given in Box 19-1.

DISEASES

A common endpoint of many disease processes that are amenable to fetal therapy is hydrops fetalis leading to death in utero. This state is characterized by the accumulation of fluid in two or more of the following compartments: skin (e.g., scalp edema) or the pericardial, pleural, abdominal, or amniotic (i.e., in polyhydramnios) spaces. The placenta also becomes enlarged in this state. Just as in children and adults, these fluid collections are a manifestation of heart failure. Ultrasound examination readily reveals these fluid collections and the placentomegaly. Red cell alloimmunization is the most common cause of immune-mediated hydrops, whereas mechanical compression of cardiovascular structures is often the cause of nonimmune hydrops. Addressing the pathophysiology that gave rise to the hydrops is a goal of fetal therapy.

Nonimmune hydrops threatens the lives of both the fetus and mother (van Selm et al., 1991). The aptly named *maternal mirror syndrome* is a state of maternal edema that mirrors that of the fetus. The pathophysiology of this process is unclear, but it may involve a maternal inflammatory response to shedding of debris from a hydropic placenta (Redman and Sargent, 2000). In contrast to preeclampsia, the mother is hemodiluted rather than hemoconcentrated, and the fetus, by definition, must show signs of hydrops (Vidaeff et al., 2002). Pulmonary edema secondary to the mirror syndrome may be

TABLE 19-1. Fetal Interventions, Timing, and Therapy

Disease Process	Timing	Therapy	Rationale
Twin-twin transfusion	Early to mid gestation	Amnioreduction	Reduces polyhydramnios, less risk for preterm labor, may improve uterine blood flow
		Laser ablation of placental vessels	Ablation of vessels that are allowing unbalanced blood flow
		Bipolar umbilical cord cautery Radiofrequency ablation of the umbilical cord	In cases of imminent fetal demise
Twin reversed arterial perfusion	Early to mid gestation	Bipolar umbilical cord cautery Radiofrequency ablation of the umbilical cord	Prevents high output failure as pump twin supplies the acardiac cell mass
Cystic hygroma or airway teratoma	Late gestation	EXIT procedure	Secures airway or resects mass while umbilical cord is patent
Congenital high airway obstruction syndrome	Mid gestation	Tracheal decompression	Allows egress of lung fluid, prevents hydrops from cardiovascular compression by pulmonary hyperplasia
	Late gestation	EXIT procedure	Secures airway
Congenital cystic adenomatoid malformation or bronchopulmonary sequestration	Early, mid, or late gestation	Drain or thoracoamniotic shunt	Reduces size of cystic lesions or drains fluid collections causing fetal compromise
	Mid gestation	Pulmonary lobectomy	Resects large masses (not amenable to tap or shunt) causing fetal compromise
	Late gestation	EXIT for pulmonary lobectomy	Resects masses that will interfere with neonatal resuscitation
Congenital diaphragmatic hernia	Mid gestation	Tracheal occlusion	Prevents egress of lung fluid, stimulating lung growth
Aortic stenosis with evolving hypoplastic left heart	Mid gestation	Balloon dilation of aortic valve	Improves left ventricular outflow, which may allow better development of left ventricle
Hypoplastic left heart with intact or highly restrictive atrial septum	Mid gestation	Atrial septoplasty	Creates necessary communication between left and right atria
Myelomeningocele	Mid gestation	Closure of defect	Prevents exposure of neural elements to amniotic fluid
Bladder outlet obstruction	Mid gestation	Bladder decompression	Prevents renal injury, allows increased production of amniotic fluid
Sacroccygeal teratoma	Mid gestation	Debulking or ablation of feeding vessels	Prevents high-output cardiac failure

life threatening, and treatment of maternal mirror syndrome involves either delivery of the fetus or treatment of the cause of the hydrops (Heyborne and Chism, 2000; Pirhonen and Hartgill, 2004; Livingston et al., 2007).

Complicated Multiple Gestations

Monozygotic twin gestations are at increased risk for complications. If a monozygotic cell mass splits within 3 days of fertilization, a dichorionic diamniotic twin gestation should result. If the mass splits later than 13 days after fertilization, conjoined twins will result. If the cell mass splits between days 3 and 13, the twins will be “conjoined” to varying degrees at the level of the placenta and placental vessels (Lewi et al., 2003). These conjoined placental vessels may result in a net flow of blood from one twin (donor) to the other twin (recipient). The donor will suffer from hypovolemia, oligohydramnios, and growth restriction, whereas the recipient will suffer from hypervolemia,

polyhydramnios, hydrops, and heart failure (Luks et al., 2005). Ultrasound and fetal echocardiographic changes may be used to describe the severity of disease (Quintero et al., 1999; Rychik et al., 2007). This process, twin-twin transfusion syndrome, places both twins at risk for preterm delivery, death, and neurologic disability.

Traditional treatment of twin-twin transfusion syndrome involves serial amnioreduction to relieve the polyhydramnios. This may decrease the risk of preterm labor and may allow better perfusion of the donor twin; however, this therapy does not target the physiologic problem, which arises from the connected placental vessels (Lewi et al., 2005). Newer therapies target the placental vessels, employing percutaneous placement of endoscopes into the amniotic fluid to allow visualization and ablation of the connected placental vessels (Fig. 19-1). Minimally invasive fetoscopic laser ablation of the vessels has been shown to be superior to amnioreduction in a randomized clinical trial (Senat et al., 2004). Another trial showed no difference between amnioreduction and laser ablation, but there

Box 19-1. Acronyms and Glossary

Amnioreduction: Percutaneous needle drainage of excess amniotic fluid

BPS: Bronchopulmonary sequestration, or lung tissues in the thoracic cavity that are not in communication with the pulmonary circulation or the pulmonary blood supply. These tissues are often supplied by a feeder vessel arising from the aorta.

CCAM: Congenital cystic adenomatoid malformation, a lung lesion formed by an overgrowth of terminal bronchioles

CDH: Congenital diaphragmatic hernia

CHAOS: Congenital high airway obstruction syndrome

EXIT: Ex utero intrapartum therapy

HLHS: Hypoplastic left heart syndrome

Hydrops fetalis: A manifestation of heart failure in the fetus, characterized by skin edema, pleural or pericardial effusions, ascites, or polyhydramnios

Maternal mirror syndrome: A potentially life-threatening state of maternal edema that may arise when the fetus suffers from hydrops fetalis

MMC: Myelomeningocele

Polyhydramnios: Excess amniotic fluid, which may be a sign of fetal pathology

SCT: Sacrococcygeal teratoma

TRAPS: Twin reversed arterial perfusion sequence

TTTS: Twin-twin transfusion syndrome

were differences in the studies that do not allow direct comparison (Crombleholme et al., 2007). More research is needed to fully define the role of minimally invasive laser therapy and amnioreduction in the treatment of twin-twin transfusion syndrome.

Twin reversed arterial perfusion sequence (TRAPS) is a similar clinical entity in which one of the twin cell masses may be acardiac, acephalic, or both. The normal or “pump” twin is at risk for death from high-output heart failure

because it must supply cardiac output for itself and the acardiac cell mass (Tan and Sepulveda, 2003). In these cases, selective fetocide of the acardiac cell mass will allow the normal pump twin to survive. This is accomplished by occlusion of blood flow to the umbilical cord of the acardiac mass either by bipolar cautery or radiofrequency ablation (Tsao et al., 2002). If the twins are monochorionic and monoamniotic, the umbilical cord of the acardiac cell mass must also be divided to prevent cord entanglement and death of the normal twin. These umbilical cord occlusions are accomplished with minimally invasive techniques, using ultrasound or fetoscopic guidance.

Neurologic

Fetal therapies for prenatally diagnosed hydrocephalus and myelomeningocele (MMC) have been described. Results for in utero treatment of hydrocephalus with ventriculoamniotic shunts have not been encouraging, and this therapy is no longer actively studied or offered (Manning et al., 1986; Bruner et al., 2006). However, in utero closure of MMC defects is more promising. This closure involves accessing the midgestation fetus via maternal laparotomy and hysterotomy (Fig. 19-2). The MMC is repaired, and uterine and abdominal incisions are closed. Pregnancy is continued with the goal of delivering as close to term as possible.

The rationale for in utero closure of MMC is based on animal models of fetuses with these lesions, where it appears that prolonged bathing of neurologic elements in the amniotic fluid worsens the neurologic outcome (Meuli et al., 1995; Meuli et al., 1996). In human studies, closure of fetal MMC decreases the need for postnatal ventriculoperitoneal shunting and the incidence of hindbrain herniation and Chiari malformation. Motor function may be somewhat improved, and cognitive behavioral testing does not appear to be adversely affected (Bruner et al., 1999; Tulipan et al., 1999; Johnson et al., 2003; Johnson et al., 2006). A randomized trial sponsored by the National Institutes of Health (NIH) is currently enrolling patients who are randomized either to standard postnatal closure of MMC or to in utero closure of MMC. Enrollment in the trial is, at this time, the only avenue for this surgery.

FIGURE 19-1. Three panels demonstrating the minimally invasive treatment of twin-twin transfusion. Airway

Airway obstruction is life threatening in the postnatal period, especially when airway patency cannot be established immediately on delivery by intubation. Extrinsic causes of airway obstruction include cystic hygroma and oral teratoma. Cystic hygroma is a type of lymphatic malformation that may develop in the neck, resulting in large, fluid-filled cystic masses (Fig. 19-3). Teratomas are germ cell tumors composed of tissues foreign to their normal location (Fig. 19-4). Polyhydramnios may result from an inability of the fetus to swallow amniotic fluid. Intrinsic causes of airway obstruction include laryngeal cysts, webs, and atresia. The spectrum of disease due to intrinsic compression has been called

■ **FIGURE 19-3.** A newborn who underwent aspiration of a cystic hygroma and subsequent intubation during an EXIT procedure. (Photo courtesy of Alan W. Flake, MD, Children's Hospital of Philadelphia.)

■ **FIGURE 19-4.** A newborn with a massive oral teratoma. The infant was delivered via an EXIT procedure, during which she underwent an emergent tracheostomy. Tumor is protruding from the oral cavity and both nares. The anesthesia circuit is attached to a tracheostomy tube, which is obscured by the tumor. She was immediately taken to a second operating room for further debulking of the tumor. (Photo courtesy Lynne G. Maxwell, MD, Children's Hospital of Philadelphia.)

congenital high airway obstruction syndrome (CHAOS) (Hedrick et al., 1994; Lim et al., 2003).

Airway obstruction may be fatal in utero. This is not immediately intuitive, because the placenta serves as the organ of respiration, but complete airway obstruction will not allow egress of lung fluid into the amniotic space. This fluid will collect, and massive pulmonary hyperplasia may result. The fetal diaphragm may be flattened or even project into the abdominal space (Fig. 19-5). The intrathoracic pressure is presumably increased and will impede cardiovascular filling and function, resulting in nonimmune hydrops and fetal demise (Mong et al., 2008). If hydrops is not present, fetal airway obstruction is well served by the ex utero intrapartum therapy (EXIT) procedure. The EXIT procedure for a near-term fetus involves a maternal laparotomy and hysterotomy, exteriorization of the fetus, and securing of the fetal airway before clamping and division of the umbilical cord. After the cord is divided, the fetus is delivered and given to a neonatology team for further stabilization. If hydrops is present and the lungs are immature, midgestation tracheal decompression may be a treatment option (Kohl et al., 2006; Kohl et al., 2009).

Lung Lesions

Lung lesions that may be diagnosed in utero include congenital diaphragmatic hernia (CDH), congenital cystic adenomatoid malformation (CCAM), and bronchopulmonary sequestration (BPS). CDH has been a target for in utero therapy for decades. Results with both open and minimally invasive techniques have thus far been equivalent to those with optimal postnatal therapy. Thus, the risk-benefit analysis would support postnatal therapy. However, efforts at refining minimally invasive therapy continue and may prove to be of benefit in the future

■ **FIGURE 19-5.** Magnetic resonance image of a maternal pelvis. The mother is pregnant with twins. **A**, Normal twin on the left with the *white arrow* pointing out the normal configuration of the fetal diaphragm. The *white arrowhead* marks the area of complete tracheal obstruction, the *black arrows* demonstrate the inverted diaphragms, and the *asterisk* demonstrates the massive ascites in this twin with congenital high airway obstruction syndrome (CHAOS). **B**, Sagittal view of the twin with CHAOS, clearly demonstrating massive ascites outlining both the bowel and the liver. (From Mong A, Johnson AM, Kramer SS, et al: *Congenital high airway obstruction syndrome: MR/US findings, effect on management, and outcome*, *Pediatr Radiol* 38:1171, 2008, with permission from Springer.)

(Harrison et al., 1997; Harrison et al., 2003; Deprest et al., 2005; Doné et al., 2008; Peralta et al., 2008).

The management of prenatally diagnosed CCAM is instructive because its natural history is variable (Fig. 19-6). CCAM results from an overgrowth of terminal bronchioles. These masses do not participate in gas exchange, may predispose to infection and malignancy, may cause mediastinal shift and cardiac compression, and may result in hypoplasia of the remaining lung tissue. Some CCAMs will grow and some will shrink—each at unpredictable, variable rates. Regular prenatal assessment is required. Lesion composition (microcystic or macrocystic) and size have varying physiologic effects. Taking pulmonary maturity into consideration, the treatment of CCAM may occur in early, mid, or late gestation. Therapies may be minimally invasive or require open fetal surgery. Compromise results mostly from mass effect or fluid collection, resulting in a tamponade physiology. Solitary lesions with a large single cyst may be treated minimally invasively with one-time or serial needle aspiration. Ultrasound-guided minimally invasive placement of a thoracoamniotic shunt may negate the need for serial procedures in large, cystic lesions.

In contrast to large lesions with a single cyst, microcystic lesions are not amenable to aspiration or shunting. If a mid-gestation fetus with immature lungs has significant physiologic compromise, an in utero fetal pulmonary lobectomy may be pursued. After the lobectomy is completed, the fetus is returned to the uterus for further growth and development (Adzick et al., 2003). If the fetus is late in gestation and the lesion is causing distress or may interfere with neonatal resuscitation, a delivery via the EXIT procedure can be undertaken, with fetal thoracotomy and pulmonary lobectomy before umbilical cord clamp (Hedrick et al., 2005). If the mass is asymptomatic, the child can be delivered normally, and a postnatal pulmonary lobectomy can be electively scheduled.

■ **FIGURE 19-6.** Fetal therapy for congenital cystic adenomatoid malformation (CCAM). **Upper:** The left chest of a fetus undergoing thoracotomy. **Lower:** MRI of a fetus with a large cystic CCAM (*white arrow*).

BPS is distinct from CCAM, because these lesions are composed of lung tissue that typically has no communication to the tracheobronchial tree or pulmonary circulation. Blood supply to a BPS typically comes from a feeder vessel originating from the aorta. Treatment of BPS is similar to that of CCAM and depends on multiple factors, such as size, location, and composition, which influence the physiology of the fetus.

Cardiac Disease

Most of the therapies for congenital cardiac malformations are minimally invasive and catheter based, with most of the reported literature describing fetal aortic valvuloplasty for treatment of severe aortic stenosis—a possible precursor to hypoplastic left heart syndrome (Tworetzky et al., 2004; Marshall et al., 2005; Wilkins-Haug et al., 2006). In utero atrial septoplasty (Fig. 19-7) has also been described for patients with hypoplastic left heart with an intact or highly restrictive atrial septum (Marshall et al., 2008). Pulmonary atresia with an intact ventricular septum may also be amenable to fetal cardiac intervention, as this is the “right-sided” equivalent of hypoplastic left heart syndrome (Tworetzky and

Marshall, 2004). Earlier surgical techniques involved a maternal laparotomy and exteriorization of the uterus. The necessary needles and catheters were then inserted through an otherwise intact uterus, and subsequently guided through the fetal chest wall and myocardium to the chambers or vessels of interest. Currently, an even less invasive approach to the fetal heart is performed. The approach is entirely percutaneous: through the maternal abdomen, uterus, and fetal chest wall. Great care and skill come into play as the trajectory of the needles, catheters, and wires is planned. Outcomes from fetal cardiac interventions have been encouraging but are not definitive yet.

Bladder Outlet Obstruction

Fetal urinary tract obstruction (Fig. 19-8) may result in a host of complications, such as pulmonary hypoplasia, renal dysplasia, bladder dysfunction, renal failure, skeletal abnormalities, and abdominal wall muscular abnormalities (Harrison et al., 1981; Harrison et al., 1982). Patient selection for therapy is challenging, because the disease process must be severe enough to warrant a prenatal surgical intervention, but not so far advanced that the renal damage is irreversible (Cendron et al., 1994). Fetal evaluation is quite involved and includes ultrasound examination of the urinary tract, measurement of amniotic fluid volumes, and analysis of fetal urine electrolytes and proteins (Crombleholme et al., 1990). Minimally invasive therapy may involve needle decompression of the

■ **FIGURE 19-7.** Ultrasound images of in utero fetal atrial septoplasty. The large arrows demonstrate the tip of the introducer needle. **Upper:** The introducer needle is indenting the fetal chest wall. **Lower:** The needle is crossing the fetal atrial septum. The dashed line highlights the fetal atrial septum. The thin arrows demonstrate the right atrium (RA) and left atrium (LA), respectively. ■ **FIGURE 19-8.** Magnetic resonance image of a fetus with lower urinary tract obstruction. The fetus is facing to the right of the image. Notice the massively distended bladder, proximal urethra, and fetal abdomen, and the distinct lack of amniotic fluid surrounding the fetus. A, Ascites in the fetal abdomen; L, liver; S, spine.

bladder, vesicoamniotic shunting, or ablation of posterior urethral valves. Open surgery for bladder marsupialization or ureterostomies has also been reported (Crombleholme et al., 1988). Decompression may reduce the severity of oligohydramnios and the resulting pulmonary hypoplasia, but it may not allow recovery of renal function. Placement of a vesicoamniotic shunt may be technically successful, but the shunt may become dislodged. Bladder function may still not be optimal, as the fetal bladder is not exposed to cyclic filling and emptying. Open fetal surgery has been performed, but the risks and benefits must be carefully considered (Crombleholme et al., 1988).

Sacroccygeal Teratoma

Sacroccygeal teratoma is a germ cell tumor arising from the coccyx (Fig. 19-9). Prenatal diagnosis is associated with much higher mortality than postnatal diagnosis (Flake, 1993). In utero, the teratoma places the fetus at risk of hydrops and death from high-output heart failure (Bond et al., 1990). Serial echocardiography is used to monitor the cardiac status of the fetus, and ultrasound is used to monitor tumor growth (Tran et al., 2008). The tumor may cause a vascular steal phenomenon, where much of the fetal cardiac output goes to supplying the tumor instead of the fetus. This is evidenced by increased flow in the descending aorta and increased diameter of the fetal inferior vena cava (Hedrick et al., 2004). The tumor may also rupture in utero, resulting in fetal anemia. Treatment may be minimally invasive in select cases of cystic tumors and involves aspiration of the cystic components. Therapy with radiofrequency ablation has not yielded consistent results (Paek et al., 2001; Ibrahim et al., 2003). In certain cases, midgestation debulking of the tumor may be attempted. An EXIT procedure for resection of a massive sacroccygeal teratoma has also been performed. For large tumors, at the very least, a planned cesarean delivery is necessary, with provisions for immediate resection if necessary.

■ FIGURE 19-9. Fetal sacroccygeal teratoma for debulking.

PHYSIOLOGY

Maternal

The physiologic changes of pregnancy are well described and deserve mention, as these changes have an impact on anesthesia management. Although many organ systems are affected, the most relevant are the neurologic, respiratory, cardiovascular, gastrointestinal, and hematologic.

Sensitivity to anesthetic agents increases during pregnancy. Early in gestation, the minimum alveolar concentrations (MACs) for isoflurane and for halothane are approximately 30% lower in pregnant women than in nonpregnant women (Gin and Chan, 1994; Chan et al., 1996). CSF volume decreases, and the epidural venous plexus becomes distended (Kerr et al., 1964). Pregnancy enhances the spread of local anesthetics in the spinal fluid (Hirabayashi et al., 1995b); in the epidural space, the spread of small dosages of local anesthesia is increased, but the spread of large dosages is about the same in pregnant and nonpregnant women (Kalas et al., 1966; Grundy et al., 1978). Increased dermatomal spread of epidural anesthetics is likely to result from increased nerve sensitivity, hormonal changes, reduced protein levels, and pH changes in the CSF (Flanagan et al., 1987; Hirabayashi et al., 1995a; Hirabayashi et al., 1996; Popitz-Bergez et al., 1997).

Plasma cholinesterase activity decreases during pregnancy, but this decrease does not clinically affect the dosing of succinylcholine. Pregnancy also increases sensitivity to nondepolarizing muscle relaxants. Onset time is faster for vecuronium, and recovery time is longer for rocuronium (Baraka et al., 1992; Puhlinger et al., 1997).

Airway management in a pregnant woman is potentially more difficult than in a nonpregnant woman. Capillary engorgement of the airway mucosal tissues has multiple implications. Resultant airway narrowing forces downsizing of endotracheal tubes, and nasal intubation is likely to cause epistaxis. The potential for difficult intubation is increased and airway complications are a significant factor in anesthesia-related morbidity and mortality (Cormack and Lehane, 1984; Samsoun and Young, 1987; Pilkington et al., 1995; Ezri et al., 2001; Ross, 2003; Munnur et al., 2005; Rudra et al., 2006; Goldszmidt, 2008). Respiratory and metabolic changes place the mother at increased risk of hypoxia. Oxygen consumption increases by as much as 60% (Spatling et al., 1992) and functional residual capacity (FRC) begins to decrease in the second trimester, reaching 80% of the nonpregnant volume at term (Alaily and Carrol, 1978). FRC decreases further in the supine position. Tidal volume and minute ventilation increase by 45% at term, and $Paco_2$ decreases to 30 mm Hg by the second trimester (Kelman and Templeton, 1975; Templeton and Kelman, 1976; Alaily and Carrol, 1978). The risk of pulmonary edema increases after open fetal surgery (DiFederico et al., 1998). This increased risk may be secondary to decreased plasma protein concentration, decreased colloid oncotic pressure, or medications used to terminate premature labor, or a combination of these (Mendenhall, 1970; Wu et al., 1983). In addition, surgical manipulation of the uterus and hysterotomy may release factors that increase pulmonary vascular permeability (DiFederico et al., 1998).

Pregnancy is a high cardiac output state. Heart rate and stroke volume increase as early as the first trimester, and at term cardiac output is increased approximately 50% from nonpregnant values (Laird-Meeter et al., 1979; Hunter and Robson,

1992). Cardiac output increases even more during labor and immediately postpartum (Robson et al., 1987). Systemic vascular resistance decreases by about 20% secondary to vasodilation and the addition of the placenta, which is a low-resistance vascular circuit (Clark et al., 1989). Supine hypotension may occur because of compression of the inferior vena cava by the gravid uterus. This compression results in a decrease of right atrial pressure in the supine position (Kerr, 1965). Compression of the aorta is most pronounced in the supine position and becomes negligible in the full lateral position (Eckstein and Marx, 1974). Human studies suggest a reduced response to arterial vasoconstriction by alpha agonists but an increased sensitivity to venous constriction (Nisell et al., 1985). Thus, any pressor response may be more likely to result from increased venous return and increased stroke volume. Plasma volume increases relatively more than red blood cell volume increases, and hemoglobin concentrations decrease in pregnancy.

The pregnant patient is at increased risk for pulmonary aspiration of gastric contents. Hormonal changes and displacement of the stomach with resultant reduction of tone in the lower esophageal high-pressure zone may allow reflux of gastric contents (Ulmsten and Sundstrom, 1978). Intra-gastric pressure is highest in the third trimester. Gastric emptying of solids and liquids is not slowed during pregnancy, but gastric emptying does slow down during labor (Davison et al., 1970; O'Sullivan et al., 1987; Macfie et al., 1991; Sandhar et al., 1992; Whitehead et al., 1993; Chiloiro et al., 2001; Wong et al., 2002). Although gastric acid production has not definitively been shown to be greater in pregnancy, acid aspiration is still a major concern.

The coagulation system is in a state of accelerated but compensated intravascular coagulation. This hypercoagulable state is suggested by an increase in the majority of coagulation factors, a decrease in prothrombin and partial thromboplastin times, and a decrease in antithrombin III. Increased fibrinolysis is suggested by an increase of fibrin degradation products. Particular attention must be paid to prophylaxis for venous thromboembolism, and a high index of suspicion for thromboembolic events must be maintained in a pregnant woman with shortness of breath.

Fetal

Fetal physiology is as complex as maternal physiology. Logistical considerations necessitate some extrapolation from animal studies. Neurologic pathways for cortical transmission of noxious stimuli in humans are still developing into the third trimester (Lee et al., 2005). Fetal sensitivity to volatile anesthetic agents is increased. With both isoflurane and halothane, the anesthesia requirement of fetal lambs is lower than that of a pregnant ewe (Gregory et al., 1983; Bachman et al., 1986). Perception and processing of pain are controversial, but noxious stimuli will elicit a physiologic response in the human fetus, as evidenced by increases in cortisol and β -endorphin, and decreases in the pulsatility index of the fetal middle cerebral artery (Fisk et al., 2001). These physiologic responses are attenuated by administration of fentanyl directly to the fetus. The pharmacokinetics and pharmacodynamics of fentanyl in the fetus remain to be studied.

The cardiopulmonary physiology of the fetus is not dependent on the lungs, because the placenta acts as the organ of respiration. A major role of the lungs in utero is the produc-

tion of amniotic fluid. The lung epithelium actively secretes fluid, which fills the lungs. Excess fluid passes out the trachea and into the oropharynx. This fluid is then either swallowed or expelled into the amniotic space and becomes a component of amniotic fluid. Fluid in the lungs causes distention and allows lung development (Olver and Strang, 1974; Perks and Cassin, 1985; Harding and Hooper, 1996). Restriction of egress of this fluid from the lungs results in pulmonary hyperplasia, whereas continuous drainage results in pulmonary hypoplasia (Alcorn et al., 1977).

The fetal circulation is notable for being a parallel system prior to transitioning to a serial circulation at birth. The ductus venosus allows much of the blood from the umbilical vessels to bypass the liver and go directly to the inferior vena cava. The foramen ovale and ductus arteriosus allow mixing of blood between the left and right heart circulations. Oxygenated blood travels from the umbilical veins into the right atrium and preferentially across the foramen ovale to the left atrium. It then flows to the left ventricle to supply the most oxygen-rich blood to the brain and the preductal circulation. Deoxygenated blood returns from the superior vena cava and preferentially travels to the right ventricle via the right atrium. The majority of blood from the right ventricle travels out the pulmonary artery across the ductus arteriosus to supply the postductal circulation. Enough mixing occurs to supply the necessary oxygen to the lower extremities. Blood travels from the aorta to the iliac arteries to the umbilical arteries and then to the placenta, where oxygenation of this blood occurs.

When the pulmonary and systemic circulations are in a series, as in a normal adult heart, cardiac output can be quantitatively described by either the left or the right ventricular output. Because the fetus has a parallel circulatory system, fetal cardiac output is measured and reported as the sum of both the left and right ventricular output, or combined cardiac output (CCO). Echocardiographic studies have found that a normal human fetus has a CCO of 425 to 550 mL/kg per minute, with the right ventricle contributing 60% to 70% of the total output (De Smedt et al., 1987; Mielke and Benda, 2001; Rychik, 2004). The fetal myocardium has a greater proportion of noncontractile elements and is also stiffer with impaired relaxation compared with adult myocardium (Friedman, 1972; Rychik, 2004). Functioning close to the upper limit of the Starling curve, increases in preload provide only minimal, if any, incremental increases of stroke volume and cardiac output (Gilbert, 1980). Variation in heart rate provides a relatively greater contribution to variation in cardiac output. This lack of response to preload has been attributed to poor compliance of the myocardium, but it may also result from extrinsic compression of the fetal heart that is relieved with aeration of the lungs and clearance of lung fluid (Grant, 1999; Grant et al., 2001).

The blood volume of a fetus varies over gestation. At 16 to 22 weeks, blood volume of the fetoplacental unit has been estimated to be 120 to 162 mL/kg of fetal weight (Morris et al., 1974; Nicolaidis et al., 1987). At 31 weeks, blood volume has been reported as 93 mL/kg of fetal weight (Nicolaidis et al., 1987). It is important to note that about two thirds of the blood volume is contained on the placental side of the fetoplacental unit (Barcroft and Kennedy, 1939; Yao et al., 1969). A 16-week fetus weighs approximately 100 g, at 22 weeks 430 g, and at 31 weeks 1500 g.

Studying hemostasis is challenging because of the rapid evolution of the coagulation system in the fetal and neonatal period. The fetus produces coagulation factors independently of the mother, and these factors do not cross the placenta (Cade et al., 1969). The plasma concentrations of these proteins increase with increasing gestational age (Reverdiau-Moalic et al., 1996). A fetus at 19 to 23 weeks of gestation has a mean prothrombin time (PT) of 32.5 seconds with an International Normalized Ratio (INR) of 6.4 and a mean activated partial thromboplastin time (aPTT) of 168.8 seconds. At 30 to 38 weeks of gestation, mean PT is 22.6 seconds with an INR of 3.0 and an aPTT of 104.8 seconds (Reverdiau-Moalic et al., 1996).

While in utero, fetal temperature is closely linked to maternal variations in temperature. Fetal tissue is more metabolically active than adult tissue, and fetal heat production results in a fetal-to-maternal gradient of 0.5 °C. Excess heat flows from the fetus and is dissipated by the mother. After birth, an increase in heat production is required for homeostasis with the loss of the maternal “heat clamp,” and with new evaporative and convective heat losses. The sympathetic nervous and endocrine systems generally activate and regulate this heat production. Shivering and nonshivering thermogenesis take a primary role in the generation of heat for the newborn (Power et al., 2004). A fetus removed from the uterus during open surgery has a similar need for increased heat production as a newborn, but it cannot increase its production adequately. Both fetal shivering and nonshivering thermogenesis responses are largely absent in utero if the umbilical cord is patent (Gunn et al., 1986). Maintenance of normothermia in a fetus exposed during open fetal surgery can be challenging, with a lack of shivering and nonshivering thermogenesis, immature skin barriers, and increased evaporative losses.

Uteroplacental Blood Flow

The fetus depends on intact uteroplacental blood flow and patent umbilical vessels for respiration and nutrition. Uterine blood flow, a surrogate for fetal oxygen delivery, correlates with fetal umbilical venous P_{O_2} (Skillman et al., 1985; Bilardo et al., 1990). Human uterine blood flow at term is extrapolated to be 700 mL/min (12% of cardiac output), compared with 200 mL/min in the nonpregnant uterus (Thaler et al., 1990).

Uterine blood flow is directly related to uterine perfusion pressure (the difference between uterine arterial pressure and uterine venous pressure) and inversely related to uterine vascular resistance (Box 19-2). Of note for fetal surgical procedures, maternal hypotension, aortocaval compression, and uterine contractions will decrease uterine blood flow. The effect of vasopressors, vasodilators, and anesthetic agents on uterine blood flow is variable because these agents affect uterine arterial pressure and uterine vascular resistance at the same time. Ephedrine has been suggested as the vasopressor of choice in obstetrics, as it may not cause as much uterine arterial vasoconstriction as phenylephrine. Several studies have shown no dramatic clinical differences in neonatal outcome and lend slightly more support to phenylephrine to support maternal blood pressure. When phenylephrine is compared with ephedrine to support blood pressure during cesarean section, newborn pH measurements are statistically but not clinically different (Thomas et al., 1996; Lee et al., 2002; Ngan Kee et al., 2008). Apgar scores are similar. In clinical practice, ephedrine would be a logical choice if the

maternal heart rate were low, whereas phenylephrine could be used if the maternal heart rate were high. Local factors such as nitric oxide are released by the uterine vascular endothelium and modulate the effect of systemically administered vasoactive medications (Weiner et al., 1991).

Neuraxial and general anesthetics have variable effects on uterine blood flow. As long as maternal systemic pressure is maintained, epidural anesthesia does not seem to alter uterine blood flow in elective cesarean sections (Alahuhta et al., 1991). If a neuraxial technique causes significant hypotension, uterine blood flow will be decreased. In sheep models, pain and stress decrease uterine blood flow (Shnider et al., 1979). Relief of pain with an epidural may attenuate this reduction of flow. Barring resultant hypotensive decreases in blood flow, intravenous (IV) induction agents, thiopental, propofol, etomidate, and ketamine do not affect uterine blood flow dramatically. Volatile anesthetics decrease uterine tone and increase risk of bleeding (Cullen et al., 1970). Light and moderate levels of volatile anesthesia slightly depress blood pressure, but uterine vasodilation maintains blood flow. In a sheep model of fetal surgery, with deeper levels of volatile anesthesia, uterine vasodilation cannot compensate for the reductions in maternal blood pressure and cardiac output, and fetal acidosis occurs (Palahniuk and Shnider, 1974). It is important to note, however, that no medications were given to the pregnant ewes to support their blood pressure while undergoing general anesthesia with high dosages of volatile agent.

Although the studies are not entirely in agreement, maternal hypocapnia, with or without the mechanical effect of hyperventilation with positive pressure, is likely to decrease uterine blood flow, placental–umbilical blood flow, and fetal oxygenation in sheep, monkey, and human studies. In contrast, maternal hypercapnia is associated with an increase in fetal oxygenation and may be beneficial during labor and delivery (Motoyama et al., 1966, 1967; James, 1967; Rivard et al., 1967; Parer et al., 1970; Peng et al., 1972; Levinson et al., 1974).

Simple mechanical factors are important in the maintenance of uteroplacental perfusion and fetal oxygen delivery. Kinking or compression of the umbilical cord, either from loss of amniotic fluid volume or from surgical manipulation of the fetus, will cause a rapid deterioration in the condition of the fetus. Likewise, integrity of the uteroplacental interface must also be maintained. Separation of the placenta from the uterus results in catastrophic decreases in fetal perfusion.

Placental Anatomy and Transport

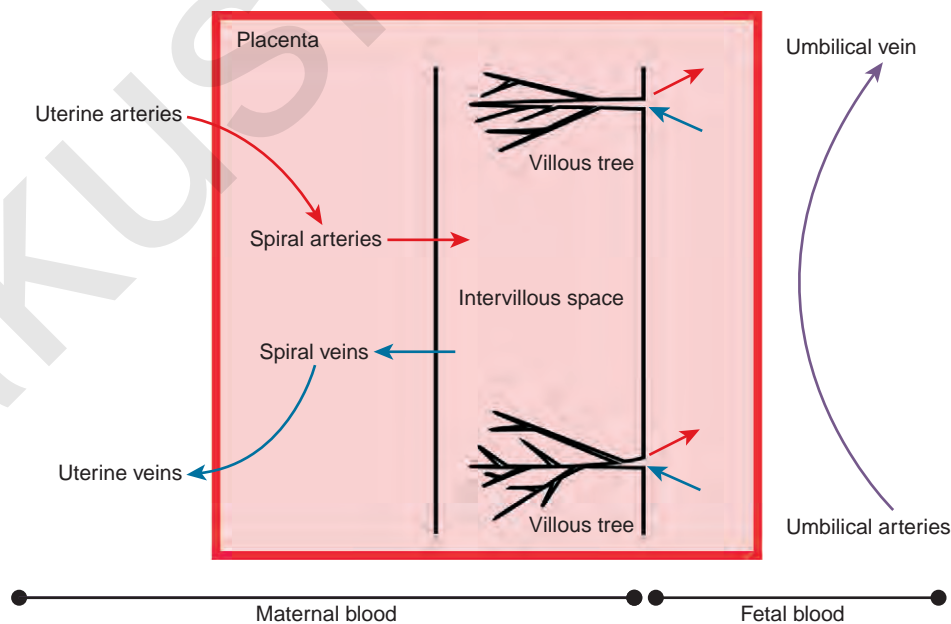

Maternal spiral arteries arise from the uterus and deposit oxygenated blood and nutrients into the intervillous space. The space is a cavernous expanse, into which the villous trees from the fetal circulation extend. The intervillous space contains maternal blood and is bounded on the maternal side by the basal plate, and on the fetal side by the chorionic plate. The villous trees and terminal villi contain the terminal umbilical arterioles and capillaries that arise from the umbilical arteries and transport the deoxygenated blood and waste products from the fetus for exchange in the intervillous space. These vessels return blood to the fetus via the umbilical veins (Fig. 19-10).

In maternal and fetal blood, the difference in partial pressures of oxygen drives oxygen across the placenta and into the fetal circulation. Fetal hemoglobin has a higher affinity for oxygen than maternal hemoglobin, and this affinity may also help with oxygen transport. Normal newborn umbilical arterial P_{O_2} is 17 mm Hg, and umbilical venous P_{O_2} is 29 mm Hg (Helwig et al., 1996). At term, fetal oxygen consumption is 6.8 ± 1.4 mL/kg per minute (Bonds et al., 1986). Fetal oxygen saturation has been shown to be 60% to 70% in term human fetuses (measured by scalp oximetry) and in fetal sheep (Johnson et al., 1991; Luks et al., 1998). Glucose is transported to the fetus by facilitated diffusion (Rice et al., 1979; Challier et al., 1985).

Passage of drugs across the placenta is influenced by size, lipid solubility, protein binding pKa, pH of fetal blood, and blood flow. Increased lipid solubility allows rapid transfer, but it may also result in trapping of the drug in the placenta. Drugs such as local anesthetics and opioids with higher acid dissociation constants may be trapped in ionized form in the fetal circulation if the fetal pH is lower than the drug's pKa. Protein binding has a variable effect, depending on the particular drug and protein combination.

Although the newer volatile anesthetics have not been studied as thoroughly as halothane and isoflurane, the low molecular weight and lipid insolubility of these medications should allow rapid transfer with relatively high fetal-to-maternal (F/M) ratios. A higher F/M ratio indicates that more of the agent in question is found in the fetal blood than in the maternal blood. Most human in vivo studies have been performed in patients undergoing elective termination of pregnancy or elective cesarean section. Isoflurane has an F/M ratio of 0.7 (Biehl et al., 1983b; Kangas et al., 1976; Dwyer et al., 1995), whereas the F/M ratio of desflurane is reported to be 0.5 (Schwarz et al., 2003). Cautious extension of the findings with halothane and isoflurane to desflurane and sevoflurane is reasonable (Fig. 19-11). After 3 minutes, nitrous oxide has an F/M ratio of 0.83 (Polvi et al., 1996).

Thiopental crosses rapidly into the fetal circulation, but F/M ratios range widely, between 0.4 and 1.1 (Levy and Owen, 1964; Finster et al., 1966). Propofol has been studied at term after bolus administration, with and without infusions. F/M ratios range between 0.5 and 0.85 (Dailland et al., 1989; Valtonen et al., 1989; Gin et al., 1990; Gregory et al., 1990). If used only for induction of general anesthesia for open fetal surgery, differences between propofol and thiopental are not likely to be clinically significant. Propofol infusions may be used for maternal sedation in early pregnancy for minimally invasive cases. In women between 12 and 18 weeks of gestation, the F/M ratio was 0.5 and was independent of time between 5 and 20 minutes of infusion (Jauniaux et al., 1998). Diazepam is a commonly used drug for maternal and fetal sedation; within minutes of injection, the F/M ratio approaches unity and ratios approach 2.0 after an hour (Erkkola et al., 1973; Mandelli et al., 1975). Although midazolam has a lower F/M ratio of 0.76, at term it is still frequently used as a sedative in noninvasive surgery (Wilson et al., 1987). No studies have shown any teratogenic relationship between oral clefts and benzodiazepines given in pregnancy (Koren et al., 1998). Morphine is hydrophilic, and

■ **FIGURE 19-10.** Diagram of placental circulation. The arrows demonstrate blood flow, and the colors signify relative levels of oxygenation. The villous trees contain umbilical arterioles and capillaries with fetal blood. These trees extend and branch into the intervillous space and form the interface for exchange of nutrients and waste between maternal and fetal blood.

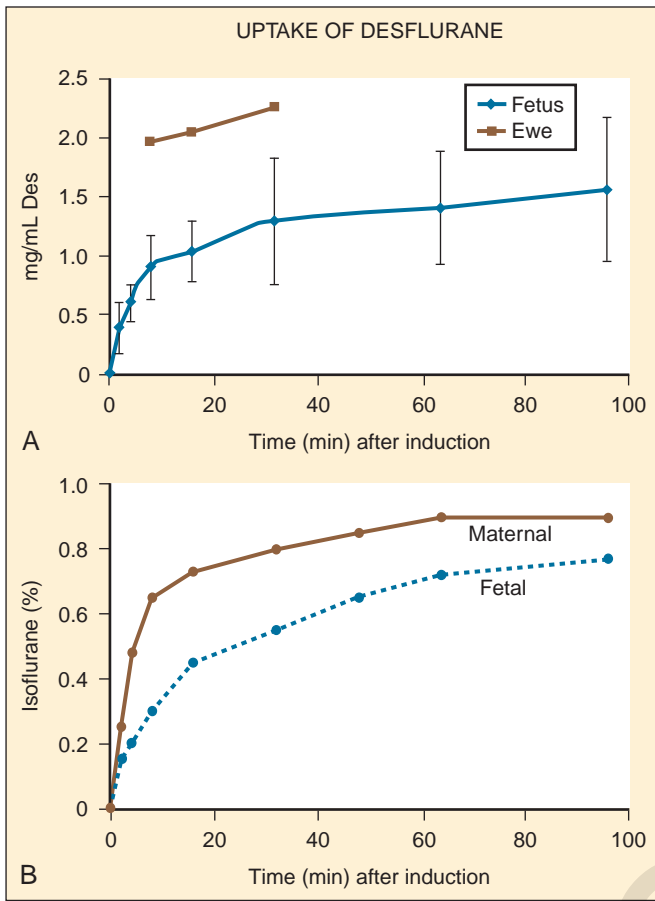

FIGURE 19-11. Comparison of fetal and maternal levels of volatile anesthetic agents in sheep models. **A**, Desflurane (From Schwarz U, Galinkin JL, Biard JM, et al: *The uptake of desflurane in fetal sheep preliminary results. Presented at the Annual Meeting of the Society for Pediatric Anesthesiology, Fort Myers, FL, Feb 20–23, 2003*). **B**, Isoflurane (From Biehl DR, Tweed WA, Cote J, et al: *Effect of halothane on cardiac output and regional flow in the fetal lamb in utero, Anesth Analg 62:489, 1983*).

also quite commonly used for maternal and fetal analgesia and sedation. Intramuscular maternal administration of morphine (0.12 to 0.19 mg/kg) decreases fetal breathing movement; however, fetal tone and gross movement are not as affected by morphine, and the F/M ratio is 0.61 (Kopecky et al., 2000). In early gestation, fentanyl is detectable in fetal brain tissue between 10 and 30 minutes after maternal administration (Cooper et al., 1999). The F/M ratio of fentanyl varied from 0.16 to 1.2 in a small study of maternal IV administration (Shannon et al., 1998). Remifentanyl, a short-acting potent opioid, is finding some use in both obstetric anesthesia and anesthesia for fetal surgery. With remifentanyl infusions at term for cesarean section, umbilical vein to maternal artery ratio was 0.88, and umbilical artery to umbilical vein ratio was 0.29 (Kan et al., 1998). Succinylcholine in large (300 mg) or repeated doses crosses the placenta and affects the fetus. Nondepolarizing muscle relaxants and anticholinesterase agents are large, ionized molecules that do not easily cross the placenta. Vecuronium F/M ratios are 0.06 to 0.11 (Dailey et al., 1984; Iwama et al., 1999). Rocuronium has been used in mothers undergoing cesarean section with no adverse effects (Abouleish et al., 1994; Baraka et al., 1997). Atropine readily crosses the placenta, as opposed to glycopyrrolate, which has a mean F/M ratio of 0.22. A case of fetal brady-

TABLE 19-2. Documented Fetal-to-Maternal Ratios of Medications Administered to the Mother

Drug	Fetal-to-Maternal Ratio

Ephedrine	0.7

cardia has been attributed to placental passage of neostigmine (Clark et al., 1996). Ephedrine crosses the placenta readily, with an F/M ratio of 0.7 (Hughes et al., 1985) (Table 19-2).

SURGICAL ISSUES

Minimally Invasive Interventions

Minimally invasive interventions are the most frequently performed fetal surgical procedures. The uterine cavity is accessed percutaneously with needles and small sheaths. Visualization of structures is provided by ultrasound guidance or fetoscopes inserted through the sheaths. Because minimally invasive techniques allow a wide range of therapeutic options via a wide range of operative techniques, a clear understanding of the surgical plan helps to shape the anesthesia plan. Placental vessels allowing unequal blood flow between monochorionic twins (twin-twin transfusion syndrome) may be ablated with lasers (Lewi et al., 2005; Habli et al., 2008). The umbilical cord of an acephalic acardiac twin mass (twin reversed arterial perfusion sequence) can be coagulated with radiofrequency to prevent harm to the normal twin (Tan and Sepulveda, 2003). With ultrasound guidance, fetal thoracoamniotic shunts can be placed to allow drainage of fluid from cystic lung lesions into the amniotic fluid (Adzick and Kitano, 1993). Tracheal occlusion can be performed to prevent egress of lung fluid, and this may attenuate the lung hypoplasia that results from congenital diaphragmatic hernia (Peralta et al., 2008). The efficacy of tracheal occlusion continues to be studied. Fetal cardiac catheterization and intervention may allow fetuses with evolving hypoplastic left heart syndrome to develop two ventricle circulations (Towretzky and Marshall, 2003). Vesicoamniotic shunts have been placed in the bladders of fetuses with lower urinary tract obstruction to relieve hydronephrosis and hydronephrosis and perhaps allow improved bladder function (Crombleholme et al., 1990). Attempted treatment of fetal sacrococcygeal teratomas with radiofrequency ablation has been associated with

too much morbidity at this time (Paek et al., 2001; Ibrahim et al., 2003). Techniques for endoscopic closure of fetal MMC also continue to be refined (Fichter et al., 2008).

Because of the wide range of therapeutic options, the requirements for surgical access to the fetus are also quite varied. The access may be as minimal as one small-gauge radiofrequency probe or may be as involved as multiple trocars for a robot-assisted MMC repair. Endoscopes range from 1.0 to 3.8 mm in external diameter (Klaritsch et al., 2009). The timing of these procedures is typically in early or middle gestation. However, given the varied pathophysiology of the disease processes to be treated and the varied nature of these interventions, it is possible that minimally invasive interventions may be done at any time in gestation. Tracheal balloons placed at around 26 weeks gestation to obstruct the egress of lung fluid are removed in late gestation before delivery (Deprest et al., 2005).

Open Midgestation Surgery

Open fetal surgery has been performed to relieve bladder outlet obstruction, repair congenital diaphragmatic hernia, resect lung lesions causing significant mass effect and hydrops, debulk sacrococcygeal teratomas, and close MMCs (Crombleholme et al., 1988; Harrison et al., 1997; Adzick et al., 2003; Hedrick et al., 2004; Fichter et al., 2008). Presently, open midgestation surgery is largely reserved for closure of MMC and resection of lung lesions causing hydrops. Open treatment for bladder outlet obstruction is also being performed at some institutions. Treatment of MMC in utero is currently restricted to patients enrolled in the NIH-sponsored Management of Myelomeningocele Study (MOMS trial).

After induction of anesthesia, a maternal laparotomy is performed. The location of this incision is transverse, but more cephalad than that performed for a low-segment transverse cesarean section, to allow easier access to the uterus and fetus. Once the uterus is exposed, the placental edges are mapped carefully with sterile ultrasound to plan for an appropriate hysterotomy. Implantation of the placenta on the anterior or posterior aspect of the uterus will influence the surgical approach, and an anterior placenta may necessitate exteriorization of the uterus for a posterior hysterotomy. Special uterine stapling devices are used to minimize blood loss (Bond et al., 1989). The fetus is exposed, but only the necessary anatomy is delivered via the hysterotomy. For example, in an MMC closure, the lesion is exposed while the rest of the fetus remains bathed in amniotic fluid in the uterus. If a fetal thoracotomy is planned, an arm is delivered, and the shoulder and chest are exposed while the rest of the fetus remains in the uterus (see Fig. 19-6). After surgery and skin closure, the fetus is placed back into the uterus, warmed crystalloid is infused to restore amniotic volume, and intrauterine antibiotics are given. The uterus is closed and a patch of omentum is sewn over a two-layer uterine closure to further prevent amniotic fluid leakage.

EXIT Procedure

The EXIT procedure is similar in approach to an open midgestation procedure, but with several key differences. Because the fetus will be delivered at the end of the case, these procedures are performed at or near term to optimize fetal lung maturity.

Before the umbilical cord is clamped, surgical intervention is performed that will allow successful transition to extrauterine life (Mychaliska et al., 1997). This intervention may involve laryngoscopy, rigid bronchoscopy, and intubation, or it may involve resection of airway tumors or tracheostomy (Liechty et al., 1997; Bouchard et al., 2002; Rahbar et al., 2005). Pulmonary pathology necessitating an EXIT procedure includes large lung lesions that would make neonatal resuscitation difficult because of mediastinal shift, air trapping, or compression of the normal lung (Hedrick et al., 2005). After completion of the procedure, the umbilical cord is clamped and cut. The newborn is taken to a team headed by a neonatologist for further neonatal resuscitation and management in an intensive care unit.

It is important to note that in these cases, no ventilation of the lungs can occur until after the fetal skin is closed and the umbilical cord is ready to be clamped. Ventilation of the lungs will initiate the cascade of events leading to a transitional neonatal circulation, and the benefits of operating on placental support are lost.

ANESTHETIC PLAN

Teamwork and Communication

Participation in fetal surgical cases is truly an exercise in teamwork and communication. The disciplines that may interact can include, but are not limited to, pediatric general surgery, pediatric otolaryngology, obstetrics, pediatric anesthesia, obstetric anesthesia, cardiology, radiology, neonatology, neonatal nursing, and operating room nursing. Weekly meetings are necessary to keep team members apprised of the new patients and new developments or progress of existing patients. Before any open surgical procedure, a multidisciplinary team meeting is held with the family in attendance to introduce the team members, discuss the details of the procedure, and address any concerns from any of the involved parties. Minimally invasive procedures also necessitate discussion to delineate special requirements, equipment, and issues.

Preoperative Preparation

The maternal preoperative preparation begins with the standard anesthetic history and physical, including a history of problems with anesthesia or difficult intubation. Specific questions for the mother would evaluate respiratory or circulatory compromise by the gravid uterus, as evidenced by symptoms of shortness of breath or lightheadedness. More-severe symptoms of aortocaval compression would call for meticulous left uterine displacement and would raise the level of suspicion in a mother with persistent hypotension after induction of anesthesia. Severity of gastroesophageal reflux may change the anesthesia plan in minimally invasive cases when maternal sedation is often considered. Examination of the airway and spine is particularly important. Maternal imaging and blood work will be guided by the history and physical examination. A blood type and screen is reasonable for most minimally invasive fetoscopic cases, but open cases should not proceed without cross-matched blood for the mother and type O, Rh-negative blood for the fetus immediately available. Maternal antibodies to blood antigens can cross the placenta, and the O negative blood for the fetus

can be cross-matched with the maternal blood sample. A preoperative chest radiograph may be obtained if indicated.

More specific questions about the fetus are also necessary. Location of the placenta may alter surgical approach. The estimated fetal weight by ultrasound is used to determine dosage of drugs given directly to the fetus. The actual disease process and pathophysiology, and the extent of anatomic or physiologic derangement will give the providers an idea of the physiologic reserve of the fetus. Fetal studies to elucidate the lesion and extent of physiologic derangements include ultrasound, echocardiography, and fetal magnetic resonance imaging. Serial studies track the physiologic changes occurring in the fetuses. Lung lesions may grow or shrink, airway compression may worsen or resolve, combined cardiac outputs may change, hydrops fetalis may ensue, and polyhydramnios may develop at any time.

Aspiration prophylaxis in the obstetric population may include oral sodium citrate, histamine receptor blockers or proton pump inhibitors, and prokinetic agents such as metoclopramide.

Minimally Invasive Procedures

Because these cases are the most variable in terms of degree of invasiveness, need for maternal analgesia and anesthesia, and need for fetal analgesia or immobility, communication and understanding of needs of the case are vital. An anesthesia plan can range from local anesthetic infiltration to sedation to neuraxial technique to general anesthesia. Medications can be given directly to the mother by the anesthesia team and thus indirectly to the fetus by placental transfer (Van de Velde et al., 2005). Medications can also be given directly to the fetus by the surgical team. Route of direct administration can be variable, and intramuscular, IV, and intracardiac routes have been described (Fisk et al., 2001; Deprest et al., 2005; Mizrahi-Arnaud et al., 2007). Sheep models of intraamniotic opioid instillation have also been reported (Strumper et al., 2003). Maternal analgesia can often be accomplished with local anesthetic infiltration, whereas in other cases a neuraxial technique or general anesthesia may be necessary.

As instrumentation for treatment of twin-twin transfusion syndrome has shrunk and invasiveness has decreased, anesthesia techniques at some institutions have similarly changed. Initially, procedures were performed with general or neuraxial anesthesia techniques, but these procedures are now done with sedation. Routine use of magnesium sulfate tocolysis and severe IV fluid restriction are no longer needed. Pulmonary edema has been reported after fetoscopic surgery, but this was more likely the result of absorption of irrigation fluids through venous channels in the myometrium than a capillary leak phenomenon (Robinson et al., 2008). As surgical techniques vary, fluid restriction may be necessary, as well as close observation of irrigation fluids used during these cases.

At some institutions, the current practice for laser ablation of placental vessels includes maternal fasting, placement of one IV catheter, aspiration prophylaxis, and tocolysis with preoperative indomethacin. Light sedation and analgesia are administered to the mother to provide maternal comfort and decreased fetal movement to make the surgical procedure easier. Multiple regimens for sedation have been used successfully,

including combinations of opioids and other sedatives such as benzodiazepines or propofol. In a randomized double-blind trial comparing diazepam and remifentanyl for fetal immobilization in minimally invasive surgery, the remifentanyl group (0.1 mcg/kg per minute) had significantly less fetal movement and surgeons reported better operating conditions (Van de Velde et al., 2005). The degree of maternal sedation needed often competes with the need to avoid paradoxical chest and abdominal breathing motions that make the surgical procedure impossible.

In contrast to the anesthesia for laser ablation of placental vessels, providing anesthesia for balloon dilation of fetal aortic stenosis involves maternal general endotracheal anesthesia and intramuscular administration of fentanyl, vecuronium, and atropine to the fetus (Tworetzky and Marshall, 2003). The potential risks of administration of general anesthesia in a pregnant woman are outweighed by the need for a completely immobile mother and fetus, along with the potential need for fetal analgesia as the catheters and needles are advanced through the fetal chest wall and heart. These different techniques for minimally invasive surgery illustrate the need for collaboration between the teams to prioritize needs and balance risks and benefits to arrive at an optimal anesthesia plan.

The location of the placenta plays an important role in determining the surgical approach. The approach selected needs to avoid trespass of the placenta with the instruments; careful mapping of the placenta with sterile intraoperative ultrasound guides safe instrument trajectories. If the placenta is implanted on the anterior surface of the uterus, trocars and curved instruments are inserted in the lateral aspect of the uterus if possible, or a laparotomy is made, the uterus exteriorized, and the instruments passed through the posterior aspect of the uterus. If instruments are to be introduced laterally, positioning the mother may involve “bumps” for left or right uterine displacement, or even placing the mother in full lateral decubitus position. It is conceivable that some approaches may preclude effective uterine displacement, and in these cases, the anesthesia and surgical teams must have a flexible plan if supine hypotension from aortocaval compression is clinically significant.

As with any minimally invasive procedure, the possibility of conversion to an open procedure exists. Conversion to an open procedure would probably involve a maternal laparotomy for exteriorization of the uterus, or for an exceedingly unlikely maternal hysterectomy for maternal hemorrhage. The fetus may also be manipulated more readily in cases of fetal cardiac catheterization. Strategies must be in place for failed procedures or fetal distress. These plans will depend on the gestational age of the fetuses, their projected viability, and preoperative discussion with the family. Plans may range from supportive or palliative therapy to emergent cesarean delivery.

Fetal monitoring is typically limited to measurement of the fetal heart rate by the obstetricians using ultrasound. Echocardiography may be used in cardiac interventions. Minimally invasive cases usually do not require the intense uterine relaxation required in open cases. Initial tocolytic regimens involved combinations of preoperative indomethacin with postoperative magnesium infusions and post-discharge oral nifedipine or subcutaneous terbutaline. Obstetricians are present for minimally invasive procedures, whereas both obstetricians and pediatric surgeons are present for open procedures. Post-discharge tocolytic requirement is rare.

Open Midgestation Procedures

Open midgestation surgery requires significant uterine relaxation. General endotracheal anesthesia with deep inhalational anesthesia (twice the minimum alveolar concentration) is most often used to achieve the necessary uterine relaxation for open surgery. Desflurane is the agent chosen at some institutions because its low solubility allows for timely emergence from deep levels of anesthesia, but isoflurane has also been used successfully. Nitroglycerin boluses can be used to further relax the uterus if sufficient relaxation cannot be achieved (Clark et al., 2004; George et al., 2007). Uterine relaxation allows easier fetal manipulation and decreases the likelihood of initiation of labor from uterine surgical manipulation. Uterine relaxation may allow increased uterine blood flow as long as maternal blood pressure is maintained, and it results in fetal exposure to some volatile anesthetic agents. The mother is at risk for hypotension both from the anesthetic agents and from aortocaval compression. With careful patient positioning and judicious use of vasopressors, a goal of systemic blood pressure within 10% of normal blood pressure should be achievable.

After fasting, placement of a peripheral IV catheter, and aspiration prophylaxis, a high lumbar epidural catheter is placed for postoperative analgesia. A test dose of local anesthetic is given, but a standard epidural dose is not given if volatile anesthesia is to be used. Oral tocolysis with indomethacin is also given. Standard monitors are placed, the mother is placed supine with left uterine displacement, and she is preoxygenated. After rapid-sequence induction of general anesthesia, she is intubated, and an orogastric tube and a Foley catheter are placed. Ventilation should maintain normocapnia. Hypocapnia should be avoided to prevent umbilical vasoconstriction and fetal hypoxia, but hypercapnia may be beneficial (Motoyama et al., 1966; Peng et al., 1972). Because of the risk for rapid bleeding and hemodynamic instability, a second large-bore peripheral IV line is placed, as well as an arterial catheter. Small changes in maternal blood pressure may have dramatic effects on the fetal oxygen saturation and heart rate and function. Swings in blood pressure are likely to be exacerbated by the restrictive administration of fluids and frequent use of vasopressors. Intravenous crystalloid administration is kept to a minimum because of the risk of maternal pulmonary edema after fetal surgery (DiFederico et al., 1998). Administration of 500 mL of crystalloid is typical. Restricting fluid administration may be more of an issue when nitroglycerin is used more liberally. Clinically, the maternal blood pressure improves with exteriorization of the uterus and with surgical manipulation. Phenylephrine and ephedrine should be prepared for use. Infusions of phenylephrine allow smoother blood pressure control and may allow more rigorous control of crystalloid administration. The anesthesia literature is still exploring the relative advantages and disadvantages of phenylephrine and ephedrine in the obstetric population, but no specific data exist to guide the choices in fetal surgery. Central venous pressure measurement has guided fluid therapy in the past but has not been used recently because it is very restrictive (500 cc), and hypotension is treated with either vasopressors or transfusion if bleeding is noted. Low central venous pressure would probably not trigger much change in fluid management.

When the uterus is exposed, some time is taken for mapping of the placenta to optimize the surgical approach. After hysterotomy and exposure of the fetus, an intramuscular injection

of fentanyl (20 mcg/kg), atropine (20 mcg/kg), and vecuronium (0.2 mg/kg) is given by the surgical team. Amniotic fluid is lost through the hysterotomy, but it is replaced with a continuous pressurized infusion of warmed lactated Ringer's solution. If fetal IV access is deemed necessary, it is obtained at this time, and sterile IV tubing is handed over the surgical drapes to the anesthesia team. Monitoring of the fetus in these cases may include fetal heart rate by ultrasound, fetal echocardiography, and pulse oximetry (Fig. 19-12) (Luks et al., 1998; Keswani et al., 2005) in addition to direct fetal observation. The sterile pulse oximeter is placed by the surgical team, the hand is covered with sterile foil to prevent artifact from the operating room lights, and a sterile cable is passed to the anesthesia team over the surgical drapes. Values for fetal oxygen saturation range from 40% to 70% (Johnson et al., 1991; Helwig et al., 1996). Fetal echocardiography may be intermittent or continuous depending on the nature of the surgery. Cardiac filling, contractility, and rate, along with patency of the ductus arteriosus are helpful in intraoperative management of the fetus. Umbilical blood gas measurement may be used in select cases, although cord injury is a risk. Drugs may be given to the fetus intravenously or intramuscularly.

The anesthesia team must watch closely for fetal bradycardia, maternal or fetal bleeding, and maternal blood pressure changes. Careful observation and understanding of the events occurring in the surgical field are important. Maternal bleeding when the uterus is opened is often difficult to appreciate. A decrease in fetal oxygen saturation seems to be the most sensitive indicator of fetal distress (Luks et al., 1998). In the absence of a decrease in fetal oxygen saturation, the most common sign of fetal distress is bradycardia. Blood products should be readily available during this time. Prior to the resection of large chest lesions, a 10- to 20-mg/kg fluid bolus (usually packed red blood cells) to the fetus maintains fetal hemodynamic stability by preserving cardiac output when large shifts in mediastinal anatomy occur during the resection. With closure of the uterus, tocolysis is begun with a bolus of IV magnesium sulfate, the epidural block is initiated, and the volatile anesthetic is reduced. The maternal abdomen is closed, and the mother is extubated awake. Postoperative tocolysis continues with a magnesium infusion that is later transitioned to oral nifedipine.

■ **FIGURE 19-12.** A pulse oximeter placed on the fetal hand during open surgery. This probe is covered by foil to prevent artifact from the surgical lights.

EXIT Procedure

Several key differences for the EXIT procedure result from the fact that the fetus is to be delivered at the conclusion of the case. Because magnesium tocolysis is no longer needed, pulmonary edema is less of a problem, so fluid management can be more generous. Another difference is the need for two operating rooms and a resuscitation area for the neonatal team. Although general endotracheal anesthesia is often used to provide high-dosage volatile anesthetics and is the technique of choice at some institutions, adequate uterine relaxation with nitroglycerin infusion is possible. Several reports have described neuraxial techniques for the EXIT procedure in conjunction with infusions of nitroglycerin (Clark et al., 2004; George et al., 2007).

After the patient has been adequately anesthetized, the surgical team passes sterile items off the field for the anesthesia team. These may include tubing for IV fluids, pulse oximeter cables, and oxygen tubing for a sterile Mapleson D circuit. Keeping fetal IV fluids and medication separate from maternal fluids and drugs is important to avoid confusion, especially in emergent or urgent parts of the procedure. Fetal well-being is monitored with pulse oximetry, heart rate, and possibly echocardiography. After maternal laparotomy, placental mapping, and hysterotomy, the fetus is externalized as little as possible to permit a surgical approach to the lesion while promoting placental circulation through the umbilical vessels. Once the airway is secured or the lesion resected, surfactant is aerosolized to the fetus and the lungs are ventilated. As mentioned previously, it is crucial that no ventilation take place until the umbilical cord is ready to be divided. Increases in oxygen saturation, the presence of end-tidal CO_2 , and good chest movement are indicators of successful intubation. Fiberoptic bronchoscopy can also be used as confirmation. The baby is delivered for care by neonatologists.

Once the umbilical cord is cut and the placenta is delivered, uterine relaxation must be promptly reversed. Administration of oxytocin and rapidly decreasing the inspired concentration of volatile anesthetic is adequate in most cases, but methylergonovine and prostaglandin $\text{F}_{2\alpha}$ should be readily available. After uterine tone is established, the hysterotomy is closed. Epidural anesthesia is given after maternal hemodynamic stability is ensured, and the mother is extubated awake.

Additional considerations for the EXIT procedure include the presence of a neonatal resuscitation team and a second operating room team with separate anesthesia and surgical teams. The neonatal team receives the newborn if the EXIT is technically successful, and the operating room team is prepared to take the newborn and complete the surgery when the EXIT procedure is not successful. The neonatal team may receive the newborn in a variety of states, but always with a stable airway—either intubated or with a tracheostomy. If the fetus does not tolerate the procedure well, the umbilical cord must be cut, and the newborn taken immediately to the second operating room for further resuscitation and completion of the surgery if possible. The second anesthesia team must be immediately ready to receive a newborn in extremis. The airway may not be controlled, ventilation may not have been established, IV access may be lacking, and the newborn may be actively bleeding. The second operating room should also have a second set of nurses. The surgical team may easily be divided between two rooms, as the maternal operating room is staffed with obstetricians and pediatric surgeons. If the newborn is taken to the second room,

the obstetric team stays with the mother to control bleeding and close her uterus and abdomen, while the pediatric surgical team follows the newborn.

Because of the multiple teams that must be ready for multiple clinical pathways during an EXIT procedure, communication is important. The maternal room should have blood available for mother and fetus, but all parties should know how much blood is available for the fetus and where that blood is located. The blood for the fetus may be transfused while on placental support, after cord clamp while under care of the neonatal team, or after cord clamp while under care of the anesthesia team. All teams should have appropriate emergency resuscitation equipment and medications.

Intraoperative Fetal Resuscitation

Fetal distress may occur during any surgical procedure. Bradycardia or hypoxia may result from cord compression or kinking, placental separation, high uterine tone, maternal hypotension, hypoxia, or anemia. Fetal hypothermia, hypovolemia and anemia are also potential causes of fetal distress. Cardiac dysfunction may also result from prolonged exposure to high dosages of volatile anesthetic agents. As with any change in vital signs, the cause of the derangement must be sought as soon as possible.

The well-being and hemodynamic stability of the mother should be ensured. The umbilical cord must be patent, aortic compression should be avoided, and the integrity of the uteroplacental unit must also be confirmed. Placental abruption can be catastrophic if unnoticed. Signs of separation would include excessive, unexplained blood in the amniotic fluid; unexplained, new-onset maternal hypotension or anemia; fetal oxygen desaturation; or fetal bradycardia. Ultrasound can be used to confirm the diagnosis. Direct observation of the fetus can also assist with these diagnoses. The surgical team should be able to confirm adequate uterine relaxation, and fetal echocardiography will inform the team about cardiac filling and function, and patency of the ductus arteriosus.

Measures to resuscitate the fetus depend on how much access the surgical and anesthesia teams have to the fetus, and they range from simple measures, such as ensuring left uterine displacement or administration of maternal vasopressors, to more advanced measures, including administration of medications or blood directly to the fetus. In open cases, emergency medications such as atropine and epinephrine are given sterilely to the surgical team. Medications may be given via the intramuscular, IV, or even intracardiac route.

Pain and the Fetus

Controversy surrounds our understanding of the experience of pain by the fetus (Wise, 1997; Glover and Fisk, 1999; Lee et al., 2005; Lowery et al., 2007). Impeded by our inability to critically study human fetal physiology and neural development, a variety of contradictions drawn from available animal and human sources obfuscate our knowledge of this area. At what point, if ever, a fetus “feels” or experiences pain is unknown. The functional neurodevelopment of pain pathways in several experimental animal models is well described, although the exact correlation to human development and experience is

unclear (Fitzgerald and Walker, 2009). Even less understood is the experience of pain. Some animal data imply that the fetus is unaware until birth; other data question the need for cortical function in the experience of pain (Mellor et al., 2005). Just as confusing is the relationship between pain and stress. A fetus in the second trimester can mount a stress response to a stimulus that is blocked by the administration of analgesics to the fetus; yet how this phenomenon relates to pain is unclear, especially because a similar stress response can be noted in an adult under deep anesthesia (Giannakoulopoulos et al., 1994; Teixeira et al., 1999; Fisk et al., 2001; Gruber et al., 2001; Baldini et al., 2008). The late effects of this stress response are worrisome, although these effects are as ambiguous and unsettled. Also ambiguous are the possible deleterious effects on the developing nervous system from the medications used to block this response and provide analgesia and anesthesia to the fetus (Jevtovic-Todorovic et al., 2003). In animal models, opioids have also been associated with adverse hemodynamic changes in fetuses (Sedgwick et al., 2005; Mizrahi-Arnaud et al., 2007). Finally, the significant risks to the mother when using her as a conduit to deliver medications to the fetus have to be considered (Golombeck et al., 2006). With the lack of clarity in this area, continued observation, research, and questioning are of paramount importance for the anesthesiologist caring for both mother and fetus.

Currently, transplacental administration of medications for fetal surgery is the norm. Procedures are performed either with maternal general anesthesia or with local anesthesia with maternal systemic anxiolysis and analgesia. Halothane and probably the other volatile anesthetics are transferred to the fetus through the placenta (Dwyer et al., 1995). Opioids and sedatives similarly pass through the placenta to the fetus (Bakke and Haram, 1982; Kan et al., 1998). Open procedures are often supplemented with IV or intramuscular analgesics, neuromuscular blockers, and anticholinergics. Until microsampling and microanalysis techniques are improved and long-term outcome studies are executed, the anesthesiologist will need to strive to provide the best possible conditions for the surgeon while subjecting the mother and fetus to as little risk or harm as possible.

SUMMARY

Fetal surgery is an exciting area for innovation and growth in medicine. The trends toward minimally invasive surgery are mirrored in the field of fetal surgery. Decreasing invasiveness is likely to mean decreased anesthesia and surgical risk, and this may allow an expansion of maternal eligibility criteria for fetal interventions. With decreasing invasiveness comes decreasing maternal risk of bleeding. A hysterotomy mandates a cesarean delivery for all subsequent pregnancies because of the risk of uterine rupture, but the use of needles and sheaths will allow for normal vaginal deliveries. Open fetal surgery is admittedly an undertaking that is intensive in its use of medical resources, and we can hope that decreasing invasiveness will allow more equitable distribution of limited resources. With improving therapy, neonatal care may be simplified, stays shortened, and outcomes improved.

More outcome studies are needed, as well as further studies to refine anesthesia techniques and methods. Some institutions are exploring the use of IV anesthesia to minimize fetal exposure to high-dosage volatile agents during portions of the case that do not require intense uterine relaxation (Boat, 2008). Research in this field is limited by practical, medicolegal, and ethical considerations, and the number of these cases is small in comparison with other fields. Protection of vulnerable populations such as pregnant mothers and fetuses is important, but these protections will limit flexibility in study design. Most anesthesia studies in this area are, however, still in the descriptive, hypothesis-generating stages, as compared with rigorous hypothesis testing. Many questions remain to be answered, and much progress remains to be made.

Summary 673

This chapter describes the perioperative management of major forms of congenital heart disease (CHD) that require surgery with the use of cardiopulmonary bypass. Congenital cardiac lesions that are primarily addressed in the catheterization laboratory or without CPB are discussed in Chapter 21, Congenital Cardiac Anesthesia: Non-Bypass Procedures.

Congenital anomalies of the heart and cardiovascular system occur in 7 to 10 per 1000 live births. Congenital heart disease is the most common congenital disease, accounting for approximately 30% of all congenital diseases. CHD has become the principal cause of pediatric heart disease as the incidence of rheumatic heart disease has declined. Ten percent to 15% of children with CHD have associated congenital anomalies of the skeletal, genitourinary, or gastrointestinal system. The U.S. population of adults with CHD, surgically corrected or uncorrected, is estimated to exceed 1 million and is increasing steadily. As a result, it is not uncommon for adult patients with CHD to present for noncardiac surgery (see Chapter 21, Congenital Cardiac Anesthesia: Non-Bypass Procedures).

Transthoracic and transesophageal echocardiography has facilitated early, accurate diagnosis of congenital heart disease. Unlike in adults, who may have limited transthoracic echocardiographic windows, high-quality echocardiographic images in pediatric patients are easily obtained. Most neonates with CHD can have sufficient and thorough evaluation of their cardiac lesions by echocardiography and thus avoid catheterization

studies for diagnosis and management. In some instances, catheterization and angiography are necessary to clearly delineate coronary or aortopulmonary collateral anatomy and other intracardiac defects, to assess pressure gradients, and to potentially intervene for palliative or reparative purposes. Fetal cardiac ultrasonography has permitted antenatal diagnosis of congenital heart defects, allowing subsequent perinatal management in specialized tertiary care centers. Imaging modalities such as cardiac magnetic resonance imaging (MRI) and three-dimensional echocardiography are being used with increasing frequency.

Advances in molecular biology have provided a new understanding of the genetic basis of CHD. Chromosomal abnormalities are associated with an estimated 10% of congenital cardiovascular lesions. Two thirds of these lesions occur in patients with trisomy 21; the other one third of lesions are found in patients with other chromosomal abnormalities, such as trisomy 13 and trisomy 18, and in patients with Turner's syndrome. Conotruncal lesions (tetralogy of Fallot, interrupted aortic arch, truncus arteriosus, ventricular septal defects) are commonly associated with a 22q11.2 chromosomal deletion. This defect is associated with DiGeorge syndrome, velocardiofacial syndrome, and conotruncal anomaly face syndromes. These syndromes can be associated with hypocalcemia, immunodeficiency, facial dysmorphism, palate anomalies, velopharyngeal dysfunction, renal anomalies, and developmental, speech, and feeding disorders. The remaining 90% or so of congenital cardiovascular lesions are currently without defined genetic association and are postulated to be the

results of interactions of one or more genes with external or environmental factors (e.g., rubella, ethanol, lithium, maternal diabetes mellitus, folate deficiency).

Signs and symptoms of congenital heart disease in infants and children often include dyspnea, poor feeding, poor growth, delayed physical development, and the presence of a cardiac murmur. The diagnosis of CHD is apparent during the first week of life in about 50% of patients, and before 5 years of age in virtually all remaining patients. Echocardiography is the initial diagnostic step if CHD is suspected.

Congenital heart disease can be associated with specific complications. For example, infective endocarditis is a risk associated with most congenital cardiac anomalies. Sudden death occasionally occurs in patients who undergo surgical correction of CHD, presumably reflecting the effects of chronic abnormal hemodynamic loads, myocardial scarring and fibrosis, damage to the cardiac conduction system, or underlying (and presently occult) abnormal molecular and ion channel defects. Cardiac dysrhythmias are not usually a prominent presenting feature of CHD but can be more common as patients age and pathophysiologic sequelae of abnormal cardiac structure, function, and surgery accrue (see later and Chapter 21, Congenital Cardiac Anesthesia: Non-Bypass Procedures). Table 20-1 summarizes the pathophysiology and clinical picture associated with a wide variety of congenital heart defects. Table 20-2 summarizes the surgical repair options for each type of lesion.

PATHOPHYSIOLOGY OF CONGENITAL HEART DISEASE

Although some congenital heart defects involve purely obstructive or regurgitant valvular lesions, shunts (both physiologic and anatomic) are a hallmark of CHD. The concepts of shunting (both physiologic and anatomic), single-ventricle physiology, and intercirculatory mixing require discussion.

Shunting. Shunting is the process whereby venous return into one circulatory system is recirculated through the arterial outflow of the same circulatory system. Flow of blood from the systemic venous atrium or right atrium (RA) to the aorta produces recirculation of systemic venous blood. Flow of blood from the pulmonary venous atrium or left atrium (LA) to the pulmonary artery (PA) produces recirculation of pulmonary venous blood. Recirculation of blood produces a physiologic shunt. Recirculation of pulmonary venous blood produces a physiologic left-to-right (L-R), whereas recirculation of systemic venous blood produces a physiologic right-to-left (R-L) shunt.

Effective blood flow is the quantity of venous blood from one circulatory system reaching the arterial system of the other circulatory system. Effective pulmonary blood flow is the volume of systemic venous blood reaching the pulmonary circulation, whereas effective systemic blood flow is the volume of pulmonary venous blood reaching the systemic circulation. Effective pulmonary blood flow and effective systemic blood flows are the flows necessary to maintain life. Effective pulmonary blood flow and effective systemic blood flow are always equal, no matter how complex the lesions. Effective blood flow is usually the result of a normal pathway through the heart, but it may occur as the result of an anatomic R-L or L-R shunt, as in transposition physiology.

Total pulmonary blood flow (\dot{Q}_P) is the sum of effective pulmonary blood flow and recirculated pulmonary blood flow. Total systemic blood flow (\dot{Q}_S) is the sum of effective systemic blood flow and recirculated systemic blood flow. Total pulmonary blood flow and total systemic blood flow do not have to be equal. Therefore, it is best to think of recirculated flow (physiologic shunt flow) as the extra, noneffective flow superimposed on the nutritive effective blood flow. These concepts are illustrated in Figures 20-1 to 20-3.

Single-Ventricle Physiology. Single-ventricle physiology describes the situation in which there is complete mixing of pulmonary venous and systemic venous blood at the atrial or ventricular level, and the ventricle (or the ventricles) then distribute output to both the systemic and pulmonary beds. As a result of this physiology (1) ventricular output is the sum of pulmonary blood flow (\dot{Q}_P) and systemic blood flow (\dot{Q}_S), (2) distribution of systemic and pulmonary blood flow is dependent on the relative resistances to flow (both intracardiac and extracardiac) into the two parallel circuits, and (3) oxygen saturations are the same in the aorta and the pulmonary artery. This physiology can exist in patients with one well-developed ventricle and one hypoplastic ventricle, as well as in patients with two well-formed ventricles.

In the case of a single anatomic ventricle, there is always obstruction to either pulmonary or systemic blood flow as the result of complete or near-complete obstruction to inflow or outflow (or both) from the hypoplastic ventricle. In this circumstance, there must be a source of both systemic and pulmonary blood flow to assure postnatal survival. In some instances of a single anatomic ventricle, a direct connection between the aorta and the pulmonary artery via a patent ductus arteriosus (PDA) is the sole source of systemic blood flow (e.g., hypoplastic left heart syndrome [HLHS]) or of pulmonary blood flow (e.g., pulmonary atresia with intact ventricular septum). This is known as *ductal dependent circulation*. In other instances of a single anatomic ventricle, intracardiac pathways provide both systemic and pulmonary blood flow without a PDA. This is the case when tricuspid atresia occurs along with normally related great vessels, a nonrestrictive ventricular septal defect (VSD), and minimal or absent pulmonary stenosis.

In certain circumstances, single-ventricle physiology can exist in the presence of two well-formed anatomic ventricles: (1) tetralogy of Fallot (TOF) with pulmonary atresia (in which pulmonary blood flow is supplied via a PDA or multiple aortopulmonary collateral arteries), (2) truncus arteriosus, and (3) severe neonatal aortic stenosis and interrupted aortic arch (in which a substantial portion of systemic blood flow is supplied via a PDA).

Table 20-3 lists a number of single-ventricle physiology lesions. All patients with single-ventricle physiology who have severe hypoplasia of one ventricle will ultimately undergo the staged surgeries that comprise the single-ventricle pathway and result in Fontan physiology (described later). Patients with single-ventricle physiology and two well-formed ventricles are usually able to undergo a two-ventricle repair. In some cases, the two-ventricle repair will be complete. In others, significant residual lesions (VSD, aortopulmonary collaterals) will remain. In patients with single-ventricle physiology, the arterial oxygen saturation (S_{aO_2}) is determined by the relative volumes and saturations of pulmonary venous and systemic venous blood flows that have mixed and reach the aorta (see Fig. 20-1).

TABLE 20-1. Pathophysiology and Clinical Picture of Congenital Heart Defects

Lesion Type	Pathophysiology	Clinical Signs and Symptoms
Shunt Lesion without Outflow Tract Obstruction		
<ul style="list-style-type: none"> • Atrial septal defects • Ventricular septal defects • Atrioventricular canal defects • Patent ductus arteriosus • Aortopulmonary window 	<ul style="list-style-type: none"> • Intracardiac L-R shunt • Increased pulmonary blood flow 	<ul style="list-style-type: none"> • CHF (systemic and pulmonary vascular congestion) • No cyanosis (unless high pulmonary blood flow leads to increased left atrial pressure, pulmonary edema, and intrapulmonary V/Q mismatch and shunt)
Shunt Lesions with Right Ventricular Outflow Tract Obstruction		
<ul style="list-style-type: none"> • Tetralogy of Fallot • Ebstein's anomaly • Pulmonary stenosis with atrial or ventricular septal defects • Eisenmenger's syndrome 	<ul style="list-style-type: none"> • Intracardiac R-L shunt • Decreased pulmonary blood flow 	<ul style="list-style-type: none"> • Cyanosis
Transposition Physiology (Intercirculatory mixing)

CHF, Congestive heart failure; PAPVR, partial anomalous pulmonary venous return; TAPVR, total anomalous pulmonary venous return.

Intercirculatory Mixing. Intercirculatory mixing is the unique situation that exists in transposition of the great arteries (TGA) (see Fig. 20-2). In TGA, there are two parallel circulations because of the existence of atrioventricular concordance (right atrium to right ventricle [RA-RV], and left atrium to

left ventricle [LA-LV]) and ventriculoarterial discordance (right atrium to aorta [RV-Ao], and left ventricle to pulmonary artery [LV-PA]). This produces a parallel rather than a normal series circulation. In this arrangement, parallel recirculation of pulmonary venous blood in the pulmonary circuit

and systemic venous blood in the systemic circuit occurs. Therefore, the physiologic shunt or the percentage of venous blood from one system that recirculates in the arterial outflow of the same system is 100% for both circuits.

Thus, this lesion is incompatible with life unless there are one or more communications (atrial septal defect [ASD], patent foramen ovale [PFO], VSD, PDA) between the parallel circuits to allow intercirculatory mixing. In the presence of mixing, arterial saturation (Sa_{o_2}) is determined by the relative volumes and saturations of the recirculated systemic and effective systemic venous blood flows reaching the aorta (see Fig. 20-3).

FIGURE 20-1. Blood flows in a nonrestrictive atrial septal defect (ASD). Effective pulmonary and effective systemic blood flows are equal (2.0 L/min/m^2). The $\dot{Q}_P:\dot{Q}_S$ (ratio of total pulmonary to total systemic blood flow) is 2:1. \dot{Q}_P ($4.0 \text{ L/min per meter-squared}$) is the sum of the effective pulmonary blood flow (2.0 L/min/m^2) and a L-R physiologic shunt (2.0 L/min/m^2). This L-R shunt is recirculation of pulmonary venous blood into the pulmonary artery that imposes a volume load on the left atrium, right atrium, and right ventricle.

Fontan Physiology. Fontan physiology (see also later) is a series (i.e., “normal”) circulation in which one ventricle has sufficient diastolic, systolic, and atrioventricular valve function to support systemic circulation (Figs. 20-4 and 20-5). This ventricle must in turn be in unobstructed continuity with the aorta and pulmonary venous blood return; there must also be unobstructed delivery of systemic venous blood to the pulmonary circulation (total cavopulmonary continuity).

General Approach to Anesthetic Management

Preparation for Anesthesia

Preparation for anesthesia begins with a thorough assessment of the patient's medical and surgical conditions (as with any preoperative assessment). Also necessary is a complete understanding of the patient's “original” cardiac anatomy and physiology, any previous surgical or catheterization procedures and complications, the present status of the patient's anatomy and pathophysiology, current medications, and involvement of other organ systems (e.g., renal insufficiency). Also necessary is detailed knowledge of the anatomic and functional information contained in the most recent diagnostic studies (echocardiography or Doppler on most patients, and often catheterization and cardiac MRI data as well), as well as of the planned procedure and its acute physiologic consequences and potential complications.

Basic operating room preparation begins with the considerations common to all pediatric anesthesia, including the presence of appropriately sized airway; ventilator; monitoring; cardioversion, defibrillation, and external pacing (including external pads or paddles and internal paddles of appropriate sizes); temperature control (capability for warming and cooling); blood and fluid administration; and vascular

FIGURE 20-2. Saturations, pressures, and blood flows in tricuspid atresia with a mildly restrictive atrial septal defect (ASD), a small restrictive ventricular septal defect (VSD), and mild pulmonic stenosis (PS). Complete mixing or blending occurs at the atrial level. This complete mixing is the consequence of an obligatory physiologic and anatomic R-L shunting across the ASD. Effective pulmonary and effective systemic blood flows are equal (1.5 L/min/m²). Effective systemic blood flow occurs via a normal pathway through the heart. Effective pulmonary blood flow is the result of an anatomic R-L shunt at the atrial level, and an anatomic L-R shunt at the ventricular level. This illustrates the concept that when complete outflow obstruction exists and there is obligatory anatomic shunting, a downstream anatomic shunt must exist to deliver blood back to the obstructed circuit. Total pulmonary blood flow (\dot{Q}_P) is 2.8 L/min/m² and is the sum of effective pulmonary blood flow (1.5 L/min/m²) and a physiologic and anatomic L-R shunt (1.3 L/min/m²) at the VSD. Total systemic blood flow (\dot{Q}_S) is 3.3 L/min/m² and is the sum of effective systemic blood flow (1.5 L/min/m²) and a physiologic and anatomic R-L shunt (1.8 L/min/m²) at the ASD. Here, there is a small pressure gradient at the atrial level and a large pressure gradient at the ventricular level. In addition, there is a small additional gradient at the level of the pulmonic valve.

FIGURE 20-3. Saturations, pressures, and blood flows in transposition of the great arteries with a nonrestrictive atrial septal defect and a small left ventricular outflow tract gradient. Intercirculatory mixing occurs at the atrial level. Effective pulmonary and effective systemic blood flows are equal (1.1 L/min/m²) and are the result of a bidirectional anatomic shunt at the atrial level. The physiologic L-R shunt is 9.0 L/min/m²; this represents blood recirculated from the systemic veins to the pulmonary artery. The physiologic R-L shunt is 1.2 L/min/m²; this represents blood recirculated from the systemic veins to the aorta. Total pulmonary blood flow ($\dot{Q}_P = 10.1$ L/min/m²) is almost five times the total systemic blood flow ($\dot{Q}_S = 2.3$ L/min/m²). The bulk of pulmonary blood flow is recirculated pulmonary venous blood. Here, pulmonary vascular resistance is low (approximately 1/35 of systemic vascular resistance) and there is a small (17 mm Hg, peak to peak) gradient from the left ventricle to the pulmonary artery. These findings are compatible with the high pulmonary blood flow shown.

■ **FIGURE 20-4.** Total cavopulmonary connection (Fontan) using an intraatrial lateral tunnel or baffle. The tunnel is prosthetic graft material such as Gore-Tex. A fenestration has been placed in this prosthetic material allowing a physiologic R-L shunt to exist when baffle pressure exceeds common (pulmonary venous) atrial pressure. This pop-off allows systemic cardiac output to be maintained (at the expense of arterial saturation) when the resistance to pulmonary blood flow is high. (Redrawn from Children's Hospital Boston, Boston, Mass.)

access equipment and supplies. In addition, an extra blood pressure cuff and pulse oximeter should be on hand in case the need arises for some specific lesions. Size-appropriate equipment and supplies (including vascular ultrasound devices and pressure monitoring transducers) to perform peripheral and femoral arterial and central venous cannulation and pressure monitoring are necessary. In addition to standard drugs, one should have predrawn and hence immediately available syringes con-

■ **FIGURE 20-5.** Total cavopulmonary connection (Fontan) using an extracardiac conduit or baffle. The conduit is prosthetic graft material such as Gore-Tex. In this example, no fenestration or pop-off is present to allow physiologic R-L shunting when baffle pressure exceeds common (pulmonary venous) atrial pressure. (Redrawn from Children's Hospital Boston, Boston, Mass.)

taining weight-appropriate concentrations of emergency drugs including epinephrine, calcium (gluconate or chloride salt), phenylephrine, and atropine. Other agents, such as sodium bicarbonate, glucose, potassium chloride, antiarrhythmics (e.g., adenosine, procainamide), β -blockers, heparin, and inotropes and other vasoactive drugs for infusion (e.g., dopamine, dobutamine, epinephrine, phenylephrine, milrinone, vasopressin, nitroglycerin, nitroprusside, esmolol) should be immediately available. Many find it helpful to complete a patient-specific emergency card for each patient that contains weight-based concentrations, dosages, and bolus volumes or infusion rates for the most frequently used agents before starting the case.

No one anesthetic induction technique is suitable for all patients with congenital heart disease. The patient's age, cardiopulmonary function, degree of cyanosis, and emotional state all play roles in the selection of an anesthetic technique. Intravenous administration of induction agents clearly affords the greatest flexibility in terms of drug selection and drug titration and allows prompt control of the airway. We believe that intravenous induction is the preferred technique in the majority of patients, including those with significantly impaired ventricular systolic function, significant obstruction to blood flow (e.g., severe aortic stenosis), and systemic or suprasystemic pulmonary artery pressures. In all patients, ensuring adequacy of the airway and gas exchange is a preeminent consideration.

Sevoflurane, halothane, isoflurane, and fentanyl plus midazolam do not change the ratio of pulmonary-to-systemic blood flow ($\dot{Q}_P:\dot{Q}_S$) in children with atrial and ventricular septal defects when cautiously administered with 100% oxygen (Laird et al., 2002). Sevoflurane (1 minimum alveolar concentration [MAC]) and fentanyl plus midazolam have no significant effect on myocardial function in patients with a single ventricle (Ikemba et al., 2004). Halothane (1 and 1.5 MAC) depresses cardiac index and contractility more than comparable levels of sevoflurane, isoflurane, and fentanyl plus midazolam anesthesia (Rivenes et al., 2001). In addition, halothane anesthesia may result in more severe hypotension and emergent drug use than sevoflurane anesthesia in children with CHD (Russell et al., 2001).

Mask Induction. Mask induction of anesthesia can be accomplished safely in the subset of children without severe cardiorespiratory compromise. However, reduced pulmonary blood flow in cyanotic patients will prolong the length of induction and the interval during which the airway is only partially controlled. In addition, in these patients, even short intervals of airway obstruction or hypoventilation may result in hypoxemia. Sevoflurane has probably become the inhalation induction agent of choice (halothane, even if desired, has become unobtainable in many places). Sevoflurane causes less myocardial depression, hypotension, and bradycardia than halothane. Isoflurane and particularly desflurane are unsuitable agents, as their pungency causes copious secretions, airway irritation, and laryngospasm.

Intravenous Induction. Many of these patients come to the operating room with functioning intravenous (IV) access. For those without it, effective premedication may facilitate IV placement and allow the attendant risks of mask induction in this population to be avoided. In some patients, oral midazolam (0.5 to 1.0 mg/kg) may suffice. Others have used oral combinations of meperidine (3 mg/kg) and pentobarbital (4 mg/kg) successfully in this group of patients (Nicolson et al., 1989). Ketamine (~3 to 6 mg/kg) and midazolam (1 mg/kg) given orally in combination can be quite effective in terms of producing deep sedation and conditions favorable for IV placement and subsequent intravenous induction (Auden et al., 2000).

High-dosage synthetic narcotics in combination with pancuronium (0.1 mg/kg) are commonly used for intravenous induction in neonates and infants. The vagolytic and sympathomimetic effects of pancuronium counteract the vagotonic effect of synthetic opioids. In patients with a low aortic diastolic blood pressure and a high baseline heart rate, vecuronium (0.1 mg/kg) or cisatracurium (0.2 mg/kg) may be used without

affecting heart rate. In older children with mild to moderately depressed systolic function, lower dosages of a synthetic opioid can be used in conjunction with etomidate (0.1 to 0.3 mg/kg) (Sarkar et al., 2005).

Ketamine (1 to 2 mg/kg) is a useful induction agent. For patients with both normal and elevated baseline pulmonary vascular resistance (PVR), ketamine causes minimal increases in pulmonary artery pressure as long as the airway and ventilation are supported (Murray et al., 1984). The tachycardia and increase in systemic vascular resistance (SVR) induced by ketamine may make it unfavorable for use in patients with systemic outflow tract obstructive lesions (Williams et al., 2007).

The myocardial depressive and vasodilatory effects of propofol and thiopental make them largely unsuitable as induction agents except in patients with simple shunt lesions in whom cardiovascular function is preserved (Williams et al., 1999b).

An alternative to IV induction in patients with difficult peripheral IV access is intramuscular induction with ketamine (3 to 5 mg/kg), succinylcholine (2 to 5 mg/kg), and glycopyrrolate (8 to 10 mcg/kg). Glycopyrrolate is used to reduce airway secretions associated with ketamine administration and to prevent the bradycardia that may accompany succinylcholine administration. The required dosage of succinylcholine per kilogram body weight is highest in infants. This technique provides prompt induction and immediate control of the airway with tracheal intubation. It is useful when it is anticipated that initial IV access will have to be obtained via the internal or external jugular vein or the femoral vein. One potential problem is that the short duration of action of succinylcholine limits the period of patient immobility. An alternative technique combines intramuscular ketamine (4 to 5 mg/kg), glycopyrrolate (8 to 10 mcg/kg), and rocuronium (1.0 mg/kg). This technique is limited by the longer time interval until attainment of adequate intubating conditions and the longer duration of action of rocuronium as compared with succinylcholine.

Maintenance of Anesthesia

Anesthesia is generally maintained using a synthetic opioid (fentanyl or sufentanil)-based technique. These opioids may be used in high dosages (25 to 100 mcg/kg fentanyl or 2.5 to 10 mcg/kg sufentanil) or in low to moderate dosages (5 to 25 mcg/kg fentanyl or 0.5 to 2.5 mcg/kg sufentanil). In either instance, opioids are typically used in combination with an inhalation agent (generally isoflurane 0.5% to 1.0% or sevoflurane 1.0% to 2.0%) or a benzodiazepine (generally midazolam 0.05 to 0.1 mg/kg), or both. Caution must be exercised because the combination of narcotics and benzodiazepines is synergistic in reducing systemic vascular resistance. The high-dosage opioid technique is particularly useful for neonates and infants. Patients in this age group presenting for surgery often have significant ventricular pressure or volume overload. In addition, many of these patients have tenuous subendocardial and systemic perfusion secondary to the volume overload in combination with runoff into the pulmonary circulation and associated low aortic diastolic blood pressure. Given the limited contractile reserve available in the immature myocardium, it is not surprising that the myocardial depressive and systemic vasodilatory effects of inhalation agents and the synergistic vasodilatory effects of benzodiazepines and opioids may be poorly tolerated in this patient group.

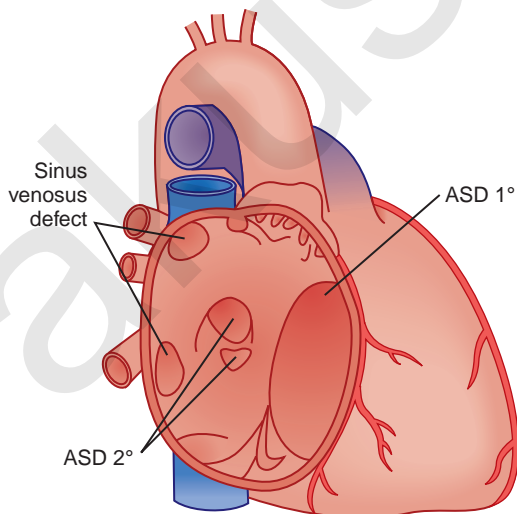

SPECIFIC LESIONS

Atrial Septal Defect

Atrial septal defect accounts for about one third of the congenital heart disease detected in adults, with the frequency in women two to three times that in men. See related video online at www.expertconsult.com. Strictly speaking, an ASD is a communication between the left and right atrium resulting from a defect in the intraatrial septum, which consists of a central membranous portion and a thicker inferior and superior fatty limbus. The central membranous portion is formed by tissue of the septum primum, ultimately forming the fossa ovalis. This membrane lies posterior to the superior aspect of the fatty limbus.

ASDs are classified by their location (Fig. 20-6). There are four morphologic types: ostium secundum defects, ostium primum defects, inferior and superior sinus venosus defects, and coronary sinus (CS) defects. Although they are classified as ASDs, sinus venosus and CS defects are not truly defects in the intraatrial septum. Secundum ASDs account for 80% of all ASDs. Whereas a PFO results from incomplete fusion of an intact fossa ovalis membrane with the superior aspect of the fatty limbus, an ostium secundum ASD is the result of actual deficiencies in the membrane (septum primum) of the fossa ovalis. Isolated ostium primum ASDs, also known as partial atrioventricular canal defects, are discussed later (see Atrioventricular Canal Defects). The isolated ostium primum defect extends from the inferior intraatrial septum fatty limbus, to the crest of the intact ventricular septum.

Both types of sinus venosus defects are associated with partially anomalous pulmonary venous return. In the case of the superior defect, anomalous drainage of the right upper pulmonary vein into the junction of the superior vena cava (SVC) and the RA is the most common finding. In the case of the inferior defect, scimitar syndrome (anomalous drainage of the right upper and lower pulmonary veins to the junction of the inferior vena cava [IVC] and RA, aortopulmonary collaterals to the right lower lobe, and hypoplasia of the right lung) can be seen.

■ **FIGURE 20-6.** Location of atrial septal defects (ASDs). ASD 1°, primum ASD; ASD 2°, secundum ASD. Superior and inferior sinus venosus defects are shown. (Redrawn from *Children's Hospital Boston, Boston, Mass.*)

Clinical Presentation

The physiologic consequences of ASDs are the same regardless of the anatomic location and reflect the shunting of blood from one atrium to the other; the direction and magnitude of the shunt are determined by the size of the defect and the relative compliance of the ventricles. A small defect (less than 0.5 cm in diameter) is associated with a small shunt and no hemodynamic sequelae. When the diameter of the ASD approaches 2 cm, it is likely that left atrial blood is being shunted to the right atrium (the right ventricle is more compliant than the left ventricle), resulting in increased pulmonary blood flow. A systolic ejection murmur audible in the second left intercostal space may be mistaken for an innocent flow murmur. The electrocardiogram (ECG) may reflect right axis deviation and incomplete right bundle branch block. Atrial fibrillation and supraventricular tachycardia may accompany an ASD that remains uncorrected into adulthood. The chest radiograph is likely to reveal prominent pulmonary arteries. Echocardiography is the mainstay of diagnostic imaging for these patients, with catheterization usually reserved for assessment of pulmonary artery pressures when indicated.

Because they initially produce no symptoms or striking findings on physical examination, ASDs may remain undetected for years. Symptoms resulting from large ASDs include dyspnea on exertion, supraventricular dysrhythmias, right heart failure, paradoxical embolism, and recurrent pulmonary infections. Prophylaxis against infective endocarditis is not recommended for patients with an ASD unless a concomitant valvular abnormality (mitral valve prolapse or mitral valve cleft) is present. Supraventricular dysrhythmias and pulmonary hypertension can increase in frequency, even for moderately sized defects, as patients enter the second and third decades of life.

Some small ostium secundum ASDs can be primarily closed, whereas larger defects are patched, usually with pericardium. An alternative is nonoperative device closure of secundum ASDs in the cardiac catheterization laboratory (see Chapter 21, Congenital Cardiac Anesthesia: Non-Bypass Procedures). Primum ASDs generally require patch closure and suture closure of the anterior leaflet mitral cleft. Sinus venosus defects without partially anomalous pulmonary venous return can be closed primarily with a patch. An alternative procedure is performed when the pulmonary vein or veins anomalously enter the SVC. The SVC is transected above the origin of the anomalous vein or veins, and the SVC orifice is directed across the defect into the LA with a pericardial patch. The distal end of the SVC is then anastomosed in an end-to-end fashion to the roof of the RA appendage, recreating SVC-to-RA continuity.

Management of Anesthesia

The goals of anesthetic management for patients with ASD before cardiopulmonary bypass (CPB) follow from the aforementioned principles and are outlined in [Box 20-1](#). The goals for these patients after CPB are outlined in [Box 20-2](#).

Ventricular Septal Defect

Ventricular septal defect is the most common congenital cardiac abnormality in infants and children. See related video online at www.expertconsult.com. A large number of VSDs close

Box 20-1 Anesthesia Management Goals for ASD, VSD, AVC Defect, and PDA before Cardiopulmonary Bypass (CPB)

- Maintain heart rate, contractility, and preload to maintain cardiac output.
 - A reduction in cardiac output compromises systemic perfusion, despite a relatively high pulmonary blood flow.
- Avoid maneuvers that decrease the PVR-to-SVR ratio.
 - The increase in pulmonary blood flow that accompanies a reduced PVR-to-SVR ratio necessitates an increase in cardiac output to maintain systemic blood flow, thereby compromising systemic (e.g., coronary, cerebral, GI, renal) perfusion.
- Maintain normoxia and normocarbia or mild hypercarbia.
 - Some patients overcirculate (excessive pulmonary blood flow) despite these measures, and it may be necessary to support systemic perfusion prior to CPB, with additional volume expansion or inotropes (or both).
 - The right pulmonary artery can be partially or completely occluded to mechanically control the magnitude of a left-to-right shunt and thus support systemic perfusion once adequate surgical exposure is attained.
- Avoid large increases in the PVR-to-SVR ratio.
 - A substantial increase may result in production of a right-to-left shunt.
- When a right-to-left shunt exists, ventilatory measures to decrease PVR should be entertained, and SVR must be maintained or increased.
 - These measures will reduce the magnitude of the right-to-left shunt.

ASD, Atrial septal defect; AVC, atrioventricular canal; GI, gastrointestinal; PDA, patent ductus arteriosus; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance; VSD, ventricular septal defect.

Box 20-2 Management Goals for ASD, VSD, and AVC Defect after Cardiopulmonary Bypass (CPB)

- Maintain heart rate (preferably sinus rhythm) at an age-appropriate rate.
 - Cardiac output is likely to be more heart rate dependent in the post-CPB period.
- Reduce PVR through ventilatory interventions.
 - This is particularly important if PVOD is present.
- Inotropic support of the right ventricle may be necessary, particularly if PVR is high. In patients with VSD or AVC, the left ventricle will no longer contribute to ejection of blood via the pulmonary artery, and the right ventricle will face a high afterload.
 - Dobutamine (5 to 10 mcg/kg per minute) or dopamine (5 to 10 mcg/kg per minute) provide inotropic support without increasing PVR.
 - Milrinone (0.5 to 1.0 mcg/kg per minute) after a loading dose of 50 mcg/kg has more-direct PVR-reducing effects in addition to inotropic, lusitropic, and SVR reducing effects.
- Infants with large VSDs or AVC defects, particularly in association with trisomy 21, are candidates for development of severe pulmonary hypertension and hypertensive crises after CPB.
 - Consider inhaled nitric oxide (iNO) when pulmonary hypertension and resultant RV dysfunction and low cardiac output persist.

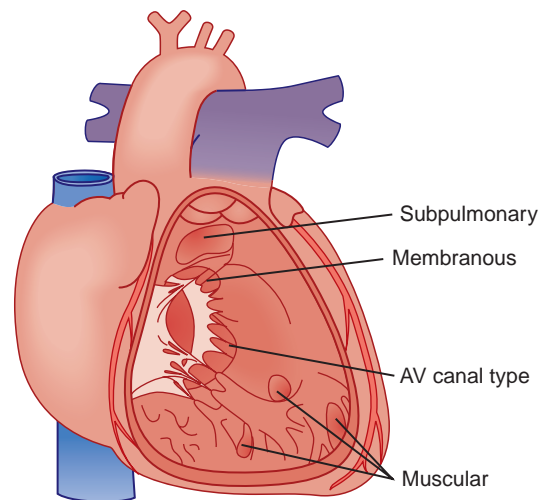

From Bizzarro M, Gross I: Inhaled nitric oxide for the postoperative management of pulmonary hypertension in infants and children with congenital heart disease, *Cochrane Database Syst Rev* (4):CD005055, 2005. ASD, Atrial septal defect; AVC, atrioventricular canal; PVOD, pulmonary vascular occlusive disease; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance; VSD, ventricular septal defect.

spontaneously by the time a child reaches 2 years of age. VSDs can be classified by their location in the septum (Fig. 20-7).

Subpulmonary or supracristal defects are located in the infundibular septum just below the aortic valve. Subpulmonary lesions may be associated with aortic insufficiency due to a lack of support for the right coronary cusp of the aortic valve and prolapse of this leaflet. Membranous or perimembranous defects comprise approximately 80% of all VSDs and are located in the subaortic region of the membranous septum, near or under the septal leaflet of the tricuspid valve, and they communicate with the LV just below the aortic valve. These defects are commonly partially closed by a collection of tricuspid valve and membranous septal tissue, giving an aneurysmal appearance to the septum. Conoventricular defects involve the same area as perimembranous defects, but they extend anteriorly and superiorly in the septum. Inlet- or canal-type defects involve the posterior septum near the atrioventricular (AV) valves. Muscular defects are located in the lower trabecular septum and may appear deceptively small on inspection from the right ventricular aspect of the septum because of heavy trabeculation. These defects may be apical, midmuscular, anterior, or posterior.

Clinical Presentation

The physiologic significance of a VSD depends on the size of the defect and the relative resistance in the systemic and pulmonary circulations. Restrictive VSDs have a substantial pressure gradient across them (i.e., left ventricular pressure signifi-

■ **FIGURE 20-7.** Locations of ventricular septal defects. (Redrawn from Children's Hospital Boston, Boston, Mass.)

cantly greater than the right) and, as the name suggests, are sufficiently small to limit the amount of flow (and pressure) entering the RV via the defect. In contrast, flow through unrestrictive VSDs is largely based on the relative resistance in the systemic and pulmonary circulations. If the defect is small, there

is minimal functional disturbance, as pulmonary blood flow is only modestly increased. The newborn infant with a large VSD may have near-normal pulmonary blood flow as a result of the high PVR present at birth. However, by the second week of life and continuing into the second month, PVR begins to fall to near-normal levels and pulmonary blood flow increases dramatically. Continued decreases in PVR after birth may be delayed by the elevated left atrial pressure that accompanies increased pulmonary blood flow (PBF).

Patients with large VSDs present with one or more signs and symptoms of pulmonary overcirculation and congestive heart failure (CHF) that increase as PVR falls. These include tachypnea, other signs of increased work of breathing (including retractions and nasal flaring), poor feeding, poor growth, diaphoresis, delayed capillary refill, diminished pulses, and hepatomegaly. Patients can be managed medically with diuretics, at times in combination with digoxin; however, significant symptoms usually result in early surgery.

Large VSDs also predispose to the development of pulmonary vascular occlusive disease (PVOD) during the first few years of life as a result of exposure of the pulmonary vasculature to high flows and systemic blood pressures. The increases in PVR that accompany PVOD ultimately produce bidirectional and right-to-left shunts. Patients with advanced PVOD and markedly increased PVR (Eisenmenger's complex) are not generally candidates for VSD closure, because closure will result in an enormous increase in RV afterload and RV-afterload mismatch. For this reason, large VSDs ($\dot{Q}P:\dot{Q}s > 2:1$) are corrected early in childhood. Whether to close smaller, more restrictive VSDs (i.e., when the $\dot{Q}P:\dot{Q}s$ is $< 1.5:1$) remains controversial. Here, the major long-term risk is most likely subacute bacterial endocarditis, and much less likely the development of CHF or PVOD, which must be balanced against the risks of CPB and surgery.

The murmur of a moderate to large VSD is holosystolic and is loudest at the lower left sternal border. The ECG and chest radiograph remain essentially normal in the presence of a small VSD. When the VSD is large, there is evidence of left atrial and ventricular enlargement on the ECG. The chest radiograph in patients with larger VSDs typically demonstrates cardiomegaly and increased PBF; increased interstitial markings, enlarged central pulmonary arteries, and hyperinflation may also be seen, particularly as CHF worsens. If pulmonary hypertension develops, the QRS axis shifts to the right, and right atrial and ventricular enlargement are noted on the ECG. A significant finding on physical examination is a loud second single heart sound. Here again, echocardiography is the major diagnostic imaging modality. Cardiac catheterization is usually reserved to assess other potential lesions and the degree of pulmonary hypertension and its responsiveness to pulmonary vasodilators.

Treatment

VSDs are generally closed with a patch by a variety of approaches, depending on their location. To avoid postoperative compromise of a small ventricle, with its poor compliance and limited capacity for tension development, a ventriculotomy to approach and correct VSDs is usually avoided. Many defects are approachable through the right atrium and tricuspid valve, aorta, or pulmonary artery.

Management of Anesthesia

The before-CPB goals of anesthetic management for patients with VSD are outlined in [Box 20-1](#). The goals for these patients after CPB are outlined in [Box 20-2](#).

Atrioventricular Canal Defects

Embryologically, four endocardial cushions contribute to the development of the lower ostium primum portion of the atrial septum and the upper, posterior inlet portion of the intact ventricular septum (IVS), where the AV valves insert. See related video online at www.expertconsult.com. The endocardial cushions also contribute to the tissue that forms the septal leaflets of the mitral and tricuspid valves. Therefore, cushion defects, or atrioventricular canal (AVC) defects, can include abnormalities in all these structures. The terminology of these lesions can be confusing and is summarized as follows:

Partial AVC. This is an ostium primum ASD in association with a cleft mitral valve. There are two separate AV valve (mitral and tricuspid) annuli. No inlet VSD is present.

Transitional AVC. This is an ostium primum ASD, common AV valve orifice, common anterosuperior and posteroinferior bridging leaflets, with dense chordal attachments to the crest of the IVS creating functionally separate mitral and tricuspid valves. There is a very small or absent inlet VSD.

Complete AVC. This is an ostium primum ASD, common AV valve orifice, common anterosuperior and posteroinferior bridging leaflets, with varying chordal attachments to the crest of the IVS. There is a moderate to large inlet VSD.

Clinical Presentation

These defects can result in communication between all four heart chambers as well as in abnormalities of the mitral and tricuspid valves. Approximately 50% occur in patients with trisomy 21. Because the orifice between the four chambers is large, as with large VSDs, this results in (1) production of a large left-to-right shunt, (2) increased pulmonary blood flow, (3) transmission of systemic pressures to the right ventricle and pulmonary arteries, and (4) volume overloading of the right and left ventricles. The signs and symptoms are related mainly to pulmonary overcirculation and the development of CHF, and they are similar to those outlined previously for large VSD.

As with large VSDs, complete AVC defects predispose to the early development of PVOD. Advanced PVOD may increase the PVR:SVR ratio so that a bidirectional or right-to-left shunt develops. This is a particular concern for patients with trisomy 21, who appear to develop earlier and more significant irreversible PVOD than the patient without trisomy 21 who has a similar hemodynamic disturbance. In some complete AVC defects, the presence of severe mitral insufficiency results in regurgitation of left ventricular blood directly into the right atrium (LV to RA shunt). This increases the left-to-right shunt. In addition, mitral regurgitation increases the volume work of the LV. Use of echocardiography and catheterization are generally similar to that outlined for ASDs and VSDs.

Treatment

Repair of AV canal defects involves closure of the ostium primum ASD and inlet VSD, and septation of the common AV

valve tissue into two separate, competent, nonstenotic tricuspid and mitral valves. This can usually be accomplished using a one-patch technique, wherein a single patch is used to close both the VSD and the ASD, and the reconstructed AV valves are resuspended by sutures to the patch. When the VSD is large and extends to other areas of the septum, two patches (atrial and ventricular) may be necessary. When the inlet VSD component is small, the AV valve tissue can be sutured down to the crest of the ventricular septum, essentially closing the VSD. A patch is then sutured to the crest of the ventricular septum and is used to close the ASD.

Management of Anesthesia

The before-CPB goals of anesthetic management for patients with AVC are outlined in [Box 20-1](#). The goals for these patients after CPB are outlined in [Box 20-2](#).

Tetralogy of Fallot

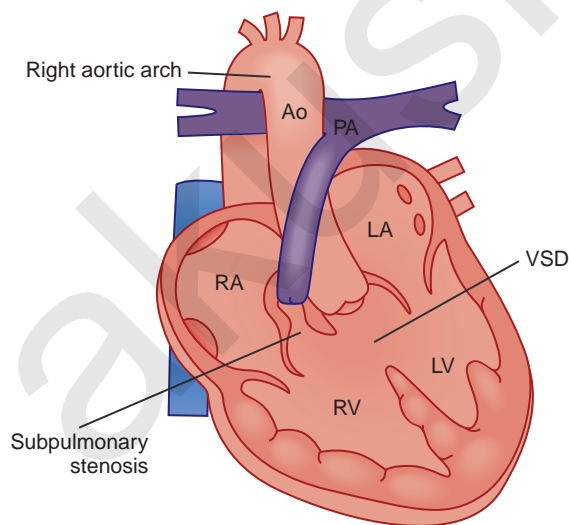

Tetralogy of Fallot is the most common cyanotic congenital heart defect. See related video online at www.expertconsult.com. It is characterized by a VSD, an overriding aorta, a right ventricular hypertrophy, and pulmonic stenosis (infundibular or subvalvular, valvular, supravalvular, or a combination thereof) ([Fig. 20-8](#)). The critical pathophysiologic malformation is underdevelopment of the right ventricular infundibulum and displacement of the infundibular septum, which together result in right ventricular outflow tract (RVOT) stenosis. Patients with TOF have displacement of the infundibular septum in an anterior, superior, and leftward direction. The posterior wall of the right ventricular outflow tract is formed by the infundibular septum, and its abnormal displacement results in narrowing of the right ventricular outflow tract. In addition, displacement of the infundibular septum creates a large malalignment VSD, with

the aorta overriding the intraventricular septum. Abnormalities in the septal and parietal attachments of the outflow tract further exacerbate the infundibular stenosis.

Seventy-five percent of TOF patients have both infundibular and valvular stenosis. A small proportion of patients will have multiple muscular VSDs. The pulmonary valve is almost always bi-leaflet. At one end of the spectrum of TOF, the pulmonary valve may be mildly hypoplastic (reduced annulus size), with minimal fusion of the pulmonary valve leaflets. At the other end of the spectrum, the pulmonary annulus may be very small, with near fusion of the valve leaflets. In addition, there are varying degrees of main pulmonary artery and branch pulmonary artery hypoplasia. The most common associated lesion, present in 25% of patients, is a right aortic arch with mirror-image arch vessel branching (the innominate artery gives rise to the left carotid and left subclavian, and the right carotid and right subclavian arise separately).

In most patients with TOF, there is both a fixed and a dynamic component to RV outflow obstruction. The fixed component is produced by the infundibular, valvular, and supravalvular stenosis. The dynamic component (subvalvular pulmonic stenosis) is produced by variations in the caliber of the RV infundibulum. In patients with TOF, magnitude of the right-to-left shunt and resultant arterial saturation are a direct reflection of the effects of these fixed and variable obstructions on pulmonary blood flow. A small subset of TOF patients (“pink tet” patients) have minimal obstruction to pulmonary blood flow at the right ventricular outflow and pulmonary artery level and may have normal oxygen saturation. Some of these patients have a left-to-right shunt with increased pulmonary blood flow and symptoms of CHF. Another subset where the pulmonary valve is completely or largely absent (“tetralogy-absent valve”) can have massive pulmonary artery enlargement and resultant prominent airway symptoms because of airway compression and tracheobronchomalacia.

■ **FIGURE 20-8.** Anatomy of tetralogy of Fallot (TOF). The following features are notable: malalignment ventricular septal defect (VSD), overriding aorta (Ao), infundibular pulmonic stenosis, and small pulmonary arteries. There is a right aortic arch with mirror-image arch vessel branching, as occurs in 25% of patients with TOF. (Redrawn from *Children’s Hospital Boston, Boston, Mass.*)

Diagnosis

Echocardiography is used to establish the diagnosis and assess the presence of associated abnormalities, the level and severity of the obstruction to right ventricular outflow, the size of the main pulmonary artery and its branches, and the number and location of the VSDs. Right-to-left shunting through the VSD is visualized by color Doppler imaging, and the severity of the RVOT obstruction can be determined by spectral Doppler measurement. Cardiac catheterization and angiography is necessary only when echocardiography cannot rule out coronary artery abnormalities. Approximately 8% of patients have either the left main coronary artery or the left anterior descending artery as a branch of the right coronary artery. In these cases, a right ventriculotomy to enlarge the RVOT will endanger the left coronary artery. In such cases, an extracardiac conduit (RV to main PA) may be necessary to bypass the outflow tract obstruction and avoid injury to the coronary artery.

Clinical Presentation

Most patients with tetralogy of Fallot have cyanosis, frequently progressive, from shortly after birth or beginning during the first months to 1 year of life. The most common auscultatory finding is an ejection murmur heard along the left sternal border resulting from blood flow across the stenotic pulmonic valve.

CHF rarely develops because of the RVOT obstruction limitation to PBF, and the large VSD permits equilibration of intraventricular pressures and cardiac workload. Chest radiographs show evidence of decreased lung vascularity, and the heart is “boot shaped” with an upturned right ventricular apex and a concave main pulmonary arterial segment. The ECG is characterized by changes of right axis deviation and right ventricular hypertrophy. Squatting is a common feature of in older children with tetralogy of Fallot. It is speculated that squatting increases the systemic vascular resistance by kinking the large arteries in the inguinal area. The resulting increase in systemic vascular resistance tends to decrease the magnitude of the right-to-left intracardiac shunt, which leads to increased pulmonary blood flow and subsequent improvement in arterial oxygenation.

Hypoxic or Hypercyanotic Episodes (“Tet Spells”)

The occurrence of hypoxic episodes in TOF patients may be life threatening and should be anticipated in every patient, even those who are not normally cyanotic. Spells occur more frequently in cyanotic patients, with the peak frequency of spells between 2 and 3 months of age. The onset of spells usually prompts urgent surgical intervention, so it is not unusual for the anesthesiologist to care for an infant who is at great risk for spells during the preoperative period.

The etiology of spells is not completely understood, but infundibular spasm or constriction may play a role. Crying, defecation, feeding, fever, and awakening can all be precipitating events. Paroxysmal hyperpnea is the initial finding. There is an increase in rate and depth of respiration, leading to increasing cyanosis and potential syncope, convulsions, or death. During a spell, the infant appears pale and limp secondary to poor cardiac output. Hyperpnea has several deleterious effects in maintaining and worsening a hypoxic spell. Hyperpnea increases oxygen consumption through the increased work of breathing. Hypoxia induces a decrease in SVR, which further increases the right-to-left shunt. Hyperpnea also lowers intrathoracic pressure and leads to an increase in systemic venous return. In the face of worsening infundibular obstruction, this results in an increased RV preload and an increase in the right-to-left shunt. Thus, episodes seem to be associated with events that increase oxygen demand while simultaneous decreases in PO_2 and increases in pH and $Paco_2$ are occurring. Treatment of a Tet spell includes the following points:

- Administration of 100% oxygen.
- Compression of the femoral arteries or placing the patient in a knee-to-chest position, which transiently increases SVR and reduces the R-L shunt. Manual compression of the abdominal aorta is particularly effective for the anesthetized patient. After the chest is open, the surgeon can manually compress the ascending aorta to increase impedance to ejection through the LV.
- Administration of morphine sulfate (0.05 to 0.1 mg/kg), which sedates the patient and may have a depressant effect on respiratory drive and hyperpnea.
- Administration of 15 to 30 mL/kg of a crystalloid solution. Enhancing preload increases heart size, which may increase the diameter of the RVOT.
- Administration of sodium bicarbonate to treat the severe metabolic acidosis that occurs during a spell. Correction of the metabolic acidosis will normalize SVR and reduce

hyperpnea. Bicarbonate administration (1 to 2 mEq/kg) in the absence of a blood gas determination is warranted during a spell.

- Phenylephrine in relatively large dosages (5 to 10 mcg/kg IV as a bolus, or 2 to 5 mcg/kg per minute as an infusion) increases SVR and reduces R-L shunting. In the presence of severe RV outflow obstruction, phenylephrine-induced increases of PVR have little or no effect in increasing RV outflow resistance. It is important to point out that treatment with α -adrenergic agents to increase SVR does nothing to treat the underlying cause of the spell, although the decrease in unstressed venous volume induced by these agents may augment preload.
- β -Adrenergic agonists are absolutely contraindicated. Increasing contractility will further narrow the stenotic infundibulum.
- Administration of propranolol (0.1 mg/kg) or esmolol (0.5 mg/kg followed by an infusion of 50 to 300 mcg/kg per minute) may reduce infundibular spasm by depressing contractility. In addition, slowing of heart rate may allow improved diastolic filling (increased preload), increased heart size, and an increase in the diameter of the RVOT.
- Resuscitation by extracorporeal membrane oxygenation (ECMO) in refractory episodes, when immediate operative intervention is not possible.

Cerebral Complications

Cerebrovascular accidents are common in older children with severe tetralogy of Fallot. Cerebrovascular thrombosis or severe arterial hypoxemia may be the explanation for these adverse responses. Dehydration and polycythemia may contribute to thrombosis. Hemoglobin concentrations exceeding 20 g/dL are common in these patients. A cerebral abscess is suggested by the abrupt onset of headache, fever, and lethargy, followed by persistent emesis and the appearance of seizure activity. The most likely cause is arterial seeding into areas of prior cerebral infarction.

Infective Endocarditis

Infective endocarditis is a constant danger in patients with tetralogy of Fallot and is associated with a high mortality rate. Appropriate antibiotics should be administered whenever dental or surgical procedures are planned in these patients.

Treatment

Without surgery, mortality exceeds 50% by 3 years of age. Currently, most patients with TOF have an elective full correction between the ages of 2 and 10 months. In some centers, surgery is delayed as long as possible within this time interval, with the precise timing of repair dictated by the onset of cyanotic episodes. Definitive repair for TOF is being accomplished in neonates in some centers if favorable anatomy is present. Surgery is aimed at relieving the outflow obstruction by resection of hypertrophied, obstructing muscle bundles and augmentation and enlargement of the RVOT with a pericardial patch. In a somewhat older approach, unless the pulmonary annulus was near normal size, and the pulmonary valve only mildly stenotic, enlargement of the RVOT frequently included

extension of the patch across the pulmonary valve annulus and into the main pulmonary artery (transannular patch). Because a transannular patch creates pulmonic insufficiency, which has been associated with a negative impact on long-term RV function and outcome, more recent data suggest it is best avoided when possible; as a result, the current approach for many is to enlarge the infundibular area with a patch (and resect interfering muscles bundles) and repair the pulmonary stenosis to the extent possible, thereby relieving most if not all of the outflow obstruction (and resultant RV hypertension) without creating significant pulmonary regurgitation. If stenosis of the pulmonary artery extends to the bifurcation of the pulmonary artery, a pericardial patch can be placed beyond the bifurcation of the pulmonary arteries (either de novo or as a continuation of the transannular patch). Finally, the VSD is closed. In neonates, this is usually done through the right ventriculotomy created for resection of RVOT obstruction, and with placement of the infundibular, pulmonary artery, or transannular patch. In infants and older children, the VSD can be closed via a trans-tricuspid valve approach, thereby avoiding the likely deleterious consequences of a right ventriculotomy. The overall goals of the surgery are to reduce RV pressure (ideally to below one half to three fourths of the systemic pressure), to avoid inducing RV volume overload (pulmonary regurgitation), and to successfully close the VSD (Apitz et al., 2009; Jonas, 2009; Khairy et al., 2009).

In the past, infants underwent palliative procedures that involved anastomosis of a systemic artery to a pulmonary artery in an effort to increase pulmonary blood flow and improve arterial oxygenation. These palliative procedures were the Waterston shunt (side-to-side anastomosis of the ascending aorta and the right pulmonary artery), the Potts shunt (side-to-side anastomosis of the descending aorta to the left pulmonary artery), the Blalock-Taussig shunt (end-to-side anastomosis of the subclavian artery to the pulmonary artery), and the modified Blalock-Taussig shunt (interposing a length of Gore-Tex tube graft between the subclavian or innominate artery and the branch pulmonary artery). Often, however, these procedures were associated with long-term complications such as pulmonary hypertension, left ventricular volume overload, distortion of the pulmonary arterial branches, reduced RV function, ventricular dysrhythmias, and sudden death.

Management of Anesthesia

The anesthetic management goals for patients with tetralogy of Fallot are summarized in [Box 20-3](#). Preoperatively, it is important to avoid dehydration by maintaining oral feedings in infants and young children or by providing intravenous fluids before the patient's arrival in the operating room. Crying associated with intramuscular administration of drugs used for preoperative medication can lead to hypercyanotic spells in those prone to do so. β -Adrenergic antagonists (now used infrequently) should be continued until the induction of anesthesia in patients receiving these drugs, for prophylaxis against hypercyanotic attacks.

An IV induction may be desirable, particularly in patients with significant outflow obstruction. In patients without a pre-existing intravenous catheter, IV placement may be facilitated by administration of adequate premedication (see earlier).

Mask induction of anesthesia with either sevoflurane or halothane (if still available) is usually effective, as there is a parallel decrease in PVR and SVR. Interestingly, halothane may

Box 20-3 Goals of Anesthesia Management for Tetralogy of Fallot

1. Maintain heart rate, contractility, and preload to maintain cardiac output.
 - Euvolemia prevents exacerbation of dynamic RVOT obstruction from hypovolemia and reflex increases in HR and contractility.
2. Avoid increases in the PVR-to-SVR ratio.
 - Increases in PVR relative to SVR, and decreases in SVR relative to PVR, will increase R-L shunting, reduce pulmonary blood flow, and produce or worsen cyanosis.
3. Use ventilatory measures to reduce PVR.
 - Minimize mean airway pressure to avoid mechanical obstruction of pulmonary blood flow and effects to decrease preload.
4. Maintain or increase SVR.
 - This is particularly important when RV outflow obstruction is severe and changes in PVR have little or no effect on shunt.
5. Treat hypercyanosis promptly.
6. Avoid RV contractility depression with severe fixed RV outflow obstruction except in patients with dynamic infundibular obstruction (tet spell).
 - Reducing contractility during tet spells may reduce RV outflow obstruction via relaxation of the infundibulum.

HR, Heart rate; PVR, pulmonary vascular resistance; RV, right ventricle; RVOT, right ventricular outflow tract; SVR, systemic vascular resistance.

better attenuate the dynamic component of RVOT obstruction than sevoflurane, because of halothane's more potent negative inotropic effect. Regardless of induction technique, systemic hypotension should be avoided or treated promptly. Systemic hypotension is particularly likely to cause or increase right-to-left shunting when RV outflow obstruction is severe, because anesthesia-induced decreases in PVR have little effect on decreasing RV outflow resistance. Hypotension responds to intravascular volume expansion, and, if necessary, markedly reduced SVR and worsening hypoxemia can be treated with phenylephrine (0.5- to 1.0-mcg/kg intravenous boluses).

Ketamine is a useful induction agent in patients with TOF. Ketamine has been shown to cause no significant alteration in $\dot{Q}_P:\dot{Q}_S$ in these patients. Fentanyl or sufentanil provide very stable induction and maintenance hemodynamics and will blunt stimulation-induced increases in PVR. Maintenance of anesthesia with fentanyl or sufentanil, a muscle relaxant (perhaps avoiding pancuronium because of tachycardia, and because of its effects on RV preload and contractility), and modest amounts of benzodiazepine or inhalation agent is appropriate.

Regardless of the mode of induction, volume expansion with 10 to 15 mL/kg (or greater) of 5% albumin or normal saline should be initiated once intravenous access is obtained. This is particularly necessary in patients who have received nothing by mouth for a long interval before induction. This is the most effective first-line therapy in preventing and treating dynamic RVOT obstruction. In addition to the peri-induction period, pericardial incision and retraction and aortic and pulmonary artery manipulation are other frequent points of acute hypoxemia and tet spell-like behavior prior to CPB. In addition to aggressive volume expansion, phenylephrine may be needed to reverse precipitously declining systemic oxygen saturations; at times, rapid institution of CPB is the effective therapy.

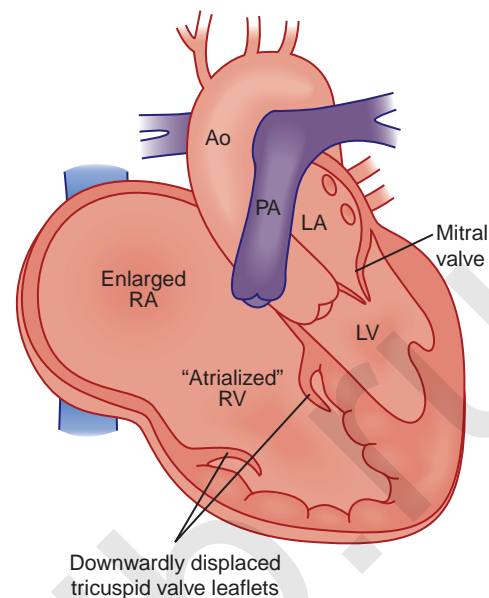

After definite repair for TOF, several factors may contribute to impaired RV systolic and diastolic function. First, there is likely to be preexisting dysfunction as a result of hypertrophy, and perhaps cyanosis. Myocardial preservation of the RV in TOF is widely felt to be insufficient for several reasons, including difficulties protecting hypertrophic muscle, increased tendency to free radical injury, and increased washout of cardioplegia due to collaterals. There is likely to be a mechanical component of RV dysfunction because of the use of a right ventriculotomy and RVOT patch. Finally, there may be new or residual abnormal hemodynamic loads because of pulmonary regurgitation, created by enlargement of the RVOT with a transannular patch, which imposes a new volume load on the RV, or residual pressure load because of RVOT obstruction below (infundibular), at, or distal to (main or branch PA stenosis) the pulmonary valve.

A residual VSD is likely to be very poorly tolerated in the patient with TOF, with the most likely manifestation being low cardiac output syndrome associated with elevated central venous pressure, left atrial pressure (LAP), and pulmonary arterial pressure (PAP). RVOT obstruction should be nearly completely eliminated after repair. PVR is likely to be low and the pulmonary vasculature very compliant. As a result, there will be potential for a large left-to-right intracardiac shunt with a residual VSD. This will place a large volume load on the LV and RV. An acute volume load will not be well tolerated by the RV, which is likely to be concentrically hypertrophied and poorly compliant in response to the chronic pressure overload that existed preoperatively. The presence of pulmonary insufficiency will further exacerbate RV dysfunction by imposing an additional volume load. Any distal pulmonary artery stenoses, high mean airway pressures, and elevated PVR will all increase the regurgitant volume and subsequent RV volume load.

After complete repair of TOF with no residual lesions and minimal intrapulmonary shunt, the SaO_2 should be 100%, and most patients require only modest to moderate degrees of inotropic support with dopamine or dobutamine (3 to 10 mcg/kg per minute). The need for substantially higher levels of support should raise the suspicion of a residual anatomic defect. In infants and small children, particularly those left with pulmonary insufficiency as the result of a transannular patch and those expected to have RV dysfunction as a result of a ventriculotomy or extensive RV hypertrophy (this may be an especially prominent problem in repairs in infants < 3 to 4 months old), the surgeon may choose to leave a pop-off valve by leaving the PFO open or by creating a small (3 to 4 mm) atrial-level fenestration. This will allow physiologic intracardiac R-L shunting (there will be direct delivery of some desaturated venous blood to the LA), with the ability to augment systemic cardiac output at the expense of systemic oxygen saturation in the setting of RV dysfunction. In these patients, a Pao_2 of 40 to 50 mm Hg and a SaO_2 of 70% to 80% is acceptable until RV function improves over the course of days. A right bundle branch block is common. Rarely, heart block requiring temporary (or permanent) pacing can occur as a consequence of the VSD closure; a large VSD patch can also occasionally be associated with LV outflow tract obstruction.

Ebstein's Anomaly

Ebstein's anomaly is an abnormality of the tricuspid valve in which the septal and often the posterior valve leaflets are displaced downward into the right ventricle (Fig. 20-9). See related

■ **FIGURE 20-9.** Anatomy of Ebstein's anomaly. There is apical displacement of the posterior and septal leaflets of the tricuspid valve. As a result, there is an atrialized right ventricle and an enlarged right atrium. The anterior tricuspid valve leaflet is not shown. An atrial septal defect or patent foramen ovale would be present. (Redrawn from Children's Hospital Boston, Boston, Mass.)

video online at www.expertconsult.com. In addition, the anterior tricuspid valve leaflet is abnormal. It is generally elongated and sail-like, with chordal attachments to the RV free wall. There may be RV outflow obstruction from the anterior leaflet. The result is a dilated right atrium with atrialization of the proximal RV and reduced effective RV cavity size and function. The tricuspid valve is usually regurgitant but may also be stenotic. Most patients with Ebstein's anomaly have an interatrial communication (ASD, PFO), through which there may be right-to-left shunting of blood, the magnitude of which depends on the severity of the tricuspid valve abnormality and degree of RV dysfunction.

Clinical Presentation

The severity of the hemodynamic derangements in patients with Ebstein's anomaly depends on the degree of displacement and the functional status of the tricuspid valve and RV. As a result, the clinical presentation varies from congestive heart failure in neonates to the absence of symptoms in adults in whom the anomaly is discovered incidentally. Neonates often manifest systemic venous congestion and cyanosis that worsens after ductus arteriosus closure reduces pulmonary blood flow. Older children with Ebstein's anomaly may be diagnosed as a result of an incidental murmur, whereas adolescents and adults are likely to present with supraventricular dysrhythmias that lead to CHF, worsening cyanosis, and occasionally syncope. Patients with Ebstein's anomaly and an interatrial communication are at risk for paradoxical embolization, brain abscess, CHF, and sudden death.

The severity of cyanosis depends on the magnitude of the right-to-left shunt. A systolic murmur caused by tricuspid regurgitation is usually present at the left lower sternal border. Hepatomegaly resulting from passive hepatic congestion

due to increased right atrial pressures may be present. The ECG is characterized by tall and broad P waves (resembling right bundle branch block), and first-degree atrioventricular heart block is common. Paroxysmal supraventricular and ventricular tachydysrhythmias may occur; and as many as 20% of patients with Ebstein's anomaly have ventricular preexcitation by way of accessory electrical pathways between the atrium and ventricle (Wolff-Parkinson-White syndrome). In patients with severe disease (marked right-to-left shunting and minimal functional right ventricle), marked cardiomegaly is present that is largely the result of right atrial enlargement.

Echocardiography is used to assess right atrial dilation, distortion of the tricuspid valve leaflets, and the severity of the tricuspid regurgitation or stenosis. The presence and magnitude of interatrial shunting can be determined by color Doppler imaging studies. Enlargement of the right atrium may be so massive that the apical portions of the lungs are compressed, resulting in restrictive pulmonary disease.

Treatment

Treatment of neonatal Ebstein's anomaly is controversial and varies with the specific subtype of abnormality. Approaches range from tricuspid valve repair (for patients whose valve is amenable to repair and in whom the RV is likely to be able to support normal cardiac output), staging to a Fontan procedure (for those with significantly reduced RV size and function), and transplantation. In older patients, treatment is based on the prevention of associated complications, including antibiotic prophylaxis against infective endocarditis and administration of diuretics and digoxin for the management of CHF. Patients with supraventricular dysrhythmias are treated pharmacologically or with catheter ablation if an accessory pathway is present. Repair or replacement of the tricuspid valve in conjunction with closure of the interatrial communication is recommended for older patients who have severe symptoms despite medical therapy. Complications of surgery to correct Ebstein's anomaly include third-degree atrioventricular heart block, persistence of supraventricular dysrhythmias, residual tricuspid regurgitation after valve repair, and prosthetic valve dysfunction when the tricuspid valve is replaced (da Silva et al., 2007; Knott-Craig et al., 2007; Bove et al., 2009).

Management of Anesthesia

Delayed onset of pharmacologic effects can be expected after IV administration of an anesthetic, which may result in part from pooling and dilution in an enlarged right atrium. The major hazards during anesthesia in patients with Ebstein's anomaly include depression of RV function and reduced forward flow into the pulmonary artery, accentuation of arterial hypoxemia because of increases in the magnitude of the right-to-left intracardiac shunt, and the development of supraventricular tachydysrhythmias (Lerner et al., 2003). Increased right atrial pressures may indicate the presence of right ventricular failure. Both ventilatory and pharmacologic measures should focus on minimizing mechanical and metabolic effects of ventilation on RV afterload and on maintaining RV contractility. In the presence of a PFO, an increase in right atrial pressure above the pressure in the left atrium can lead to a right-to-left intracardiac shunt through the foramen ovale. Unexplained arterial hypoxemia or paradoxical air embolism during the

perioperative period may result from shunting of blood or air through a previously closed foramen ovale.

Tricuspid Atresia

Tricuspid atresia (TA) involves a lesion with single-ventricle physiology. See related video online at www.expertconsult.com. These patients are staged to a Fontan procedure. Patients with TA have complete obstruction to RV inflow and variable obstruction to RV outflow. A communication (ASD or PFO) results in an obligatory right-to-left shunt at the atrial level with complete mixing of systemic and pulmonary venous blood in the left atrium. When the ASD or PFO is restrictive, there is a large right atrial to left atrial pressure gradient, which results in poor decompression of the RA and systemic venous congestion. Pulmonary blood flow can be provided by a downstream shunt from intracardiac (VSD) and extracardiac (PDA, multiple aortopulmonary collateral arteries) sources. Anatomic classification is based on the presence or absence of transposition of the great arteries, the extent of pulmonary stenosis or atresia, and the size of the VSD. Approximately 70% of all patients with TA are type 1, and 50% percent of all TA patients are type 1B (Fig. 20-10, and see Fig. 20-2 and Table 20-3).

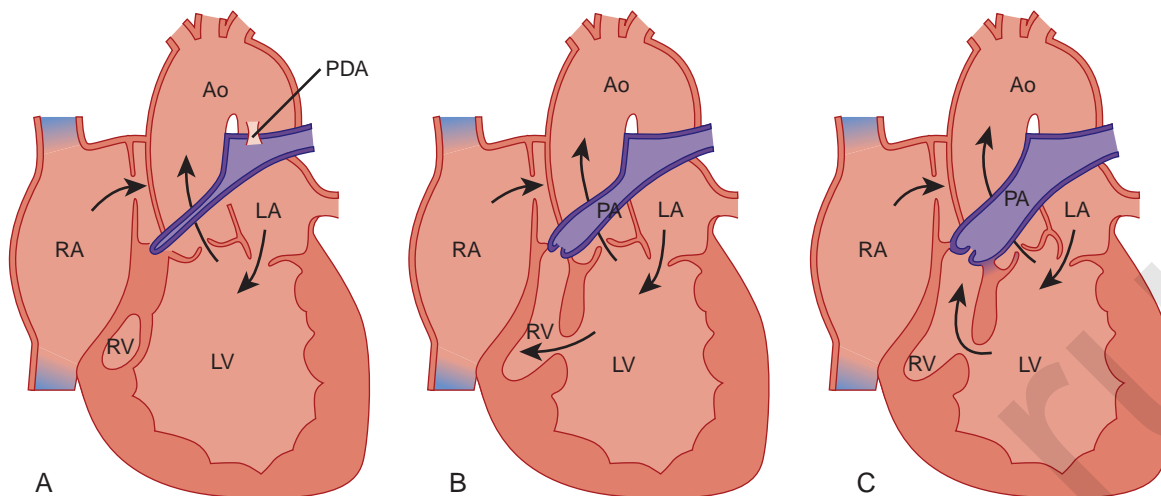

Treatment

Initial palliation depends on the anatomic variant. Infants with TA, adequate ASD, adequate VSD, and an "appropriate" amount of pulmonic stenosis can have a balanced circulation and require little or no intervention until later in infancy. Prostaglandin E₁ (PGE₁) is frequently necessary to augment PBF, and a balloon atrial septostomy may be necessary to allow adequate mixing and right atrial decompression. A Blalock-Taussig (BT) shunt may be required to provide a stable source of augmented pulmonary blood flow (e.g., TA with no VSD or with VSD but also with severe pulmonary stenosis or atresia). A staged approach to a Fontan procedure as described previously (see Figs. 20-4 and 20-5; Fig. 20-19) is the usual definitive treatment approach for TA.

Management of Anesthesia

Anesthetic management of patients with TA largely depends on their specific anatomy and where they are in their course of single-ventricle physiology. In general, IV induction techniques as outlined earlier are preferred for their reliability (e.g., uncertain uptake of inhaled agents in the presence of a "complete" right-to-left shunt) and hemodynamic stability; anesthetic maintenance typically uses "balanced" combinations of opioid, low-concentration inhaled agent, and muscle relaxation. The patient on PGE₁ presenting for balloon atrial septostomy or BT shunt creation is ductal dependent for PBF. As described previously, the major goals are to preserve overall cardiac contractility and output and to balance the relationship between PVR and SVR so that arterial oxygen saturations in the mid 70% to 80% range are maintained. Factors that raise PVR, decrease SVR, or reduce cardiac output can all contribute to increased hypoxemia by reducing ductal flow into the lungs. On the other hand, it may be possible to markedly compromise systemic perfusion by significantly reducing PVR (e.g., hyperoxic and hyperventilation or hypocarbia), thereby promoting increased left-to-right flow through the PDA. This occurrence may be signaled by increased arterial oxygen saturations, widened pulse pressure, and hypotension.

■ **FIGURE 20-10.** Anatomy and blood flow in tricuspid atresia type 1. Type 1A: pulmonary atresia with pulmonary blood flow via patent ductus arteriosus or major aortopulmonary collateral arteries (MAPCAs). Type 1B: small ventricular septal defect and pulmonary stenosis. Type 1C: large ventricular septal defect and no pulmonary stenosis.

Considerations after BT shunt creation have been discussed. In brief, one typically expects arterial oxygen saturations in the range of 75% to 85%. Substantially lower values may indicate shunt obstruction (arterial BP will be close to normal or high), low cardiac output or SVR, and, occasionally, high PVR. Pulmonary overcirculation (high arterial oxygen saturations, hypotension) may be managed by ventilatory maneuvers to increase PVR; at times, partial clipping of the shunt may be necessary. Controlled ventilation and inotropes are frequently required for several hours to days, as these infants adapt to the shunt-dependent circulation. The patient with TA, VSD, and no obstruction to PBF can be prone to pulmonary overcirculation and systemic hypoperfusion as PVR falls in the postnatal period. Initial management considerations are the same as those for other situations of potential excessive PBF—support systemic cardiac output and attempt to prevent increases in PBF by avoiding increased fraction of inspired oxygen (F_{iO_2}) and hypocarbia; some patients will require palliation with a pulmonary artery band to mechanically control PBF before more definitive surgery.

Total Anomalous Pulmonary Venous Return

Anatomy

Total anomalous pulmonary venous return (TAPVR) results in blood return from all of the pulmonary veins into the *systemic* venous system rather than directly into the left atrium. See related video online at www.expertconsult.com. The individual pulmonary veins usually drain into a common pulmonary venous confluence that has no direct connection to the LA; this confluence connects to the systemic venous circulation via one of four anatomic variants (Fig. 20-11):

1. Supracardiac TAPVR. Drainage of the pulmonary vein confluence is into a supracardiac venous structure. This occurs in nearly 50% of TAPVR cases, most often employing a “vertical

■ **FIGURE 20-11.** Types of total anomalous pulmonary venous return (TAPVR). **A**, Supracardiac (46%). Pulmonary venous blood returns to common pulmonary vein; the common pulmonary vein drains via a left vertical vein to the innominate vein, the superior vena cava (SVC), and finally to the right atrium. **B**, Infracardiac (22%). A common pulmonary vein passes through the diaphragm at the esophageal hiatus. The common vein then drains into the portal vein, hepatic vein, or ductus venosus. Obstruction of flow into the inferior vena cava (IVC) and right atrium may be caused by obligatory passage through the liver. **C**, Cardiac (24%). A common pulmonary vein directly enters the right atrium via the coronary sinus. **D**, Mixed (8%). The mixed type involves components of supracardiac, infracardiac, and cardiac drainage. Illustrated here is a combination of cardiac and supracardiac connections. LA, Left atrium; RA, right atrium. (Redrawn from Children's Hospital Boston, Boston, Mass.)

- vein" that connects the pulmonary venous confluence with the innominate vein, which then drains into the SVC.
2. Infracardiac TAPVR. This next most frequent subtype, occurring in approximately 25% of patients, involves drainage of the pulmonary venous confluence into an infracardiac vessel, such as the IVC, portal vein, or hepatic vein, via an inferiorly directed vertical vein that goes through the diaphragm to connect to one of these infracardiac vessels.
 3. Infracardiac TAPVR. Here, the pulmonary venous confluence drains directly into the RA via the coronary sinus.
 4. Mixed TAPVR. In a small percentage (<10%) of patients, pulmonary venous drainage is some combination of types 1, 2, and 3.

Infracardiac TAPVR is most frequently associated with pulmonary venous obstruction, at least in part because of the long course of the vertical vein and its passage through the diaphragm. Some patients with supracardiac TAPVR exhibit compression of the vertical vein between the left main stem bronchus and left pulmonary artery.

Physiology

There is a complete mixing lesion where all of the systemic and pulmonary venous blood mixes in the right atrium. The return of all pulmonary venous blood to the right atrium results in a large L-R shunt. Thus, an anatomic R-L shunt (an ASD or a PFO) is necessary for left heart filing and postnatal survival. These patients usually have a nonrestrictive or only mildly restrictive atrial level defect; however, R-L flow across the atrial septum is usually hampered by poor LA and LV compliance, in part because the reduced blood flow to the left side of the heart in utero caused these chambers to be smaller and stiffer than normal.

Taken together, these factors have the following results. In the absence of pulmonary venous obstruction, newborn infants with TAPVR have a $\dot{Q}_P:\dot{Q}_S$ close to 1:1. The decrease of PVR that occurs shortly after birth, in combination with significantly decreased left-sided compliance, promotes delivery of the mixed systemic and pulmonary venous blood to the pulmonary circuit. Pulmonary artery pressures will then be near systemic because, although PVR is not markedly elevated, the $\dot{Q}_P:\dot{Q}_S$ is usually quite high (>2:1 to 3:1).

Compression of the vertical venous pathway produces obstructed TAPVR. This distinction and diagnosis are critical, because obstruction causes pulmonary venous hypertension, elevated PVR, and systemic or even suprasystemic RV and PA pressures. Some of these patients may develop PVOD in utero as well. In addition, pulmonary venous obstruction will produce pulmonary edema, further elevating PVR, much as it does with mitral stenosis. Obstructed TAPVR is a surgical emergency, one of the few remaining in the era of PGE₁ therapy

Clinical Presentation

Systemic cardiac output and organ perfusion can be severely compromised in these patients. Systemic or suprasystemic RV pressures can result in a leftward shift of the interventricular septum (known as ventricular interdependence) that pancakes the LV and further reduces the compliance and filling of the already small LV; a secondary effect of these alterations is to reduce R-L flow across the atrial septum (because the impedance to LA emptying has increased). There is also likely to be RV afterload mismatch, resulting in RV distention and tricuspid

regurgitation. Thus, systemic cardiac output largely depends on a physiologic R-L shunt across the ductus arteriosus, but one that is supplied by a failing RV. These patients have a small heart and congested lungs on chest radiograph, the latter appearing worse in the case of obstructed TAPVR. The diagnosis is usually confirmed by surface echocardiography.

Patients with TAPVR are hypoxemic because of complete mixing; their degree of hypoxemia is further exacerbated by low cardiac output (which reduces mixed venous oxyhemoglobin saturation [S_{vo_2}] and hence the S_{aO_2} , that results from complete mixing), pulmonary edema (which causes intrapulmonary shunt and V/Q mismatch, leading to low pulmonary venous oxyhemoglobin saturation [S_{pvo_2}]), and reduced PBF arising from increased PVR. Efforts to increase pulmonary blood flow in these patients will only worsen the pulmonary edema (thus, e.g., inhaled nitric oxide [iNO], as well as other inhaled pulmonary vasodilators, are clearly contraindicated).

Patients with *obstructed* TAPVR present at birth with hypoxemia and poor systemic perfusion. In many, there is an ongoing metabolic acidosis and evidence of end-organ (hepatic and renal) dysfunction. In patients with severe pulmonary venous obstruction leading to suprasystemic RV and PA pressures and R-L shunting across the ductus arteriosus, ductal patency is necessary to maintain cardiac output (i.e., use of PGE₁ for temporary palliation may be indicated); frequently, inotropic support is required. In patients with less severe obstruction and subsystemic RV and PA pressures, ductal flow will be bidirectional or L-R. In these patients, ductal patency may exacerbate pulmonary edema.

Surgical Therapy

Definitive repair involves anastomosis of the pulmonary venous confluence to the posterior LA, ligation of the vertical vein, and closure of the ASD (Boger et al., 1999; Wang et al., 2004; Lacour-Gayet, 2006; Siles and Lapierre, 2008).

Anesthetic Management

General Considerations. The infant with TAPVR is frequently extremely ill and demonstrates both severe respiratory and circulatory compromise. This is especially true of TAPVR infants with pulmonary venous obstruction, in whom emergency surgery is the only viable therapeutic option. Efforts to increase pulmonary blood flow by ventilatory interventions will worsen pulmonary edema in these patients.

Overall, it is important to maintain heart rate, contractility, and preload so as to maintain systemic cardiac output. As noted previously, decreased cardiac output reduces systemic venous oxygen saturation, which, in a complete mixing lesion, will reduce arterial oxygen saturation. For patients with increased pulmonary blood flow, decreases in the PVR-to-SVR ratio should be avoided. The increase in pulmonary blood flow that accompanies a reduced PVR-to-SVR ratio necessitates an increase in cardiac output to maintain systemic blood flow, which will be difficult if not impossible in these patients for the reasons discussed previously. For patients with increased pulmonary blood flow and right ventricular volume overload, ventilatory interventions should be used to increase PVR, reduce pulmonary blood flow, and decrease the volume load on the right ventricle.

Induction and Maintenance. Neonates with pulmonary venous obstruction generally arrive in the operating room intubated, ventilated, and on inotropic support. Nonintubated patients are probably best managed by intravenous induction with etomidate or high-dosage potent opioid and muscle relaxation. The primary goals are to maintain systemic cardiac output and gain rapid control of ventilation without adversely affecting the tenuous relationships that affect the PVR-to-SVR ratio, systemic venous return, and cardiac output. Management of ventilation prior to CPB is therefore based on the aforementioned principles. These patients are best anesthetized with a high-dosage-narcotic technique that includes fentanyl or sufentanil and muscle relaxation. Patients with TAPVR, particularly those with venous obstruction, have a highly reactive pulmonary vasculature. High dosages of fentanyl and sufentanil may be useful for blunting increases in PVR associated with surgical stimulation.

Post-CPB Management

After surgical repair, the primary problems in these patients relate to left-sided filling and output compromise related to (1) small and noncompliant LA and LV, along with superimposed acute myocardial ischemia–reperfusion injury, and (2) reactive pulmonary vasculature, pulmonary hypertension, right ventricular hypertension, and RV dysfunction. The initial goals are to maintain heart rate (ideally, sinus rhythm) at an age-appropriate rate, using temporary pacing if necessary. Cardiac output is likely to be more heart-rate dependent in the post-CPB period.

Pulmonary hypertension (frequently at systemic or even suprasystemic levels of PA pressure) and limited systemic cardiac output are the major challenges after CPB. For patients' reactive pulmonary vasculature, blunting of stress-induced increases in PVR with narcotics is indicated. In addition, ventilatory interventions that reduce PVR and the use of selective pulmonary vasodilators such as iNO are frequently necessary; indeed, this group of patients with CHD are among those most likely to respond to iNO after CPB with a clinically significant decrease in PVR and improvement in cardiac function (Adatia and Wessel, 1994; Curran et al., 1995; Bizzarro and Gross, 2005; Roberts et al., 1993).

Despite maneuvers to decrease PVR, inotropic support of the RV may be necessary. Dobutamine (5 to 10 mcg/kg per minute) or dopamine (5 to 10 mcg/kg per minute) is useful in this instance because both agents provide potent inotropic support without increasing PVR. In the absence of systemic hypotension, milrinone (0.25 to 1.0 mcg/kg per minute after a 50-mcg/kg loading dosage, preferably administered on CPB) can be considered. Left-sided (e.g., LA) pressures are often high (~12 to 20 mm Hg) because of the combination of intrinsic, poor left-sided compliance, acute myocardial injury, and RV distention. It is easy to both underfill (resulting in low output) and overfill (acute distention and mitral regurgitation) the left heart. One, thus, needs to keep up with ongoing blood loss and replacement of clotting factors, but volume administration needs to be done with significant caution. The overall goal is to keep LA pressures within a reasonable target range while maintaining a reasonable (e.g., ~60 mm Hg systolic) blood pressure and evidence of adequate systemic perfusion (e.g., urine output, pH, cerebral oximetry, or SVC saturation).

Residual RV and PA hypertension can be caused by one or more of the following: (1) pulmonary venous obstruction, a technical (surgical) problem arising from the failure to construct

a nonrestrictive anastomosis of the pulmonary venous confluence to the LA; (2) LA (and hence pulmonary venous) hypertension due to the small, noncompliant LA and LV and post-CPB LV dysfunction; and (3) labile increases in PVR due to reactive pulmonary vasoconstriction (capillary and precapillary). In the presence of postoperative pulmonary venous obstruction, efforts to increase pulmonary blood flow may worsen pulmonary edema. Surgical revision may be necessary (Lacour-Gayet, 2006).

The use of surgically placed PA and LA monitoring catheters, often in combination with echocardiography (surface “on-heart” or transesophageal echocardiography [TEE], depending on patient size and probe availability), can be helpful in sorting out these issues. For example, the presence of high PA pressure, elevated LAP, and a PA diastolic pressure of less than 5 mm Hg above the LAP suggests that LA hypertension is the primary cause of PA hypertension. In contrast, the presence of high PA pressure, low or normal LAP, and a PA diastolic pressure of greater than 15 to 20 mm Hg above the LAP suggests that reactive pulmonary vasoconstriction, PVOD, or anastomotic pulmonary venous obstruction exists. Similarly, the presence of reactive pulmonary vasoconstriction or PVOD is suggested by a pulmonary wedge pressure of less than 3 to 5 mm Hg above the LAP, whereas a wedge pressure of greater than 7 to 10 mm Hg above the LAP is consistent with pulmonary venous obstruction. Echocardiography can be helpful in assessing the status of the pulmonary venous connection to the LA, and in assessing ventricular function and filling.

Transposition of the Great Arteries

Anatomy

In patients with TGA, there is discordance of the ventriculoarterial connections and concordance of the atrioventricular connections. See related video online at www.expertconsult.com. In other words, a right-sided RA connects via a right-sided tricuspid valve and RV to a right-sided and anterior aorta. A left-sided LA connects via a left-sided mitral valve and LV to a left-sided and posterior pulmonary artery (Fig. 20-12). The coronary arteries in dextro- (D-)TGA arise from the aortic sinuses that face the pulmonary artery. In normally related vessels, these sinuses are located on the anterior portion of the aorta, whereas in D-TGA they are located posteriorly. In the majority of D-TGA patients (70%), the right sinus is the origin of the right coronary artery, whereas the left sinus is the origin of the left main coronary artery. In the remainder of cases, there is considerable variability in this coronary anatomy. The exact coronary anatomy must be delineated; variants can contribute significantly to operative difficulty and the success of surgical repair.

TGA can occur with an intact ventricular septum or with a VSD, with or without subpulmonic stenosis. In D-TGA, subpulmonic stenosis causes left ventricular outflow tract (LVOT) obstruction, which is present in about 25% of patients with VSD and is most often due to a subpulmonary fibromuscular ring or posterior displacement of the outlet portion of the ventricular septum (or both). In addition, the foramen ovale is almost always patent, whereas a true secundum ASD exists in only about 5% of patients; approximately 50% of patients with D-TGA present with a PDA. Although angiographically detectable VSDs may occur in 30% to 40% of patients, only about one

■ **FIGURE 20-12.** Anatomy of dextro-transposition of the great arteries (D-TGA). The aorta is in continuity with the right ventricle, and the pulmonary artery is in continuity with the left ventricle, producing a parallel rather than a series circulation. Ao, Aorta; LV, left ventricle; RV, right ventricle. (Redrawn from *Children's Hospital Boston, Boston, Mass.*)

third of these defects are hemodynamically significant. Thus, from a functional standpoint, 75% of patients will behave as if they have an intact ventricular septum (see later). Only 5% of patients with IVS have significant LVOT obstruction. Valvular pulmonary stenosis is rare in patients with TGA. Other less commonly seen lesions are tricuspid or mitral regurgitation (4% of each) and a coarctation of the aorta (5%). Bronchopulmonary collateral vessels arising from the aorta are visible angiographically in 30% of patients with D-TGA, more frequently and extensively to the right lung. These collaterals provide a site for intercirculatory mixing and have been implicated in the accelerated development of pulmonary vascular occlusive disease in TGA patients.

D-TGA produces two parallel circulations with recirculation of systemic and pulmonary venous blood. Short-term survival depends on the presence of one or more communications between the two parallel circuits to allow intercirculatory mixing; the potential sites in patients with D-TGA are both intracardiac (PFO, ASD, VSD) and extracardiac (PDA, bronchopulmonary collaterals). Several factors determine the amount of intercirculatory mixing and hence arterial oxygen saturation and delivery. One large, nonrestrictive communication provides better mixing than two or three restrictive communications. Reduced ventricular compliance and elevated systemic and pulmonary vascular resistance tend to reduce intercirculatory mixing by impeding flow across the anatomic communications. The location of the communications is also important. Poor mixing occurs even with large anterior muscular VSDs because of their unfavorable positions.

In TGA with VSD, some intercirculatory mixing can occur at the ventricular level, but there is predominantly anatomic R-to-L shunting (effective pulmonary blood flow) at the VSD (RV→LV→PA) and PDA (RV→Ao→PA) and anatomic L-to-R shunting (effective systemic blood flow) at the PFO or ASD

(LA→RA→RV→Ao). Clearly, the more severe the LVOT obstruction, the more dependent the effective pulmonary blood flow will be on the presence of a PDA.

Patients with pulmonary stenosis sufficient to limit PBF may be hypoxemic despite a relatively large intercirculatory communication. Patients with high pulmonary blood flow, particularly those with a large VSD, are at risk of developing both overcirculation and congestive symptoms and PVOD. In the presence of a good-sized intercirculatory communication and no obstruction to PBF, most of these patients will not initially be hypoxemic but will have a large volume load imposed on the LA and LV and develop signs and symptoms of pulmonary overcirculation and CHF. However, the progressive development of PVOD can eventually reduce pulmonary blood flow and produce hypoxemia.

In TGA with an intact ventricular septum, the anatomic mixing sites are typically restricted to a PDA and a PFO. The factors determining the degree of intercirculatory mixing in TGA/IVS are complex and potentially problematic clinically. Anatomic shunting at the atrial level is mainly determined by the size of the atrial communication and the cyclic pressure variations between the left and right atrial chambers. The volume and compliance of the atria, ventricles, and vascular beds in each circuit, as well as heart rate and respiration, all influence the result. Shunting is from the right atrium to the left atrium during diastole as a result of the reduced ventricular and vascular compliance of the systemic circuit. In systole, the shunt is predominantly from the left atrium to the right atrium, primarily because of the large volume of blood returning to the left atrium as a result of the high volume of recirculated pulmonary blood flow.

The direction of shunting across the PDA largely depends on the PVR and the size of the intraatrial communication. When the PVR is low and the intraatrial communication is nonrestrictive, shunting is predominantly from the aorta to the pulmonary artery via the PDA, and predominantly from the left to right atrium (and hence into the systemic right ventricle) across the atrial septum. When the PVR is elevated, shunting across the PDA is likely to be bidirectional, which would in turn encourage bidirectional shunting across the atrial septum.

When the PVR is high and pulmonary artery pressure exceeds aortic pressure, shunting at the PDA will be predominantly from the pulmonary artery to the aorta. This causes a phenomenon known as reverse differential cyanosis, where the preductal arterial oxygen saturation is lower than the postductal arterial oxygen saturation. This is usually the result of a restrictive atrial communication producing left atrial hypertension and is associated with poor mixing and hypoxemia. A balloon atrial septostomy can be lifesaving in this setting. Decompression of the left atrium promotes mixing at the atrial level and also reduces PVR and pulmonary artery pressure, thereby promoting mixing (bidirectional shunting) at the level of the PDA.

The majority of neonates with D-TGA and IVS are hypoxemic (arterial saturation $\leq 70\%$) immediately after birth, with some patients demonstrating severely reduced effective pulmonary and systemic blood flow. This can result in severe hypoxemia ($Pao_2 < 20$ mm Hg), hypercarbia, and increasing metabolic acidosis secondary to the poor tissue oxygen delivery. PGE_1 (0.01 to 0.05 mcg/kg per minute) is administered to dilate and maintain the patency of the ductus arteriosus and facilitate mixing at this level. This maneuver increases effective pulmonary and systemic blood flow and can improve Pao_2 and tissue oxygen delivery if PVR is less than SVR (see earlier) and there is a

nonrestrictive or minimally restrictive atrial septal communication. PGE₁ infusion is associated with apnea, pyrexia, fluid retention, and platelet dysfunction, which are largely dosage dependent.

If PGE₁ does not improve tissue oxygen delivery, then an emergent balloon atrial septostomy can be performed in the catheterization laboratory (using angiography) or in the intensive care unit (ICU) (using echocardiographic guidance). These patients require tracheal intubation and mechanical ventilation if not already in place. This allows reduction of PVR via induction of a respiratory alkalosis and elimination of pulmonary V/Q mismatch; in addition, we have noted significant numbers of apnea episodes when trying to provide procedural sedation to neonates receiving PGE₁ infusions. In rare circumstances, the combination of PGE₁, a balloon atrial septostomy, and mechanical ventilation with sedation and muscle relaxation may be ineffective at improving oxygen saturation and systemic oxygen delivery. In this circumstance, ECMO (either veno-arterial or veno-veno) support to improve tissue oxygenation and to reverse end-organ insult and lactic acidosis prior to surgery may be necessary.

Surgical Therapy

Two general types of procedures have been performed to repair D-TGA, namely intraatrial baffle and arterial switch procedures.

Mustard and Senning Procedures. Both the Mustard and the Senning procedures are atrial switch procedures, which surgically create discordant atrioventricular connections in the presence of the preexisting discordant ventriculoarterial connections. As a result of atrial baffling, systemic venous blood is directed to the LV, which remains in continuity with the pulmonary artery, and pulmonary venous blood is baffled to the RV, which is in continuity with the aorta. This arrangement results in physiologic but not anatomic correction of D-TGA. After these procedures, the right ventricle remains the systemic ventricle and the tricuspid valve remains the systemic AV valve (Fig. 20-13).

■ **FIGURE 20-13.** Interior of right atrium showing the baffle that rearranges and redirects atrial blood flow after the Mustard procedure. Pulmonary vein openings can be seen. CS, Coronary sinus; IVC, inferior vena cava; MV, mitral valve; TV, tricuspid valve. (From Reed CC, Stafford TB, editors: *Cardiopulmonary bypass*, ed 2, Houston, 1985, Texas Medical Press, p 78.)

The Mustard procedure redirects pulmonary and systemic venous return via an intraatrial baffle made from pericardium or artificial graft material that is created after excision of the interatrial septum. The Senning version uses autologous right atrial tissue instead of pericardium or synthetic material. As a result of either procedure, pulmonary venous blood is essentially guided over the top of the baffle and across the tricuspid valve, while systemic venous blood is directed beneath the baffle to cross the mitral valve.

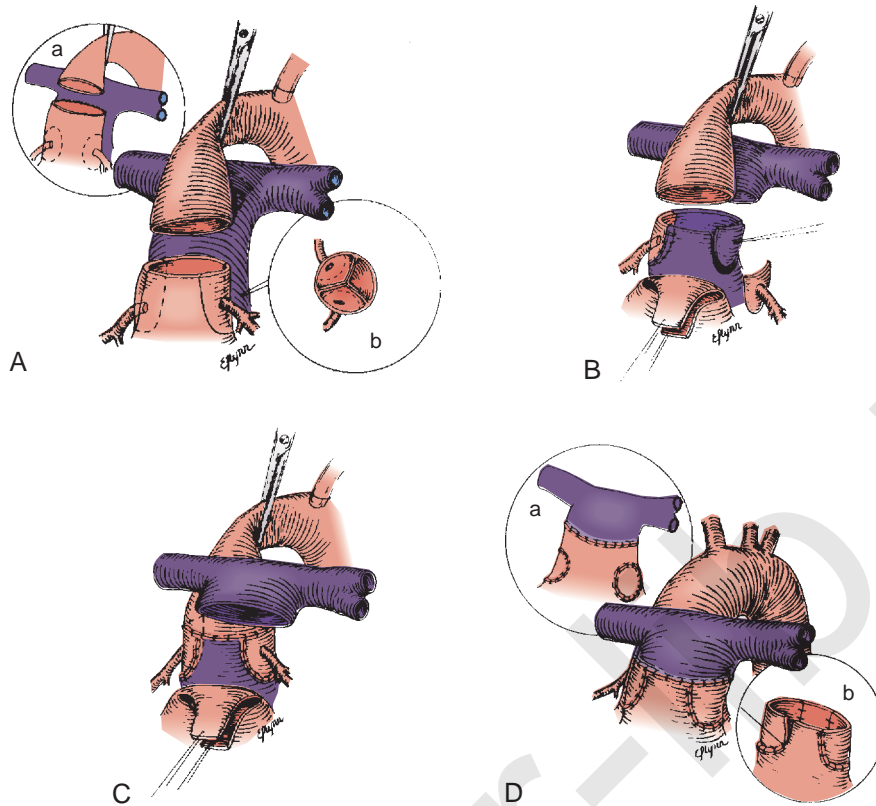

Both systemic and pulmonary venous obstruction by baffle material may occur as the result of either procedure. Because of the extensive atrial suture lines and at times atrial distention, dysrhythmias occur frequently after these procedures: about 60% to 70% of patients have some form of dysrhythmia, 30% of which are serious (bradycardia, sick-sinus syndrome, atrial flutter). Long-term exposure of the right ventricle and tricuspid valve to systemic pressure can result in progressive and severe right ventricular dysfunction (Horer et al., 2008).

Anatomic Repair or the Arterial (Jatene) Switch Procedure.

The arterial switch operation (ASO) surgically reverses the discordant ventriculoarterial connections so that after repair, the right ventricle is connected to the pulmonary artery and the left ventricle is connected to the aorta. This is now the most common procedure performed for D-TGA (DeBord et al., 2007; Gottlieb et al., 2008; Quinn et al., 2008). In brief, the pulmonary artery and the aorta are transected distal to their respective valves. The coronary arteries are excised from the ascending aorta with 3 to 4 mm of surrounding tissue and these sites repaired either with pericardium or synthetic material. The coronary arteries are reimplanted into the proximal pulmonary artery (neo-aorta), the distal pulmonary artery is brought anterior (LeCompte maneuver) and reanastomosed to the proximal aorta (right ventricular outflow), and the distal aorta is reanastomosed to the proximal pulmonary artery (left ventricular outflow) (Fig. 20-14). As mentioned earlier, variants in coronary anatomy can complicate this scenario. Although most patients with D-TGA have coronary anatomy that is suitable for coronary reimplantation, some variants, such as a single right coronary artery, are at risk for postoperative myocardial ischemia and death because reimplantation can result in distortion of the coronary ostia or narrowing of the artery itself. Inverted, intramural, or parallel coronary arteries can also be a problem.

The ASO was originally described in patients with D-TGA and a large VSD or a large PDA, in whom the LV (the pulmonary ventricle prior to ASO) is exposed to systemic pressures, and the LV mass remains sufficient to support the systemic circulation. This situation requires that the ASO be performed within the first few months (usually within the first few weeks) of life to avoid the development of progressive CHF or PVOD. The VSD is usually closed via the tricuspid valve to avoid a right ventriculotomy and resultant RV dysfunction. A brief period (<15 minutes) of deep hypothermic circulatory arrest is often used to facilitate closure of the ASD.

In patients with D-TGA and IVS, the ASO can be performed primarily or as the second phase of a staged procedure. A primary ASO procedure is usual for these patients and is usually performed within the first week of life. This is because the LV mass (and thus its ability to support the systemic circulation after ASO) in these patients declines as the elevated PVR that is characteristic of the normal fetus and newborn declines in the days to weeks after birth. Adequate LV mass to support the

■ **FIGURE 20-14.** Arterial switch procedure. **A**, The aorta is transected, and left and right coronary arteries and their bases are excised. **B**, An equivalent segment of pulmonary arterial wall is excised, and coronary arteries are sutured to the pulmonary artery. **C**, The distal pulmonary artery is brought anterior to ascending aorta, and the proximal pulmonary artery is anastomosed to the distal aorta. **D**, Sites of coronary artery extraction are repaired with use of either (a) a patch of prosthetic material or (b) a segment of pericardium. Finally, the proximal aorta is sutured to distal pulmonary artery. (Modified from Castaneda AR, Norwood WI, Jonas RA, et al: *Transposition of the great arteries and intact ventricular septum: anatomical repair in the neonate*, Ann Thorac Surg 38:438, 1984, with permission from the Society of Thoracic Surgeons.)

systemic circulation exists in these patients for only the first 2 to 3 months after birth, at most. Two-dimensional echocardiography is used to assess the LV-to-RV-pressure ratio and to quantify the adequacy of LV mass, size, and function.

A two-stage repair for D-TGA with IVS can be used for neonates and infants in whom significant regression of LV mass has occurred. These are generally infants on whom surgery was not performed during the first several weeks of life because of other factors (e.g., delayed diagnosis and referral, other anomalies, sepsis, or prematurity). To reestablish the ability of the LV to perform systemic workload, a pulmonary artery band is placed as a first stage; in addition, a BT shunt (one that enters the pulmonary artery distal to the band) is created to prevent hypoxemia. The goal of the band is to increase the LV (which is still the pulmonary ventricle) pressure to approximately one-half to two-thirds that in the systemic (right) ventricle to prevent further regression of LV mass and in fact promote a moderate degree of LV hypertrophy. These patients can initially be quite ill after the banding procedure, requiring mechanical ventilation and inotropic support as the adaptation occurs over several days; if the band is too tight, frank LV decompensation secondary to afterload mismatch can ensue.

After this first stage, the actual ASO can be performed as early as several days to 1 week after the pulmonary artery band procedure that was done to prepare the LV. The timing is often guided by noninvasive assessment of LV mass and function;

somewhat surprisingly, a marked increase of LV mass can be seen within a week or less of pulmonary artery banding in most patients. Nonetheless, some degree of impaired LV function after ASO should be anticipated in these patients (see later), and at times a period of ECMO support and “training of the LV” (where ECMO flows and support are slowly and progressively weaned over several days after ASO) are needed. In addition to the difficulties of obtaining appropriate band tightness and of its effects on LV function, the systemic-to-pulmonary artery shunt can distort the pulmonary artery, making the subsequent ASO more difficult.

Rastelli Procedure. The ASO is generally not performed on patients with significant anatomic and fixed LVOT obstruction (subpulmonic stenosis; patients with dynamic LVOT obstruction are likely to have no gradient across the LV outflow tract after the ASO). Correction of some types and severities of anatomic LVOT obstruction is possible and these patients are also potential candidates for ASO. For patients with D-TGA, VSD, and severe anatomic LVOT obstruction (subpulmonic stenosis), a Rastelli procedure is performed (Fig. 20-15).

Here, the VSD is closed via a right ventriculotomy using a more complicated patch, so that LV blood is directed through the aorta. The proximal pulmonary artery is ligated and a valved conduit is placed from the right ventriculotomy to the pulmonary artery, thereby bypassing the subpulmonic stenosis.

■ **FIGURE 20-15.** **A**, In the Rastelli procedure, closure of ventricular septal defect results in the left ventricle (LV) ejecting blood into the aorta (Ao). **B**, An external right ventricle (RV)-to-pulmonary artery (PA) conduit is placed to provide pulmonary circulation. (From Strafford M: *Transposition of the great vessels*. In Lake CL, editor: *Pediatric cardiac anesthesia*, Norwalk, Conn, 1988, Appleton & Lange, p 237.)

Subaortic stenosis may result from placement of the complex VSD patch. Balloon dilations and eventual replacement of the valved RV-PA conduit are usually necessary because of calcification and patient growth.

Anesthetic Management

Several principles of anesthetic management pertain to all D-TGA infants, and some are specific for the individual subtypes. These will be discussed in turn.

For all patients, it is important to select drugs and other strategies that maintain cardiac output by their effects on heart rate, contractility, and preload. This is important because decreases in cardiac output decrease systemic venous saturation, with a resultant decrease in arterial saturation. Although this is true of all patients on PGE, it can be a critical consideration in patients with TGA and IVS, in whom optimizing preload and cardiac output may be the most reliable means to maintaining adequate intercirculatory mixing and avoid severe derangements in oxygen saturation (both systemic venous and arterial) and delivery.

When a patient has evidence of pulmonary overcirculation and congestive signs or symptoms, maneuvers (particularly ventilatory) that further decrease PVR should be avoided. It is also important to avoid significant increases in PVR relative to SVR, which will decrease pulmonary blood flow and reduce intercirculatory mixing. Similarly, reductions in SVR relative to PVR should also be avoided, because SVR promotes recirculation of systemic venous blood (and thus intercirculatory mixing) and decreases arterial saturation. Again, in general, promoting overall filling and ventricular output are the most reliable ways to maintain intercirculatory mixing, oxygenation, and oxygen delivery. Positive pressure ventilation needs to be sufficient to ensure adequate lung volume and gas exchange without promoting unwanted metabolic effects (e.g., hypocarbia and alkalosis in patients with already low PVR and evidence of pulmonary overcirculation) or substantial mechanical compromise of venous return, ventricular function, or mixing (e.g., increased PVR).

Induction and Maintenance. In prostaglandin-dependent neonates, the PGE₁ infusion (0.01 to 0.05 mcg/kg per minute) should be continued until shortly before CPB to ensure sufficient intercirculatory mixing. Anesthetic-related myocardial depression can occur on several counts and is more likely in these patients because of myocardial immaturity, the effects of positive pressure ventilation, and increased pulmonary blood flow with limited cardiac reserve. Therefore, this is another situation in which inhaled agent-based induction and maintenance techniques are not favored. Instead, anesthesia is usually induced and maintained using high-dosage fentanyl or sufentanil to provide hemodynamic stability and blunting of the stress response without adversely affecting intercirculatory mixing. In addition to muscle relaxation, judicious and divided doses of benzodiazepines (or low-concentration inhaled agent) can be added to promote amnesia.

In patients with reduced pulmonary blood flow or poor intercirculatory mixing, efforts to reduce PVR should be made to increase pulmonary blood flow and intercirculatory mixing (again with the caveat of not impeding PBF or cardiac output by excessive ventilatory maneuvers). Again, volume expansion and the addition of inotropic support (e.g., dopamine, 5 to 10 mcg/kg per minute) may be indicated to improve overall mixing and output and offset to some extent the alterations imposed by anesthetic agents and mechanical ventilation. In patients with PVOD, ventilatory measures to reduce PVR are useful if PVR is not fixed. Hypercarbia, acidosis, and hypoxemia further increase PVR and should be avoided because of limited myocardial reserve and deleterious effects on PVR (and therefore mixing as well). This is particularly true in neonates with TGA and IVS, where systemic oxygen delivery is tenuous, and in infants with TGA and VSD, in whom left ventricular volume overload is present. Indeed, it is not uncommon to see S-T segment changes on the ECG in these infants when systemic output and oxygenation are compromised, particularly in the face of LV volume overload. In addition, reactive increases in PVR are commonly seen in the immature pulmonary vasculature and may severely compromise pulmonary blood flow.

Post-CPB Management

After CPB and surgical repair, the most frequent problems include myocardial ischemia due to coronary insufficiency, decreased myocardial function, bleeding due to extensive and pressurized suture lines after neonatal CPB and hypothermia (i.e., clotting factor dilution, thrombocytopenia, and platelet dysfunction [see later]), and reactive pulmonary vasculature. Heart rate should be maintained at age-appropriate levels, using atrial pacing if necessary, as cardiac output is likely to be more heart-rate-dependent during the post-CPB period, particularly in these neonates and young infants. Although blood pressure should also be kept at age-appropriate norms (especially after hypothermic CPB or deep hypothermic circulatory arrest [DHCA] when cerebral autoregulation is likely to be impaired), at times reducing aortic or pulmonary artery pressure (or both) may be used to reduce suture line bleeding after the ASO. Systemic ventricular (RV after atrial baffle procedures and LV after arterial switch procedures) dysfunction may necessitate inotropic and vasodilator therapy to terminate CPB. Dobutamine (5 to 10 mcg/kg per minute) or dopamine (5 to 10 mcg/kg per minute) is most often used. Milrinone (0.25 to 1.0 mcg/kg per minute after a loading dose of 50 mcg/kg) may be used if SVR is high. Milrinone not only reduces LV afterload but may also contribute inotropic, lusitropic, and PVR-reducing effects.

Obstruction of pulmonary or systemic venous return can occur after atrial baffle (Mustard or Senning) repairs. Systemic venous obstruction will produce evidence of systemic venous congestion and a measurable gradient between a catheter located in the SVC and one in the RA. Pulmonary venous obstruction may result in pulmonary venous and pulmonary arterial hypertension, pulmonary edema, and hypoxemia. Efforts to reduce SVR will reduce the RV afterload and help prevent tricuspid regurgitation. Therapy for atrial dysrhythmias also may be necessary. Echocardiography can help assess the presence of pulmonary or systemic venous obstruction, as well as atrial baffle leaks; any of these will require surgical revision if significant.

After the arterial switch procedure, there may be extensive bleeding from the aortic and pulmonary suture lines. Clotting factors (see later) and avoidance of hypertension are indicated. Myocardial ischemia after reimplantation of the coronary arteries is a potential and not infrequent problem after the ASO. In some circumstances, ischemia is caused by coronary air emboli and is transient. Maintenance of high perfusion pressures on CPB after aortic cross-clamp removal can promote distal migration and eventual dissipation of coronary air emboli. Echocardiography can help ensure adequate de-airing of the left atrium and ventricle prior to separating from CPB. It can also detect and distinguish between regional (i.e., potentially due to coronary insufficiency) and global (more likely due to ischemia–reperfusion injury) myocardial dysfunction and assess the presence of flow in the proximal portions of the reimplanted coronary arteries.

Evidence of myocardial ischemia after coronary reimplantation should be treated aggressively and should prompt immediate reevaluation of the anastomoses as well as the possibility of coronary kinking or external coronary compression by clot or hemostatic packing material. Such evidence is typically in the form of focal ECG abnormalities such as S-T/T wave changes, but it can also include various dysrhythmias and forms of AV block. Kinking of a reimplanted artery or obstruction of the implanted coronary ostia is likely to require immediate

surgical intervention. If the quality of the repair is good and it was accomplished relatively swiftly (i.e., to limit myocardial ischemia–reperfusion damage), then it is unusual to require significant inotropic support or artificial pacing (for anything other than a relative sinus bradycardia) or experience much in the way of ECG abnormalities, dysrhythmias, or AV block. On the other hand, the need for AV pacing, the occurrence of dysrhythmias, or the need for unexpected degrees of vasoactive support (e.g., epinephrine) should lead to a search for a technical problem.

A sequence of LV dilation both initiating and exacerbating myocardial ischemia can occur in D-TGA patients after the ASO. Myocardial ischemia, afterload mismatch, or excessive volume infusion can result in LV distention and LA hypertension. This is particularly likely if there is mitral insufficiency from either (ischemic) papillary muscle dysfunction or dilation of the mitral valve annulus. LV distention may result in tension on and kinking of the coronary reanastomosis sites. LA hypertension produces elevations in pulmonary artery pressure and distention of the pulmonary artery. Because the LeCompte maneuver brings the distal pulmonary artery anterior to the ascending aorta, distention of the pulmonary artery may actually compress or place tension on the coronary ostia. The resulting myocardial ischemia produces further LV dilation, progressive elevations in LA and pulmonary artery pressures, and continuing compromise of coronary blood flow.

In some TGA patients, the LV may have limited ability to support the systemic circulation after the ASO. This may occur as the result of myocardial ischemia, inadequate LV mass, poor protection of the LV during aortic cross-clamping, or a combination thereof. Echocardiography can be useful in identifying both global and regional LV systolic dysfunction. It also detects mitral regurgitation, which may occur secondary to papillary muscle dysfunction or to dilation of the mitral valve annulus. Inotropic support of the LV and afterload reduction may be necessary to terminate CPB. Initial inotropic support is accomplished with dopamine (3 to 10 mcg/kg per minute). In rare instances when LV failure (that, again, has been proven not to be the result of a coronary problem) is severe, epinephrine (0.05 to 0.5 mcg/kg per minute) may have to be added. Milrinone (0.25 to 1.0 mcg/kg per minute after a 50-mcg/kg loading dose) can be a useful agent based on its inodilator properties (Hoffman et al., 2002, 2003). These patients are at particular risk for LV dysfunction in the immediate postoperative period secondary to afterload mismatch (insufficient contractility for the degree of systemic afterload). Although the vasodilation that accompanies milrinone administration in infants is substantially less than that seen in adult patients, it is nonetheless advisable to administer the loading dose of milrinone over 10 to 15 minutes or longer.

Truncus Arteriosus

Anatomy

A single great vessel arising from the base of the heart and giving rise to the pulmonary, coronary, and systemic arteries characterizes truncus arteriosus (Figs. 20-16 and 20-17). See related video online at www.expertconsult.com. There is a single semilunar valve, which is usually abnormal, and invariably a large (nonrestrictive) conoventricular septal VSD is present. The truncus straddles this large VSD (see Fig. 20-16). Truncus arteriosus is classified based on the origin of the pulmonary

■ **FIGURE 20-16.** Anatomy of tricus arteriosus. Type 1 tricus arteriosus is illustrated here with a short pulmonary trunk arising from the truncus. There is a large conoventricular septal defect with truncal override. (Redrawn from *Children's Hospital Boston, Boston, Mass.*)

arteries. In type 1, a short pulmonary trunk originates from the truncus and gives rise to both pulmonary arteries. In type 2, both pulmonary arteries arise from a common orifice of the truncus, whereas in type 3, the right and left pulmonary arteries arise separately from the lateral aspect of the truncus. The VSD is usually of the infundibular or perimembranous infundibular type. The truncal valve is tricuspid in most patients, but multiple cusps (four to seven) are common, and the valve itself may be regurgitant or stenotic. Extracardiac anomalies are seen in approximately 30% of patients.

Physiology

Tricus arteriosus is a single-ventricle-physiology lesion amenable to a two-ventricle repair. The large (nonrestrictive) VSD allows equalization of pressures in the right and left ventricles. As a result, there is bidirectional shunting and complete mixing of systemic and pulmonary venous blood in a functionally common ventricular chamber. This blood is then ejected into the truncal root, which gives rise to the pulmonary, systemic, and coronary circulations. As with all simple shunts, $\dot{Q}P:\dot{Q}S$ is

■ **FIGURE 20-17.** Tricus arteriosus. There are similarities between the Collett and Edwards and the Van Praagh classifications of tricus arteriosus. Type I is the same as A1. Types II and III are grouped as a single type A2, because they are not significantly distinct embryologically or therapeutically. Type A3 denotes a unilateral pulmonary artery with a collateral supply to the contralateral lung. Type A4 is tricus arteriosus associated with interrupted aortic arch (13% of all cases of tricus arteriosus). (From *Mavroudis C, Backer CL, editors: Pediatric cardiac surgery, Stamford, Conn, 1999, Appleton & Lange, p 340.*)

determined by the ratio of PVR to SVR. However, in truncus arteriosus, the pulmonary and systemic circulations are supplied in parallel from a single vessel, and for a given ventricular output, increases in flow to one circulatory system will produce reductions in flow to the other.

As with all single-ventricle lesions, a low $\dot{Q}_P:\dot{Q}_S$ reduces arterial saturation, whereas a high $\dot{Q}_P:\dot{Q}_S$ produces ventricular volume overload without a substantial increase in arterial saturation. Shortly after birth, the balance of PVR and SVR is such that pulmonary blood flow is high and the patient with truncus arteriosus has symptoms of CHF with mild cyanosis. After cardiac reserve has been exhausted, further decreases in PVR increase pulmonary blood flow at the expense of systemic and coronary perfusion. This produces a progressive metabolic acidosis. If truncal valve insufficiency is present, it imposes an additional volume load on the ventricles. Given the high pulmonary blood flow and the transmission of systemic arterial pressures to the pulmonary vasculature present in this lesion, development of PVOD is rapid. With development of PVOD comes a progressive decrease in pulmonary blood flow relative to systemic blood flow, and progressive hypoxemia.

Surgical Therapy

Because of the risk for early development of PVOD, surgical intervention in the first months of life is undertaken. Definitive repair of truncus arteriosus requires patch closure of the VSD, detachment of the pulmonary arteries from the truncus, and establishment of right-ventricular-to-pulmonary-artery continuity with a valved homograft. The RV-to-PA conduit requires placement of the proximal end of the conduit over a ventriculotomy in the RV free wall. The truncal valves must be assessed at the time of surgery. In some instances, valve repair or replacement is necessary to address valvular insufficiency or stenosis. Valvuloplasty is preferred over valve replacement. Valve replacement in a child necessitates subsequent replacements as the child grows. Management of the systemic anticoagulation necessary with a mechanical valve is also difficult in growing children. The RV-to-PA valved conduit eventually requires replacement as the child grows.

Anesthetic Management

These patients are managed according to the principles described later (see Hypoplastic Left Heart Syndrome and Single-Ventricle Physiology). This is a non-ductal-dependent lesion.

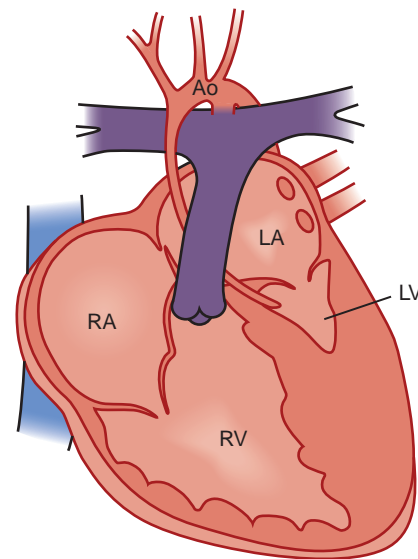

Post-CPB Management

Some degree of RV dysfunction is likely to exist because of the presence of a ventriculotomy and a large VSD patch. This is particularly problematic in patients with high PVR or early PVOD. Left ventricular volume overload may occur secondary to truncal valve insufficiency. The goals of management include maintenance of heart rate (preferably sinus rhythm) at an age-appropriate rate, as cardiac output is likely to be more heart rate dependent in the post-CPB period. PVR should be reduced when necessary through ventilatory interventions. Inotropic support of the left and right ventricles may be necessary for the reasons addressed previously.

Hypoplastic Left Heart Syndrome and Single-Ventricle Physiology

HLHS is characterized by hypoplasia of all left heart structures, and it is an example of single-ventricle physiology with ductal-dependent systemic blood flow. See related video online at www.expertconsult.com. In the most severe form, mitral and aortic atresia with hypoplasia of the left atrium, left ventricle, ascending aorta, and aortic arch (including coarctation) is present. Distal aortic blood flow occurs via the PDA. Proximal aortic blood flow and coronary blood flow occur by retrograde filling of a tiny ascending aorta via the PDA (Figs. 20-18 and 20-19). There is complete mixing of pulmonary venous and systemic venous blood in a single ventricle, which is connected in parallel to both the pulmonary and systemic circulations. Systemic blood flow is dependent on a PDA. Survival depends on a balance between systemic (\dot{Q}_S) and pulmonary (\dot{Q}_P) blood flow, because both circulations are supplied from the right ventricle in parallel. The major determinant of the distribution of \dot{Q}_S and \dot{Q}_P is their relative systemic and pulmonary vascular resistances (Barron et al., 2009).

The primary goal in the management of patients with HLHS, as for all patients with single-ventricle physiology, is optimization of systemic oxygen delivery and perfusion pressure. This is necessary if end-organ (myocardial, renal, hepatic, splanchnic) ischemia and injury are to be prevented. This goal is achieved by balancing the systemic and pulmonary circulations (Table 20-4). The term *balanced circulation* is used because both laboratory and clinical investigations have demonstrated that maximal systemic oxygen delivery (the product of systemic oxygen content and systemic blood flow) is achieved for a given single-ventricle

■ **FIGURE 20-18.** Anatomy of hypoplastic left heart syndrome (HLHS). There is severe mitral stenosis or mitral atresia, left ventricular hypoplasia, aortic valve atresia or severe stenosis, and hypoplasia of the ascending aorta (Asc. Ao) and transverse aortic arch. Pulmonary and systemic blood flows are both delivered via the right ventricle (RV). Aortic blood flow is provided via a large ductus arteriosus. There is antegrade flow from the patent ductus arteriosus to the descending aorta (Desc. Ao), and retrograde flow to the proximal aortic arch and cerebral circulation. The coronary arteries receive retrograde perfusion via the tiny ascending aorta. The left ventricle (LV) is diminutive. (Redrawn from Children's Hospital Boston, Boston, Mass.)

■ **FIGURE 20-19.** Sequence of repairs in the surgical staging of hypoplastic left heart syndrome (HLHS) to a fenestrated lateral-tunnel Fontan. *Upper left:* HLHS. *Upper right A:* Initial repair performed shortly after birth involving atrial septectomy, Damus-Kaye-Stansel (DKS) anastomosis of main pulmonary artery to ascending aorta, homograft augmentation of the aortic arch, and a right modified Blalock-Taussig shunt (BTS) to supply pulmonary blood flow. *Upper right B:* Alternate initial repair performed shortly after birth involving atrial septectomy, DKS anastomosis of main pulmonary artery to ascending aorta, homograft augmentation of the aortic arch, and a right ventricle-to-pulmonary artery conduit to supply pulmonary blood flow. *Lower left:* Superior cavopulmonary shunt or bidirectional Glenn (BDG), generally performed at 6 to 8 months of age. The right modified BTS has been taken down and ligated. *Lower right:* The completed total cavopulmonary connection or Fontan procedure generally performed at 2 to 3 years of age. A lateral-tunnel Fontan with a fenestration is shown. The *small arrows* indicate flow from the systemic venous baffle to the common pulmonary venous atrium, causing a small right-to-left physiologic shunt.

TABLE 20-4. Effects on Aortic and Mixed Venous Saturation of Pulmonary and Systemic Blood Flows in Patients with Single-Ventricle Physiology

Aortic Saturation (%)	Svo ₂ (mm Hg)	Q _P :Q _S	Clinical Considerations
80	55	1:1	Balanced shunt
85	55	2:1	Mild reduction in systemic flow
90	55	4:1	Severe reduction in systemic flow
70	45	1:2	Mild reduction in pulmonary flow
70	70	1:4	Severe reduction in pulmonary flow
80	50	2:1	Decreased cardiac output, increased Q _P
80	30	>2:1	Decreased cardiac output, increased Q _P

Q_P, Pulmonary blood flow; Q_S, systemic blood flow.

output when Q_P:Q_S is at or just below 1:1. Increases in Q_P:Q_S in excess of 1:1 are associated with a progressive decrease in systemic oxygen delivery because the subsequent increase in systemic oxygen content is more than offset by the progressive decrease in systemic blood flow. There will be inadequate systemic oxygen delivery (systemic venous desaturation, a wide

difference in systemic arterial and superior vena caval oxygen saturation [Sa-v_o], metabolic acidosis) and low perfusion pressure in the presence of a seemingly high arterial saturation of 85% to 90%. Decreases in Q_P:Q_S below 1:1 are associated with a precipitous decrease in systemic oxygen delivery because the subsequent increase in systemic blood flow is more than offset by the dramatic decrease in systemic oxygen content. There will be inadequate systemic oxygen delivery (arterial and venous desaturation, metabolic acidosis) in the presence of a seemingly adequate arterial blood pressure. In either case, circulatory collapse will ultimately occur.

Treatment

Treatment can begin with interventions that temporarily stabilize the single-ventricle circulation in neonates, including PGE₁ infusion to maintain systemic perfusion via the ductus arteriosus. A balloon atrial septostomy may be performed if there is clinical and echocardiographic evidence of left atrial hypertension and significant restriction of circulatory mixing at the atrial level; however, a modest degree of restriction is felt by many to be desirable as it may help limit the tendency to pulmonary overcirculation (by maintaining a degree of left atrial hypertension) that can occur in these patients in the initial postnatal days while awaiting surgery. Usual management consists of spontaneous ventilation in room air and PGE₁ infusion prior to stage I palliative surgery. Inotropic agents may be required in some to support cardiac output and systemic perfusion. The use of different inspired gas mixtures to balance the single-ventricle

circulation and in particular to improve systemic oxygen delivery remains fairly controversial (Tabbutt et al., 2001; Li et al., 2008; Barron et al., 2009).

Surgical correction of HLHS begins with a palliative procedure that eliminates the need for continued patency of the ductus arteriosus. This stage I procedure is performed during the first several days to a week of life using CPB in conjunction with 40 to 60 minutes of deep hypothermic circulatory arrest or low-flow selective cerebral perfusion during reconstruction of the aortic arch (see later) (Edwards et al., 2007; Pigula et al., 2007; Reemtsen et al., 2007; Silva et al., 2007). The procedures necessary are outlined in [Figure 20-19](#). The first stage essentially consists of establishing unimpeded flow of venous return from both the systemic and pulmonary circulations into the right ventricle and then into the aorta and creating a stable conduit for pulmonary blood flow. In practice, this requires a freely patent atrial septum (an atrial septectomy is often necessary), a functioning tricuspid valve, construction of a proximal pulmonary artery–ascending aorta end-to-side anastomosis (the Damus-Kaye-Stansel procedure), so that the combined venous return is ejected by the right ventricle into the aorta, and reconstruction and enlargement of the aortic arch (using both the proximal pulmonary artery and homograft material). The distal PA is oversewn and the PDA ligated. Pulmonary blood flow is established via either a modified BT shunt (the proximal insertion of which is typically into the innominate artery) or an RV-PA conduit (the Sano modification). The completed stage I procedure leaves the infant with single-ventricle physiology.

Management of Anesthesia

Management of anesthesia is as described for patients with single-ventricle physiology ([Box 20-4](#), and see earlier). An intravenous induction using a high-dosage synthetic narcotic technique in combination with a muscle relaxant is recommended. A benzodiazepine (usually midazolam) can be added as tolerated. Inhalation agents are generally poorly tolerated. Pancuronium is normally used. However, in patients with a low aortic diastolic blood pressure and a high baseline heart rate, consideration should be given to using one of the muscle relaxants that do not affect heart rate, such as vecuronium or rocuronium, so as to avoid iatrogenic subendocardial ischemia.

Post-CPB management is as summarized in [Box 20-5](#). The major pathophysiologic perturbations after CPB include hypoxemia, hypotension, low systemic perfusion, difficulties with gas exchange, and significant bleeding (extensive suture lines and coagulopathy from hemodilution, hypothermia, coagulation factor and platelet consumption due to profuse bleeding [see Bleeding after Pediatric Cardiopulmonary Bypass]). End-organ injury, the result of CPB effects, preoperative or post-CPB hypoperfusion, and DHCA or selective perfusion strategies, is also relatively common, with myocardial, renal, and cerebral dysfunction and damage predominating (Mahle and Wernovsky, 2004; Wernovsky, 2007; Ohye et al., 2009; Aiyagari et al., 2010).

Myocardial dysfunction contributing to a low systemic cardiac output state is relatively common after stage I HLHS repairs. Given adequate filling pressures (common atrial pressure of ~8 to 15 mm Hg), dopamine (5 to 15 mcg/kg per minute) and at times α -agonist doses of epinephrine (0.03 to 0.05 mcg/kg per minute) may be necessary. The need for artificial pacing (for other than a relative sinus bradycardia), the presence of ST-T wave changes or dysrhythmias, or the need for substantially greater degrees

Box 20-4 Goals of Anesthesia Management for Single-Ventricle (SV) Physiology before Cardiopulmonary Bypass

1. A continuous infusion of PGE_1 is used to maintain ductal patency in patients with ductal dependent blood flow (either systemic or pulmonary).
2. A target Pao_2 of 40 to 45 mm Hg and an SaO_2 of 70% to 80% are associated with adequate systemic O_2 delivery.
3. In SV patients with unrestricted pulmonary blood flow,
 - -PVR manipulation is essential and $\dot{Q}P:\dot{Q}S$ is accomplished, most reliably with ventilatory interventions.
 - -Hypercarbia in combination with a 21% FiO_2 , and normocarbia in combination with a 17% FiO_2 (inspired N_2), is used to increase PVR and reduce $\dot{Q}P:\dot{Q}S$.
4. Hypercarbia ($Paco_2$ of 45 to 55 mm Hg) can be achieved with alveolar hypoventilation or with increased inspired CO_2 (3% $FiCO_2$).
5. Avoid a high FiO_2 unless the Pao_2 is less than 35 to 40 mm Hg.
6. Because ventilatory interventions are incapable of reducing $\dot{Q}P:\dot{Q}S$ much below 2:1, increased cardiac output is often necessary to ensure adequate systemic oxygen delivery and coronary perfusion pressure.
 - -Increased stroke volume with preload augmentation, limited
 - -Increased heart rate (>140-150 bpm) can cause myocardial ischemia in patients with aortic diastolic blood pressures in the range of 20 to 30 mm Hg.
 - -Inotropic support may be necessary
7. After sternotomy, the surgeon can limit pulmonary blood flow and reduce $\dot{Q}P:\dot{Q}S$ with a vessel loop around a PA (usually the right).
8. Infants with SV physiology who arrive in the operating room unintubated from the ICU have a balanced circulation, but after induction, intubation and mechanical lung expansion, these patients may have a precipitous decrease in PVR and immediate compromise of systemic circulation.

FiCO₂, Fraction of inspired CO₂; *FiO₂*, fraction of inspired oxygen; *ICU*, intensive care unit; *Pao₂*, arterial oxygen tension; *PGE₁*, prostaglandin E₁; *PVR*, pulmonary vascular resistance; *Q̇P:Q̇S*, ratio of pulmonary-to-systemic blood flow; *SaO₂*, arterial oxygen saturation of hemoglobin.

of vasoactive support should prompt consideration of potential technical problems with the repair (e.g., coronary insufficiency arising from the construction of the Stansel anastomosis).

In a somewhat oversimplified and artificial fashion, one can describe three general clinical situations in the post-CPB period after stage I repairs:

1. Too much PBF, or shunt too large. This is characterized by higher-than-expected arterial oxygen saturations (90% or higher), frequently in combination with low systolic and particularly diastolic blood pressure, systemic hypoperfusion, acidosis, and oliguria; ECG evidence of ischemia may also be present if of sufficient magnitude. This is perhaps the least common of the three because of the current use of smaller shunts placed more distally on the innominate artery. Although ventilatory maneuvers to increase PVR (e.g., hypoventilation, added inspired CO_2 , or adding N_2 to create a hypoxic gas mixture [17% to 18% O_2]) or increased levels of inotropic support can be attempted, usually narrowing of the shunt is required.

Box 20-5 Anesthetic Management of Single-Ventricle Physiology after Cardiopulmonary Bypass (CPB)

1. After CPB, high PVR, reduced pulmonary blood flow, and hypoxemia ($Pao_2 < 40$ mm Hg) are common.
2. The modified Blalock-Taussig shunt or RV-PA conduit may be too large (resulting in pulmonary overcirculation and systemic hypoperfusion) or too small (inadequate pulmonary blood flow, excessive cyanosis) for prevailing physiologic conditions.
3. Ventricular dysfunction may exist. Low venous oxygen saturation may contribute to increased arterial desaturation, which can further exacerbate myocardial dysfunction.
4. Myocardial and tissue edema may be significant and preclude chest closure.
5. Bleeding may be significant.
6. Inhaled pulmonary vasodilators such as NO may be necessary to improve Sao_2 or reduce the transpulmonary gradient in these patients. This is particularly true in the subgroup of patients who have repair of partially obstructed pulmonary venous drainage at the time of their initial repair, and perhaps those with left atrial hypertension (e.g., restrictive atrial septum) prior to surgery.

NO, Nitric oxide; PA, pulmonary artery; Pao_2 , arterial oxygen tension; PVR, pulmonary vascular resistance; RV, right ventricle; Sao_2 , arterial oxygen saturation of hemoglobin.

2. Too little PBF or shunt too small. These patients display arterial oxygen saturations substantially lower than expected, often with normal or even elevated systemic blood pressures and perfusion (if myocardial performance is adequate). Causes include insufficient shunt diameter, narrowing at the proximal or distal insertion sites, more distal PA narrowing, increased intrinsic pulmonary vascular resistance, and lung disease (resulting from CPB or preoperative overcirculation or other processes). In the absence of technical difficulties or mechanical obstruction, maneuvers that decrease PVR, improve ventilation, or increase systemic arterial blood pressure and cardiac output can be attempted.
3. Low arterial oxygen saturation or low systemic blood pressure. This may be the most common symptom complex in most institutions, and it can be the most difficult to sort out. Some degree of myocardial injury occurs in all of these patients; significant myocardial dysfunction leads to low cardiac output, low shunt perfusion, and reduced venous oxygen saturation, which, taken together, result in low oxygenation. Alternatively, poor oxygenation (see #2) in at least some patients (perhaps including those who were not particularly cyanotic preoperatively and hence have less myocardial tolerance to reduced saturations postoperatively) results in compromised myocardial function, which then follows the low cardiac output scenario just described. Measuring SVC saturation can be helpful in making this determination, as a value that is more than about 25 saturation points lower than the arterial value (e.g., an SVC saturation of 25% when the arterial is 68% equals 43 saturation points) is indicative of some contribution of low oxygen delivery to the reduced arterial oxygen saturation. Echocardiography and measuring the saturation of pulmonary venous blood can at times be helpful in delineating myocardial versus pulmonary etiology. From a practical standpoint (once the possibility of

technical problems has been eliminated), treatment begins with ensuring appropriate ventilation parameters, oxygen-carrying capacity (hematocrit of 35% to 40%), and optimizing cardiac output (adequate filling, ionized calcium, and inotropic support) and arterial blood pressure (to ensure adequate PBF via the shunt).

The major differences between a BT and Sano-type shunt in the immediate postoperative period relate to these types of interactions between RV function, RV output, PBF, and oxygenation. In both situations, systemic and pulmonary blood flows and oxygenation are governed by RV function and output and the balance of SVR:PVR (with PVR affected by factors related to shunt- and lung-based resistances; the Sano, for example, is a wider [5 mm versus 3.5 mm] but substantially longer shunt). However, a major physiologic difference in the Sano is that there is no diastolic runoff from the aorta into the lungs. As a result, for a given degree of RV output, blood pressures (particularly diastolic) tend to be higher in the Sano than in the BT shunt patients, with resultant benefits to coronary perfusion and perhaps myocardial performance. Comparisons of the two types of shunts with regard to death, cardiac transplantation, cardiovascular interventions, and RV size and function have been reported in a large multicenter randomized study. Although transplantation-free survival at 12 months was better with an RV-to-PA shunt, after 12 months the difference between the two groups was not significant (Ohye et al., 2010). Questions about longer-term complications such as greater propensity to shunt and pulmonary artery narrowing and increased cyanosis, and perhaps RV dysfunction (perhaps at least in part due to the right ventriculotomy's being more prevalent after the Sano modification) are under study (Ohye et al., 2010).

Hybrid Procedure

The stage 1 hybrid procedure for HLHS is an alternative to the Norwood stage I procedure with either a modified BT shunt or an RV-to-PA conduit (Sano modification). The hybrid procedure obviates the need for CPB and the associated use of either DHCA or antegrade cerebral perfusion (ACP) in the neonate. This procedure must be done in a location (the hybrid operating room) that provides full cardiac catheterization infrastructure, including biplane cardioangiography, in a sterile operating room environment. The procedure (see Fig. 21-13 in Chapter 21, Congenital Cardiac Anesthesia: Non-Bypass Procedures) involves off-pump placement of a bare metallic stent in the ductus arteriosus, bilateral pulmonary artery banding, and dilation/stenting of the intraatrial septum. The balloon atrial septostomy is generally performed prior to discharge from the hospital unless there is obstruction of pulmonary venous blood delivery to the right ventricle and pulmonary venous hypertension detected earlier. The physiologic burden associated with CPB and DHCA or ACP avoided in the first stage is then incurred at the time of the comprehensive stage 2 (bidirectional Glenn [BDG] shunt, Stansel anastomosis, aortic arch reconstruction, and definitive atrial septectomy) performed at 3 to 6 months of age.

Superior Cavopulmonary Shunt or Bidirectional Glenn

Glenn's original description of a superior vena caval shunt was an end-to-side anastomosis of the cranial end of the transected superior vena cava to the distal end of the transected right

pulmonary artery (RPA) performed through a right thoracotomy without the use of CPB. Both the proximal SVC and the RPA were oversewn. The current modified BDG procedure anastomoses the cranial end of the transected SVC in an end-to-side fashion to the RPA (which is left in continuity with the main and left PAs); the cardiac end of the SVC is oversewn. This creates SVC continuity with both the left and right pulmonary arteries and bidirectional pulmonary blood flow (i.e., the BDG directs systemic venous blood from the SVC directly into the pulmonary circulation). The BDG procedure is usually performed with the patient on CPB, and through a median sternotomy. If there were prior palliative procedures, the aortopulmonary shunt is ligated or the PA band taken down. The azygos vein is usually ligated so that the SVC does not decompress retrograde to the IVC, thereby reducing the quantity of blood delivered to the PAs (unless, e.g., the IVC is interrupted with azygous continuation, as occurs in frequently in patients with heterotaxy syndrome and some others). Normally, all upper extremity and cerebral venous return drains via the SVC. In some patients (particularly those with heterotaxy syndrome), there may be bilateral SVCs that are not in continuity via a connecting vein. In this case, a bilateral BDG must be done with one SVC anastomosed in an end-to-side fashion to the RPA and the other SVC anastomosed in an end-to-side fashion to the LPA.

The BDG is normally undertaken at about 3 to 8 months of age, at which point the PVR has decreased sufficiently such that systemic venous pressure (SVC pressure) is sufficient to drive pulmonary blood flow. Patients who have outgrown their PA band, their modified BT shunt, or their RV-to-PA conduit (as in the Sano-type stage I HLHS operation), or those who have a low SaO_2 , as well as those who are not tolerating the additional volume load on their ventricle because of a loose PA band or large modified BT shunt, frequently undergo BDG at the earlier end of the spectrum.

There are physiologic differences between an aortopulmonary shunt and a BDG. Effective pulmonary blood flow in the aortopulmonary shunt and BDG circulations are essentially equal. However, for a given cardiac output, SaO_2 , $SpvO_2$, and SvO_2 , the volume load on the systemic ventricle is twice as large with an aortopulmonary shunt as it is with a BDG. This is because in the aortopulmonary shunt circulation there is recirculated pulmonary blood (physiologic L-R shunt), whereas in the BDG circulation there is no recirculated pulmonary blood flow. As a result, a child with a BDG will have the same SaO_2 as a child with an aortopulmonary shunt (typically in the range of 80% to 85%) but with a significant reduction in the volume load on the systemic ventricle.

Part of the confusion with these procedures arises from the large number of nomenclature and procedural modifications, many of which have been devised to simplify subsequent conversion to a Fontan. The *hemi-Fontan* is a procedure in which an atriopulmonary anastomosis is constructed between the dome of the right atrium at the RA/SVC junction and the inferior surface of the right pulmonary artery. A Gore-Tex baffle or plug is used to supplement the central pulmonary artery area and to isolate the cavopulmonary connection from the RA. Another modification involves creation of a double cavopulmonary anastomosis. The cranial end of the divided SVC is anastomosed to the superior surface of the RPA. The cardiac end of the divided SVC is anastomosed to the inferior surface of the RPA. The internal orifice of the SVC is closed with a Gore-Tex patch.

Anesthetic Management before BDG

The principles outlined previously regarding the management of single-ventricle physiology apply here, with some modifications. Most important, by the age of 3 to 8 months, when these infants present for BDG, they have generally grown and gained weight so that their Qp:Qs is less likely to be (or to become) excessive—typically between 1.0:1 and 1.5:1. As a result, these patients are much less likely to develop an excess of pulmonary blood flow and hence compromised systemic O_2 delivery due to anesthetic induction and positive pressure ventilation (unless they are in the smaller subset being done early for excessive PBF and systemic ventricular volume overload). On the other hand, infants who have outgrown (or who have developed a narrowed shunt or RV-PA conduit) and thus have limited PBF and are more cyanotic as a result are at risk for significantly reduced PBF and arterial oxygen saturations if systemic ventricular cardiac output and SVR (the driving forces for flow through the narrowed or obstructed conduit) fall. As discussed previously, their baseline oxygen saturation is a reasonably good (albeit physiologically somewhat simplistic) indicator of which of the two general categories (pulmonary overcirculation versus limited PBF) they belong in.

In either case, an IV induction is generally preferred. Vascular access may be difficult, as many require prolonged ICU stays and other procedures (e.g., catheterizations, gastrostomy tubes) after the initial repair. In addition, some of these patients appear tolerant to opioids and benzodiazepines after their ICU stay. This should be considered if premedication is planned prior to IV placement. Once an IV line is in place, volume expansion (crystalloid or 5% albumin) is a reasonable consideration prior to induction. Induction techniques that favor prompt and reliable airway control as well as hemodynamic stability are preferable to ones associated with decreased myocardial contractility or SVR (e.g., propofol). Patients with significant ventricular dysfunction, ventricular volume overload, or critically narrowed sources of PBF may also benefit from the inclusion of inotropic support as part of the induction regimen.

Post-CPB Management of BDG Patients

The success of this circulation and the resultant arterial oxygen saturation depend not only on a technically satisfactory anastomosis but also on a number of hemodynamic and related parameters. The SVC return needs to flow unimpeded and at sufficient pressure to traverse the pulmonary vascular bed, where mechanical and intrinsic resistance must be low, followed by unimpeded egress via the pulmonary veins (here again without mechanical obstruction or increased pulmonary venous tone) to fill the common systemic ventricular atrium, traverse a nonstenotic, nonregurgitant atrioventricular valve, and fill a well-functioning systemic ventricle (for example, the mitral valve and LV in the case of tricuspid atresia, the tricuspid valve and RV in HLHS). It is therefore critical to maintain heart rate and sinus rhythm, contractility, and appropriate preload so as to maintain cardiac output. Decreases in cardiac output reduce IVC saturation; IVC and pulmonary venous blood mix in a common atrium, which will reduce arterial saturation.

A central line located in the internal jugular vein will measure SVC pressure (which also equals mean pulmonary artery pressure [mPAP] after a BDG). A surgically placed atrial catheter will measure common atrial pressure (a common atrium

exists because of the large atrial septectomy). The difference between these two pressure measurements (SVC [or internal jugular] pressure and the common atrial pressure) is the transpulmonary gradient (TPG). A TPG of about 6 to 10 mm Hg is the norm in terms of driving adequate PBF and filling of the downstream systemic ventricle. Thus, with a common atrial pressure of 6 to 10 mm Hg (the expectation in the presence of preserved ventricular function, adequate arterial blood pressure, and other evidence of adequate systemic cardiac output), the proximal pressure in the SVC will be in the range of 12 to 18 mm Hg. Hypoventilation, lung disease, or increased PVR can widen the TPG; thus, to obtain a comparable degree of ventricular filling and cardiac output, the SVC pressure must increase (either by exogenous volume administration or by activation of adrenal and renal mechanisms that expand intravascular volume, which of course will be slower). Increased SVC pressure is also necessary to maintain preload and cardiac output in the case of systemic ventricular dysfunction. Here, the TPG is likely to be relatively normal (6 to 10 mm Hg), but the higher ventricular end-diastolic pressure (e.g., 12 to 16 mm Hg) results in an SVC pressure of 18 to 26 mm Hg to achieve comparable cardiac output.

In addition to adequate preload, inotropic support of the systemic ventricle may be necessary because of ventricular dysfunction induced by chronic volume overload, prior injury, and the acute effects of CPB and ischemia-reperfusion injury. Typically, dopamine (3 to 5 mcg/kg per minute, occasionally as high as 10 mcg/kg per minute) is used. Milrinone (0.25 to 0.5 mcg/kg per minute, at times up to 1.0 mcg/kg per minute) can benefit this circulation, although others reserve it for use in combination with dopamine or for patients who have hypertension or poor perfusion in the face of normal or elevated blood pressure.

In general, normocarbia should be the goal of post-CPB ventilatory management. Hypoventilation and atelectasis can compromise pulmonary blood flow and consequently systemic ventricular filling and cardiac output. High mean airway pressure will mechanically limit nonpulsatile pulmonary blood flow, thereby impairing it. After construction of the Glenn anastomosis, there is an acute increase in SVC pressure and presumably in intracranial pressure. The volume load reduction and elevated SVC pressure are believed to contribute to the (reflex) systemic hypertension and postoperative irritability that is commonly seen in these patients. The majority of pulmonary blood flow is supplied via venous blood from the brain, which is the largest single source of venous drainage from the upper body. Hyperventilation and hypocarbia, although beneficial in reducing PVR, also reduce cerebral blood flow (CBF) and cerebral venous drainage. Maintaining normocarbia after BDG has been demonstrated to provide maximal $\dot{Q}_P:\dot{Q}_S$ and Sa_{O_2} . These patients tend to have a large end-tidal- CO_2 - $Paco_2$ gradient because of increased physiologic dead space. An increased portion of the lungs in these patients is ventilated but not perfused because of the low PA driving pressure (SVC pressure). Thus, mean airway pressure should be kept at the minimal level that is compatible with delivery of an adequate tidal volume and normal lung expansion. This can usually be accomplished with a relatively large tidal volume (10 to 12 mL/kg), slow respiratory rates (10 to 15 breaths/min), and short inspiratory times (inspiratory-to-expiratory ratio of 1:3 or 1:4) positive end-expiratory pressure (PEEP) can be used beneficially (i.e., for maintenance of functional residual capacity and gas exchange) but with caution.

BDG patients have an Sa_{O_2} of about 76% to 85%, similar to that prior to their shunt. However, their $\dot{Q}_P:\dot{Q}_S$ ranges from 0.5:1 to 0.8:1, and as a result there is an acute reduction in volume load on the systemic ventricle. The most likely cause of a low Sa_{O_2} after a BDG is low cardiac output with a low IVC saturation. Comparison of the SVC and common atrial pressures, perhaps in combination with surface echocardiography or TEE, may help delineate the cause (e.g., primary ventricular dysfunction, hypovolemia, AV valve dysfunction). If a low Sa_{O_2} persists despite optimization of filling status and ventricular function, other causes of reduced pulmonary blood flow should be considered, such as a stenotic anastomosis or the presence of decompressing veno-venous collaterals (typically from the SVC to the IVC, or the SVC to the pulmonary veins or left atrium).

Reduced pulmonary venous oxygen saturation (Pp_{vO_2}) may also be a source of low Sa_{O_2} . Ventilatory maneuvers to reduce V/Q mismatch and intrapulmonary shunt should be done. A high F_{iO_2} may be necessary in the presence of significant V/Q mismatch. Response to inhaled pulmonary vasodilators such as inhaled NO can be variable; the BDG (and Fontan) patients most likely to respond with improvements in arterial oxygen saturation and apparent cardiac output usually have significantly elevated proximal venous or TPG pressures (>18 to 20, and >10 mm Hg, respectively) (Gamillscheg, 1997; Agarwal, 2006).

Definitive Repair: The Fontan Procedure or Total Cavopulmonary Connection

Fontan Physiology

The Fontan procedure is generally performed at 2 to 3 years of age, and it is typically the final staged correction after one of the aforementioned palliative single-ventricle operations. See related video online at www.expertconsult.com. Fontan physiology is a series ("normal") circulation that is characterized by one ventricle with sufficient diastolic, systolic, and atrioventricular valve function to support the systemic circulation. This ventricle must be in unobstructed continuity with the aorta and receive unobstructed pulmonary venous return. In addition, there must be unobstructed flow of systemic venous blood to the pulmonary circulation (total cavopulmonary continuity).

The Fontan procedure was first performed in 1968 and was initially described for patients with tricuspid atresia. The original version included a Glenn shunt, which drained the SVC into the distal right pulmonary artery. The proximal end of the right pulmonary artery was joined to the right atrial appendage via an aortic valve homograft, and a pulmonary valve homograft valve was placed at the IVC-RA junction. The main pulmonary artery was ligated and the ASD was closed. In subsequent early iterations, creation of the Glenn shunt and placement of homograft valves at the RA-PA and IVC-RA junctions were eliminated, resulting in creation of a direct atriopulmonary connection. Since that time, many additional modifications have been described, but the goals of the procedure remain the same: to deliver all systemic venous blood directly to the pulmonary arteries in the absence of a reservoir or ventricular pump. This requires total cavopulmonary connection that is created either directly or via the systemic venous atrium. The most commonly performed procedures now are the lateral tunnel and extracardiac Fontan procedures (see Figs. 20-4, 20-5, and 20-19).

The lateral tunnel procedure incorporates a small amount of systemic venous atrium in the cavopulmonary pathway, whereas

the extracardiac procedure does not incorporate any atrial tissue. These procedures are referred to as total cavopulmonary connections. Experience with direct atriopulmonary connections suggested that elevated systemic venous pressure leads to progressive and severe atrial dilation (volumes as large as 300 to 500 mL). The massive dilated atrium was believed to contribute to stasis (and hence thromboembolism) as well as being a source of atrial arrhythmias. In theory, the extracardiac procedure may offer additional protection from development of atrial arrhythmias because of a lack of suture lines in the atrium.

In the absence of any residual physiologic intracardiac or intrapulmonary R-L shunting, these patients should have an essentially normal SaO_2 (it may be depressed 3% to 5% as a result of drainage of coronary venous blood via the coronary sinus into the systemic ventricle). Although it is often stated that pulmonary blood flow is passive and driven by the components of the TPG (systemic venous pressure > mean pulmonary artery pressure > pulmonary venous atrial pressure), the systemic ventricle generates the energy necessary to provide flow through the pulmonary capillary bed because the systemic vascular bed and pulmonary vascular bed are in continuity, without an intervening atrium and ventricle to provide reservoir and pumping capacity. As a result, the single ventricle in a series Fontan circulation is faced with higher afterload than the systemic ventricle in a two-ventricle series circulation. Additional circulatory abnormalities that may contribute to impaired ventricular function, exercise capacity, and altered hemodynamic behaviors (e.g., in response to blood loss, stress, or exercise) include increased arteriolar tone and venous capacitance, limited preload augmentation ability, limited ability to increase heart rate, increased resistance across the total cavopulmonary connection, and decreased diastolic compliance of the systemic ventricle (Ghanayem et al., 2007; Sundareswaran et al., 2008; Krishnan et al., 2009; Goldstein et al., 2010).

Absolute contraindications to the Fontan procedure typically include early infancy, PVR greater than 4 Wood units/m², severe pulmonary artery hypoplasia, systemic ventricular ejection fraction (EF) less than 25% to 30%, and a ventricular end-diastolic pressure greater than 20 to 25 mm Hg. Many coexisting lesions previously believed to be at least relative contraindications (e.g., AV valve regurgitation or stenosis, significantly narrowed or distorted pulmonary arteries) are now corrected at the time of the Fontan (or prior palliative) procedure.

The acute reduction of systemic ventricular volume that occurs in the univentricular heart as a result of transitioning directly from stage I to Fontan physiology results in impaired ventricular compliance because wall thickness does not regress as quickly as ventricular volume. The result is impaired ventricular diastolic function and elevated end-diastolic pressure. This will impede pulmonary venous return, which is a liability in the Fontan procedure, because it subsequently reduces pulmonary blood flow. A low cardiac output state results because systemic ventricular output can only equal the quantity of blood that transverses the pulmonary vascular bed. One reason for interposing a BDG procedure in the staged single-ventricle pathway is that it results in reduced morbidity and mortality as compared with moving directly from single-ventricle to Fontan physiology. Performing the BDG shunt at 3 to 6 months of age allows early reduction in the volume overload to the systemic ventricle that accompanies univentricular physiology and thereby promotes remodeling of the ventricle at lower end-diastolic volume. As noted previously, the impaired ventricular

diastolic function that accompanies acute ventricular volume reduction is better tolerated in BDG or hemi-Fontan physiology than in Fontan physiology. When there is impairment of pulmonary venous return after the BDG or hemi-Fontan, blood from the IVC will continue to provide systemic ventricular filling and cardiac output at a lower pressure than that required to traverse the pulmonary bed; similar conceptual thinking underlies the creation of a fenestration in the Fontan pathway (see Fenestrated Fontan, later).

One risk of the staged procedures is the development of pulmonary arteriovenous malformations, which develop as a result of diversion of hepatic venous blood flow to another capillary bed (the systemic) before delivery to the pulmonary capillary bed. This of course is the blood flow pattern in BDG patients, approximately 10% of whom will develop significant pulmonary arteriovenous malformations and resultant increased arterial desaturation. These lesions usually resolve after the BDG is converted to a Fontan, and when hepatic-to-pulmonary blood flow “continuity” is restored.

Fenestrated Fontan

In patients with Fontan physiology, increased impedance to systemic venous blood flow return through the pulmonary capillary bed results in decreased delivery of blood to the pulmonary venous atrium, systemic ventricle, and aorta, producing a low cardiac output state with a normal or near normal SaO_2 (“pink but poor cardiac output”). This increased impedance is not uncommon in the initial days and weeks after Fontan surgery. Attempts to increase cardiac output by increasing systemic venous pressure may result in the development of refractory pleural effusions and ascites but does not necessarily improve ventricular filling and cardiac output. In many institutions, a 4-mm hole or fenestration is intentionally left in the cavopulmonary pathway or baffle. This allows systemic venous blood to “pop off” into the pulmonary venous atrium and ultimately into the systemic ventricle and aorta. This physiologic R-L shunt allows maintenance of systemic cardiac output at the expense of SaO_2 (“blue with cardiac output”—preferable). This fenestration can be easily closed in the cardiac catheterization laboratory with an occlusion device at a later date after demonstration of adequate hemodynamics, gas exchange, and cardiac output, with balloon occlusion of the fenestration (Bridges et al., 1998). Other practitioners do not believe in the need for routine fenestration of the Fontan pathway to reduce morbidity (e.g., low cardiac output, increased pleural effusions, increased volume requirements) in the postoperative period; some find the use of extracardiac conduits or inhaled NO to achieve similar benefits (Thompson et al., 1999; Harada et al., 2009).

Anesthetic Management, Pre-Fontan

The principles outlined in the section on managing BDG physiology after CPB generally apply here. These patients are typically 2 to 3 years of age with a superior cavopulmonary (BDG) shunt, generally with a stable cardiovascular system. Arterial SaO_2 is 76% to 85% unless there are significant decompressing venous collateral vessels from the SVC to either the IVC or the pulmonary venous system. These are usually addressed by coil occlusion in the cardiac catheterization laboratory prior to the Fontan.

Although these patients might tolerate an inhalation induction from a cardiovascular standpoint, it should be recognized that several factors might make a pure inhalation induction

difficult: (1) venous congestion of the head and tongue resulting from a relatively high SVC pressure; (2) coughing, breath-holding, or any other cause of high intrathoracic pressure impeding pulmonary blood, resulting not only in hypoxemia but altered uptake and distribution; and (3) significantly delayed rate of inhalation induction than expected in the typical child with $\dot{Q}_P:\dot{Q}_S$ of 0.5:1 to 0.7:1. Based on these factors, an IV induction is preferred by many. Premedication should be considered, because these patients and their families generally have had multiple hospital exposures and procedures. In addition, many of these patients are tolerant to opioids and benzodiazepines after neonatal and subsequent exposure. Midazolam, 0.75 to 1.0 mg/kg orally (maximum dosage, 20 to 30 mg by mouth [PO]), alone or with ketamine, 3 to 6 mg/kg PO, is usually effective for sedation and allowing IV placement.

The key physiologic principle in patients with BDG or Fontan physiology is maintaining filling and function of the systemic ventricle. *Optimal* physiology depends on adequate preload, unobstructed systemic venous return, low PVR, low mean intrathoracic pressure, normal lung parenchymal and alveolar ventilation, unobstructed pulmonary venous return, sinus rhythm (primarily resulting from the atrial contribution to ventricular filling, normal atrioventricular valve function and competency, normal ventricular function, and low ventricular afterload. Any significant departure from these requirements can result in severe compromise. Thus, considerations for anesthetic induction and pre-CPB management include (1) ensuring adequate preload, (2) avoiding significant myocardial depression, and (3) preventing mechanical or metabolic events that significantly increase PVR, including excessive stress response, airway obstruction, hypoventilation, hypoxemia, hypercarbia, acidosis, atelectasis, and excessive intrathoracic pressure. From a practical standpoint, volume expansion (isotonic crystalloid or colloid) followed by hemodynamically stable induction regimens such as etomidate (0.2 to 0.3 mg/kg) or opioid (e.g., fentanyl, 10 to 25 mcg/kg) supplemented with either etomidate or benzodiazepine and muscle relaxant are frequently used. Maintenance of anesthesia typically includes additional opioid, benzodiazepine, or low-concentration inhaled agent (or a combination of these), in combination with muscle relaxant. As with most other situations, an arterial catheter is placed after induction (usually in either radial artery, but at times guided by the location of prior arterial cutdown or systemic–pulmonary artery shunt procedures). Many centers also place an internal jugular multilumen catheter to measure proximal venous pressure and provide a reliable access site for drug infusions and other therapies; this catheter can provide useful information both before and after CPB (particularly in conjunction with a common atrial catheter) in terms of, for example, venous pressures, TPG, and potential anastomotic and cannulation issues. In addition, as discussed previously, measuring SVC saturation with an allowance for concurrent arterial oxygen saturation can provide a reasonable estimate of systemic oxygen delivery and cardiac output. Other centers, however, avoid SVC cannulation in most or all infants and in particular in Glenn and Fontan patients because of concerns about SVC thrombosis, as well as infection and other risks common to most forms of vascular access.

Post-CPB Management after the Fontan Procedure

Management goals immediately after a Fontan procedure also derive from the aforementioned principles (Table 20-5). It is

TABLE 20-5. Causes of Low Cardiac Output after Fontan Completion

	Systemic Venous Pressure	Common Atrial Pressure	Transpulmonary Gradient
Anatomic			
● Pulmonary artery stenosis or obstruction	↑	↓	↑
● Restrictive intraatrial septum	↑	↑	↓
● Systemic outflow tract obstruction	↑	↑	N to low
● Superior vena cava clot or obstruction*	↑	↓	↑
● Atrioventricular valve regurgitation or stenosis	↑	↑	N
● Systemic aortic valve stenosis or regurgitation	↑	↑	N
● Coarctation of the aorta	↑	↑	N
● Pulmonary venous obstruction	↑	↓	↑
Physiologic			
● Systemic ventricle dysfunction	↑	↑	N
● Pulmonary hypertension	↑	↓	↑

*Superior vena cava–to–pulmonary artery pressure gradient > 2 mm Hg. Note: After the cavopulmonary anastomosis, because inferior vena caval blood flow enters the systemic ventricle without first passing through the lungs, any anatomic obstruction through the lungs will result in low oxygen saturation but a preserved cardiac output.
N, Normal; ↑, increase; ↓, decrease.

important to maintain heart rate, contractility, and preload to maintain cardiac output. These patients frequently require substantial amounts of volume supplementation in the immediate postoperative period, even in the absence of significant bleeding. Low pulmonary blood flow produces low cardiac output because the systemic ventricle can pump only the volume of blood that is delivered to it across the pulmonary vascular bed. This differs from the situation after superior cavopulmonary shunts because there is a source of blood supply to the systemic ventricle that does not cross the pulmonary bed (i.e., IVC blood) in BDG patients.

It should also be emphasized that patients with Fontan physiology are expected to be fully saturated (with the aforementioned caveat regarding location and contribution of coronary sinus blood) and that low cardiac output will not result in a reduced Sa_{O_2} unless there are significant sources of intrapulmonary, intracardiac (fenestration, baffle leak), or physiologic R-to-L shunting. In contrast, low cardiac output in a normal patient results in a low Sa_{O_2} only if a significant quantity of intrapulmonary R-to-L shunt exists and low cardiac output produces a low Sv_{O_2} . When low cardiac output in a Fontan patient is caused by ventricular dysfunction, common (pulmonary venous) atrial hypertension may be sufficient to cause pulmonary edema and physiologic R-to-L intrapulmonary shunting. This situation is analogous to that in a normal patient with

series circulation and no intracardiac lesions. The presence of a fenestration or baffle leak will exacerbate this Sa_{O_2} decrease in the Fontan patient.

As discussed previously, a central catheter placed in the internal jugular vein will measure caval (baffle) pressure, which equals mPAP after a Fontan. A surgically placed atrial catheter will measure common atrial pressure. Allowing for individual variations, expected values can be summarized as follows:

- An mPAP of about 15 to 18 mm Hg is usually seen in the presence of reasonably good systemic ventricular function, absence of lung injury, appropriate ventilation, and so on.
- Reasonably good ventricular function will be associated with an EDP (and hence common atrial pressure) of about 5 to 10 mm Hg.
- The TPG (mPAP minus common atrial pressure) is usually less than 10 mm Hg with appropriate ventilation and no significant lung injury, mechanical or anastomotic obstructions, and so on.

Inotropic support of the systemic ventricle may be necessary as a result of ventricular dysfunction induced by chronic volume overload, prior surgical or ischemia–reperfusion injury, and the acute effects of CPB. Dopamine (3 to 5 mcg/kg per minute) is usually sufficient. Milrinone (0.5 to 1.0 mcg/kg per minute) may be useful for those patients who have high SVR and afterload/contractility mismatch. Occasionally, higher dosages of dopamine or the addition of other inotropes such as epinephrine (0.03 to 0.05 mcg/kg per minute) are needed to support systemic ventricular function.

There are several possible causes of reduced oxygen saturation after Fontan surgery. First, did the procedure include a fenestration? As noted earlier, the fenestration is meant to allow R-to-L shunting to preserve ventricular filling at the expense of some continued relative systemic oxygen desaturation. Thus, one expects at least a moderate decrease in Pao_2 compared with the completely separated two-ventricle circulation. For example, a newly fenestrated Fontan patient being ventilated with 100% oxygen, having relatively normal cardiac output and hemoglobin concentration, and with appropriate ventilation and minimal lung disease (after CPB) usually has a Pao_2 well below 100 mm Hg (50 to 70 mm Hg is not uncommon).

In Fontan patients with a patent fenestration, decreases in cardiac output will reduce Svo_2 and hence further reduce Pao_2 and Sao_2 (as a result of the R-to-L mixing via the fenestration); the magnitude of reduction depends on both the relative size of the shunt and the degree of venous desaturation. As noted previously, Svo_2 can be easily determined using a sample drawn from a central venous catheter. A difference of greater than 20% to 25% (e.g., 50% SVC saturation versus 88% arterial saturation) between Sao_2 and Svo_2 is indicative of low cardiac output (assuming normal hemoglobin concentration). The relatively sudden occurrence of hypotension, increased SVC pressure, or increased Pao_2 (i.e., >150 to 200 mm Hg on 100% oxygen) should raise the possibility of acute fenestration closure.

As in the BGD circulation, low $Ppvo_2$ saturation is another cause of low Sao_2 . Maneuvers to reduce V/Q mismatch and intrapulmonary shunt should be undertaken. A high Fio_2 may be necessary in the presence of significant V/Q mismatch. Ventilation and acid-base management should be optimized to keep PVR low. Mean airway pressure should be kept at the minimal level that is compatible with delivery of adequate minute ventilation and maintenance of normal lung expansion. This can usually

be accomplished with a relatively large tidal volume (10 to 12 mL/kg), slow respiratory rates (10 to 15 breaths/min), and short inspiratory times (inspiratory-to-expiratory ratio of 1:3 or 1:4). Excessively high mean airway pressure will mechanically limit venous return, pulmonary blood flow, and potentially cardiac output (the severity of cardiac output effect will depend in part of fenestration presence/patency). Similarly, PEEP should be used with caution; however, it may be beneficial at levels sufficient to maintain functional residual capacity and support gas exchange without causing overdistention. As discussed previously, inhaled NO may benefit some patients with significantly increased SVC and TPG pressures (assuming the increased TPG is not the result of ventricular dysfunction) and low cardiac output, or desaturation resulting from V/Q mismatch.

It is commonly stated that early tracheal extubation and spontaneous ventilation enhance pulmonary gas exchange and hemodynamics in Fontan patients (Morales et al., 2008; Hammer et al., 2000). On the other hand, positive pressure ventilation can improve the function of a dysfunctional systemic ventricle by reducing effective afterload (Laplace's law), as well as potentially reducing the work of breathing. In addition, low lung volumes, hypercarbia, and hypoxemia, along with potential resultant effects on ventricular filling and function, have the potential to negate any advantages produced by spontaneous ventilation.

CARDIOPULMONARY BYPASS IN INFANTS AND CHILDREN

The use of extracorporeal circulation to repair congenital cardiac defects began in the mid to late 1950s, following the conceptual development of CPB and the construction of heart-lung machines. The first report of use in children is attributed to Gibbon (1954), who repaired an atrial septal defect; this early CPB circuit required a dozen or more units of blood prime. At around the same time, Lillehei and coworkers used cross circulation to repair a variety of defects in relatively young infants and children, including ASDs, VSDs, AV canal defects, and TOF. Their reported overall survival was greater than 60%, which was remarkable considering the time frame and equipment available (Lillehei et al., 1986). Shortly thereafter, Kirklin et al. (1989) developed a bubble-type pump oxygenator that required approximately half the amount of fresh blood prime compared with the initial efforts of Gibbon and others. However, extreme blood foaming, which was lethal, was one major complication; nonetheless, survival was about 50% (Kirklin, 1989). These early reports prompted many subsequent investigations aimed at developing the scientific and technological knowledge needed to successfully undertake extracorporeal circulation in infants and children. In spite of these efforts, the morbidity and mortality of CPB remained high throughout the 1960s.

Continued attempts to understand the science and advance the technology to successfully perform CPB and complex congenital heart surgeries continued into the 1960s and 1970s, albeit with improvements that might best be characterized as necessary but incremental. In the early 1970s, Aldo Castaneda and others provided the next major conceptual advance when they described the use of deep hypothermic circulatory arrest in infants (Barratt-Boyes, 1973; Castaneda et al., 1974). These techniques relied primarily on surface cooling because difficulties and toxicities continued to be associated with infant CPB (which was typically limited to less than 20 to 30 minutes and

used mainly to augment core cooling and rewarming). From the late 1970s to early 1990s, major advances in CPB science and technology were made so that the relative contribution of CPB per se to mortality in infants and children was progressively reduced to minimal levels, allowing the exploration and perfection of the complex surgeries required to approach lesions such as HLHS and TGA. Nonetheless, the morbidity associated with the use of CPB in infants and children is still widely held to be a major limitation to completely successful outcomes, and current research efforts include developing methods to operate on beating infant hearts without the use of CPB (Perrin et al., 2009).

Patient- and Lesion-Related Factors Affecting Infant and Pediatric CPB

The conduct and outcome of CPB in neonates, infants, and small children are particularly affected by patient-related variables as well as those linked to specific types of cardiac defects and pathophysiology. Neonates, in general, and particularly those who are premature or weigh less than 1.8 to 2.0 kg, comprise a high-risk group because of their immature organ function, as well as coexisting diseases such as sepsis, respiratory distress syndrome, or one or more other congenital anomalies (Pawade et al., 1993; Ungerleider and Shen, 2003; Oppido et al., 2004). There is increasing evidence that the central nervous system is more immature for a given postconceptual age in infants with CHD and that central nervous system injury may exist prior to surgery in many of these patients (Miller et al., 2004, 2007; Dent et al., 2006; McQuillen et al., 2006, 2007; Wheeler et al., 2008).

The immature myocardium may be similarly prone to CPB-related dysfunction for several reasons, including its relatively deficient (compared with adult) contractile protein mass and organization, the presence of fetal contractile protein isoforms, immature calcium cycling (which occurs primarily via the sarcolemmal membrane as opposed to the sarcoplasmic reticulum, which is less abundant and less well organized), and fewer mitochondria. Various features of congenital cardiac lesions can complicate CPB as well. For example, hypertrophic and cyanotic myocardium is more likely to be injured by ischemia–reperfusion and other consequences of CPB (del Nido, 1997; del Nido et al., 1988; Stamm et al., 2001; Friehs and del Nido 2003). Collateral vessels to the coronary circulation, perhaps most common in cyanotic patients, can wash out cardioplegia and thereby hinder effective myocardial preservation. Pulmonary dysfunction after CPB may be more prevalent in infants with other routes of high pulmonary blood flow (e.g., truncus arteriosus, hypoplastic left heart syndrome, transposition of the great arteries) and in cyanotic infants (Allen, 2003; Ungerleider and Shen, 2003). Aortopulmonary collaterals, which can be particularly significant in various lesions associated with cyanosis, may induce a steal phenomenon from the arterial compartment to the lungs, thereby promoting pulmonary dysfunction due to high flow on CPB while at the same time compromising arterial organ perfusion (low mean arterial pressures despite high flow rates while on CPB). Diffuse organ dysfunction is likely to be more common in patients who were severely cyanotic and hypoperfused at the time of delivery, or who required complex surgery in the early neonatal period.

For the neonate who suffered asphyxia or significant hypoperfusion and acidosis at the time of delivery or thereafter, most centers have found it beneficial to allow a period of stabilization of the circulation and recovery of organ function before undertaking CPB and cardiac surgery. Depending on the lesion (see later), interventions such as PGE₁, inotropic support, ventilatory strategies to balance systemic and pulmonary blood flow, and even extracorporeal circulatory support (ECMO or ventricular assist device [VAD]) are initiated preoperatively. Post-CPB organ dysfunction (e.g., renal, liver) can also be a source of morbidity for both neonates and infants, as well as for older (i.e., adult age) patients with various forms of CHD complicated by longstanding cyanosis, low cardiac output, and high systemic venous pressures.

Cannulation and Circuit Considerations

The cannulae used in infant and pediatric CPB are likely to be smaller than those used for adult cardiac operations. More significantly, their locations are likely to be different and more variable than in adults. It is therefore critical to understand potential cannulation locations for the different lesions and repairs and their potential effects on the conduct of the surgery and the locations and functions of venous and arterial pressure monitoring catheters.

Arterial cannulae for neonates and small infants must be of sufficient size to permit appropriate arterial inflow rates at reasonable line pressures, with minimal shear forces (which can damage the vessel intima, aortic valve, or blood elements), yet small enough to fit in small aortas without obstructing aortic flow. Small arterial cannulae (e.g., 8 Fr [Biomedicus]) with a thin-walled, reinforced design that prevents cannula kinking and allows a larger luminal diameter for a given external diameter have become popular. After insertion, it is important not to kink or compress the infant's pliable aorta by the location and orientation of the aortic cannula and its tubing, as well as to be aware that the cannula itself can significantly obstruct flow in the vessel. Location of the tip can direct blood flow toward or away from specific vessels; for example, locating and directing the tip more distally toward the transverse arch may reduce flow through the right carotid artery, or may favor lower body perfusion at the expense of cerebral perfusion and optimal brain cooling (Kern et al., 1992a).

Certain congenital cardiac lesions require unique aortic cannulation sites. For example, the aortic cannula is typically placed more distally in the aorta for repairs that involve extensive proximal aortic surgery such as the arterial switch procedure for transposition of the great vessels; this distal location may alter distribution of blood flow to the carotid vessels. Repair of interrupted aortic arch requires two arterial cannulae, one in each segment of the aorta (perfusing both the head and lower body). The aortic cannula is placed in the pulmonary artery at the beginning of CPB for stage I repair of HLHS because of the typically diminutive size of the ascending aorta in this lesion. The distal pulmonary arteries are occluded with tourniquets, and the aorta is perfused via the ductus arteriosus until the aortic reconstruction is completed, at which time the cannula is repositioned in the neo-aorta; at times, the aortic cannula can be inserted into a surgically constructed shunt attached to the right carotid or innominate artery to allow perfusion of the head during parts of complicated aortic repairs.

In small infants (without recent sternotomy), the neck vessels are the preferred extrathoracic cannulation site for emergency access, or when there is concern about the proximity (and hence uncontrolled hemorrhage risk accompanying sternotomy) of major vascular or cardiac structures to the underside of the sternum. Unlike in adults, femoral arterial cannulation for CPB is not usually a viable option in infants and small children (weighing less than ~10 to 15 kg). This is because small vessel size precludes inserting an arterial cannula that is large enough to allow arterial inflow rates that are sufficient to completely meet metabolic needs. It is important to note, however, that in emergent situations (e.g., cardiopulmonary arrest in the cardiac catheterization laboratory, particularly when femoral vascular access is already in place), smaller perfusion cannulae located in the femoral vessels of small infants can allow a reduced but nevertheless life-saving amount of perfusion support. Femoral access is performed occasionally for older children, again either electively when there is concern that a cardiac chamber or vascular conduit lies immediately beneath the sternum, or emergently when one of these structures is entered inadvertently during the dissection.

The sizing and location of venous cannulae can also be fairly complex to take into account variations in venous anatomy and drainage as well as the operative approach. Venous cannulae are available in a variety of sizes and with design features for particular indications (Table 20-6). For example, thin-walled cannulae with multiple side holes enhance venous drainage; right-angled tips are frequently used in the SVC to improve alignment (and therefore drainage) and minimize impact on the surgical field; metal-tipped cannulae are used to prevent kinking; straight, short-tipped cannulae are used in the IVC to limit hepatic venous obstruction.

Overall, most repairs use separate SVC and IVC cannulae to achieve maximal collection of venous return and to minimize interference with the operative field. Common variations in venous anatomy that can complicate venous cannulation and must be taken into account include left or bilateral SVCs, azygous or hemiazygous continuation of the IVC, and direct drainage of the hepatic veins into the atrium. A single atrial cannula is frequently used when deep hypothermic circulatory arrest is

planned; in this instance, the venous cannula is removed after the patient is adequately cooled, to have a clear operative field.

Regardless of location, the cannula must be appropriately sited and must cause as little obstruction to venous drainage as possible. Poor venous drainage may be difficult to detect, and is more likely to occur in patients with complicated venous anatomy. The consequences of impaired venous drainage and increased venous pressures are likely to be magnified during CPB because arterial perfusion pressure is frequently reduced. Obstruction of the SVC may promote cerebral edema and otherwise increase the risk for brain injury by decreasing cerebral blood flow and hindering effective brain cooling. Many practitioners find monitoring of SVC pressure by a catheter placed in the internal jugular vein useful to detect possible SVC obstruction in this setting; the patient's head and face should also be inspected at regular intervals during CPB for the appearance of congestion or swelling. It is likely that monitoring cerebral blood flow velocity using transcranial Doppler methodology might also be useful. IVC obstruction will increase lower body venous pressures and potentially decrease hepatic, renal, and mesenteric perfusion; isolated hepatic vein obstruction can also occur. Consequences can include hepatic dysfunction, renal dysfunction, ascites, and perhaps increased inflammatory consequences due to mesenteric congestion (Friesen and Thieme, 1987; Hickey and Andersen, 1987). Detection of IVC obstruction during CPB can be difficult, and it should be suspected whenever there is development of ascites, decreased urine output, or impaired venous return.

A sample schema for cannulae and other circuit components for the full size range of patients is shown in Table 20-7. Compared with adults, the surface area and volume of the CPB circuit relative to patient size and blood volume are much greater in neonates and infants. To minimize hemodilution, various circuit components and tubing diameters are kept as small as possible. Nonetheless, hemodilution that is equivalent to one to two blood volumes from the circuit prime and cardioplegia is fairly common in neonates and small infants. Pump flow rates can range from no flow for brief or extended periods (i.e., circulatory arrest) to more than 200 mL/min. Mean arterial pressures can vary from 10 to 20 mm Hg during low-flow CPB to more than 50 mm Hg at full flow rates. The temperatures used are typically lower for infant CPB and for complex repairs (15° to 18° C core temperatures for deep hypothermia, 22° to 28° C is frequently used for complex repairs, and 28° to 32° C is typical for ASDs and VSDs). Deep hypothermic circulatory arrest, although used much less frequently than even a few years ago (primarily because of increasing evidence of associated brain injury [see later]), is still employed occasionally. Different blood pH management strategies may be employed (i.e., alpha-stat versus pH-stat) depending on institutional practice, degree of cooling, and, in some cases, patient age and lesion type. Extensive use of cardiotomy suction and resultant blood trauma (including hemolysis) are common. In part because of the differences related to circuit area, bypass duration, blood trauma, temperature, and so on, the magnitude of neuroendocrine stress responses and systemic inflammatory responses to CPB, as well as their consequences, are generally believed to be more profound in neonates and infants than in adults.

TABLE 20-6. Venous Cannula Sizes

Patient Weight (kg)	Cannula Size (for SVC/IVC) (French)
<3.5	12/12
3.5-6	12/14
6-8	12/16
8-12	14/16
12-16	14/18
16-23	16/18
23-28	16/20
28-36	18/20
36-48	18/22
48-60	20/22

IVC, Inferior vena cava; SVC, superior vena cava.

Oxygenators

Membrane-type oxygenators are now used in virtually all instances. Oxygenators for infants and children must function

TABLE 20-7. Specifications for Oxygenators for Patients of Different Sizes

Oxygenator	Patient BSA (m ²)	Oxygenator Prime (mL)	Total Circuit Prime Including Oxygenator (mL)	Arterial and Venous Tubing Diameter (inch)	Manufacturer Reference Flow (mL/min)
Terumo FX 05	<0.5	43	Neonate 240 Infant 255	$\frac{3}{16}$ $\frac{1}{4}$	1500
Terumo FX 15-30	0.5-1.66	135	Toddler 555 Child 710	$\frac{1}{4}$ or $\frac{3}{8}$ $\frac{3}{8}$	4000
Terumo FX 25	>1.67	250	Adult 1030	$\frac{1}{2}$	7000

BSA, Body surface area.

over a wide range of pump flow rates (maximal flow rates range between 800 and 4000 mL/min), temperatures, and hematocrits. These are of essentially two types: microporous (hollow-fiber or folded-membrane) and nonporous membrane oxygenators. The major advantage of microporous membranes is their ability to affect gas exchange with a relatively modest membrane surface area, typically in the range of 0.2 to 1.5 m², depending on the specific oxygenator and configuration. Major disadvantages of the microporous type include some blood-to-gas contact at the start of CPB (until protein accumulation blocks the sub-micron-sized pores) and protein leakage across the membrane, along with the potential for gas embolization if negative pressure develops on the blood side of the artificial membrane. Nonporous oxygenator membranes require a larger surface area to achieve gas exchange but do not accumulate or leak protein as readily, and are therefore more often the choice for longer-term applications such as ECMO.

Pumps

Most pediatric circuits use roller pumps, in which pump output (i.e., flow rate) is determined by the number of revolutions per minute (rpm) of the pump head, the degree of occlusion produced by the rollers, and the internal diameter of the tubing. A significant advantage is that pump flow is relatively independent of resistive and hydrostatic forces in the circuit. However, adequate flow is highly dependent on the proper setting of roller head occlusion (which also affects the degree of blood trauma and hemolysis), and on accurate knowledge of pump head revolution rate and tubing size. Failure to accurately account for any of these variables can lead to excessive or inadequate pump flow.

Tubing

The CPB pump is usually placed as close to the surgical field as possible to reduce tubing length, which is a major contributor to overall circuit volume. Choice of circuit tubing for infants (see Table 20-7) is based on having an internal diameter large enough to accommodate the required full flow rate (or greater) without inordinately increasing circuit line pressures, while simultaneously being as narrow and short as possible to minimize the contribution of priming volume. Some neonatal circuits use $\frac{1}{4}$ -inch tubing on both the arterial and venous limbs, and most centers have further decreased the diameter of the arterial tubing to $\frac{3}{16}$ inch; some use $\frac{3}{16}$ inch for both arterial and venous limbs (although vacuum-assisted venous drainage may be required in this instance) (Ungerleider and Shen, 2003).

Priming volume is usually defined as the total volume of the oxygenator apparatus, tubing, and the minimal amount required for the venous reservoir. Typical priming volumes of commercial membrane oxygenators range from approximately 225 to 375 mL when used in the open configuration. Minimizing circuit priming volume is important to reduce hemodilution, blood product exposure, and the potential for fluid overload and edema. There are examples of membrane oxygenators with substantially smaller prime volumes (~70 mL; Dideco Lilliput hollow-fiber), but they are not yet available in an open system configuration. Various schemes for achieving low priming volume and thereby reducing or avoiding the need for blood products as a component of the priming solution have been described (Durandy, 2007, 2009; Miyaji et al., 2007, 2008).

Important Circuit Characteristics

Venous Drainage

As in adult circuits, venous blood usually flows from the patient to the venous reservoir of the CPB circuit by gravity. The level of blood in the venous reservoir serves as an important safety mechanism: it is a source of volume to increase arterial inflow, and to assess the adequacy of venous return. If venous return and the level in the venous reservoir decline, causes (e.g., unrecovered or lost blood in the surgical field, malpositioned venous cannulae, or excessive capillary leak) can be identified, and appropriate interventions (e.g., decreasing pump flow rate, adding volume, adjusting operating table height, or repositioning the cannulae) can be performed. Vacuum-assisted venous drainage is being used in larger (typically >30 kg) congenital heart surgery patients (Ojito et al., 2001; Ungerleider and Shen, 2003; Durandy, 2009). Potential advantages include reducing circuit volume by using lower venous reservoir volume and the ability to improve venous drainage (as opposed to gravity) through smaller (e.g., $\frac{3}{16}$ inch) venous tubing and venous cannulae (which decreases circuit volume and may improve visibility in the surgical field). An improvement in venous drainage could lead to reduced tissue and organ edema and congestion, improved organ function, and reduced inflammatory activation (e.g., via endotoxin release from congested, hypoperfused intestine). A major potential complication of vacuum-assisted venous drainage is venoarterial air embolism (Davila et al., 2001; Wang et al., 2008; Win et al., 2008).

Many venous reservoirs are rigid and open to the atmosphere. Some advantages include ease of removal of entrained venous air, free flow of venous drainage (i.e., no air lockage or buildup of pressure in the reservoir), integration of the cardiotomy

reservoir (as opposed to having a separate reservoir for cardiomy suction), and the ability to accurately measure reservoir volume via calibration lines on the side of the chamber. This last feature is a useful aid to assess the patient's intravascular volume and may therefore facilitate weaning from CPB. Major disadvantages of open (usually rigid) venous reservoirs include the presence of a blood-to-air interface, which may promote blood trauma and activation of the coagulation, fibrinolytic, and inflammatory cascades (see later), and the need for a larger priming volume. For these reasons, a soft, collapsible venous reservoir bag that expands and contracts in relation to overall blood volume, venous return, and arterial inflow rate is being used with increasing frequency in infant CPB. Advantages include the absence of direct blood-to-air contact and the fact that air is not entrained if the venous reservoir becomes empty, which collapses the bag. A major disadvantage can be the inability to accurately measure venous reservoir volume or recognize subtle but important changes in venous return. Other relative disadvantages compared with rigid reservoirs include the need for a removal mechanism if air is entrained, the need for a separate cardiomy suction reservoir, and the fact that venous drainage will be significantly reduced if pressure builds up because of overfilling of the reservoir with blood or air.

Filters

Most but not all centers use an arterial filter (40 micron). Although filtering arterial inflow is believed by many to be required to reduce the amount of microemboli and other debris arising from cardiomy suction, coagulation and fibrinolysis activation, and blood trauma, particularly as potential contributors to post-CPB neurologic and other end-organ injury, others omit arterial line filters, at least in part to reduce priming volume and hemodilution (Ungerleider and Shen, 2003).

Almost all pediatric CPB systems use 0.2-micron filters in the gas inflow lines to prevent bacterial or particulate contamination. Similarly, all crystalloid prime and cardioplegia solutions are passed through 0.2-micron filters prior to final addition to the CPB circuit. A 20- or 40-micron filter is usually used on the cardiomy suction return line to remove macroaggregates and microaggregates and other debris from the blood returning from the surgical field. Specific removal of blood polymorphonuclear leukocytes using leukocyte-depleting filters placed in line on the CPB circuit (which typically reduce circulating leukocyte counts in the patient by ~75%) is advocated by some centers as a significant means of reducing reperfusion injury (Chiba et al., 1998; Allen, 2003).

CPB Prime Composition

Dilution of red cells, clotting factors, and other plasma constituents is usually greater in infant and pediatric CPB than in adult CPB, because the priming volume of even the smallest neonatal and infant CPB circuits is roughly equivalent to approximately 1.5 to 3 times the patient's blood volume. Physiologic crystalloid solutions (e.g., Normosol) are the major component of CPB priming solutions in infants and children; primes based on colloid are used infrequently. Packed red blood cells (or occasionally whole blood) are often required; fresh frozen plasma or other colloids such as albumin are also added by many centers.

Other agents that may be included in the pump prime include mannitol, steroids (see later), heparin, and buffers (e.g., sodium

bicarbonate or tris[hydroxymethyl]-amino-methane [THAM]). Mannitol is used primarily for its osmotic properties and is intended to reduce organ and cellular edema as well as to promote diuresis and thereby contribute to renal protection. The osmotic diuresis may be particularly beneficial in those congenital cardiac operations in which a substantial amount of hemolysis from blood trauma due to cardiomy suction and high pump flow rates occurs. Stabilization of cellular membranes and various antioxidant properties, including radical scavenging, have also been attributed to mannitol. The significance of any of these effects is not proven in pediatric CPB.

The use of albumin or other colloid to prime CPB circuits is also controversial (Myers, 1997; Tigchelaar et al., 1997; Boks et al., 2001). There is evidence that reduced plasma protein concentrations and diminished plasma oncotic pressure can reduce lymphatic flow and increase capillary leak in the lungs and other vascular beds (Byrick et al., 1977; Schupbach et al., 1978; Marelli et al., 1989; Riegger et al., 2002). Although fluid balance and weight gain were favorably influenced, a recent study that randomized pediatric CPB patients to crystalloid or colloid prime could not demonstrate significant differences in mortality or in length of mechanical ventilation, ICU, or hospital stay (Riegger et al., 2002). These results are similar to those obtained in adults, in whom albumin does prevent CPB-induced reductions in colloid oncotic pressure and lung water accumulation, but where it appears to have little effect on overall outcome or measures of pulmonary, myocardial, or renal function.

Hemodilution

As noted earlier, some centers have gone to substantial lengths to modify circuit design to reduce the degree of hemodilution associated with infant CPB and decrease the use of exogenous blood and other products. These modifications have included the use of the smallest possible tubing, cannulae, and oxygenators; altered orientation of the CPB circuit to decrease tubing length; vacuum-assisted venous drainage to improve return through the small cannulae and tubing; and omission of arterial filters. Resultant priming volumes in the 180- to 250-mL range have been reported. Ultrafiltration techniques (see later) are also used to offset the hemodiluting effects of CPB and thereby reduce the requirement for donor blood and blood products. With the possible exception of ultrafiltration, there is no evidence that edema, the inflammatory response to CPB, or overall outcome is improved by these measures and, at present, it remains difficult to avoid the use of exogenous blood or blood products in patients weighing less than approximately 10 to 20 kg.

Both packed red cells and whole blood have been used to ensure age-, lesion-, and temperature-appropriate hematocrit during CPB. Although packed red cells are readily available and increase and maintain the patient's hematocrit during CPB, questions about the actual oxygen carrying and delivery capacity of stored red blood cells have been raised (Spiess, 2002). Exogenous blood should also be filtered through a standard blood filter before adding it to either the pump circuit or cardioplegia. A major disadvantage of whole blood compared with packed red cells is the higher glucose load that accompanies whole blood: hyperglycemia may increase the risk for brain injury during cerebral ischemia. On the other hand, fresh whole blood more effectively maintains plasma factor concentrations,

which can be significantly reduced by CPB in these patients (see later) and may have other outcome advantages as well (Mou et al., 2004; Gruenwald et al., 2008).

The optimal hematocrit for neonatal and infant CPB is uncertain. Perhaps the most important consideration is the combination of temperature and flow rate that is to be used (e.g., deep hypothermia, low-flow, or circulatory arrest). More profound degrees of hypothermia are used in pediatric patients to suppress metabolic demands and increase tolerance to periods of low flow (25° to 18° C) or absent flow (15° to 18° C). Although the oxygen-carrying capacity of hemoglobin increases at lower temperatures, its ability to off-load oxygen to the tissues is also reduced. Moreover, the increase in blood viscosity that accompanies hypothermia is a significant impediment to microcirculatory flow and can lead to sludging and regional ischemia. The nonpulsatile flow patterns typical of most CPB applications may also decrease microcirculatory flow, particularly in the setting of increased viscosity. It is also important to note that the oxygen-carrying capacity of the non-red cell fluid component of blood (i.e., plasma) increases at decreasing temperatures because of the increased solubility of gas in the liquid phase. This occurs as temperature declines, and, as a result, the net effect of hemodilution during hypothermia is to improve microvascular flow and oxygen delivery.

Despite these theoretical considerations, the optimal and maximal levels of hemodilution for a given degree of hypothermia are not established. The longstanding practice has been to target hematocrits in the 18% to 22% range during deep hypothermic CPB. The choice of this value was based on the aforementioned improvements in blood flow viscosity and overall oxygen-carrying capacity that accompany the combination of hemodilution and hypothermia. Normovolemic hemodilution with hematocrit levels down to 15% are believed to be well tolerated during normothermia in terms of cerebral and myocardial function, as long as blood pressure, oxygenation, and cardiac output are maintained (Spahn et al., 1993; Pua and Bissonnette, 1998). Animal studies and reports of children of the Jehovah's Witness faith undergoing hypothermic CPB suggest no detectable effect on overall outcome or cerebral or cardiovascular morbidity at hematocrits in the 10% to 18% range, as long as low temperature, perfusion pressure, and flow rate are maintained (Henling et al., 1985; Stein et al., 1991; Johnston et al., 1995; Pua and Bissonnette, 1998). Hematocrits of 10% or less in infants were associated with acidosis and other evidence of inadequate oxygen delivery.

More recent evidence has cast doubt on the safety of very low hematocrits during hypothermic CPB in infant patients. In experimental infant CPB models in animals, a higher hematocrit (in the 25% to 30% range) has been associated with enhanced preservation of brain high-energy phosphates, intracellular pH, tissue oxygenation, maintained capillary density and microvascular flow, reduced leukocyte activation, and reduced neurologic injury (Duebener et al., 2001, 2002; Jonas, 2002). A recent clinical study that randomized infants to either a low-hematocrit (mean hematocrit, 22% ± 3%) or high-hematocrit (28% ± 3%) strategy at the start of low-flow hypothermic CPB found lower postoperative cardiac index, higher serum lactate, and higher total body water in the low-hematocrit group. At 1 year, overall neurologic evaluations and Mental Development Index scores were similar in the two groups, but the low-hematocrit group had significantly lower Psychomotor Development Index scores (Jonas et al., 2003). A hematocrit level at the onset

of low-flow cardiopulmonary bypass of around 25% was associated with higher Psychomotor Development Index scores and reduced lactate levels (Newburger et al., 2008; Wypij et al., 2008). In addition to any direct effects, it is likely that the somewhat higher hematocrit provides some degree of safety margin against other problems with perfusion, collaterals, and alterations in cerebral autoregulation and cerebral blood flow (Greeley et al., 1989; Greeley et al., 1991a, 1991b; Kern et al., 1993; Johnston et al., 1995; Newburger et al., 2008; Wypij et al., 2008). However, similar variations (e.g., in patient age, anatomy, collaterals, flow rate, pH strategy, cooling) make it impossible to proclaim a single optimal hematocrit for infants or children.

The optimal hematocrit for *weaning* from CPB is also controversial. The overall goal is adequate systemic oxygen delivery. Based on the preceding, hematocrits in the range of 30% or even somewhat higher (e.g., stage I repair of HLHS) are aimed for during rewarming and for termination of CPB. These levels (and perhaps even somewhat lower) are likely to be well tolerated by patients who have good myocardial function, minimal or no hemodynamic lesions, and a physiologic repair with normal oxygen saturation at the conclusion of the surgery. Consideration should be given to increasing hematocrit to improve oxygen-carrying capacity and oxygen delivery in patients with reduced myocardial function, or with palliative or staged operations that result in cyanosis. In these cases, hematocrits of 40% or even slightly higher may be beneficial, but here again definitive data are lacking.

Pump Flow Rates During Pediatric CPB

Optimal pump flow rates for pediatric CPB are, as for adults, based on furnishing appropriate systemic oxygenation, oxygen delivery, and organ perfusion as assessed by oxygen consumption and metabolic rate, mixed venous oxygen saturation, acid-base balance, and lactate production (Fox et al., 1982). These are typically indexed to body weight and are of course dependent on temperature. The higher metabolic rate of neonates and infants (approximately 1.5- to 2.5-fold greater than adults) mandates proportionately higher flow rates during normothermic CPB.

Heparinization

Heparin is usually given in a dosage of about 4 mg/kg (400 U/kg) prior to initiation of bypass, either directly into the right atrium or into a central venous catheter. Confirmation of heparin injection by blood aspiration, as well as the adequacy of heparin effect, should be performed before beginning CPB. The activated clotting time (ACT) remains the primary method of monitoring the efficacy of heparin anticoagulation (and reversal) in infants and children. Most centers mandate an ACT of greater than 400 seconds before initiating CPB, and maintaining ACTs between 400 and 600 seconds during CPB to prevent activation of blood coagulation pathways and clot formation. Inadequate concentrations of heparin are believed to be a major contributor to excessive activation of the coagulation and fibrinolytic systems (Chan et al., 1997). Other methods of monitoring heparin effect, anticoagulation, and clotting parameters such as blood heparin concentration and thromboelastography are adjunctive at present, and used mainly to assess residual heparin activity and diagnose and treat coagulopathies after termination of CPB (Miller et al., 2000; Guzzetta et al., 2008).

Neonates and young infants may be more sensitive to the effects of heparin administered for CPB, and the efficacy and duration of heparin-based anticoagulation is significantly more variable in neonates and young infants (Horkay et al., 1992; D'Errico et al., 1996a; Chan et al., 1997; Malviya, 1997). Potential mechanisms include the variable and generally lower levels of both procoagulant and anticoagulant factors present during the first few months of life and in some patients with CHD (Peters et al., 1985; Andrew et al., 1987; Odegard et al., 2002a, 2002b). The degree of hypothermia, amount of hemodilution, and relative immaturity of drug metabolism may also contribute to increased and a prolonged heparin effect in infants. Heparin resistance, on the other hand, is seen infrequently in infants, although examples resulting from recent heparin exposure or antithrombin III deficiency do occur. Heparin-induced thrombocytopenia and thrombosis appear to be less common in infants and children than in adult heart surgery patients, but the incidence may go up as the number of children who are repeatedly exposed in the operating room, catheterization laboratory, and other sites continues to increase (Severin et al., 2002; Newall et al., 2003; Mullen et al., 2008). There is at present only limited and anecdotal experience with the use of heparin alternatives such as the direct thrombin inhibitors for anticoagulation during pediatric CPB.

Heparin Reversal

Protamine sulfate is administered at the end of CPB to reverse the anticoagulant effects of heparin. Protamine dosing is usually based on body weight (3 to 4 mg/kg) or in a ratio to the heparin dosage (milligram-to-milligram) of 1:1 or 1.3:1; in vitro titration to neutralize heparin in a patient sample is also employed by some. In general, the target ACT after protamine administration should be within about 10% of the pre-CPB baseline. The first two dosing methods are likely to result in relative protamine excess, which is intentional because of greater heparin sensitivity and duration in infants and other factors that may potentiate heparinization, such as hemodilution, hypothermia, and delayed metabolic clearance. However, as for adults, there is evidence that empirical protamine dosing associated with excess protamine administration is possibly related to greater blood loss and transfusion requirements than with dosages that directly measure blood heparin using titration or other methods (Horkay et al., 1992; Martindale et al., 1996; Malviya, 1997; Guzzetta et al., 2008). Another argument against empirical dosing is that relatively small excesses of circulating protamine compared with heparin may have direct antiplatelet effects that can exacerbate bleeding after CPB (Griffin et al., 2001).

Typically, the drug is administered slowly over approximately 10 minutes. For unclear reasons, severe hypotensive, pulmonary vasoconstrictive, or anaphylactic/anaphylactoid reactions to protamine are uncommon in infants and children (Seifert et al., 2003). Of these, hypotension is most frequent, occurring in between about 1.5% to 3% of protamine administrations. It is dependent on dosage and rate of administration, most likely caused by histamine release, usually fairly mild and transient, and responsive to volume replacement or calcium administration. Severe pulmonary vasoconstriction appears to be much less common than in adults, may be caused by complement activation or pulmonary thromboxane release

(or both), and can be particularly problematic in patients with depressed contractile function (Lowenstein et al., 1983).

Conduct of Pediatric Cardiopulmonary Bypass

CPB is initiated once the arterial and venous cannulae are correctly positioned and connected to the circuit, the absence of air in the arterial line is confirmed, and adequate anticoagulation is demonstrated (usually by ACT). When it is important to keep the heart beating and possibly ejecting, the electrolyte concentration of CPB prime—specifically calcium and potassium—is usually normalized, along with solution temperature, so as to maintain myocardial function, prevent myocardial distention, and potentially allow an extended period of dissection and surgery, thereby potentially shortening the duration of aortic cross-clamping and myocardial ischemia that are required.

Large arterial collateral vessels (as may be seen in many forms of cyanotic heart disease, including TOF and pulmonary atresia), patent ductus arteriosus, and surgical aortopulmonary shunts can promote runoff from the systemic circulation at the start of CPB and thereby reduce cooling and perfusion pressure of critical organs despite seemingly adequate total pump flow. Thus, prompt surgical control and occlusion of large aortopulmonary collateral vessels, surgical shunts, and the PDA is accomplished immediately before or shortly after commencing CPB. Significant aortopulmonary collateral vessels that are not important sources of pulmonary blood flow or contributors to arterial oxygenation can be coil-occluded in the cardiac catheterization laboratory prior to surgery, which will also decrease the volume load on the systemic ventricle.

Monitoring During Pediatric CPB

Circuit Monitoring During Pediatric CPB

Arterial line pressure, pump flow rate, oxygenator gases, and temperature are important CPB variables that are usually monitored by the perfusionist. Arterial line pressure, measured via a pressure transducer placed in the arterial inflow limb, can be substantially higher than patient arterial pressure because of the driving pressure required to achieve adequate flow through the smaller diameter of infant arterial cannula and tubing; it will typically be in the range of 225 to 275 mm Hg at mean arterial pressures of 40 to 60 mm Hg. Excessively high arterial line pressures (>300 to 400 mm Hg) can be caused by tubing or cannula obstruction or cannula malposition and can result in circuit rupture. Many circuits include a sensor on the oxygenator reservoir to detect critically low volume levels and one on the arterial line to detect air.

Flow rate is critical. The flow produced by roller pumps is determined by roller head rpm, occlusion pressure, and the internal tubing diameter. It is important to know that pump flow rate on most CPB pumps is *calculated* by the perfusionist (or electronics on the pump) based on the aforementioned variables. Thus, because flow is not measured directly, incorrectly measuring or inputting rpm, tubing size, or occlusion, as well as possible shunts within the circuit, can lead to potentially harmful perfusion errors (either increased or decreased flow). Unexpectedly low or high mean arterial pressure for the calculated flow rate may be the first clue to these possibilities. In the case of low flow in particular, abnormal biochemical variables result if the condition is of sufficient magnitude and duration (see later).

The most common oxygenator gases are oxygen, air, and carbon dioxide. Continuous in-line monitors of pH, P_{O_2} , and P_{CO_2} are used frequently. The gas “sweep speed” (flow rate) and oxygen concentration delivered to the oxygenator are controlled with a flow meter or blender and measured with appropriate electrodes. Variability in pump flow rates, temperatures, and blood gas management strategies leads to wide variations in the flow rates and composition of the gases administered during pediatric CPB. Use of pH-stat management (see later) can require altered gas sweep rates and the ability to widely vary and control CO_2 in the sweep gas.

Thermistors measure temperatures of the water bath and heat exchanger, along with arterial and venous blood temperatures. The temperature gradient between the patient and perfusate should not exceed $10^\circ C$; this may be especially important during rewarming to prevent formation of gaseous bubbles and emboli caused by decreased gas solubility as fluid temperature increases.

Patient Monitoring During Pediatric CPB

Monitoring of mean arterial pressure is required during CPB. This is most often accomplished via catheters in either the radial or femoral artery. Choice of arterial catheter location can occasionally be affected by issues that include the location of a previous surgery or shunt (e.g., BT) and the current lesion and planned operation. Femoral arterial pressure monitoring (with or without concomitant radial arterial monitoring) is preferred by some for aortic reconstructions and for increased reliability when very complex surgeries or deep hypothermia is planned, particularly in small infants. Left atrial (catheter placed intraoperatively) and central venous (SVC) or right atrial (intraoperatively placed) filling pressures are also measured routinely, depending on the surgery.

Nasopharyngeal, esophageal, and rectal temperatures are measured using appropriate thermistors. Nasopharyngeal or tympanic membrane temperatures are most often used and probably are the most accurate in terms of tracking brain temperature, although no extracranial site is truly reliable in this regard (Pua and Bissonnette, 1998). Rectal temperature is most often used to monitor core temperature. Esophageal temperature reflects aortic temperature and does not correlate well with core or brain temperatures.

Arterial and venous blood gases should be measured within 5 to 10 minutes after commencing bypass, and then at 15- to 30-minute intervals thereafter; more frequent measurements may be required if there is evidence of compromised perfusion. In addition to on-line measurements of pH, P_{O_2} , and P_{CO_2} , measurements include hematocrit, and serum electrolytes including sodium, potassium, and ionized calcium. Many centers favor allowing or even promoting (e.g., via the chelating effects of citrate in added blood products) reduced ionized calcium during CPB in an attempt to reduce the contribution of calcium to reperfusion injury. Ionized hypomagnesemia, another potential contributor to ischemia–reperfusion damage and dysrhythmias, has been found after pediatric CPB, although its clinical significance is uncertain (Munoz et al., 2000b; Mencia et al., 2002; Manrique et al., 2010). Increasing blood lactate concentrations before and after pediatric CPB has been suggested to correlate postoperative morbidity and mortality (Munoz et al., 2000a; Li et al., 2007; Wypij et al., 2008).

The oxygen saturation of venous blood (S_{vO_2}) is an important index of tissue perfusion. It can be measured from venous blood samples at intervals as discussed earlier and also continuously via a calibrated in-line monitor on the venous catheter. Optimal and minimal acceptable values for S_{vO_2} during CPB, particularly as temperature and flow rate decrease, are not well defined. At normothermic or near normothermic temperatures, S_{vO_2} can be interpreted in a fashion similar to non-CPB situations, and hence low values (<~60% to 70%) should raise concern about inadequate tissue oxygen delivery (e.g., inadequate flow, low hemoglobin). As hypothermia progresses, dissolved oxygen contributes an increasing proportion of total oxygen delivery, and, more importantly, the increased affinity of hemoglobin for oxygen impairs transfer from hemoglobin to tissue (Dexter et al., 1997). As a result, the interpretation of S_{vO_2} during deep hypothermia becomes somewhat problematic. It may be prudent to assume that substantially higher levels of S_{vO_2} (~>90%) are required to infer the adequacy of perfusion during deep hypothermic CPB. The development of shunting around major vascular beds that may occur as a consequence of CPB, in addition to any preexisting collateral vessels, may also increase S_{vO_2} without indicating adequate perfusion of those tissues, meaning that organ hypoperfusion can exist despite what appear to be acceptable S_{vO_2} values.

Frequent monitoring of blood glucose and efforts to maintain it in the normoglycemic range are important during CPB in neonates, infants, and children. The major cause of hypoglycemia appears to be limited hepatic glycogen stores and gluconeogenic capability, especially in neonates, and perhaps also in cyanotic and malnourished (e.g., CHF) infants and young children. Failure to provide exogenous glucose can result in severe hypoglycemia and neurologic injury. The potential neurologic consequences of hypoglycemia may be exacerbated by hypocarbia, which seems to lower the threshold for hypoglycemic neuronal damage, and by patient lesions (e.g., aortopulmonary collaterals) and bypass strategies that independently reduce cerebral autoregulation and cerebral blood flow (Siesjo et al., 1983; Sieber et al., 1989; Glauser et al., 1990a).

Hyperglycemia can also be a frequent occurrence during pediatric CPB. Blood glucose may increase because of an increased supply from exogenous sources such as IV fluids and cardioplegia, as well as because of reduced glucose uptake, which is primarily the result of insulin resistance arising from the counter-regulatory effects of increases in stress hormones such as cortisol, growth hormone, and catecholamines (Anand et al., 1990; Furnary and Wu, 2006; Gandhi et al., 2007; Dickerson et al., 2008). Deep hypothermia can also suppress glucose-stimulated insulin secretion during hypothermic CPB and for at least a few hours thereafter. It has become well accepted that hyperglycemia can potentiate cerebral ischemia–reperfusion injury under a variety of circumstances in both infants and children (Lanier, 1991; Michaud et al., 1991; LeBlanc et al., 1994); a trend toward similar results occurs in pediatric CPB patients, although the data are largely retrospective and uncontrolled (Steward et al., 1988; Glauser et al., 1990a). Proposed mechanisms of hyperglycemic–ischemic brain injury include hyperosmolar cellular swelling from glucose loading, and promotion of lactic acidosis or increased intracellular acidosis caused by increased anaerobic glycolytic flux.

However, this issue remains controversial. There was only a weak correlation between blood glucose with creatine kinase-BB levels and no correlation with neurodevelopmental

outcome in the Boston Circulatory Arrest study, and there was some evidence that post-CPB hyperglycemia was in fact protective, particularly against seizures, which were associated with worse neurodevelopmental outcomes (Burrows and McGowan, 1996; Rappaport et al., 1998). There are also substantial data in a variety of non-CPB animal models that preischemic hyperglycemia may protect the immature brain from hypoxia, asphyxia, or hypoxia–ischemia (Callahan et al., 1990; Hattori and Wasterlain, 1990; Vannucci, 1990; Vannucci and Mjuscic, 1992). One important caveat is that these studies were conducted almost exclusively in immature rat models in which circulation and ventilation were unsupported, and some of the protective effect of hyperglycemia may have been the result of better maintenance of the circulation or ventilation in hyperglycemic animals (an effect that would be largely irrelevant during CPB). Further complicating this issue are reports that relatively modest degrees of hyperglycemia were associated with worse overall outcome in a variety of circumstances, including in adult cardiac surgery and in at least some adult and pediatric intensive care patients, and that tight glucose control could be beneficial (Van den Berghe, 2004, 2007; Dickerson et al., 2008; Lecomte et al., 2008; Oeyen, 2008; Patel, 2008; Rossano et al., 2008; Wiener et al., 2008; Levy and Rhodes, 2009). Particularly in the case of adult cardiac surgery patients, at least some of the benefit appeared to be obtained in diabetic (and perhaps prediabetic) patients and involve risks and complications not typically associated with infant congenital heart surgery (Furnary et al., 2004; Furnary and Wu, 2006; Lazar et al., 2009). However, additional and more recent analyses have called this conclusion into question, with a number of studies suggesting that moderate degrees of hyperglycemia are not associated with worse outcome and that tight control may in fact be detrimental (Gandhi et al., 2007; Rossano et al., 2008; Finfer et al., 2009; Inzucchi and Siegel, 2009; Levy and Rhodes, 2009).

Cardioplegia

The need to deliver cardioplegia is often a direct consequence of aortic cross-clamping, which is placed to enhance surgical exposure by excluding the heart from the circulation and providing a bloodless field. The heart must survive this interval of ischemia (the cross-clamp interval) without injury. Cardioplegia solutions arrest the heart in diastole, resulting in a profound reduction in metabolic demand. In addition, cardioplegia plays a restorative role, replenishing energy stores in ischemic hearts. Arrest in diastole can be induced by depolarized arrest (elevated potassium), polarized arrest (adenosine, potassium channel openers, procaine, lidocaine), or arrest by influencing calcium mechanisms (elevated magnesium, calcium antagonists).

Composition

There is considerable variability in the composition of cardioplegia solutions used in different institutions. Despite this wide variety of composition, there are certain properties all solutions must share:

- Potassium. Increasing extracellular potassium concentration to induce depolarized arrest is the primary method used to induce electromechanical arrest in most cardioplegia solutions. Cardioplegia solutions generally have a potassium concentration ranging from 15 to 30 mEq/L. This concentration produces prompt electromechanical arrest. Concentrations of potassium higher than 40 mEq/L are detrimental because they increase calcium influx by increasing calcium conductance.
- Hypothermia. Hypothermia is an important component of cardioplegia solutions because it reduces myocardial oxygen consumption even in the arrested heart, reduces the degree of extracellular hyperkalemia needed to cause electromechanical arrest, and is additive with potassium-induced arrest in preventing ischemic damage.
- Calcium. Loss of calcium homeostasis is associated with cell dysfunction and death after ischemia. For this reason, one might assume that the addition of calcium to cardioplegia solutions is detrimental. In fact, a small amount of calcium is necessary to prevent the calcium paradox and to allow functional recovery after aortic cross-clamp removal. Calcium paradox is the massive cellular destruction that occurs when the myocardium is perfused with a calcium-containing solution after a period of calcium-free perfusion.
- Sodium. The optimal sodium concentration is unknown, but most cardioplegia solutions avoid extreme hyponatremia or hypernatremia relative to intracellular sodium concentration.
- Osmolarity. Because myocardial edema accompanies ischemia, cardioplegia solutions are formulated to minimize further accumulation of intracellular fluid. Cardioplegia solutions with osmolarities of greater than 400 mOsm/L exacerbate myocardial edema, probably by inducing increases in intracellular sodium. On the other hand, solutions with a low osmolarity will result in accumulation of intracellular water and further edema. The ideal osmolarity remains undetermined, but probably is approximately 370 mOsm/L. Mannitol and albumin are the additives commonly used to manipulate osmolarity in cardioplegia solutions.
- Buffering. Anaerobic metabolism accompanying ischemia results in cellular acidosis. Buffering allows anaerobic metabolism to continue and reduces ATP depletion in the ischemic myocardium. As myocardial temperature decreases, the appropriate uncorrected pH becomes more alkalotic. Therefore, the buffers chosen must be effective at the alkalotic pH found in the hypothermic myocardium. THAM, bicarbonate, phosphate, and histidine are all used as buffers in cardioplegia solutions.

Cardioplegia solutions are formulated as either a crystalloid or a blood medium. There are important differences between the two formulations. Crystalloid solutions are generally prepared by the hospital pharmacy in containers that are delivered to the perfusionist. Blood solutions are prepared by drawing off oxygenated blood from the CPB circuit into a separate reservoir and mixing it with a pre-prepared crystalloid base solution. The ratio of blood to crystalloid base varies from institution to institution (4:1 to 1:4). Potassium and other additives are then added to the blood in sufficient amounts to obtain the desired concentration. Both solutions can be temperature regulated.

Delivery

Cardioplegia is delivered under pressure to the heart via either a pressurized bag or a roller pump system. The advantages of roller pump system include easy incorporation of a continuous cooling system to maintain cardioplegia hypothermia, easy

incorporation of the mixing apparatus necessary for blood cardioplegia systems, and second-to-second control of cardioplegia infusion pressure and flow rates. Optimal delivery of cardioplegia must be tailored to the operative procedure and operative technique. Cardioplegia delivery may be antegrade via the arterial system (aortic root or directly into the coronary ostia) or retrograde via the venous system (coronary sinus).

Hypothermia

Hypothermia continues to be the mainstay for protection of the brain and other organs during CPB, especially when reduced flow rates are required to facilitate the procedure. The major effect of hypothermia is a decrease in metabolic rate and consequently metabolic demand for oxygen and other substrates. During ischemia, hypothermia slows consumption of high-energy phosphate compounds and also maintains them intracellularly, thereby facilitating recovery of ATP and phosphocreatine during reperfusion. Hypothermia delays loss of ionic homeostasis during ischemia, particularly entry of sodium and calcium and resultant cellular edema, by energy-dependent, energy-independent, and membrane-stabilizing mechanisms (Kern et al., 1996). Reduced amounts of free radical generation, inflammatory cytokine production, white cell activation, and leukocyte adhesion molecule synthesis have all been associated with hypothermia or hypothermic CPB. Hypothermia suppresses release of excitatory amino acid neurotransmitters during ischemia and reperfusion, which is likely to be an important cerebral protective mechanism, especially in the neonatal and immature brain (Burrows and McGowan, 1996; Kern, 1996).

Hypothermic protection of the brain during periods of low or absent flow depends on homogenous cooling of all brain regions. There is evidence that this may not occur, based on the temperature or oxygen saturation of jugular bulb venous blood, which indicates the likelihood of ongoing cerebral metabolic activity despite low tympanic or nasopharyngeal temperatures (Kern et al., 1992a; Pua and Bissonnette, 1998). These data indicate that tympanic or nasopharyngeal temperatures may not identify subsets of patients with inadequately cooled brains. Risk factors for nonhomogeneous and delayed brain cooling in pediatric CPB patients may include the position of the aortic cannula, vascular anomalies, aortopulmonary and other collaterals, blood gas and pH management strategy (see later), and the duration of cooling. For example, using alpha-stat pH management, the duration of core cooling prior to a period of DHCA was the intraoperative variable most closely associated with postoperative cognitive outcome. Over cooling times between 11 and 18 minutes, increasing cooling time by 5 minutes increased development score by 26 points. It was speculated that shorter cooling times (<~15 minutes) permitted ongoing metabolism in nonhomogeneously cooled regions of the brain, making them more susceptible to injury during the period of DHCA (Bellinger et al., 1991). Also of interest, there was a trend for worse neurodevelopmental outcome (that did not reach statistical significance) with cooling times longer than 20 minutes, perhaps due to the effects of prolonging exposure to the deleterious consequences of CPB, including microembolic events.

The reductions in metabolic rate produced by hypothermia allow CPB flow rates to be reduced, thereby reducing the amount of blood returning to the heart and improving surgical conditions. Most centers use values of approximately 50 mL/kg

per minute or 0.70 L/min per meter-squared for low-flow CPB. Studies in both adults and children have suggested the relative safety of low rates in this range, particularly in terms of the degree of cerebral protection afforded compared with deep hypothermic circulatory arrest (Fox et al., 1982; Miyamoto et al., 1986; Watanabe et al., 1989; Swain et al., 1991a; Pua and Bissonnette, 1998). Further reductions in pump flow to one fourth or less of normal may be used at deep levels of hypothermia (<18° C). However, there is no agreement on a “safe” degree of flow reduction for a given temperature in infants and children. Kern et al. (1993) have suggested that the critical pump flow rate in terms of the crucial juncture at which cerebral metabolism becomes flow dependent is between approximately 30 and 35 mL/kg per minute at moderate hypothermia (26° to 29° C), and 5 and 30 mL/kg per minute during deep hypothermia (18° to 22° C). The bulk of evidence suggests that cerebral autoregulation is markedly diminished or absent at temperatures below 20° C, and hence CBF becomes pressure passive at very low temperatures during CPB in infants (Pua and Bissonnette, 1998; Kern et al., 1993; Greeley, 1989). Burrows and Bissonnette (1993) showed that a significant percentage of neonates and infants who undergo low-flow CPB (<22% of normal pump flow) have no detectable CBF as measured by transcranial Doppler and require higher perfusion pressures to reestablish CBF.

Thus, it is possible that the result of low-flow CPB, at least in some infants, is the opposite of what is intended in terms of using low-flow techniques to avoid deep hypothermic circulatory arrest—that is, low-flow hypothermic CPB may result in, rather than prevent, cerebral ischemia. The development of critical closing and opening pressures may contribute to a no-reflow phenomenon and uneven brain cooling during low-flow CPB (Pua and Bissonnette, 1998). The notion of critical closing and opening pressures in the cerebral (and other vascular beds as well) also suggests that blood flow may be more dependent on arterial *pressure* than pump flow rate in these circumstances, and that a minimal mean arterial pressure is necessary to maintain adequate flow to the brain and other organs.

Antegrade Cerebral Perfusion

In an effort to prevent the potentially deleterious effects of DHCA on cerebral and somatic perfusion and oxygenation, some groups have directed efforts toward technical innovations to avoid the use of DHCA for aortic arch reconstruction in children with HLHS undergoing the Norwood procedure and in children with aortic hypoplasia or interruption undergoing biventricular repair. A number of techniques to provide continuous ACP or regional low-flow perfusion via the right innominate artery have been described and are used in conjunction with deep hypothermia (Pigula et al., 2000; Tchervenkov et al., 2000; Asou et al., 1996; Imoto et al., 1999). It is believed that these techniques provide both cerebral and somatic (subdiaphragmatic visceral) perfusion. Somatic perfusion is believed to be the result of the extensive network of arterial collaterals in the neonate that link the supradiaphragmatic and subdiaphragmatic viscera, such as the internal thoracic and intercostal arteries.

Access to the innominate artery can be obtained via placement of the arterial cannula into the open, distal end of a 3- or 3.5-mm Gore-Tex graft with the proximal end anastomosed to the distal right innominate or proximal right subclavian artery. In patients undergoing the Norwood procedure, this graft—when anastomosed distally to the right pulmonary artery—can

constitute a modified BT shunt. In patients undergoing biventricular repair, the graft serves as the primary cannulation site. The graft is oversewn at its insertion site once separation from CPB has occurred.

When the ascending aorta is of reasonable size, the aorta cannula can be advanced up the innominate artery from the right side of the aortic arch during arch reconstruction. Alternatively, the cannula can be left in the ascending aorta with a cross-clamp applied just distal to the innominate artery for reconstruction of distal and descending aortic lesions.

The flow rates necessary to provide optimal cerebral and somatic perfusion during ACP have yet to be determined. An average flow rate of 63 mL/kg per minute was required to maintain cerebral blood flow velocity (as measured by transcranial Doppler) and cerebral oxygen saturation (as measured by near-infrared spectroscopy [NIRS]) within 10% of baseline during ACP in a group of 34 infants (Andropoulos et al., 2003).

Deep Hypothermic Circulatory Arrest

DHCA has been used since the 1970s for the repair of congenital heart defects, primarily in neonates and small infants, and occasionally in older children. Use of DHCA can decrease the length of time the patient is on CPB. This was an important advantage during the early congenital cardiac surgical experience, when limitations in CPB equipment and techniques put the neonate and small infant at increased risk. The impetus to minimize exposure to CPB has diminished as CPB methods for infants have improved. Continuous refinement of perfusion methods for neonates and infants and the increasing evidence of neurologic damage that may result have led to a reduction in the frequency of DHCA use in most centers. Nonetheless, DHCA can provide optimal surgical exposure in a small heart and chest by allowing removal of the perfusion cannulae, and its use (or similar alternatives such as DHCA alternated with periods of intermittent perfusion) remains unavoidable for some lesions. However, its use has become progressively restricted and reduced over time. Overall, DHCA has been found to result in greater short-term (1 year) and long-term (8 years) functional neurologic and neurodevelopmental deficits when compared with low-flow CPB. However, both strategies were associated with increased neurodevelopmental risk (Bellinger et al., 2003; Wypij et al., 2003).

When DHCA is required, both surface cooling and core cooling are used. Surface cooling is facilitated during the induction of anesthesia and surgical exposure and cannulation for CPB by lowering the room temperature (to <20° C), placing ice-filled bags around the head and neck, and positioning the patient on a cooling blanket set to about 10° C. Using these methods, the usual rectal temperature at the time of initiating CPB is about 33° C (temperature-related dysrhythmias or ventricular fibrillation are rare in neonates and small infants at core temperatures of greater than 28° to 30° C). For most cases of DHCA, an ascending aortic arterial cannula (the pulmonary artery is cannulated initially for HLHS) and a single right atrial venous cannula are inserted. As noted, extremely rapid cooling (core temperature decreasing to between 15° and 18° C in less than ~15 minutes) is usually avoided. Cooling is continued until both rectal and tympanic membrane temperatures are less than 18° C. Cardioplegia is administered and CPB then discontinued. Several pharmacologic adjuncts are usually given as part of DHCA. Many include an α -blocker such as phentolamine

or phenoxybenzamine in the pump prime to reduce vascular resistance, improve regional blood flow, and aid in homogeneous and effective cooling. High-dosage methylprednisolone (30 mg/kg) is given for reasons already discussed. Some administer sodium pentothal, 5 to 10 mg/kg, just prior to the start of DHCA to reduce cerebral electrical activity and metabolism; this is based in part on experience that up to 20% to 30% of neonatal brains will not be electrically silent despite tympanic and core temperatures of 18° C or less. As discussed, a higher hematocrit than used previously (~25% to 28% instead of 15% to 20%) is now favored by many, based on evidence that it does not impair the hypothermic cerebral circulation and may be associated with improved myocardial function, less total body water accumulation, and perhaps improved neurodevelopmental outcome (Duebener et al., 2001; Jonas, 2002; Newburger et al., 2008; Wypij et al., 2008). Finally, drainage of blood from the patient is promoted by several inflations of the lungs and manual compression of the abdomen. The venous cannula is then usually clamped and removed.

Prior to rewarming, initial steps are taken to remove air from the left ventricle, left atrium, and pulmonary veins. Cannulae are reinserted, and CPB is slowly resumed at 18° C. Because of concerns about cerebral injury *after* DHCA and the likely protective effects of hypothermia (and harmful effects of even mild hyperthermia *after* a cerebral injury), a period (~10 to 15 minutes) of 18° C perfusion on resumption of CPB after DHCA is initiated to limit both hyperthermic reperfusion (by keeping aortic perfusate temperatures lower) and post-CPB hyperthermia (Pua and Bissonnette, 1998; Shum-Tim et al., 1998; Scallan, 2003; Ungerleider and Shen, 2003). Similarly, efforts are made after CPB (cooling blankets and fans, acetaminophen) to keep core temperature at less than 36° C after DHCA or low-flow CPB. Frequently, before aortic cross-clamp removal, mannitol (0.25 to 0.5 g/kg) is given. Ionized calcium, which had been allowed to decrease to about 0.4 to 0.8 mmol/L during cooling and early rewarming, is normalized once the heart has had a period of reperfusion and the core temperature has increased to about 30 to 32° C. It is probably important to keep both flow rate and mean arterial pressure at age-appropriate normal values because of the loss of cerebral autoregulation and consequent pressure-flow dependence of CBF after DHCA. Once calcium is normalized and the patient rewarmed to about 34° C, pulsatile ejection is stimulated by restricting venous return into the pump, and ventilation is begun. Observation of the heart, intracardiac filling pressures, arterial blood pressure, and other available information (e.g., contractility and filling on TEE) are useful at this point to estimate the degree of inotropic support required when weaning from CPB. Typically, a low dosage of dopamine (~5 to 7.5 mg/kg per minute) is all that is required if the repair is technically satisfactory.

Management of Arterial Blood Gases During Pediatric CPB

Most centers adjust oxygen delivery to the CPB circuit so that arterial PO₂ values are in the range of approximately 400 to 600 mm Hg. This hyperoxic approach is based on evidence that brain injury is greater during normoxic CPB than with hyperoxic CPB (Nollert et al., 1999). Potential explanations for this effect include that the brain mainly uses dissolved oxygen during deep hypothermic CPB, that the amount of gas microemboli is decreased when nitrogen is omitted from the sweep gas, and that oxygen microemboli are resorbed much faster than those

containing nitrogen (Dexter et al., 1997; Scallan, 2003). On the other hand, some centers favor significantly reducing P_{O_2} during CPB to reduce oxyradical production (Nollert et al., 1999; Allen, 2003). This mechanism may be especially important in cyanotic infants, in whom antioxidant reserves and scavenging enzyme systems may be downregulated (Cowan et al., 1992; Nollert et al., 1999; Allen, 2003). The issue remains unresolved, and it is likely that the relative benefits of the two oxygenation strategies depend in part on the organ system in question.

The optimal management strategy for pH and CO_2 during profound hypothermia, with or without DHCA, remains controversial. Both alpha-stat and pH-stat management strategies are used during pediatric CPB, and both have potential advantages and disadvantages. The biochemical basis of these two approaches bears some discussion. During hypothermia, the efficacy of the body's primary buffering systems (e.g., bicarbonate, phosphate) is markedly reduced, and amino acids become the most important intracellular buffers as temperature decreases. Of these amino acids, the α -imidazole ring of histidine is the most effective proton acceptor (i.e., buffer). Water is less ionized (into H^+ and OH^-) as temperature decreases, and thus the pH of water (the major fluid in the body) increases with falling temperature. The neutral point of water (i.e., the pH at which $[H^+] = [OH^-]$) also increases as temperature falls, and is about 7.4 at 37° C and about 7.7 to 7.8 at deep hypothermic temperatures. Alpha-stat management is based on preserving electrical neutrality at reduced temperatures and therefore the buffering capability of the α -imidazole ring of the amino acid histidine. Most enzyme, receptor, and metabolic systems function best at pH 7.4; several have been shown to function more efficiently at 20° C and at a pH of about 7.7 (Rahn et al., 1975; Somero and White, 1985). Blood from a normal patient cooled under alpha-stat methods will have a pH of about 7.4 and CO_2 at about 40 mm Hg when the sample is warmed to 37° C in the blood gas analyzer. Therefore, the alleged biochemical advantages of preserving electrochemical neutrality and intracellular buffering via alpha-stat management include better preservation of metabolism and of protein and enzyme function (by preserving intracellular pH $[pH_i]$ and preventing abnormal charge accumulation on proteins), and a slowing of the diffusion of key charged intermediates such as ADP and AMP out of the cell. These facets promote faster recovery of oxidative metabolism and high-energy phosphates when oxygen and substrate supply are restored (Somero and White, 1985). Alpha-stat management is likely to be associated with better preservation of cerebral autoregulation at mild to moderate hypothermic temperatures, lower cerebral blood flow, and less brain swelling.

These features may have a net beneficial effect in adults, in whom microemboli and cerebral edema appear to be major components of the insult, as compared with the higher brain blood flow and greater microemboli load associated with pH stat (Murkin et al., 1987; Burrows and McGowan, 1996). On the other hand, the alpha-stat strategy causes a leftward shift in the oxyhemoglobin dissociation curve. In the setting of low flow, low perfusion pressures, and low temperatures, overall oxygen delivery under alpha-stat management may be marginal to meet metabolic needs, and cerebral blood flow may be inadequate to evenly and effectively cool the brain (Bove et al., 1987; Burrows and McGowan, 1996; Jonas, 1996).

In contrast, pH stat uses a mathematical correction for the effects of temperature on pH and then adds CO_2 to the circuit to correct the measured pH for the fall in temperature. The pH-stat

strategy, therefore, attempts to normalize the patient's pH (i.e., make it ~7.4) and P_{CO_2} at the hypothermic temperature. In contrast to the alpha-stat example, a pH-stat sample analyzed at 37° C will be acidotic (pH ~7.1 to 7.2) and hypercarbic (P_{CO_2} at ~60 to 70 mm Hg). From a biochemical standpoint, the addition of CO_2 will theoretically lower pH_i and disrupt electrical neutrality. However, evidence suggests that the pH stat may only minimally reduce pH_i (Swain et al., 1991b; Aoki et al., 1994). On the other hand, the increase in cerebral blood flow associated with pH-stat management, along with the rightward shift in the oxyhemoglobin dissociation curve, may favor homogeneous and more rapid brain cooling and oxygen delivery as long as perfusion pressure and flow are maintained. Hypercapnia also decreases cerebral metabolic rate, energy use, glycolytic flux, and lactate production (Miller and Corddry, 1981; Tombaugh and Sapolsky, 1993; Vannucci et al., 1995; Burrows and McGowan, 1996). Hypercapnia and acidosis may decrease ischemia-reperfusion-related neurotoxic brain injury caused by excitatory amino acids by inhibiting *N*-methyl-D-aspartic acid receptor function, glutamate release, and neuronal calcium fluxes (Tombaugh and Sapolsky, 1993; Ou-Yang et al., 1994; Burrows and McGowan, 1996). Based on the work of the Aoki and Swain groups showing that cerebral pH_i becomes alkalotic during deep hypothermia even when pH-stat management is employed, it may be that the biochemical advantages of alpha stat are largely present during pH-stat management, and are supplemented by the effects of pH stat to increase CBF and oxygen availability as a result of its effect to rightward shift oxyhemoglobin dissociation (Swain et al., 1991b; Aoki et al., 1993).

The multiple potential beneficial effects of pH-stat management are likely to be particularly important in the neonate and infant exposed to low flow or no flow because hypoxic and ischemic injury probably pose the greatest risk to the infant (in contrast to the adult with significant atherosclerosis and vascular disease managed at mild or moderate hypothermia, in whom minimizing microemboli and preserving autoregulation—and therefore favoring alpha-stat management—are more pressing considerations). A small retrospective study using relatively brief cooling times (<15 minutes, average) suggested that pH stat might be preferable to alpha stat in terms of neurodevelopmental outcome when DHCA was used for Senning correction of arterial transposition (Jonas et al., 1993). In a larger, prospective, randomized, single-center study, no consistent improvement or impairment could be related to pH management strategy during deep hypothermic CPB (Bellinger et al., 2001). Based on this information, many centers choose pH-stat management for infant and pediatric CPB when deep hypothermia, low flow, and circulatory arrest are going to be employed (Aoki et al., 1993; Jonas et al., 1993; Kirshbom et al., 1995; Jonas, 1996, 2002; du Plessis et al., 2002; Forbess et al., 2002a, 2002b; Ungerleider and Shen, 2003). Patient factors can also influence this choice. The presence of cyanosis and aortopulmonary collaterals are considered by many to be indications for pH-stat management; CO_2 increases pulmonary vascular resistance, leading to improved systemic blood flow in these patients; cerebral perfusion is directly increased by CO_2 and also by the reduction in flow through the collaterals (Kirshbom et al., 1995; Kern, 1996; Scallan, 2003).

Bleeding after Pediatric Cardiopulmonary Bypass

Bleeding is one of the most significant problems after major cardiac surgical procedures in neonates, infants, and children.

Factors include difficulties surrounding heparinization and its antagonism by protamine (discussed previously), pathophysiology of the lesion, technical aspects of the operation, and multiple effects of CPB that perturb coagulation and promote blood loss. Most of the procoagulant and anticoagulant blood factors are present in reduced concentrations in neonates and infants; these concentrations approach adult values at varying rates over the first 6 to 12 months of life (Peters et al., 1985; Kern et al., 1992a; Odegard et al., 2002a, 2002b). When compared with age-matched controls, reduced levels of both procoagulant and anticoagulant factors have been found in many infants and children with congenital heart disease, particularly those with various forms of single-ventricle physiology (Odegard et al., 2002, 2003). The etiology is unclear at present, as is whether these abnormalities are linked to any functional disturbances (either increased or decreased) in ability to clot. Overall, however, the effects of hemodilution by CPB to lower clotting factor concentrations in infants, who appear to be functionally balanced albeit at a lower set point, will be increased.

Increased bleeding can occur in association with lesions that increase systemic venous pressures (e.g., Fontan physiology, Mustard or Senning atrial baffles, right ventricular dysfunction) resulting from hepatic dysfunction, development of large venous collateral vessels, and high venous pressures. Hepatic dysfunction can also occur in lesions with significant systemic hypoperfusion (large left-to-right shunt, left-sided obstructive lesion such as critical coarctation). Cardiac lesions that generate large shear forces such as aortic stenosis and VSDs can promote the degradation of active von Willebrand factor multimers to less active and inactive monomers, leading to an acquired form of von Willebrand's disease (Williams et al., 1999a; Yoshida et al., 2006; Vincentelli et al., 2003). PGE₁, used to maintain ductal patency preoperatively, can impair platelet function. Changes attributed to cyanosis that increase the risk for bleeding may include reduced platelet function, increased fibrinolysis, decreased total body amount of clotting factors (because of polycythemia and hence decreased plasma volume), and the development of collateral vessels. Compared with most adult cardiac surgery, many congenital cardiac operations require extensive suture lines and reconstructions using tissue or prosthetic graft materials, often on high-pressure vessels (e.g., stage I operation for HLHS, the arterial switch procedure). Reoperations also make up a substantial part of pediatric cardiac surgery.

The effects of CPB on blood activation, coagulation, and fibrinolysis are arguably greater in neonates and infants because of the greater degree of hemodilution, deeper degrees of hypothermia, higher shear forces caused by higher flow rates, more blood trauma and greater blood-to-air contact (higher flows, small tubing and cannulae, more cardiomy suction), and a proportionately greater degree of blood contact with the foreign surface. CPB reduces platelet number and causes platelet dysfunction by several mechanisms, including hypothermia, contact activation from the CPB circuit, activation via coagulation mechanisms, and cleavage of platelet adhesive receptors by fibrinolytic proteases that are also activated by CPB. Platelet numbers in neonates and small infants are approximately halved at the end of bypass after protamine reversal, and platelet function is believed to be markedly impaired for the reasons outlined. Ongoing consumption of platelets and clotting factors resulting from bleeding at complex and pressurized anastomotic sites can add to thrombocytopenia. Neonates presenting for CPB are likely to have normal platelet counts but reduced (compared

with age-matched subjects, who, as already noted, have lower clotting factor levels compared with adult values) concentrations of factors II, VII, VIII, IX, and X. A subset of neonates may also have significantly lower fibrinogen at the outset, which can then be critically low at the end of bypass and be a major contributor to postbypass bleeding (Kern et al., 1992b). Other significant abnormalities at the end of CPB after protamine administration include further reductions and functionally low concentrations of factors V, VII, and VIII. Low post-protamine platelet counts and fibrinogen concentrations correlate with bleeding in neonates and small infants (Miller et al., 1997).

The treatment approach to post-CPB bleeding in pediatric patients is based on the preceding coagulation considerations, coupled with the presence of complex surgical reconstructions and extensive vascular suture lines. Platelets are the initial therapy after adequate heparin reversal has been ensured. One to 2 units of platelets are typically administered to neonates and small infants to start, and up to 6 to 8 units in larger children. Each unit of platelets per 10 kg body weight usually increases the platelet count by approximately 50,000/mm³. However, the actual platelet increase during and after pediatric CPB is frequently less, at least in part because of the consumption by ongoing bleeding and large exposed tissue and endothelial surfaces. When platelets are administered, they are in fluid that is essentially plasma, so that a fair amount of clotting factors is supplied simultaneously. Cryoprecipitate is usually the next blood component administered after platelets, and it is chosen in part because it is a good source of fibrinogen in a relatively small volume. This sequence of platelets followed by cryoprecipitate has been shown to restore hemostasis in a majority of pediatric patients after CPB (Miller et al., 1997). Fresh frozen plasma is usually reserved to replete measured factor deficiencies not amenable to cryoprecipitate, particularly because there is some evidence that it has little effect on, or may even be detrimental in, most post-CPB infants (Miller et al., 1997). Some pediatric cardiac centers prefer to use fresh whole blood as the primary therapy after protamine reversal. When used within 24 to 48 hours of collection, fresh whole blood contains active platelets and significant amounts of clotting factors, and it has been shown to reduce bleeding, transfusion requirements, and the use of other components in both neonates and adults (Mohr et al., 1988; Manno et al., 1991). A major limitation is the difficulty of obtaining reliable quantities within the 48-hour time frame, in part because of required blood banking procedures and testing for infectious agents.

Although truly accelerated fibrinolysis is probably uncommon during pediatric CPB (and largely resolves after protamine administration) (Miller et al., 1997, 2000), it is likely that the activation of the fibrinolytic system that accompanies surgical trauma, bleeding, and particularly CPB-induced activation of coagulation and inflammatory cascades has a significant role in consumption of clotting factors, generation of anticoagulant degradation products, and loss of adhesive receptors on platelets. For these reasons, antifibrinolytic agents such as *e*-aminocaproic acid and tranexamic acid have become increasingly popular. Until recently, aprotinin was also used. Aprotinin is not available for clinical use now, because of reports of increased complications in *adult* cardiac surgery patients. These complications include stroke, renal failure, graft occlusion, and death. Interestingly, meta-analyses of adult aprotinin studies indicate a protective effect against neurologic injury, particularly stroke, which appeared to be due at least in part to reduced patient reinfusion of shed blood (Murkin, 2001; Smith et al., 2004).

At present, there is little controlled evidence that antifibrinolytic agents are beneficial in primary pediatric cardiac surgical operations in terms of, for example, blood loss, transfusion requirement, and platelet dysfunction, although many centers use them for complex first operations such as arterial switch and stage I hypoplastic left heart reconstructions. There is substantial evidence in favor of their use for reoperations, particularly of the complex variety (D'Errico et al., 1996b; Reid et al., 1997; Miller et al., 1998; D'Errico et al., 1999; Gruber et al., 2000; Carrel et al., 1998; McDonough and Gruenwald, 2003; D'Errico et al., 1996b). Theoretical concerns remain about potential deleterious prothrombotic consequences during low flow or deep hypothermic circulatory arrest and in tenuous anatomic or circulatory situations postoperatively (e.g., Fontan fenestration, coronary anastomoses, reconstructed HLHS ascending aortas, surgical shunts), although there are no direct reports of such, and one retrospective study was unable to identify any role for these agents in similar problems (Casta et al., 2000; Gruber et al., 2000). The role for activated factor VII in postcardiotomy bleeding continues to be controversial, and requires further study and definition (Pychynska-Pokorska et al., 2004; Agarwal et al., 2007; Guzzetta et al., 2009).

Because of concerns about inducing severe hypercoagulability and promoting the development of thrombotic complications, the use of recombinant factor VIIa should be reserved for uncontrolled bleeding that persists despite administration of clotting factors; relative normalization of platelet count, prothrombin time (PT), partial thromboplastin time (PTT), and so on; and relative certainty that all surgical sites have been controlled (Pychynska-Pokorska et al., 2004; Agarwal et al., 2007; Guzzetta et al., 2009). It may be useful to note that efficacy may be preserved while reducing thrombotic risk by using "mini" or lower dosage protocols (in the range of 60 mcg/kg or even lower), although this too remains to be proven (Ekert et al., 2006).

Organ Injury During Pediatric CPB

The potentially damaging mechanisms of CPB include global (i.e., low-flow or DHCA) and regional (e.g., heart, lung, gastrointestinal tract) periods of ischemia and reperfusion, activation of multiple limbs of the systemic inflammatory response, and intramyocardial and systemic air and particulate microemboli. During hypothermic CPB at full flow rates, skeletal muscle functions as a large capacitance reservoir, and blood flow is to some extent shunted away from the vital organs. During low-flow hypothermic CPB, skeletal muscle vasculature constricts and flow to vital organs is preserved so that oxygen delivery is able to maintain oxygen consumption down to about 50% reduction in flow rate (Lazenby et al., 1981). The presence of large collateral vessels, arterial obstructive lesions, cannula position, and other shunts from the systemic circulation may further compromise vital organ blood flow, as previously discussed.

Pulmonary Effects

Lung injury is a variable but potentially significant problem after CPB in infants and children. Likely causes include hemodilution, inflammation, and ischemia-reperfusion (Seghaye et al., 1993; Brix-Christensen, 2001). Hemodilution promotes fluid extravasation by reducing oncotic pressure. Activated complement, leukocytes, cytokines, and leukotrienes induce alveolar and capillary membrane damage, augment capillary leak, increase

platelet and white blood cell plugging, and induce the release of additional mediators that further increase pulmonary vascular resistance and pulmonary parenchymal and vascular damage. Infants with current (e.g., infection, CHF, or pulmonary overcirculation) or prior (e.g., respiratory distress syndrome, bronchopulmonary dysplasia) pulmonary processes may be at greater risk. Measurable consequences of CPB-induced lung injury include loss of endothelium-dependent dilation and increased pulmonary vascular resistance, decreased compliance, decreased functional residual capacity, increased alveolar-arterial oxygen difference, leakage of fluid into the interstitial space, and reduced surfactant activity (McGowan et al., 1993; Gillinov et al., 1994; Dreyer et al., 1995; Morita et al., 1996; Schulze-Neick et al., 1999; Ozawa et al., 2000; Brix-Christensen, 2001; Chew et al., 2001). Facilitating lung cooling by allowing a period of pulmonary blood flow on CPB during core cooling (prior to occluding venous return) has been suggested as one means of reducing ischemic lung injury and its consequences (Chai et al., 1999).

Renal Effects

Glomerular filtration rate and renal diluting and concentrating abilities are immature in neonates and very young infants. Evidence of renal dysfunction after CPB in children can be common, in the range of 3% to 10% or more (Picca et al., 1995; Aiyagari et al., 2010). Preoperative renal dysfunction or injury and low cardiac output after CPB may be the best predictors of post-CPB renal dysfunction. Preoperative renal injury appears to be more likely in neonates, who may in fact have multiorgan dysfunction after delivery and initial stabilization (e.g., HLHS, arterial transposition), as well as in older patients with longstanding systemic ventricular dysfunction, chronically elevated systemic venous pressures, or cyanosis (e.g., failing Fontan circulations, TOF with severe right or biventricular dysfunction) (Price et al., 2008). Contributing factors are likely to include low flow and reduced mean arterial pressure, nonpulsatile perfusion, and hypothermia leading to the production and release of hormones such as endothelin, catecholamines, antidiuretic hormone, atrial natriuretic factor, and rennin/angiotensin (Anand and Hickey, 1987; Anand et al., 1990; Picca et al., 1995; Brix-Christensen, 2001). In addition to renal dysfunction, these factors may contribute to increased total body water, delayed fluid clearance after CPB, and related complications such as myocardial and pulmonary interstitial edema, delayed chest closure, and prolonged ventilatory support. At present, there is little information specifically devoted to infant and pediatric heart disease patients in terms of renal protection or preventive therapies. In larger patients, vacuum-assisted venous drainage has some obvious theoretical advantages. Several recent adult cardiac surgery studies (where much of the underlying pathophysiology may differ) suggest that relatively low dosages of fenoldopam or nesiritide can reduce renal-related morbidity in at-risk patients (Chen et al., 2007; Cogliati et al., 2007; Mentzer et al., 2007; Landoni et al., 2008; Roasio et al., 2008); one recent study suggests a benefit from *N*-acetylcysteine, perhaps related to its antioxidant properties (Aiyagari et al., 2010).

Brain Injury

Neurologic injury continues to be one of the most problematic aspects of surgery for CHD. Prevention of neurologic injury has become increasingly important as overall survival has increased

and functional cardiopulmonary outcomes improve. Earlier retrospective series estimated the incidence of major neurologic injuries after pediatric heart surgery to be between 20% and 30% (Ferry, 1990; Pua and Bissonnette, 1998; Menache et al., 2002). Although there appears to have been a progressive decline in major complications such as seizures, persistent choreoathetosis, and severe developmental delay (for reasons that are largely unknown), more subtle but significant cognitive and neurodevelopmental delays in IQ, language and motor skills, attention, learning skills, visual and spatial skills, and working memory have recently been found in a number of different circumstances (Bellinger et al., 1999, 2003; Forbess et al., 2002a, 2002b; Wypij et al., 2003; Mahle et al., 2006; Mahle and Wernovsky, 2004; Tabbutt et al., 2008; Kussman et al., 2009). Cognitive development also appears to be lower in school-age survivors of HLHS and patients with Fontan physiology (Mahle et al., 2000; Wernovsky et al., 2000). Risks for lower achievement included surgery for HLHS, use of DHCA, and reoperation within 30 days.

Overall, it is clear that preoperative, intraoperative, and postoperative factors are all involved. The developing infant brain may be particularly susceptible to injury by hypoxia, ischemia–reperfusion, and the systemic inflammatory response, because of its relatively fragile vasculature, high metabolic activity, and the fact that it is undergoing an intensive period of neuronal migration, axonal outgrowth, target finding and arborization, synaptogenesis, myelination, astroglial development, and selective neuronal reduction (largely via apoptosis) (Burrows and McGowan, 1996). Most, if not all, of these processes are under the control of biochemical factors, neurotransmitters, and gene expression pathways that are likely to be affected by CPB and its consequences (e.g., cytokine and growth factor production, generation of oxyradical and nitroxyl radical species, altered release and reuptake of excitotoxic amino acid neurotransmitters due to ischemia).

The developing brain of the newborn with CHD appears to be more immature (by MRI criteria) than that of the infant of comparable gestational age without CHD. In addition, increasing evidence suggests that various structural and developmental brain abnormalities are common in infants with congenital heart disease *prior* to any surgical interventions, or after balloon atrial septostomy alone. Interestingly, there is also some recent evidence that these preexisting brain abnormalities may not worsen after surgery, at least based on brain imaging criteria (Mahle and Wernovsky, 2004; Ikemba et al., 2004; Dent et al., 2005; Dent et al., 2006; McQuillen et al., 2006, 2007; Miller et al., 2007; Block et al., 2010). A substantial number of children with CHD have genetic syndromes associated with developmental delay of various sorts, including Down syndrome and the CATCH-22 syndrome (Gerdes et al., 1999). The latter is linked to microdeletions in the 22q11 region of chromosome 22; is associated with DiGeorge and velocardiofacial syndromes, developmental delays in language and speech, and mild hypotonia; and is present in 2% to 10% of children with CHD. It seems likely that other genetic abnormalities as yet undefined result in both neurologic problems and CHD. A sizable number of children with heart disease may have congenital brain malformations; more than 30% of infants with HLHS have evidence of brain dysgenesis or other anomalies before surgery (Glauser et al., 1990b; Miller and Vogel, 1999). Low cardiac output, high venous pressures, thromboemboli, and chronic cyanosis are all likely to contribute to both gross and

subtle neurocognitive lesions prior to surgical interventions (Kern, 1996; Miller and Vogel, 1999; Scallan, 2003).

Intraoperative causes of brain injury include abnormalities of cerebral autoregulation and cerebral perfusion, ischemia–reperfusion mechanisms, and emboli. Many of these factors have been discussed. The “safe” period of DHCA remains controversial and in part depends on how it is defined, and under what conditions of flow, pH, temperature, cooling strategy, and patient population it is assessed. Clinical experience and some evidence suggests periods of DHCA as short as 20 minutes or as long as 45 minutes before major complications such as seizures or choreoathetosis begin to increase in frequency (Burrows and McGowan, 1996). In animal models, using ATP depletion or the cerebral metabolic rate for oxygen as the endpoint led to estimates of 20 to 30 minutes or 40 to 65 minutes, respectively (Greeley et al., 1991a, 1991b; Greeley and Ungerleider, 1991; Swain et al., 1991b). Overall, the consensus is that the risks for neurologic injury and developmental abnormalities increase and IQ decreases in direct proportion to the duration of DHCA (Wells et al., 1983; Jonas, 1996; du Plessis et al., 2002; Forbess et al., 2002a, 2002b; Bellinger et al., 2003; Wypij et al., 2003). As noted previously, these data in aggregate have led to reduced use or reduced duration of use of DHCA, realizing that in some anatomic circumstances, it cannot be avoided. The potential for neurologic dysfunction in association with low-flow hypothermic bypass has been discussed previously (Taylor et al., 1992; Burrows and Bissonnette, 1993; Pua and Bissonnette, 1998; Bellinger et al., 1999, 2003; Wypij et al., 2003); again, it is unclear how often and to what extent preexisting brain abnormalities and genetic factors contribute to impaired neurodevelopmental markers after CPB in infants and children.

These issues have spawned other technical modifications to reduce neurologic complications. Use of selective cerebral perfusion—for example, during stage I HLHS and other arch reconstructions—to avoid or reduce the use of DHCA appears to be an increasingly popular option. In many centers, the flow rates and perfusion pressures used during selective cerebral or arch perfusion are guided by continuous measurement of cerebral blood flow velocity or near-infrared spectroscopy (or both) (Langley et al., 1999; Pigula et al., 2001; Pigula, 2002, 2003; Williams and Ramamoorthy, 2007; Fraser and Andropoulos, 2008). These techniques have yet to be subjected to widespread and thorough appraisals, or to controlled comparisons with DHCA or other low-flow techniques, and there is evidence that selective perfusion of the cerebral circulation may in fact be harmful (Jonas, 2002; Goldberg et al., 2007; Ohye et al., 2009).

The postbypass period is also receiving increased attention as being vulnerable to neurologic injury. As discussed previously, both low-flow deep hypothermic CPB and DHCA techniques can lead to compromises in cerebral blood flow, autoregulation, and metabolism. Therefore, ensuring appropriate cardiac output, arterial blood pressure, cerebral perfusion pressure, and oxygen delivery (i.e., appropriate hematocrit for the level of oxygen saturation and cardiac output) in the postoperative period are likely to be important. In addition to standard volume replacement and inotropic therapies, more novel strategies to support cardiac output in this setting include delayed sternal closure and ready use of ECMO (Duncan et al., 1999; McElhinney et al., 2000; Ungerleider and Shen, 2003). Maintaining normothermic or even mildly hypothermic body temperatures in the first 24 to 48 hours postoperatively may also be beneficial (Shum-Tim et al., 1998).

The ability to assess various parameters of brain function and homeostasis and to use them to guide therapy are clearly critical but, unfortunately, still largely lacking. Although various forms of perioperative neurologic monitoring (e.g., electroencephalography, NIRS, cerebral Doppler blood flow velocity) are used and advocated with increasing frequency, no one technique or combination of techniques has emerged to fulfill this need (Hoffman et al., 2004; Ghanayem et al., 2006; Hoffman, 2006a, 2006b; Dickerson et al., 2008; Johnson et al., 2009). Most centers currently use some form of NIRS monitoring of cerebral (and often somatic as well) oxygen saturation. The NIRS value reflects tissue (arterioles, venules, capillaries) oxygen saturation and is algorithmically weighted to represent approximately 75% to 85% venous blood and 15% to 25% arterial blood. When the optodes are placed on the forehead, the NIRS value reflects frontal cortex oxygen content. The values measured most closely correlate with, in most patients, jugular bulb, jugular venous, or SVC oxygen saturation; thus, in some ways, it can function as a noninvasive monitor of mixed venous O₂ saturations. Some experimental data indicate that both the degree and duration of cerebral desaturation may predict neurologic injury (Kurth et al., 2002, 2009; Hirsch et al., 2009). However, human clinical data demonstrating a correlation between NIRS and neurologic injury or outcome are minimal, and data defining when intervention based on NIRS (i.e., level of desaturation) might be indicated, how to best intervene, and whether NIRS-driven interventions alter outcome remain to be seen (Kussman et al., 2007, 2009; Hirsch et al., 2009). There may also be a role for improved techniques to detect microemboli during CPB (Blauth et al., 1988; Miller et al., 2008; Win et al., 2008). It is clear the multiple and interacting genetic, maturational, procedural, and lesion-specific issues are likely to contribute to the overall neurodevelopmental outcome of CPB and surgery in infants with CHD. One theoretical advantage to hybrid-type procedures is that they avoid exposure to CPB and more complicated repairs in early infancy when neurodevelopmental vulnerability may be greatest (Gutgesell and Lim, 2007; Lim et al., 2006; Honjo, 2009).

The Stress Response to Cardiopulmonary Bypass

The stress response to CPB is characterized by the release of a large and diverse group of substances, including catecholamines, endothelin, various prostaglandins, cortisol, and growth hormone. The concentrations that have been measured in neonates and infants during or soon after CPB are some of the highest measured in humans, generally exceeding those measured in adult CPB patients by fivefold to 10-fold (Anand et al., 1990; Anand and Hickey, 1992). Stimuli include extensive and prolonged foreign surface contact, profound hypothermia, low flow, low perfusion pressure, and nonpulsatile perfusion. Clearance of many of these compounds by the liver, kidneys, or lungs may also be delayed. Possible deleterious consequences include vasoconstriction and reduced organ perfusion, direct tissue injury, pulmonary hypertension, endothelial damage, and increased pulmonary vasoreactivity. Decreased stress response hormones and possibly improved morbidity and mortality have been associated with high-dosage synthetic opioid administration to infants undergoing CPB and other stressful procedures (Anand et al., 1987; Anand and Hickey, 1992). On the other hand, the release of many of these compounds and the responses overall are likely to have adaptive benefits. It is unclear what level,

circumstances, or substances cause a net harmful response; to what extent acutely ill infants with CHD require some degree of stress response for hemodynamic stability, wound repair, and overall homeostasis; and to what degree the seemingly exaggerated response seen particularly in neonates and infants exposed to CPB is pathologic and should be attenuated. One follow-up study that attempted to clarify the role of high-dosage opioid regimens did not appear to confirm a major role for stress hormone suppression in outcome (Gruber et al., 2001).

The Systemic Inflammatory Response to CPB

Cardiopulmonary bypass causes a systemic inflammatory response via multiple mechanisms that include surgical trauma, blood contact with the CPB circuit, ischemia–reperfusion injury, and protamine administration (Butler et al., 1993; Plotz et al., 1993; Seghaye et al., 1993, 1994, 1996; Ashraf et al., 1997; Chew et al., 2001, 2002; Gessler et al., 2002). These triggers stimulate complex and interconnected cell- and humoral-based systems that include activation of the complement, coagulation, and fibrinolytic pathways; endotoxin release; cytokine production; endothelial activation and expression of leukocyte adhesion molecules; leukocyte and platelet activation; and production and release of oxyradicals, nitric oxide, prostanoids, eicosanoids, and proteolytic enzymes (e.g., myeloperoxidase and superoxide from activate neutrophils). The resultant tissue and organ injury, capillary leak, increased need for inotropic and ventilatory support, and perhaps effects on infection risk are widely believed to have a major impact on parameters affecting morbidity and duration of hospitalization (e.g., duration of ventilation, requirement for inotropic support) and overall outcome (Wheeler et al., 2008).

Complement activation occurs via the alternate (stimulated by foreign surface contact, endotoxin, and kallikrein), classical (protamine), and mannose-binding lectin pathways. Significant increases in activated complement fragments occur with initiation of bypass, and further still during rewarming, and these levels have correlated with post-CPB renal, cardiac, and pulmonary dysfunction (Butler et al., 1993; Seghaye et al., 1993, 1994; Li et al., 1994; Brix-Christensen, 2001; Busche et al., 2009). Various complement fragments cause white cell and platelet activation, white cell free radical production and degranulation, smooth muscle constriction, and capillary leak. Terminal complement fragments and the membrane attack complex can cause direct cell lysis.

Blood concentrations of bacterial endotoxin can increase because of its almost ubiquitous presence in sterile fluids and equipment, and also perhaps because of decreased intestinal perfusion, which can also augment reperfusion injury independent of endotoxin (Koike et al., 1994; Moore et al., 1994). Endotoxin can directly injure endothelial cells and cause capillary leak, as well as stimulate the production of proinflammatory cytokines such as tumor necrosis factor, interleukin (IL)-1, IL-6, and IL-8. Cytokine production can also be stimulated by foreign surface contact, complement fragments, and other cytokines. Mechanisms of cytokine-induced tissue injury are multiple. Cytokines such as IL-1 and TNF are directly toxic to endothelial and other cells, cause wasting and edema, cause myocardial contractile dysfunction, and stimulate a number of cytotoxic and cytoprotective signaling mechanisms such as inducible (high-output and potentially cytotoxic) NO production, various proapoptotic and antiapoptotic pathways and

proteins, enhanced oxyradical injury, and induction of cellular antioxidant enzymes. Levels of TNF and IL-1 are inconsistently increased by CPB in neonates and infants. Cytokine-induced NO production can result in profound hypotension (it is the major mechanism of vascular depression in septic shock), myocardial depression, and inhibition of cellular respiration and metabolism. IL-6 has been demonstrated in some studies to be a good predictor of clinical outcome and may be related to the extent of tissue injury (Brix-Christensen, 2001). IL-8 is a potent neutrophil chemoattractant and also causes leukocytosis and activation of neutrophil proteases and free radical enzymes. Increased IL-8 has been found after pediatric CPB patients in proportion to ischemic and total bypass times (Journois et al., 1994; Seghaye et al., 1996; Ozawa et al., 2000; Brix-Christensen, 2001; Chew et al., 2001). Some children have increased levels of some cytokines preoperatively; the causes and significance of this finding are uncertain, but there is some evidence that neonates with a preoperative biochemical profile consistent with inflammation (e.g., increased plasma elastase and complement fragments) are more likely to manifest a capillary leak syndrome postoperatively (Seghaye et al., 1996; Wheeler et al., 2008; Allan, in press).

Neutrophil activation is believed to be a very important mechanism of cellular injury during and after CPB. It is produced by a wide variety of stimuli, including foreign surface contact, endotoxin, cytokines, complement, platelet-activating factor, and ischemia–reperfusion. Activated neutrophils express proadhesive molecules on their cell surface (which are complementary to ones induced on endothelial and other cell membranes), marginate into the tissue, have increased lipoxygenase and myeloperoxidase activities (the sources of superoxide and hypochlorous acid, respectively), and release neutrophil elastase. These products cause damage to lipids, proteins, and DNA. Elastase also causes endothelial damage, inactivates serine proteases in the coagulation pathway, and cleaves adhesive receptors from the platelet membrane (Wachtfogel et al., 1983, 1986, 1993; Burrows and McGowan, 1996). Both myeloperoxidase and elastase, as well as evidence of neutrophil-mediated oxidant injury, have been detected after pediatric CPB (Larson et al., 1996; Brix-Christensen, 2001; Allen, 2003).

It has recently become apparent that CPB also induces a corresponding increase in antiinflammatory cytokines such as IL-10 and IL-1 receptor antagonist (IL-1ra). C-reactive protein, an acute-phase protein that is a marker of inflammation and has antiinflammatory effects by decreasing neutrophil chemotaxis, also increases during and after pediatric CPB (Seghaye et al., 1993, 1996; Brix-Christensen, 2001; Chew et al., 2001, 2002; Tarnok and Schneider, 2001). Transient immunosuppression mediated by these events and others, such as loss of activated neutrophils and inhibition of cellular immune responses, have also been found after pediatric CPB (Tarnok and Schneider, 2001).

Overall, there is substantial variability in the release pattern and plasma concentrations of cytokines in infants and children undergoing cardiac surgery compared with adults (McBride and Booth, 1996; Seghaye et al., 1996; Ozawa et al., 2000; Chew et al., 2001; Allan, in press). Although increased elements of the systemic inflammatory response are generally associated with increased risk for postoperative organ dysfunction and morbidity and mortality, better-designed studies with direct assays and endpoints are necessary to truly define any cause-effect relationship between systemic inflammatory

response mediators and organ damage. It is also likely that the *balance* between proinflammatory and antiinflammatory stimuli and their diverse effects on a wide range of cellular types and functions must be taken into account (Chew et al., 2001; Appachi et al., 2007). Finally, the possibility that at least some of these substances are required to regulate the overall response and in fact potentially contribute to eventual repair and resolution should not be overlooked. For example, although the deleterious effects of substances such as TNF α and cyclooxygenase pathway derivatives have been demonstrated in numerous cellular and animal models, genetic or pharmacologic abrogation of these pathways can also lead to increased cell death and organ dysfunction under clinically relevant circumstances (e.g., ischemia–reperfusion). Similarly, other cytokines and chemokines, although mechanistically linked to the severity of acute tissue injury, are also required to contain and resolve the injury (genetic deletion results in reduced acute injury but worse overall outcome).

Steroids

Administration of relatively high dosages of steroids (either dexamethasone or methylprednisolone) prior to pediatric CPB may suppress the production of proinflammatory cytokines and improve organ function (Langley et al., 1999; Bronicki et al., 2000; Shum-Tim et al., 2001; El Azab et al., 2002). They are frequently administered by many pediatric congenital surgery programs, with notable differences in choice of drug, dosage, timing of administration (e.g., preoperatively, prior to CPB, during CPB), and patient selection (Cecchia et al., 2005). Many believe that steroids are more likely to show a positive effect in neonates and infants because the magnitude and consequences of the systemic inflammatory response appear to be greater. Because the major mechanism of steroid action is to alter gene expression and cellular activation, maximal effect may require administration some time (up to 8 hours) before bypass and repeated dosing (Ungerleider and Shen, 2003). Improvements in body water accumulation, alveolar–arterial oxygen gradients, pulmonary artery pressure, and duration of mechanical ventilation and length of ICU stay have been observed (Bronicki et al., 2000; El Azab et al., 2002; Ungerleider and Shen, 2003). Results from more extensive investigations in adults confirm potential beneficial alterations in the balance of proinflammatory to antiinflammatory mediators (allowing for the caveats discussed earlier) (Chaney, 2002). However, there were no significant effects on fluid balance and possibly detrimental effects on pulmonary function, and glucose homeostasis (hyperglycemia) occurred as a result. Furthermore, as with the stress response, it remains unclear whether broad-spectrum and nonspecific suppression of the systemic inflammatory response by corticosteroids is beneficial. There is also some evidence that at least more prolonged periods of corticosteroid administration may be detrimental to the developing brain. Thus, caution is warranted until large, randomized, prospective, placebo-controlled studies with tightly regulated perioperative management are performed in pediatric patients.

Ultrafiltration

Conventional or modified ultrafiltration is being used with increasing frequency during pediatric cardiac surgery. Potential beneficial mechanisms include hemoconcentration, removal of

various inflammatory mediators and vasoactive compounds in the ultrafiltrate, and decreased total body water and tissue edema. Significant clinical improvements in tissue edema, post-CPB weight gain, hematocrit, blood pressure, global left ventricular function, lung compliance, oxygenation, and duration of mechanical ventilation have been reported, along with decreased postoperative bleeding, decreased postoperative transfusion and blood product requirements, and decreased pulmonary vascular resistance. One or more of these benefits have been observed in many, but not all, studies (Elliott, 1993; Journois et al., 1994; Friesen et al., 1997; Bando et al., 1998; Chaturvedi et al., 1999; Gaynor, 2001, 2003; Maluf et al., 2001; Chew et al., 2002; Hiramatsu et al., 2002). Less certain are the mechanisms responsible for these effects, because significant reductions in blood concentrations of inflammatory cytokines, complement fragments, and prostanoids have not been universally identified (Chew et al., 2002; Gaynor, 2003; Huang et al., 2003). Although ultrafiltration techniques appear to be safe for infants and children, there is theoretical concern about removal of protective mediators and deleterious increases in viscosity and clotting factors (i.e., hypercoagulability). Additional studies are needed to define the mechanisms of ultrafiltration effect and identify the patients who are most likely to benefit.

HEART, LUNG, AND HEART-LUNG TRANSPLANTATION

Heart Transplantation

History

Christian Barnard conducted the first heart transplantation on December 3, 1967. The patient lived for 18 days before succumbing to a fatal bout of pneumonia (Barnard, 1967). The first pediatric cardiac heart transplantation was carried out within a week of this landmark achievement by a group led by Adrian Kantrowitz in a 3-week-old infant with Ebstein's anomaly and pulmonary atresia. The procedure used immersion of both the donor and recipient in iced water to achieve topical cooling. As the recipient's chest was opened, the heart fibrillated and thus open cardiac massage was undertaken until the patient's temperature was low enough to commence circulatory arrest (Kantrowitz et al., 1968). Over the next few years, about 100 more heart transplantations were conducted, with a mean survival of 1 month (Mendeloff, 2002). The poor outcomes probably resulted from inadequate technological advancements in key areas such as surgical techniques, CPB, immunosuppression, and the clinical diagnosis and management of rejection.

The preliminary understanding of the immunobiology of organ rejection and its role in transplantation failure, the development of the biptome and a grading system for rejection, and the isolation of a fungal extract with immunosuppressive properties (later developed as cyclosporine) all helped spur renewed interest in transplantation (Caves et al., 1973, 1974). As adult transplantation programs began to be established, pediatric transplantation was mostly in adolescents and was conducted under the aegis of adult programs. Infant and pediatric cardiac transplantation did not become established as a separate entity until the mid 1980s, when transplantation was recommended as a primary therapy for lethal congenital

lesions, and a successful heart transplantation in an 8-month-old was performed by Cooley and colleagues (Bailey et al., 1986, 1989).

The number of pediatric patients undergoing heart transplantation steadily increased in the 1980s and early 1990s, with the rate peaking in the mid 1990s. Currently, procedures in infants and children account for up to 10% of all heart transplantations. Mortality figures have improved significantly, with an approximately 75% to 80% actuarial survival rate at 4 to 5 years (compared with less than 55% for the earlier era of pediatric heart transplantation). As indications have continued to expand (see later), continued growth in pediatric heart transplantation has been limited primarily by the availability of donor hearts. In response, particularly for neonates, most programs have opted whenever possible for staged palliation of congenital heart defects, to avoid the uncertainty (and potential death) that placement on the transplant waiting list entails. Increased use of ABO-incompatible donors is another, more recent attempt to increase the size of the useful donor pool (see later). The issue of transplantation versus palliation (for patients with congenital cardiac lesions) in early infancy is far from settled. Proponents of transplantation believe that infant transplantation may be associated with enhanced engraftment and induction of tolerance, reducing the amount of immunosuppression required. Neonates in particular may experience a window of immune tolerance, with a lower likelihood of rejection and the ability to use less aggressive immunosuppression (Mavroudis et al., 1988; Bailey et al., 1991). Heart transplantation is technically more difficult and may be associated with higher mortality in those who have undergone prior palliative cardiac surgery. Transplantation as a primary therapy also may reduce the risk for progressive organ deterioration, particularly of the pulmonary parenchyma and vasculature, that can result from some palliative procedures, or severe cardiac dysfunction arising after failed congenital procedures. On the other hand, the limited donor supply makes attempts at surgical correction the only option for many patients. Advocates of staged reconstruction argue that transplantation is a waste of resources when an alternative is available. In addition, transplantation carries the attendant complications of rejection, immunosuppression, drug toxicity, infection, malignancy, and the need for retransplantation.

HLHS is an example that outlines the nature of this conflict. The 5-year survival for this lesion after heart transplantation (including deaths while waiting for a donor) and the staged reconstruction procedures (stage I Norwood palliation, bidirectional Glenn cavopulmonary shunt, and modified Fontan procedure) are essentially the same. The transplanted heart is structurally normal but is associated with all of the complications of antirejection therapy and, when done in neonates, may require one or more retransplantations because of chronic rejection and graft failure. Staged reconstruction for HLHS mandates life with Fontan physiology, and thus a significant likelihood of severe dysrhythmias and late ventricular dysfunction, potentially resulting in a need for transplantation.

Patient Demographics

Children younger than 1 year continue to make up the majority of the transplantations performed (Fig. 20-20, A). There then appears to be a decreasing number of transplantations for the 5- to 7-year-old age group, followed by a second peak

FIGURE 20-20. A, Age distribution of pediatric heart recipients for transplantations from January 1996 through June 2008. **B,** Diagnosis distribution by location for transplantations from January 2000 through June 2008. (From Kirk R, Edwards LB, Aurora P, et al: *Registry of the International Society for Heart and Lung Transplantation: twelfth official pediatric heart transplantation report—2009*, *J Heart Lung Transplant* 28:993, 2009.)

in the teenage years. This distribution is closely linked to etiology, with CHD as the major indication for transplantation in the first year of life, and cardiomyopathy the primary indication in the older age groups. During the period from 1988 to 1995, 78% of pediatric transplantations in children less than 1 year of age were for CHD and 16% for myocarditis, whereas from 1996 to 2009, approximately 65% were in children with CHD and 30% for cardiomyopathies and myocarditis. In the other pediatric age groups, the ratios remained fairly constant. The majority of heart transplantations in older patients with CHD are performed as these patients' palliative or reconstructive surgeries become inadequate (e.g., ventricular failure, dysrhythmias). Valvular heart disease, coronary artery disease associated with hyperlipidemia, and myocardial tumors are less frequent (~2%) indications for heart transplantation in children. Drug-induced cardiomyopathy (especially anthracycline) is another infrequent indication, although there is some evidence that this may become a more frequent problem in pediatric patients as they age. Retransplantation accounted for 4% to 6% of all transplantations; this rate has not changed appreciably in the past several years (see Fig. 20-20, B). Overall, approximately 250 to 275 infant and pediatric heart transplantations are performed in the United States annually (Addonizio and Rose, 1987).

Surgical Indications for Heart Transplantation

The development of cyclosporine and other immunosuppressive agents has enabled heart transplantation to become a viable therapy for end-stage heart failure regardless of etiology. Indeed, according to the International Society for Heart and Lung Transplantation, survival at 4 years now exceeds 75%. It may thus be considered an alternative treatment to standard surgical procedures for certain congenital heart defects such as HLHS and pulmonary atresia with intact interventricular septum. The decision to perform transplantation is best made when patient survival is known to be unlikely or of short duration and other options have failed. As mentioned previously, the mortality rate of pediatric heart transplantation and concerns about long-term graft survival and immunosuppression must still be balanced against the natural history of the disease process and the results of alternative surgical repairs. For example, in the instance of dilated cardiomyopathy, particularly in children who are older than 2 years, heart transplantation may offer the only alternative to death. As noted earlier, the case for transplantation for HLHS is somewhat different. For infants with HLHS treated with heart transplantation, data indicate 1-year and overall survival rates of 84% and 63%, respectively (Bailey and Gundry, 1990), which are similar to current survival figures for staged reconstructive procedures initially described by Norwood and colleagues (Norwood et al., 1992). In the current era, both of these techniques are considered palliative. Of note, somewhat older (but likely still applicable) data from the Pediatric Heart Transplant Study Group suggest that if one were to list all neonates with HLHS for transplantation, less than 10% would receive a heart. It has been argued that using a scarce resource for conditions that can be palliated diverts donor organs from those for whom transplantation is the only option (Morrow et al., 1997; Fricker et al., 1999; Fricker, 1987).

Patient Selection

Congenital Heart Disease

Certain groups of infants have conditions that cannot be palliated—for example, the child with HLHS that consists of aortic atresia and a perforated mitral valve. These children have abnormal coronary artery anatomy and coronary myointimal hyperplasia that can predispose to systemic (right) ventricular dysfunction after staged reconstruction. Infants with this anatomic variant might therefore be better candidates for transplantation; HLHS infants with LV coronary fistulae may represent a similar group, although a hybrid procedure approach has also been recommended for this group (Weinberg et al., 1985; Pigott et al., 1988; Pigula et al., 2007; Chen and Parry, 2009). Needless to say, substantial controversy surrounds these sorts of considerations. Other lesions in neonates and infants that may be considered relatively strong indications in favor of heart transplantation include pulmonary atresia with intact ventricular septum (especially in the presence of right ventricular-dependent coronary perfusion via fistulous connections with the hypertensive RV), univentricular heart, and unbalanced forms of atrioventricular septal defect or double-outlet right ventricle. Although these conditions can usually be palliated with staged reconstructive techniques, transplantation is often favored for these infants because of the high perioperative mortality rates

(the result of problematic cardiac anatomy or physiology) and because outcome studies have shown poor long-term results of the palliative procedures.

Patients with poor outcome after palliative or staged reconstructive attempts are another group with CHD who may require subsequent transplantation. Examples include (1) patients with univentricular heart physiology in whom ventricular dysfunction has developed, thus precluding a Fontan procedure (some of these patients will also develop pulmonary hypertension necessitating a heart-lung transplantation); (2) patients who had undergone a Fontan procedure and now present with end-stage ventricular dysfunction; (3) patients with significant myocardial damage in association with anomalous left coronary artery; and (4) patients with ventricular failure following an atrial baffle procedure (such as a Mustard or Senning procedure) for TGA.

Dilated Cardiomyopathy

Dilated cardiomyopathy is the most frequent type of cardiomyopathy encountered in children. Although most cases are believed to result from a viral or an inflammatory etiology, definitive proof is often lacking. Dilated cardiomyopathy can result from other metabolic and genetic defects as well. Potentially treatable causes of heart failure such as carnitine deficiency and other metabolic abnormalities should be excluded. Children diagnosed with dilated cardiomyopathy at ages greater than 2 years have a worse prognosis (Griffin et al., 1988; Chen et al., 1990); overall mortality exceeds 50% within 1 year of diagnosis. Factors other than age that are associated with poor outcome include severe cardiomegaly, decreased ejection fraction, and low cardiac output. These children usually present with systolic dysfunction (usually biventricular), CHF symptoms, or dysrhythmias. Occasionally, sudden death may be the first sign. Empirical treatment with, for example, diuretics, inotropes, vasodilators, pheresis, or immune modulators is usually initiated. Although these therapies may provide some symptomatic improvement, it is unclear whether even maximal medical management can alter the natural course of the disease process. A subset of patients with dilated cardiomyopathy presents with acute fulminant myocarditis, which further exacerbates their condition. Some patients (approximately one third) with dilated cardiomyopathy may substantially improve after a period of intensive medical or mechanical (e.g., ECMO or VAD) cardiac support.

Dilated cardiomyopathy can also occur after the use of doxorubicin in patients who have undergone chemotherapy regimens for a variety of pediatric leukemias and solid tumors. Doxorubicin is particularly toxic to cardiac muscle, at least in part because of free radical-mediated mitochondrial injury. In addition to the total dosage administered (especially in excess of 250 to 400 mg/m²), other risk factors appear to be female gender and an age less than 4 years when treated (Lipshultz et al., 1991a, 1991b, 1995, 2003). It appears that early myocyte loss results in an inability of the heart to successfully adapt to the demands of growth and increasing afterload. These patients frequently present for heart transplantation a decade or more after cancer treatment (Wallace, 2003). One major unresolved concern regarding transplantation for this group is the risk for cancer recurrence in the setting of intensive immunosuppression. It is believed that a candidate who has no evidence of the primary malignancy

1 year after treatment has an acceptable risk for the introduction of immunosuppression (Fricker et al., 1999).

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is another major form of cardiomyopathy that occurs with some frequency in the pediatric population. One study found that hypertrophic cardiomyopathy made up 42% of all new presentations of cardiomyopathy during a 3-year period (Lipshultz et al., 2003). Left ventricular outflow obstruction and diastolic dysfunction as a result of increased ventricular mass secondary to left ventricular hypertrophy characterize this condition. Sudden death, most likely due to ventricular tachycardia, may also be the first manifesting feature. Increased risk may be associated with young age at presentation, a family history of hypertrophic cardiomyopathy, and a history of syncope (McKenna et al., 1981; Maron et al., 1987). There does not appear to be a good correlation between the severity of ventricular outflow obstruction and the risk for fatal arrhythmia (Wigle et al., 1985). Furthermore, although symptomatic improvement may occur with the use of β -adrenergic blockers or calcium channel antagonists, these therapies (as well as others that may be used to improve symptoms arising from outflow obstruction such as asynchronous biventricular pacing and ventricular myectomy) do not appear to have a significant effect on mortality, thus making the identification of at-risk patients and the timing for transplantation extremely problematic. Use of implantable cardiac defibrillator technology in pediatric patients with some forms of increased risk for sudden death has increased and appears to be associated with a survival benefit (Stephenson et al., 2006; Berul et al., 2008).

Relative Contraindications to Pediatric Heart Transplantation

A number of variables must be assessed before referring any patient for heart transplantation. Increased PVR, active infection, irreversible organ damage, pulmonary emboli or infarction, other severe systemic disease, active malignancy, and significant psychosocial limitations are among the major factors to be considered.

Pulmonary Hypertension

Particular attention is given to the degree of pulmonary hypertension, as it is a key determinant of function of the donor right ventricle after transplantation and hence of overall outcome. The incidence of increased pulmonary vascular resistance in children who are admitted for heart transplantation is probably greater than that in adults because of the number of congenital pediatric lesions that can be associated with increased pulmonary blood flow or raised left atrial pressure. Increased left atrial pressure can also be a frequent contributor to elevated PVR in patients with cardiomyopathy. In adults, PVR of greater than 6 Wood units is usually considered to be a relative contraindication for heart transplantation. The upper limit of PVR that precludes successful heart transplantation in children has not been firmly established. It has been shown that right ventricular dysfunction or critical pulmonary hypertension after transplantation is unlikely in children whose preoperative PVR is less than 6 Wood units (Addonizio et al., 1987). This same group suggests that PVR index (PVRI) rather than PVR be used, as the former allows some correction for body size. Others suggest

that the transpulmonary gradient is a more accurate predictor of early transplantation mortality than PVR, and that a TPG of greater than 15 mm Hg is associated with an increased risk, at least in adults (Murali et al., 1993). In the present era, most centers view increased PVR as only a relative contraindication, and successful heart transplantation has occurred in children with a PVRI between 7 and 15 Wood units. In such patients, one approach has been to attempt to distinguish a fixed, irreversible pulmonary vascular disease from pulmonary hypertension with a reactive component that resolves with insertion of a well-functioning heart. This distinction is frequently attempted on the basis of PVR response to vasodilators such as oxygen, nitroglycerin, PGE₁, or iNO in the catheterization laboratory, as well as assumptions based on the underlying pathophysiology.

Previously, children in whom the PVR was reduced to less than 8 Woods units after 1 to 2 weeks of prostaglandin therapy were also considered for transplantation (Baum et al., 1991; Benson et al., 1991). Evidence suggests that long-term (months rather than weeks) continuous intravenous prostacyclin (PGI₂) can significantly reduce PVR, thus reducing right ventricular afterload and allowing heart transplantation in a previously excluded group (Rosenzweig et al., 1999; Kao et al., 2001; Bush et al., 1987). Another approach to transplantation in the presence of pulmonary hypertension in infants and children is to use an oversized donor heart (1.5 to 2 times the size of the recipient heart). The oversized heart gives the recipient a greater right ventricular mass to respond to the elevated PVR. However, the usefulness of this approach has not been statistically confirmed.

Patients with truly fixed and overly severe pulmonary hypertension are not candidates for orthotopic heart transplantation. Options include either heterotopic transplantation (the recipient's heart remains in place to assist with right ventricular work) or heart-lung transplantation. Both alternatives are less desirable. The operative and long-term mortality rates of heterotopic transplantation are increased (5-year survival, 54%) compared with orthotopic transplantation (5-year survival, ~75%) (Kriett and Kaye, 1991). Survival after heterotopic transplantation is better compared with heart-lung transplantation.

Viral Infection

Cytomegalovirus (CMV) infection, in particular, is a significant cause of morbidity and mortality in transplantation patients, as well as being a likely major contributor to the manifestations and severity of chronic heart transplant rejection (see later) (Grattan et al., 1989). However, the limited donor pool has made it impossible from a practical standpoint to exclude the transplantation of hearts from CMV-positive donors into CMV-negative recipients. Use of anti-CMV therapies such as ganciclovir has become a standard component of most transplantation regimens. Whether hepatitis C viruses (HCVs) in the donor or recipient should be a contraindication remains undetermined. In an older survey of 72 thoracic transplantation centers, 64% did list HCV-positive patients for heart transplantation and 74% used HCV-positive organs (albeit in either HCV-positive recipients or UNOS 1 recipients) (Lake et al., 1997). Those in favor suggest that HCV acquisition is better than the alternative (i.e., death without transplantation). The argument against is that a significant proportion of infected posttransplantation patients begin to have progressive liver dysfunction within 5 to 10 years after transplantation. In addition, antiviral therapy appears to be less reliable; there also is an increased incidence

of hepatocellular carcinoma in this subgroup (Fishman et al., 1996). A full evaluation of liver function should be conducted on a potential HCV-positive recipient before listing, and the use of HCV-positive organs should follow the practice stated above (Fricker et al., 1999). There is a limited number of case studies of heart transplantation patients with preexisting or acquired human immunodeficiency virus (HIV) infection, making definitive recommendations problematic. Despite the fact that these individuals may be immunocompromised and more susceptible to opportunistic infections than other candidates, results in HIV-positive recipients seem to be encouraging (Calabrese et al., 2003; Morgan et al., 2003).

Psychosocial Disturbances

Psychosocial problems and noncompliance are significant issues in the pediatric population, particularly in adolescents. Severe psychiatric disorders that cannot be controlled are a contraindication to the procedure. However, postoperative noncompliance can be difficult to predict. Reliable caregivers and a stable family structure are extremely important to the success of transplantation in infants and children because of the requirements for and stresses of frequent hospital visits, procedures, numerous medications, and chronic illness.

Donor Selection

Donors are matched largely according to blood type and body size. Typically, donor weight approximates that of the recipient. As mentioned, if the PVR is increased, a donor up to 2.5 times the weight of the recipient may be sought. Human lymphocyte antibody (HLA) typing and donor lymphocyte cross-matching are usually done retrospectively.

Most infant and pediatric donors are trauma victims (motor vehicle accidents, child abuse); occasionally, they result from sudden infant death syndrome or intracranial hemorrhage. Hypotension requiring pressor support (catecholamines, vasopressin) is common in victims with severe brain injury or brain death; it should not be inferred that it indicates myocardial dysfunction. Significant myocardial damage can result directly from trauma or secondarily from hypotension, hemorrhage, or ischemia. Routine donor screening includes a chest radiograph, electrocardiogram, and echocardiogram; mild contractile dysfunction is usually not an absolute contraindication to donation. There is some evidence that increased blood concentrations of cardiomyocyte proteins such as the cardiac-specific isoform of troponin I in donor blood is predictive of graft failure. Many centers administer triiodothyronine (T₃) to the donor before harvest, based on evidence that it is associated with improved graft contractile function in the recipient; inclusion of insulin and vasopressin has also been advocated by some (Novitzky et al., 2006). Use of standardized donor management protocols and even donor management teams that, in addition to these measures, aggressively treat donor hypotension, diabetes insipidus or syndrome of inappropriate secretion of antidiuretic hormone (SIADH), neurogenic pulmonary edema, and coagulopathy have been recommended (Kutsogiannis et al., 2006; DuBose and Salim, 2008).

To expand the potential donor pool, some centers have extended the conventional limits for ischemic times. One study compared ischemic times of greater than 8 hours with less than 90 minutes in pediatric heart transplantations. They found no difference in early or late recipient outcome between the two

groups (Scheule et al., 2002). Current practice recommendations suggest that limiting the ischemia time of the donor heart to less than 6 hours, and preferably to less than 4 hours, is likely to produce the least amount of myocardial preservation injury and acceptable graft function.

Infection, such as evidence of pneumonia, in the donor is relatively common. In general, rather than being a contraindication for the use of the organ, positive cultures in the donor are used to guide postoperative antibiotic management in the recipient.

Perioperative Management of the Pediatric Heart Transplant Recipient

Preoperative Considerations

In potential recipients, blood is typed to ensure ABO compatibility, and a panel reactive antibody test (PRA), which tests recipient reactivity to antigens in a panel of random, not donor, sera, is conducted. In children with a negative PRA test, matching is done solely on the basis of blood typing. In children who react to more than 10% of random sera, a negative prospective lymphocyte cross-match is ideal. However, this is not always possible, and strategies for the recipient with a highly reactive PRA include plasmapheresis of the recipient before and after transplantation, often in combination with intravenous pooled immunoglobulin (Leech et al., 2003); however, available data suggest that outcome is markedly reduced in highly reactive PRA recipients despite aggressive immunosuppression and plasmapheresis (Jacobs et al., 2004). In general, preoperative blood transfusions should be avoided whenever possible so as not to stimulate antibody production; transfused blood should be CMV negative for CMV-negative recipients, given the apparent increased risk for rejection and coronary vascular complications in transplant recipients who seroconvert.

Solid organ transplantation between donors and *adult* recipients with incompatible blood groups is contraindicated because of the high risk for hyperacute rejection, which occurs when preformed anti-A or anti-B antibodies (isohemagglutinins) in the recipient interact with A or B blood group antigens on vascular endothelial cells. The recognition that isohemagglutinin production is essentially absent in newborns and remains low until about 12 to 14 months of age has led to increasing and successful use of ABO-mismatched organs in this subgroup of pediatric patients (West et al., 2001a, 2001b; Foreman et al., 2004; Gambino et al., 2008; Patel et al., 2008; Roche et al., 2008). Key criteria for consideration for an ABO-mismatched organ include recipient age <15 months, low or absent isohemagglutinin levels, and satisfaction of all other transplantation criteria. In general, and preoperatively if necessary, patients should receive AB plasma products (i.e., cryoprecipitate or fresh frozen plasma) and AB platelets; red cells should be ABO-matched, and patients should never receive whole blood products. Use and matching of various donor, recipient, and blood product combinations in the ABO-mismatch situation are summarized in [Table 20-8](#). Recipients typically receive a two- to three-blood-volume-plasma exchange transfusion while on CPB; this may need to be repeated one or more times in patients with measured preoperative isohemagglutinins until they reach undetectable levels prior to release of the cross-clamp and reperfusion of the new (donor) organ. The RBCs that are removed during these exchanges can be spun, washed, and reconstituted with AB or

TABLE 20-8. Blood Product Compatibility during ABO-Incompatible Heart Transplant

Donor's Blood Group	Recipient's Blood Group	Indicated Blood Group		
		Plasma	Packed RBCs	Platelets
AB	O	AB	O	AB
B	O	AB or B	O	AB or B
A	O	AB or A	O	AB or A

AB	A	AB	O or A	AB
B	A	AB	O or A	AB

From West LJ, et al: ABO-Incompatible Heart Transplantation in Infants, *N Engl J Med* 344:793, 2001.

donor-type plasma. Similarly, isohemagglutinins are measured frequently in the postoperative period to guide the need for additional pheresis treatments. In terms of CPB prime, all plasma products administered intraoperatively should be blood group AB or *donor*-blood-group-type plasma. Packed RBCs administered intraoperatively should be blood group O or the recipient's blood group. Platelets should be group AB or donor blood type washed with saline. Again, whole blood use is avoided. Induction immunosuppression (see later) usually consists of mycophenolate mofetil, tacrolimus, methylprednisolone, and antithymocyte globulin.

Although the use of ABO-incompatible donors for infants and children is increasing, the use of hearts from donors after cardiac death continues to be relatively modest (Mazor and Baden, 2007; Harrison and Laussen, 2008; Pleacher et al., 2009). This is not only because of scientific issues related to donor heart injury and viability but also because of ongoing ethical and technical controversies. At the time of this writing, relatively few attempts have been undertaken in the pediatric community, although Ali and coworkers (2009) demonstrated recovery of cardiac function after application of extracorporeal perfusion in an adult.

Medical Management Considerations of the Potential Recipient

The anesthetic approach to the perioperative management of heart transplantation for patients with CHD should be based on a comprehensive understanding of the patient's cardiovascular pathophysiology. Outflow obstruction is characterized by increased pressure work, chamber hypertrophy, and a reduced ability to increase output. Optimal function is achieved by ensuring adequate preload and controlling the heart rate to allow adequate time for chamber filling and ejection. Left ventricular outflow obstruction requires the maintenance of SVR in the face of fixed cardiac output and coronary blood flow. Right ventricular obstruction may also benefit from reducing the afterload (PVR) where possible. In the instance of significant hypertrophy of either ventricle (or both ventricles), it is important to maintain coronary perfusion pressure (and hence aortic blood pressure) and oxygen-carrying capacity (i.e., hematocrit) to ensure adequate myocardial oxygen delivery to the hypertrophied muscle mass.

Valvular regurgitation may occur as a result of congenital lesions or severe dilated cardiomyopathy. Increased ventricular volume loading is the end result. Contractile function is best preserved by keeping the heart rate normal or somewhat increased so as to decrease ventricular filling time and volume and to optimize cardiac output. Other possible maneuvers include afterload reduction and inotropic support (inodilators such as milrinone or dobutamine), which tend to decrease chamber size and wall tension, increase forward flow, and reduce the regurgitant fraction.

Large left-to-right shunts impose both volume and pressure loads on the right ventricle and pulmonary circulation as well as a volume load on the left ventricle. Systemic hypoperfusion, ventricular dysfunction, acidosis, oliguria, and eventual circulatory collapse can be induced by maneuvers that increase the magnitude of the left-to-right shunt, \dot{Q}_P/\dot{Q}_S (i.e., decrease PVR or increase SVR, or both). The increased pulmonary blood flow may also result in left atrial hypertension and pulmonary edema. Management involves the maintenance of PVR and preventing increased pulmonary flow with subsequent steal from the systemic circulation. Inotropic therapy may be required to maintain contractility and blood pressure.

Different principles apply to patients with cyanotic lesions associated with decreased pulmonary blood flow. Adequate oxygenation depends on the balance of PVR to SVR, as well as on overall cardiac output. Increasing PVR or decreasing SVR can severely compromise pulmonary blood flow. A subset of children admitted for heart transplantation are dependent on surgical systemic-to-pulmonary shunts for pulmonary blood flow. The flow through these shunts may be marginal at the time of transplantation, either because of growth or because of partial occlusion or narrowing of the shunt. Under these circumstances, systemic oxygen saturation is increased by increased cardiac output and SVR; significant increases in PVR should be avoided. The approach to shunts that are large with substantial pulmonary blood flow (best indicated clinically by high systemic oxygen saturation for the lesion [typically, ~85% to 90%] and wide pulse pressure) follows that described earlier for large left-to-right shunt lesions.

Cardiac function in end-stage dilated cardiomyopathy occurs at the extremes of the Laplace and Frank-Starling relation. This means that wall tension is maximal, subendocardial perfusion is easily compromised, and even minor changes in heart rate, contractility, preload, and afterload can lead to myocardial decompensation. The early addition of inotropic support may prevent bradycardia, augment contractility, augment myocardial blood flow, and minimize the negative inotropic effect of anesthetic agents. Positive-pressure ventilation can affect ventricular performance (Badke, 1982; Kaul, 1986). High intrathoracic pressure and large lung volumes can compress alveolar capillaries and thus increase PVR and right ventricular afterload. These effects can decrease right ventricular function. By the mechanism of ventricular interdependence, left ventricular filling and function can also be compromised by right ventricular dysfunction. Hypoventilation may also increase PVR by producing hypoxia, hypercarbia, and atelectasis. At appropriate lung volumes, positive pressure ventilation often improves function of the failing *systemic* ventricle by reducing afterload (ventricular transmural pressure is decreased by the increase in intrathoracic pressure, thereby reducing afterload as per Laplace's law) (Parmley, 1985).

The management of the child with HLHS awaiting transplantation merits specific discussion. To maintain systemic perfusion via the ductus arteriosus, an infusion of PGE₁ (0.05 to 0.10 mcg/kg per minute) is usually begun shortly after birth. Systemic perfusion may require further augmentation with inotropes and volume replacement. Any metabolic acidosis is monitored and also treated aggressively. A balloon atrial septostomy may be performed to ensure unimpeded left-to-right atrial flow.

The major goals of preoperative management of HLHS are to maintain systemic perfusion, promote optimal systemic oxygen delivery, and prevent excessive pulmonary blood flow; large increases in PVR are also to be avoided. Thus, a careful balance must be maintained between the ratio of pulmonary-to-systemic blood flow (\dot{Q}_P/\dot{Q}_S). Hyperventilation, alkalosis, and hyperoxia all decrease PVR and increase pulmonary blood flow (\dot{Q}_P), with a subsequent decrease in systemic blood flow (\dot{Q}_S). Therapeutic efforts are directed to maintaining normocarbia, normal pH, and the arterial oxygen saturation at approximately 75% to 80%. This range of SpO₂ is generally indicative of a balanced circulation (i.e., an acceptable \dot{Q}_P/\dot{Q}_S ratio) and generally favors appropriate systemic oxygen delivery, adequate myocardial contractility, and blood pressure. If excessive pulmonary blood flow arises, nitrogen can be added to the inspired gas mixture (delivered via either endotracheal tube or head box) to provide a hypoxic gas mixture (<21%), with the caveat that this intervention may have a negative impact overall on systemic oxygen delivery. Intubation, paralysis, and induced hypercarbia (usually via CO₂ added to the breathing circuit in conjunction with normal minute ventilation) can also be used to decrease excessive pulmonary blood flow while improving systemic oxygen delivery and cerebral oxygenation (Tabbutt et al., 2001; Ramamoorthy et al., 2002).

Bridges to Heart Transplantation

A significant number of children die while awaiting heart transplantation. The number varies according to age, etiology, and degree of heart failure at the time of presentation but ranges from 23% to 70% (McGiffin et al., 1997a, 1997b, 1997c, 1997d; Morrow et al., 1997; Mital et al., 2003), although the advance of ABO-incompatible heart transplantation is having some effect to reduce the waiting list. Mechanical extracorporeal life support using either venoarterial ECMO or a paracorporeal VAD has been proven to minimize myocardial oxygen consumption and permit myocardial recovery (Kirshbom et al., 2002; Vashist and Singh, 2009). In children with end-stage heart failure awaiting transplantation, the major problem is the duration of mechanical support that is required and the increase in associated complications (e.g., infectious, thromboembolic, multiple organ dysfunction) that accrue. Nonetheless, these techniques have increasingly been successful in supporting the failing circulation as a bridge to transplantation (Kanter et al., 1987; Delius et al., 1990; del Nido et al., 1992; Tissot et al., 2009; Meliones et al., 1991). Additional indications for extracorporeal life support include postoperative ventricular or pulmonary failure that prevents weaning from CPB, severe pulmonary arterial hypertension despite maximal medical support (alkalinization, inotropic agents, inhaled NO), and refractory postoperative ventricular or pulmonary dysfunction.

The selection of technique depends on patient size and sites of dysfunction (see later). When using mechanical support in the postoperative setting, care must be taken to exclude anatomic

causes of graft dysfunction that require operative intervention. The ability of mechanical support to facilitate recovery also requires that organ dysfunction be reversible. These factors mandate both appropriate patient selection and the institution of mechanical support before irreversible organ injury occurs. The importance of the latter consideration was demonstrated in early studies of ECMO treatment of respiratory failure in adults, where prolonged mechanical ventilatory support before ECMO use was associated with pathologic evidence of irreversible lung injury, minimal improvement during ECMO, and poor outcome (Gille and Bagniewski, 1976; Zapol et al., 1979).

Extracorporeal Membrane Oxygenation

ECMO reduces ventricular work by reducing wall tension, and it maintains systemic perfusion and oxygenation. It is the preferred means of mechanical support in very small infants with myocardial failure and in patients who require support of gas exchange. Arteriovenous cannulation is usually used, although venovenous bypass may be used in a patient requiring only ventilatory support. The most frequent cannulation sites are mediastinal, using single right atrial and ascending aortic cannulae, and in the neck, with cannulae in the internal jugular vein and carotid artery. Left atrial decompression is required in any patient whose left ventricular ejection fraction is inadequate or whose left atrium is not decompressed (i.e., via a PFO or ASD). This can be achieved via a separate left submammary approach to the apex of the heart or right anterior thoracotomy to the left atrium if the chest is closed. The femoral and iliac vessels in infants and young children (~10 to 15 kg) cannot usually accommodate cannulae of sufficient sizes to permit complete circulatory support. ECMO should be instituted early before significant nonthoracic end-organ damage has occurred, and complications such as pulmonary edema and infection should be treated aggressively.

The minimal circuit volume is usually 300 to 400 mL, and the complete system includes tubing, a reservoir, a membrane oxygenator, and a heat exchanger. Before cannulation, heparin (100 to 200 units/kg) is administered intravenously, with confirmation that systemic administration has occurred by measurement of the activated clotting time. The ACT is usually maintained between 180 to 200 seconds with a heparin infusion. Larger-than-usual dosages of heparin, as well as other drugs that are lipophilic (such as fentanyl or midazolam), may be required because of binding to the circuit and oxygenator (Rosen et al., 1990). Monitoring and treatment of anticoagulation during ECMO (and VAD therapies as well) continue to be difficult and imperfect. In addition to some form of ACT (which is a relatively imprecise and nonspecific measure of clot-forming capability at all times, especially in these lower ranges of test prolongation, as opposed to use in the >300- to 400-second range typical of CPB), many centers also measure heparin and antithrombin III concentrations, aiming for a heparin concentration of 0.4 to 0.6 IU/mL, and supplementing with fresh frozen plasma when ATIII activity is less than about 60%. ECMO perfusion flow rates range from 100 to as much as 150 mL/kg per minute or even somewhat greater for full circulatory support. An increased flow rate is required in the presence of a patent shunt, which also may need to be narrowed or occluded if systemic perfusion remains inadequate. Appropriate blood products are used to maintain the hematocrit between 35% and 45% and the platelet count greater than 100,000/mm³.

Fresh frozen plasma or cryoprecipitate may be needed to maintain adequate concentrations of clotting factors. If possible, the skin should be closed over the chest and cannulae, or a surgical membrane should be used instead. Echocardiography may be used frequently during ECMO to assess cardiac structure, global contractile function, and the need for left atrial venting or the evacuation of fluid and blood collections.

Once ECMO is established, levels of inotropic support are reduced. Ventilatory support and the F_{iO_2} are also decreased, although infrequent lung expansion (4 to 6 breaths/min) and low levels of PEEP are used to stabilize lung volumes, prevent alveolar collapse, and limit inactivation of alveolar surfactant. Greater amounts of PEEP may be indicated in the presence of significant pulmonary disease (Keszler et al., 1989). Mechanical ventilation of surfactant-deficient lungs may exacerbate lung injury (Jobe et al., 1985; Lewis and Jobe, 1993). Exogenous surfactant administration may have a role in improving pulmonary function and facilitating weaning from ECMO in patients with lung injury (Lewis and Jobe, 1993; McGowan et al., 1993).

ECMO has been used successfully as a bridge to cardiac transplantation, and as a mechanism to permit recovery in instances of severe postcardiotomy myocardial failure, including acute cardiac allograft failure (del Nido, 1996; Duncan et al., 1998). In one study (Delius et al., 1990), all three patients placed on ECMO while awaiting transplantation died. Del Nido (1996) reported on 14 children who were considered candidates for heart transplantation and were placed on ECMO as a bridge to transplantation. In this series, eight children had postcardiotomy myocardial dysfunction, three had dilated cardiomyopathy, and three had acute viral myocarditis. Five of the 14 patients were placed on ECMO during cardiopulmonary resuscitation. Nine patients underwent a heart transplantation and seven patients had long-term survival. One patient with viral myocarditis recovered spontaneously. Four patients died of sepsis while on ECMO, and one late death occurred from posttransplant lymphoproliferative disorder (PTLD). Poor outcome associated with ECMO is usually the result of significant coexisting disease or injury. Complications from ECMO include hemorrhage, renal dysfunction, neurologic injury, infection, dysrhythmias, and difficulties maintaining adequate nutrition (Kanter et al., 1987; Weinhaus et al., 1989; Delius et al., 1990; Pennington and Swartz, 1993).

ECMO may also be used to support the failing heart after transplantation. Delius and coworkers (1990) reported on the early survival of two of three patients placed on ECMO postoperatively for acute rejection or graft dysfunction. In patients with CHD requiring postoperative ECMO support, overall survival was between 40% and 70% (Kanter et al., 1987; Rogers et al., 1989; Weinhaus et al., 1989). Outcome appears to be substantially better for children who are placed on ECMO postoperatively after an initial period without circulatory support than for those who require ECMO in the operating room to wean from CPB. Requiring ECMO to wean from CPB may reflect a more serious degree of irreversible cardiac injury. Major bleeding complications also appear to be less common in this setting if the patient has some period off CPB and before institution of ECMO. Sustained dysrhythmias are also likely to indicate severe myocardial injury and poor outcome. Left atrial decompression to reduce left ventricular end-diastolic pressure and increase subendocardial perfusion may improve myocardial and pulmonary function in these patients.

ECMO is not designed for long-term use, and after a period of greater than 6 weeks, the risk for bleeding, sepsis, and end-organ dysfunction becomes prohibitive. VADs have been demonstrated in the adult population to be capable of supporting patients for many months without end-organ damage (Farrar et al., 1988). The systems are not exclusive, and many children may be placed on ECMO in the emergent situation and converted to a VAD on an elective basis. Despite the successful use of small-size adult VADs in children (Helman et al., 2000; Reinhartz et al., 2001), until recently, the only choice for mechanical support in neonates was ECMO. However, the development of miniature pediatric-sized VADs has permitted the use of pulsatile mechanical support in neonates and children, and the numbers and types of these devices that are available for long-term ventricular support of infants and children are increasing (Hetzer et al., 1998; Stiller et al., 2003; Schweigmann et al., 2007; Bastardi et al., 2008; Gandhi et al., 2008; Rockett et al., 2008). In one outcome study following transplantation after VAD, Gandhi and colleagues (2008) noted eight of nine survivors without any acute negative neurologic outcome and only one episode of acute rejection in the survivors. However, other groups have, in fact, noted a significant level of neurologic morbidity in children with VADs (e.g., thromboembolic events, seizures), although the overall outcome has still been positive (Schweigmann et al., 2007; Bastardi et al., 2008; Rockett et al., 2008). Here again, monitoring and achieving appropriate anticoagulation remain major problems, as does occurrence of end-organ injury with long periods of support.

Another method that deserves mention as a bridge to transplantation is the use of partial ventriculectomy and mitral valve repair. This method has been used successfully to provide a biological rather than mechanical bridge in the period before transplantation in the child with dilated, end-stage cardiomyopathy (Hsu et al., 2002, 2003). Home or in-hospital inotropic therapy, using milrinone, dobutamine, or both in combination, may be effective in many patients with CHF awaiting transplantation (Berg et al., 2007; Skoyles et al., 1992). Children with ischemic cardiomyopathy (but not other conditions) may benefit from placement of an implantable defibrillator to reduce the risk for sudden death while awaiting a donor organ (Rhee et al., 2007).

Anesthetic Management

The anesthetic management of the pediatric heart transplant recipient requires a thorough understanding of the pathophysiology of the particular underlying condition. The first step is an analysis of the patient's anatomy and assessment of cardiopulmonary function. It is useful to next outline the events that will improve or destabilize contractile function, pulmonary blood flow, and systemic perfusion. An anesthetic plan can then be formulated based on these variables and the predicted responses to anesthetic agents, cardiovascular drugs, and ventilatory manipulations (Martin et al., 1989).

Premedication

Most children coming for heart transplantation, regardless of whether they have fasted, should probably be considered to have full stomachs because of their debilitated state and poor perfusion. Therefore, the administration of nonparticulate antacids or H₂ antagonists and metoclopramide may be advisable. Sedative premedication is avoided or administered cautiously in patients

with severe ventricular dysfunction. In addition to limiting anxiety, judicious preoperative sedation can decrease PVR and myocardial oxygen demand and increase systemic saturations.

Monitoring

Standard noninvasive monitors, including a precordial stethoscope, pulse oximeter, three-lead ECG, and a noninvasive automated blood pressure monitor, are placed before induction. Arterial and central venous catheters and temperature monitors are generally placed after the induction of anesthesia and intubation of the patient's trachea. If the child has significant ventricular dysfunction, the arterial catheter may be placed using local anesthesia before induction. The avoidance of right internal jugular cannulation to preserve the vessel for subsequent endomyocardial biopsies is advocated by some. Routine pulmonary arterial catheterization before CPB has not been found to be beneficial. When such monitoring is warranted (e.g., for those with a potential for increased PVR), one practice is to insert the vascular sheath after induction. A thermolite or oximetric catheter (4 Fr or greater) can then be passed into the pulmonary artery with surgical assistance before terminating CPB.

Induction and Maintenance of Anesthesia

Anesthetic agents should be selected according to their effects on heart rate, contractility, and vascular resistance (see Chapter 4, Cardiovascular Physiology, and Chapter 7, Pharmacology of Pediatric Anesthesia). Intravenous induction agents are almost always preferred. Among intravenous agents, ketamine, etomidate, and high-dosage synthetic opioids have all been used in pediatric patients undergoing heart transplantation. Ketamine or etomidate can be combined with succinylcholine or high-dosage rocuronium/vecuronium if a rapid sequence induction is required. Ketamine effectively preserves myocardial contractility and SVR in patients with relatively normal myocardial function and adrenergic tone. In patients with severe cardiomyopathy, the ability to increase stroke volume is absent, adrenergic receptors are downregulated as a result of increased circulating catecholamines, and sympathetic tone is already maximal. Ketamine may then reduce cardiac output as a result of its direct negative inotropic effects; if ketamine administration is accompanied by increased SVR, stroke volume, particularly by the myopathic heart, may be reduced further (Gutzke et al., 1989). Etomidate probably produces minimal effects on contractility and vascular resistances at standard induction dosages, although Pagel and coworkers (1998c) noted in experimental animals that etomidate-induced increases in aortic impedance could potentially reduce the contractility of the failing systemic ventricle. The opioids fentanyl and sufentanil are generally well tolerated in children. A delay in the time to peak effect of fentanyl, and perhaps increased sensitivity to the drug are apparent in patients with severely reduced ventricular function (Benowitz and Meister, 1976). These factors mandate slow administration and careful titration in children with congestive heart failure. Larger dosages of fentanyl (25 to 75 mcg/kg) and sufentanil (5 to 10 mcg/kg) can effectively blunt increases in PVR and provide extended hemodynamic stability (Tomichack et al., 1983; Berberich and Fabian, 1987; Cirella et al., 1987; Hensley et al., 1987; Martin et al., 1989).

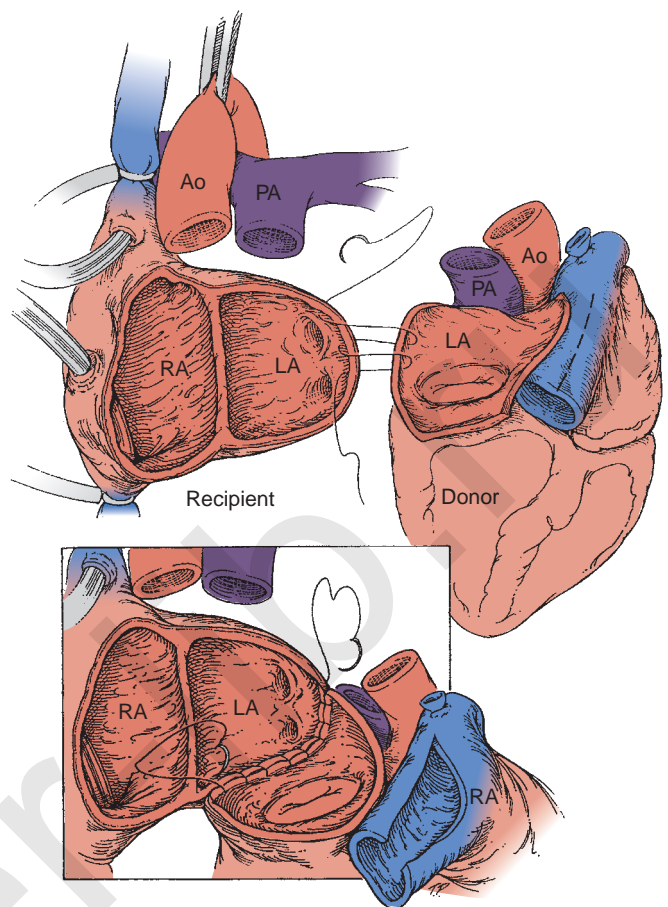

Pancuronium may be a useful muscle relaxant to offset the vagotonic and bradycardic effects of fentanyl and sufentanil. Vecuronium or rocuronium may be used when minimal effects on heart rate and blood pressure are preferred. Severe bradycardia and even asystole have been reported from the use of vecuronium and sufentanil in combination (Starr et al., 1986). Scopolamine may be useful for providing amnesia if a narcotic technique is used. Benzodiazepines can cause significant reductions in myocardial contractility and SVR when given in combination with potent opioids (Tomichcek et al., 1983; Reeves et al., 1984). Barbiturates decrease SVR and myocardial contractility. They should be avoided unless ventricular function is known to be preserved. Overall, one should expect delayed onset of sedation, induction, and muscle relaxation in patients with significant circulatory compromise, and often the appearance of increased effect (of sedatives, hypnotics, analgesics) as well.

Inhalation induction is used infrequently in this group of patients because of the hemodynamic side effects of myocardial depression and hypotension as well as the increased risk for aspiration (Borland, 1985; Demas et al., 1986). An inhalation induction with sevoflurane and careful airway management can be a satisfactory approach for the infant with CHD and preserved ventricular function. Nitrous oxide is usually avoided in older children with cardiomyopathy or increased PVR because of potentially significant reductions in myocardial contractility and uncertain effects on PVR (Lappas et al., 1975; Schulte-Sasse et al., 1982). However, in infants, Hickey and coworkers (1986) showed that N_2O does not produce the elevations in PAP and pulmonary artery resistance seen in adults. A right-to-left shunt will slow the rate of inhalation induction because less anesthetic is taken up from the lungs. The magnitude of slowing is less when using more soluble agents, because rapid uptake of soluble agents makes alveolar delivery the rate-limiting step. For insoluble agents such as nitrous oxide and sevoflurane, right-to-left shunts slow induction appreciably (see Chapter 7, Pharmacology). Of note, anesthetic removal rates and the ability to change anesthetic depth are similarly slowed, and thus inhaled anesthetic excess will be difficult to reverse in patients with significant right-to-left shunts. Left-to-right shunts do not affect the rate of inhaled induction in an appreciable manner (Tanner et al., 1985).

In summary, the potential for circulatory collapse during induction of anesthesia and conversion to positive pressure ventilation should be anticipated in the patient with severely compromised ventricular function or circulatory instability, regardless of the chosen anesthetic technique. In patients with relatively severe contractile dysfunction, it may be helpful to institute inotropic support before induction. A positive response to volume expansion, inotropic support, defibrillation, or other resuscitative measures is infrequent when acute cardiovascular collapse occurs in this setting in the severely compromised heart. The ability to proceed immediately to CPB should be available.

Operative Management

The surgical technique of pediatric heart transplantation is similar to that used in adults (Figs. 20-21 and 20-22). Increased technical difficulty and risk for hemorrhage before bypass should be expected in children who have had previous heart surgery. Hypothermic CPB is standard. A period of deep hypothermia, at times accompanied by a brief period of circulatory arrest, is

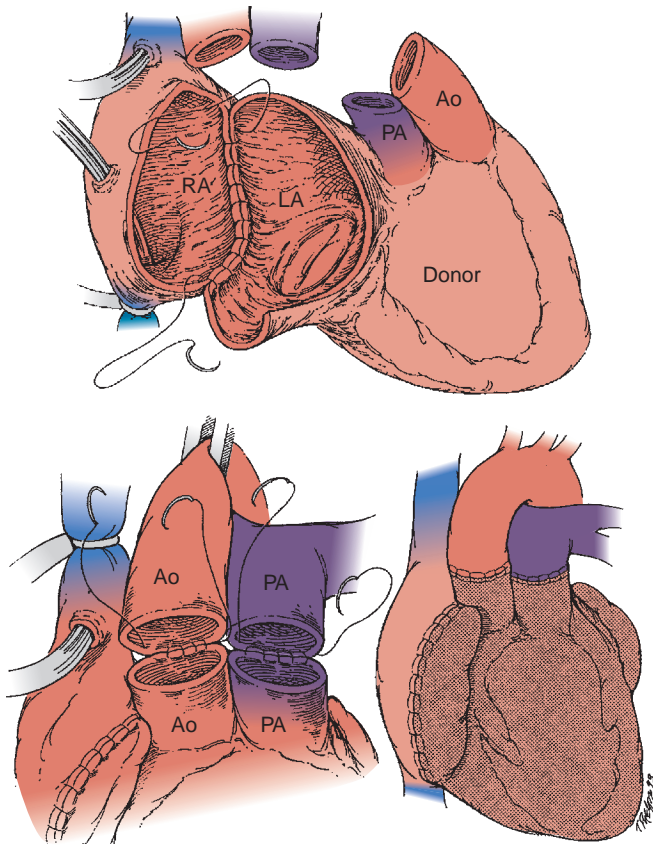

■ **FIGURE 20-21.** Cardiac implantation after recipient cardiectomy.

The venous cannulae are shown entering the superior and inferior venae cavae with retained cuffs of the right and left atrial tissue. The pulmonary artery (PA) is transected and the aorta (Ao) is cross-clamped with the aortic cannula out of the field of view. *Inset:* The first atrial anastomosis along the inferior margin of the left atrium (LA), showing the mitral valve of the donor heart. The aortic perfusion cannula is not shown. RA, Right atrium. (From the Handbook of Cardiac Transplantation, 1995, with permission of the American College of Cardiology Foundation.)

often required in young infants (e.g., those with HLHS) and those requiring extensive aortic or other vascular reconstruction (Mavroudis et al., 1988; Bailey et al., 1989).

For infants with unrepaired HLHS, the pulmonary artery is cannulated as the arterial inflow site for CPB (systemic blood flow occurs via the ductus arteriosus). Complicated repairs with extensive suture lines and anastomoses may be necessary in infants with HLHS (because of aortic hypoplasia), abnormalities of the pulmonary arteries (because of pulmonary atresia, truncus arteriosus, previous banding, or Fontan procedures), or abnormalities of the superior vena cava (after a Glenn anastomosis). Such reconstruction increases the overall risk of the procedure by prolonging the duration of bypass and circulatory arrest and also by increasing the severity of post-bypass bleeding.

Acute right ventricular dysfunction is one of the major problems in the transplanted heart immediately after CPB, with acute RV failure occurring in approximately 15% to 40% of pediatric

■ **FIGURE 20-22.** Anastomosis of the right atrial suture line. *Upper:* Right atrial anastomosis. *Lower:* After the anastomosis, the heart is swung over into position to complete the atrial free wall suture. The great artery anastomoses are made, after which the heart is de-aired and the cross-clamp is removed. The aortic perfusion cannula is not shown. Ao, Aorta; LA, left atrium; PA, pulmonary artery; RA, right atrium. (From the Handbook of Cardiac Transplantation, 1995, with permission of the American College of Cardiology Foundation.)

heart transplant recipients (Hoskote et al., 2010). It appears to be more common in patients transplanted for restrictive or dilated cardiomyopathy and failed repairs of CHD, as well as elevated pretransplantation PVR. In infants, pretransplantation mechanical ventilation and high PVR index appear to predict acute graft RV dysfunction as well (Huang et al., 2004). The initial approach is to minimize PVR so as to reduce right ventricular afterload. Ventilatory manipulations are initially used to reduce PVR and optimize right ventricular (and consequently, left ventricular) performance. Before termination of CPB, the endotracheal tube is suctioned, and gentle inflations are performed to expand atelectatic lungs. Moderate hyperventilation with 100% oxygen is then used to maximize alveolar and arterial oxygen tension and achieve a $Paco_2$ in the range of 30 mm Hg. Although no specific mode of ventilation can be universally recommended, in general the use of larger tidal volumes (e.g., ≥ 10 mL/kg) and slower respiratory rates frequently appear to provide the best balance between minute ventilation and deleterious effects of PPV on right ventricular filling and function. The use of PEEP to improve gas exchange usually does not adversely affect PVR. In addition to hyperoxia and alkalinization (via both ventilation and supplemental sodium bicarbonate), inhaled NO can be a valuable therapy in the transplantation patient at risk for post-CPB pulmonary hypertension

(Hoskote et al., 2010). Other maneuvers to support the failing right ventricle include ensuring adequate coronary perfusion pressure, preload, and use of inotropes and inodilators (Costello and Pahl, 2002); occasionally, mechanical support (i.e., ECMO) and even retransplantation may be required. Usually, a modest level of inotropic support (e.g., 5 to 10 mcg/kg per minute of dopamine) is sufficient, unless there has been more extensive preservation or reperfusion injury, at which times epinephrine may be added. Acute RV dysfunction or failure can be another indication for increased levels of inotropic support, in conjunction with the aforementioned therapies to reduce RV afterload (Calvin et al., 1991). Most find limited need for agents such as norepinephrine or vasopressin in the absence of vasodilatory shock, which can occur, but infrequently, after CPB on neonates (Lechner et al., 2007; Wolf, 2008). Typically, right and left atrial filling pressures are similar; filling pressures in the range of 10 to 15 cm H₂O are necessary to support cardiac output. Higher values or significant discrepancies between right and left atrial pressures should arouse suspicion of pulmonary hypertension, right ventricular failure (increased right atrial pressure), or severe left ventricular dysfunction (increased left atrial pressure) (Banner and Yacoub, 1990).

A situation peculiar to infant and pediatric transplantation is the occasional use of hearts from donors of smaller body size than the recipient. Such undersizing of the donor may be associated with apparent graft insufficiency or failure, manifested by low cardiac output and systemic perfusion despite optimal or maximal filling pressures and inotropic support. Pulmonary hypertension and significant preservation injury exacerbate the hemodynamic instability. ECMO may be needed to permit a period of myocardial recovery in this setting of acute postoperative graft dysfunction.

In addition to developing ischemia-reperfusion injury, the donor heart is also denervated (Cannom et al., 1973). In the absence of sinus rhythm or if the chronotropic response to vasoactive drugs is insufficient, atrial or atrioventricular sequential pacing is often needed in the immediate postbypass period to facilitate adequate heart rate, cardiac output, and control of ventricular filling. It is unusual for pacing to be required for more than several days after transplantation. The continued need for pacing suggests that more significant myocardial injury has occurred.

Postoperative bleeding is another frequent problem with multiple potential causes. Extensive scarring and adhesions from previous palliative procedures are common. Pediatric patients may require some degree of aortic or pulmonary artery reconstruction at the time of transplantation, creating potentially extensive high-pressure suture lines that are not found in other heart transplantation settings. Chronic cyanosis may be associated with coagulation factor deficiencies, accelerated fibrinolysis, platelet function abnormalities, and an increased number and size of collateral vessels. Abnormalities in a variety of coagulation proteins have also been found in patients with single-ventricle physiology (Odegard et al., 2002a, 2002b, 2003, 2009). Many patients receive chronic anticoagulant therapy (e.g., aspirin, warfarin [Coumadin]), which cannot be discontinued in sufficient time to allow recovery of the coagulation profile before transplantation. Significant hemodynamic shear stress (e.g., aortic stenosis) can result in an acquired form of von Willebrand's disease by promoting degradation of active, high-molecular-weight von Willebrand multimers into inactive monomers. CPB induces bleeding in infants and small children. The causes for bypass-related bleeding are multifactorial

and include hemodilution of coagulation factors, higher flow rates, higher shear stress (resulting in increased activation and consumption of platelets and coagulation and fibrinolytic proteins), greater blood trauma, use of colder temperatures, and an increased systemic inflammatory response.

In general, after protamine has been given to neutralize the heparin, platelets are given and can be followed by cryoprecipitate (Miller et al., 1997). Specific patients, such as those receiving warfarin preoperatively or with clinically significant preoperative coagulopathy due to hepatic dysfunction or malabsorption/protein-losing enteropathy, may also benefit from the administration of fresh frozen plasma. Use of antifibrinolytic agents such as tranexamic acid may also be beneficial, particularly in small infants and patients with a history of one or more prior thoracic procedures. The role for activated factor VII in postcardiotomy bleeding continues to be controversial and requires further study and definition (Pychynska-Pokorska et al., 2004; Agarwal et al., 2007; Guzzetta et al., 2009). At present, because of concerns about promoting hypercoagulability and thrombotic complications, use of activated factor VII is probably best reserved for ongoing and uncontrolled bleeding that has been unresponsive to administration of the aforementioned clotting factors (and relative normalization of platelet count, PT, PTT, and so forth); there may be some ability to achieve effect while reducing thrombotic risk by using mini or lower dosage protocols (in the range of 60 mcg/kg, or even lower), although this too remains to be proven (Ekert et al., 2006).

Immunosuppression in Heart Transplantation

In brief, the rejection process begins when recipient CD4 T cells recognize foreign antigen in the donor heart. Recognition leads to activation of the larger T-cell pool, with subsequent IL-2 secretion, thereby triggering activation of monocytes/macrophages, B cells, and cytotoxic CD8 cells (Rose and Yacoub, 1990). Induction of immunotherapy is thus targeted toward the prevention of T-cell activation. This can occur by depleting the T-cell pool with monoclonal or polyclonal antibodies, or by using monoclonal antibodies to prevent IL-2 secretion. OKT3 is a murine monoclonal antibody used in clinical practice that binds to the CD3 molecule on the T-cell surface (Gay et al., 1988). This complex is closely linked to the antigenic recognition site of the T-cell receptor. Within minutes of beginning the administration of OKT3, the T-cell population decreases dramatically (Delmonico and Cosimi, 1988). T cells reappear within 3 to 5 days, but without the CD3 molecule. Although OKT3 was originally used in the context of acute rejection, its current use also includes induction of immunosuppression at the time of transplantation. When OKT3 is used in this fashion, the administration of cyclosporine or tacrolimus may be delayed by 5 to 7 days. This is particularly useful in the context of patients with borderline renal function, in whom calcineurin inhibitors and their nephrotoxic properties can further compromise renal function. Other side effects of OKT3 include chills, fever, diarrhea, dyspnea, and wheezing. Pulmonary edema and cardiac arrest have also been reported (Thistlethwaite et al., 1988).

ATG and ALG are polyclonal antibodies prepared from thymocytes and lymphoblasts, respectively. They are both IgG antibodies, and although the precise mechanism of action has yet to be elucidated, their administration causes profound lymphocytolysis. Side effects include chills, febrile reactions, erythema, and pruritus. Thrombocytopenia occurs in more than 50% of

patients, and serum sickness and Stevens-Johnson syndrome have also occurred secondary to ATG or ALG therapy.

Basiliximab and daclizumab are both monoclonal antibodies to the alpha chain of the IL-2 receptor. The receptor has three noncovalently bound chains. The alpha chain is specific for IL-2, and once activated by IL-2, the T cell begins its rejection amplification cascade (Kovarik et al., 1999). The binding of these monoclonal antibodies effectively and rapidly prevents activation of the cascade. Furthermore, the alpha chain is not present in inactivated T cells, and thus only activated T cells are targeted (Denton et al., 1999). There is some concern that these agents may be associated with an increased incidence of superimposed infections such as CMV and possibly the development of PTLD.

Maintenance of Immunosuppression

Three classes of drugs are available for maintenance of immunosuppression.

Corticosteroids. Corticosteroids are nonspecific antiinflammatory agents. Their effects are numerous and include inhibiting cytokine and cell-surface-molecule gene transcription in monocytes, inhibiting phospholipase A₂ enzyme activity and thus reducing the inflammatory cell activation, signaling, and inflammatory molecule production. Steroids also inhibit the nuclear transcription factor (NF)-κB, thus reducing IL-2 gene transcription and the production of several other proinflammatory cytokines and signaling and recognition molecules (Auphan et al., 1995). In general, most pediatric transplantation immunosuppressive regimens have moved toward trying to limit or even avoid routine steroid use due to the deleterious side effects on growth, glucose homeostasis, and so on.

Antiproliferative Agents. Antiproliferative agents prevent the expansion of activated T-cell and B-cell clones. The original agent used for this purpose, azathioprine, is being replaced by newer agents such as mycophenolate mofetil (MMF) and sirolimus (rapamycin). The toxic effects of azathioprine included bone marrow depression leading to marked leukopenia, possible liver damage, and the development of pancreatitis. MMF is a selective inhibitor of the *de novo* pathway of purine biosynthesis, thus inhibiting immune cell proliferation. It is administered as a morpholinoethylester prodrug of mycophenolic acid, which is metabolized to the active compound. Its mechanism of action is the result of reversible noncompetitive inhibition of inosine-monophosphate-dehydrogenase activity; it thereby targets proliferating lymphocytes. The lymphocytes are dependent on the availability of guanine nucleotides, which are no longer generated in the presence of the drug (Allison et al., 1993; Brazelton and Morris, 1996; Shaw et al., 1999). Side effects of MMF include nausea and vomiting, but it lacks significant bone marrow and renal toxicity. There is a concern, however, about the possible development of invasive CMV infection during the use of MMF. Rapamycin (sirolimus) is a newer antiproliferative agent that, despite binding to FK506-binding protein 12, confers its action by inhibiting cellular proliferation without inhibiting calcineurin (see later). Side effects appear to be dosage-dependent elevation of triglyceride levels and dosage-dependent bone marrow suppression.

Calcineurin Inhibitors. Calne's (1979) first published use of cyclosporine as an immunosuppressive agent was in 1979, and

it continues to be one of the primary drugs used for the prevention of rejection in many transplantation programs. The mechanism of action of cyclosporine involves binding to cyclophilin in the T-cell cytosol. This cyclosporine–cyclophilin complex then binds to calcineurin and prevents calcineurin from promoting transcription of the IL-2 gene, thus preventing further IL-2 production (Schreiber and Crabtree, 1992; Schreier et al., 1993). The most significant side effect of cyclosporine therapy is nephrotoxicity; other significant side effects include liver dysfunction, hypertension, hyperlipidemia, and PTLD (Kahan et al., 1989).

Tacrolimus (FK506) is a macrolide that also acts as a calcineurin inhibitor. It forms a complex with an immunophilin, FK-binding protein, and this complex subsequently binds to calcineurin to prevent IL-2 gene transcription (Liu et al., 1991; Sigal and Dumont, 1992). Side effects include nephrotoxicity, glucose intolerance, and an increased incidence of PTLD.

Most pediatric heart transplantation programs use some form of triple immunosuppressive therapy, and calcineurin inhibitors, antimetabolites, and corticosteroids are the mainstays of antirejection therapies. Although cyclosporine is still used at times, tacrolimus use appears to be overtaking it. The nephrotoxicity of both drugs is significant. As noted earlier, use of azathioprine has decreased in favor of MMF or sirolimus. The use of sirolimus will increase further if suggestions of reduced transplantation vasculopathy associated with its use are confirmed (Mancini et al., 2003). The use of steroids remains at fairly constant levels, but increased acceptance of the newer agents is likely to lead to more rapid weaning and lower dosages of corticosteroids, thereby limiting the side effects of growth retardation, hypertension, and glucose intolerance; this is especially true in infant and pediatric transplantation. The roles of rapamycin and the IL-2 receptor antagonists continue to evolve, with the former being used with greater frequency to treat recurrent rejection, and the latter for induction and prevention of acute rejection (Sudan et al., 2007).

Data from the International Society for Heart and Lung Transplantation suggest that approximately 50% of children received induction immunotherapy between January 2001 and June 2009. The most common induction therapy included either ATG or ALG, followed by a specific IL-2 receptor antagonist. A small proportion of children also received OKT3. There are as yet no randomized multicenter studies to determine the benefits of induction therapy, but available evidence indicates that children given polyclonal ATG or other forms of induction therapy have lower mortality than those given no induction agent or OKT3 (Boucek et al., 1990, 2002; Sudan et al., 2007). In general, the use of induction therapy allows the initiation of calcineurin inhibitors to be delayed for a few days postoperatively, which may be most beneficial in patients with some degree of renal dysfunction.

Complications

Complications following heart transplantation can be divided into those associated with rejection and those arising from other causes (Behrendt et al., 1991; Steed et al., 1985). Acute rejection generally occurs in the first year after transplantation and is the most frequent cause of death during this time period. Late-onset acute rejection also occurs in a significant number of children beyond the first posttransplantation year. Acute rejection remains a major source of morbidity as well and correlates

with the ongoing need for immunosuppression (Chartrand et al., 2001; Azeka et al., 2002). Although specific risk factors for acute rejection have been sought, results have been conflicting (Kirklin et al., 1992; Webber, 2003). Overall, it appears that an older age at the time of transplantation increases the risk for acute rejection, and that an episode of acute rejection in the first year increases the risk for subsequent episodes (Webber, 2003).

Clinical detection of rejection remains difficult, as signs and symptoms are subtle and nonspecific; these include general malaise, fever, change in activity or appetite, tachycardia, and conduction or voltage changes on the surface ECG. More severe bouts may be accompanied by clinically symptomatic reductions in graft function. Other relatively noninvasive tests, such as various myocardial or inflammatory markers in blood, echocardiography, and cardiac MRI, continue to be investigated, but none of the tests has shown the necessary sensitivity and specificity. As a result, endomyocardial biopsy remains the gold standard for diagnosis of rejection (Boucek, 2000; Wagner et al., 2000; Atluri et al., 2008). It is performed at scheduled intervals as a surveillance tool, to guide immunosuppression regimens and dosing, and to diagnose acute rejection episodes.

Chronic rejection and associated posttransplantation coronary artery disease are the leading causes of death among late survivors of heart transplantation. According to data from the International Society for Heart and Lung Transplantation, approximately 20% of all pediatric transplantation patients have some degree of posttransplantation coronary artery disease at 5 years after transplantation. This accelerated vasculopathy can affect infants, children, and adults alike. The mortality after the diagnosis is substantial. The histologic appearance is that of concentric myointimal proliferation that ultimately results in luminal occlusion. In addition to repeated bouts of rejection, CMV infection is likely to be a contributing risk factor (Hussain et al., 2007; Mahle et al., 2009). Efforts have been made to more aggressively control other etiologic factors present in these patients that can contribute to the development of atherosclerosis, such as hypertension, hyperlipidemia, and glucose intolerance (Eich et al., 1991). At present, the effects of these efforts are uncertain. As the transplanted heart is denervated, chest pain caused by myocardial ischemia is a rare presenting complaint; progressive deterioration in graft function, heart failure, or sudden death are the primary evidences of rejection. For this reason, transplant recipients are routinely screened (usually on a yearly basis) for this development (Smart et al., 1991). Although coronary angiography was long thought to be the most sensitive means of detecting the development of graft vasculopathy, it underestimates the presence of early or mild disease. As a result, many centers have begun to use dobutamine stress echocardiography as the primary means of screening for coronary artery disease in transplant recipients (Pahl et al., 1999). Intracoronary ultrasound may also be useful (Dent et al., 2000; Schratz et al., 2002; Costello et al., 2003; Sudan et al., 2007).

Treatment of posttransplantation coronary artery disease is palliative coronary artery stenting (which is of limited benefit given the diffuse nature and involvement of distal vessels) or retransplantation. Rapamycin, which appears to slow the progression of transplantation vasculopathy, has shown some benefit, either as an additional immunosuppressive treatment or in the form of rapamycin-coated coronary stents (Morice et al., 2002; Mancini et al., 2003). Retransplantation for graft vasculopathy and resulting graft failure are usually felt to be associated with greater risk and diminished success, although there is some

adult evidence that it can be accomplished with reasonable 1- and 5-year survival rates (Atluri et al., 2008; Kanter et al., 2004).

Infection after heart transplantation is usually caused by bacterial pathogens that do not cause disease in the immunocompetent host (Schowengerdt et al., 1997). Immunosuppression makes the severity of infections much worse, and even with early aggressive therapy, such infections are significant causes of morbidity and mortality in the transplantation patient (Dummer, 1990; Hoflin et al., 1987). In addition to bacterial pathogens, other opportunistic pathogens such as fungi and viruses (CMV, Epstein-Barr, and adenovirus) cause significant morbidity. Infection with Epstein-Barr virus has been associated with the development of PTLD (Webber, 2003). This may be treated initially with reduction in immunosuppressive therapy and, failing this, with chemotherapeutic agents. Other complications in heart transplantation patients are mostly secondary to immunosuppressive regimens and include diabetes, growth retardation, hypertension, renal dysfunction, and malignancy (Groetzner et al., 2005; Kirk et al., 2009).

Outcome after Pediatric Heart Transplantation

Data from the International Society for Heart and Lung Transplantation show that the actuarial 10-year survival rate for all pediatric heart recipients exceeds 50% (Boucek et al., 2002; Kirk et al., 2009). The mortality rate is higher in infants in the first year of life, but this is followed by a slightly lower mortality rate of less than 2% per year in the 4- to 10-year period. If one excludes the first-year mortality rate, the conditional actuarial survival in infants exceeds 80%. Adolescents have a slightly higher average mortality—4% per year. In comparing the actuarial survival in the first 4 posttransplantation years by era, significant progress has occurred. There is some evidence that heart transplantation in adults with CHD may also be accomplished with reasonable short- and longer-term prognosis (Coskun et al., 2007a, 2007b).

From 1982 through 1987, the actuarial 4-year survival rate was just below 60%, whereas in the current era (2000 to 2008), the 4-year actuarial survival approaches 80%. The greatest risk factor for first-year mortality was the diagnosis of congenital heart disease. Recipient age was also found to be a risk factor. Patients younger than 6 years and older than 12 years were at increased risk. Other risk factors for poor first-year outcome may include ventilatory support or hospitalization before transplantation, high PVRI (>6 Wood units/m²), hepatitis C positivity, PRA greater than 40%, low creatinine clearance (<40 mL/min), donor-to-recipient weight ratio less than 0.7, and the need for retransplantation; risk appears to increase as the number of these factors increases (Davies et al., 2008). The role for and success of cardiac retransplantation in pediatric patients remain controversial, with some data indicating worse outcomes, whereas others suggest that retransplantation can be accomplished in pediatric patients with 1- and 3-year survival rates that approximate those of primary transplantation (Mahle et al., 2005). Of note, recent data (based on adult heart transplantation results) suggest that low transplantation volume in a program (perhaps in the range of less than 2 to 10 transplantations per year) was an independent risk factor for worse short-term outcome (Weiss et al., 2008).

Acute primary graft failure is the major cause of death after infant cardiac transplantation, as well as a prominent cause in older patients (Huang et al., 2004). Anoxic brain death, prolonged cardiopulmonary resuscitation, and long cardiac ischemic time

are prominent donor risk factors, with CHD (as opposed to cardiomyopathy), PVR index, and the need for preoperative mechanical support significant recipient risk factors. Recipient factors not associated with increased risk for death during the first year include the need for inotropic support, use of prostaglandin, use of ECMO, prior sternotomy, height, the need for dialysis, recent infection, and a history of malignancy. Although age did affect first-year mortality risk, weight as an independent factor posed no additional risk. Despite the increased risk for complications, use of ECMO appears to be associated with functional recovery and reasonable survival in pediatric heart transplant recipients suffering from acute graft failure and unresponsive to other therapies (Tissot et al., 2009).

Overall, the leading cause of death in transplant recipients under the age of 3 years is acute rejection. In addition to graft failure, other causes of early mortality include acute rejection and PTLD. In patients older than 3 years, coronary artery vasculopathy is a major source of morbidity and mortality, as are infections and neoplasms; hypertension and renal dysfunction can be prominent as well (Boucek et al., 2002; Gambino et al., 2007; Kirk et al., 2009). Adolescents represent a particularly problematic subgroup (for other types of transplantation as well) because of poor compliance. Among survivors, over 95% of patients report no limitation of activity at the 5-year follow-up. However, with formal exercise testing, as many as 50% may have mild to moderate limitations in exercise and aerobic capacity (Borow, 1985). In the absence of rejection, in general, myocardial and somatic growth are normal in most pediatric transplant recipients (de Broux et al., 2001; Sudan et al., 2007; Baum et al., 1991; Bernstein et al., 1992). A growing number of pediatric heart transplant recipients are entering their second and third decades after transplantation (Ross et al., 2006). There is also evidence of at least some degree of autonomic reinnervation of the cardiac allograft (Fallen et al., 1988; Stark et al., 1991).

Lung Transplantation

Demographics and Indications

At present, more than 2000 pediatric lung transplantations have been performed (Sweet, 2009). As with pediatric heart transplantation, available data suggest that the annual number of pediatric lung transplantations conducted since the late 1980s has plateaued since a peak in the late 1990s. Waiting times have increased overall; adolescents may wait as long as 1 or 2 years for cadaveric lungs (average waiting time, 20 months), whereas younger children (1 to 10 years old) wait an average of approximately 6 to 12 months. Organ donation number and viability continue to be major limitations (Burch and Aurora, 2004; Sudan et al., 2007; Sweet, 2009; Egan, 1989; Orens and Garrity, 2009), resulting in a consistent rate of approximately 50 pediatric lung transplantations per year in the United States. In 2005, the overall (adult) system of donor lung allocation was changed from one based primarily on waiting time to one based on survival models that attempt to estimate wait-list and posttransplantation survival. The effects (if any) of this change on wait times and outcome for adult and pediatric lung transplantation candidates are uncertain at the present time (Davis and Garrity, 2007; Iribarne et al., 2009; Hachem and Trulock, 2008a).

Early pediatric lung transplantation efforts emerged directly from adult experience (Egan, 1992), and the majority of the recipients were older children with cystic fibrosis (CF), primary

pulmonary hypertension, secondary pulmonary hypertension (e.g., from CHD), and pulmonary fibrosis. With increasing experience and the development of pediatric lung transplantation centers, transplantations in infants and younger children have increased, and children younger than 2 to 3 years may now comprise 10% to 20% of lung transplant recipients. In infants and young children (without CF), the most common diagnoses include interstitial lung disease, primary pulmonary hypertension, severe pulmonary vein obstruction (which typically appears with severe pulmonary hypertension and varying degrees of airspace and ventilatory abnormalities), and alveolar proteinosis (Dandel et al., 2003). In contrast, CF accounts for greater than 50% of all lung transplantations in older children and adolescents, for whom 5-year survival rates range from about 50% to 65% (Waltz et al., 2006; Faro et al., 2007; Spahr et al., 2007; Aurora et al., 2009).

Contraindications

Absolute contraindications to pediatric lung transplantation include hepatitis B or C virus infection, HIV infection, active malignancy within the past 1 to 2 years, and irreversible neurologic or neuromuscular disorders. Significant liver, heart, or renal dysfunction (requiring dialysis) is also an absolute contraindication; lung-liver or heart-lung transplantation may be considered in the presence of the first two of these conditions. Some issues such as prior thoracotomies or pleurodeses, steroid dependence, or colonization with a variety of organisms (especially in patients with CF) are no longer absolute contraindications in most centers. Relative contraindications include significant musculoskeletal disease, invasive ventilation (which has been linked to increased risk in older patients, potentially less so in infants and young children), colonization with *Burkholderia cepacia*, various fungi or atypical mycobacteria, poor nutritional status (<70% or >130% of ideal body weight), and an inability to wean from or significantly reduce dependency on systemic corticosteroids (Hadjiliadis, 2007). As with heart transplantation, significant psychological and behavioral disturbances in the potential recipient, or social and familial circumstances that could hinder access to care or compliance with complex medical regimens, may also preclude transplantation.

Organ Preservation

Achieving successful lung preservation continues to be a difficult problem. Lung ischemic time is a major factor in the development of posttransplantation lung injury. The optimal duration of preservation is between 3 and 4 hours, although lungs with ischemic times as long as 9 hours have been implanted successfully (Kaiser et al., 1991). During organ harvest, the lungs and pericardium are exposed and a prostaglandin infusion is begun. Prostaglandin is believed to cause pulmonary dilation and thereby improves the distribution of preservation solution. The venae cavae are then transected, the left atrial appendage is incised, and then the aorta is cross-clamped. This harvesting sequence prevents any left atrial hypertension and thus reduces the risk for pulmonary edema. A cold crystalloid preservation solution (e.g., Euro-Collins') with a high potassium concentration is infused into the pulmonary artery while cardioplegia is administered into the aortic root. Ventilation is discontinued and the lungs are allowed to deflate. For single-

or sequential double-lung transplantation, the left atrium is divided so that a cuff of atrial tissue surrounds the right and left pulmonary veins. The pulmonary veins may be excised in a single atrial cuff for double-lung transplantation. If both the heart and lung (or lungs) are to be used (but in different recipients), adequate segments of the left atrium and pulmonary artery must be allocated to each (Griffith and Zenati, 1990). During transportation, the lungs are generally kept deflated, although there is some experimental evidence that intermittent inflation prolongs the allowable ischemic time (Toledo-Pereyra et al., 1977). In addition, some centers believe that donor cooling with CPB also extends the permissible ischemic time (Heritier et al., 1992).

Single-Lung Transplantation

Single-lung transplantation is performed infrequently in pediatric patients (Mal et al., 1989). One general reason is that the ability of the transplanted lung to grow remains uncertain. Most practitioners believe it is wise to implant as much normal lung tissue as possible to meet the demands of future somatic growth in children. Second, the most frequent indication for pediatric lung transplantation is CF, and there is great concern about the transplanted lung being contaminated by the chronically infected native lung.

When a single-lung transplantation is performed, the most important decision is the determination of laterality, usually determined by chest radiograph, chest computed tomography, or scans. The side that appears to have the less affected lung or that has a better ventilation/perfusion scan is kept; the opposite side is transplanted. If possible, implantation is done on the side opposite to any previous thoracotomy. Typically, a more emphysematous lung is removed (or its volume reduced) so as not to compress the allograft on the opposite side. A more fibrotic lung might remain, so as to favor ventilation and blood flow distribution to the transplanted lung. There is some evidence that outcomes from double-lung transplantation may be favored (compared with single) in patients with emphysematous-type processes (Hadjiliadis and Angel, 2006).

Omentum may be fashioned to provide a vascular cuff around the bronchial anastomosis to improve bronchial blood supply. In such cases, a midline laparotomy is performed first, to mobilize omentum with an attached pedicle. This is tunneled through the diaphragm and the incision is closed (Fig. 20-23). Single-lung ventilation is then instituted (see later). A thoracotomy is performed, and the pulmonary artery, pulmonary veins, and main stem bronchus are exposed. The pulmonary artery is then test-occluded while gas exchange, PAP, and hemodynamic status are observed. The lung is removed if the patient tolerates this procedure. Allograft implantation involves connecting the donor atrial flap containing the pulmonary vein orifices to an area of recipient left atrial tissue that is isolated within a clamp. The pulmonary artery anastomosis is completed. The technique of telescoping bronchial anastomosis is used frequently (Calhoun et al., 1991). To perform this, the smaller of the two bronchial ends is placed inside the other one to a depth of one cartilaginous ring, and then the connection is oversewn. This method provides sufficient blood flow for high-quality bronchial healing and precludes the need for an omental cuff. The lung is then gently inflated. Air in the vascular spaces is removed either via the pulmonary artery (with the left atrium partially occluded, the proximal end of

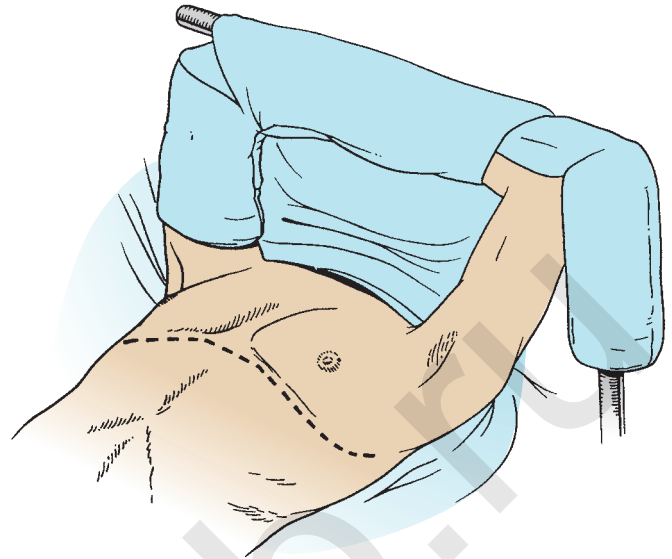

■ **FIGURE 20-23.** The bronchial anastomosis is completed first, followed by the vascular anastomoses. The vessel is reconstructed from posterior to anterior with the suture untied, allowing de-airing through the anastomosis later. (From Kirby TJ, Birnbaum PL: *Technique of single-lung transplantation*. In Patterson GA, Couraud L, editors: *Current topics in general thoracic surgery*, vol. 3: Lung transplantation, Amsterdam, 1995, Elsevier Science.)

the pulmonary artery is clamped, and its distal end vented) or via the left atrial cuff (with the pulmonary artery unclamped and the left atrial cuff vented). Pulmonary blood flow and ventilation are then established simultaneously.

Double-Lung Transplantation

Double-lung transplantation is the type of lung transplantation operation performed most frequently in pediatric patients. The technique most often used involves sequentially implanting each lung. This method has several advantages compared with en bloc implantation, which was done previously by some (Pasque et al., 1990; Kaiser et al., 1991). The lungs are harvested individually, each with a separate pulmonary artery, main stem bronchus, and two pulmonary veins encompassed within a cuff of the donor's left atrium. A bilateral anterior thoracosternotomy is performed extending across the midline by transverse sternotomy. This approach ("clamshell" incision) allows the anterior thoracic cage to be swiveled upward, providing full access to the bilateral hilar structures (Fig. 20-24). Each set of pulmonary arteries and main stem bronchi are anastomosed end to end, and each left atrial cuff is anastomosed to the recipient's left atrium. CPB is almost always used in pediatric patients, although it is possible to perform bilateral sequential lung transplantation without CPB. Omental flaps may be mobilized for each bronchial connection, although most current techniques use telescoping bronchial anastomoses. Both methods appear to result in improved healing of the airway connections, compared with tracheal anastomoses (as are used with the en bloc method). This is presumably because of enhanced blood flow. Volume reduction of the transplanted lungs may be required in infant and small child recipients from older or larger donors.

Living Donor Lung Transplantation

The shortage of donor organs has led to the development of living donor lobar lung transplantation, which requires that two separate donors each undergo lobectomies to provide right and left lower lobes. Outcomes of living donor lung transplantations have been comparable with cadaveric lung transplantations (Starnes et al., 1999; Toyooka et al., 2008). The technique of living related lung transplantations also overcomes some of the inherent difficulties of attempting to predict the clinical course of various types of lung disease and the appropriate timing for listing the patient for transplantation. Size limitations can be problematic: adult lobes are usually too large for children under 5 years, and, conversely, the amount of lung tissue may be insufficient for larger adolescents. The various anastomoses, particularly those of the pulmonary veins, can be technically difficult and prone to stenosis. The operation poses more than a minimal risk to the donors, and truly informed consent may be difficult to determine in such an emotionally difficult situation. The ethical issues are therefore complex, and this procedure is infrequently performed.

Non-Heart Beating Donors

Donation-after-cardiac-death (DCD) protocols have reemerged as a possible mechanism to increase the donor pool. This strategy remains in its infancy, and ethical issues are a significant limitation. As with the use of DCD hearts, there are technical issues relating to organ harvest and its effect on organ preservation and harvest regimens, ischemic time limitations, and resulting donor organ function. Some limited data show that this may be a useful technique that could modestly increase the donor pool with outcomes potentially similar to more conventional lung transplantation strategies (Erasmus et al., 2010; Oto, 2008; Snell et al., 2008a, 2008b).

Heart-Lung Transplantation

Because of early problems with the integrity of bronchial anastomoses, many patients with terminal lung disease received

heart-lung transplants, with the possibility of their (normal) heart going to a heart transplant recipient in a “domino” procedure (Starnes, 1990). Since the development of techniques to promote healing of bronchial anastomoses, the frequency of heart-lung transplantation has decreased substantially. At present, in pediatric patients it is considered only for patients with pulmonary hypertension or other end-stage lung disease when there is also CHD that cannot be repaired, and for patients with end-stage lung disease and severe left or right ventricular dysfunction. Pulmonary hypertension with right heart dysfunction is no longer considered an indication, unless the right ventricular dysfunction is severe, as the right ventricular dysfunction often improves after successful lung transplantation.

Anesthetic Management of the Lung Transplant Recipient

These patients are often critically ill by the time they come for lung transplantation (Armitage et al., 1995). Reasons for this include the nature of the underlying disease, reticence on the parts of both physicians and patients (or families) to undergo such a procedure, and the long waiting time required for cadaveric organs. For example, the clinical course of CF is very unpredictable. Most centers initiate the transplantation process when a CF patient's forced expiratory volume at 1.0 second (FEV₁) falls below 30% to 40% of predicted value; however, most centers would not actually transplant patients at this point if the patient thinks that his or her quality of life is acceptable (Yankaskas and Mallory, 1998; Dellon et al., 2007). Thus, the CF patient is likely to be quite compromised (pulmonary function, nutrition, and so on) by the time of actual transplantation.

In children with pulmonary hypertension, survival has been inversely related to right atrial and pulmonary artery pressures, as well as to the product of right atrial pressure and PVR (Clabby et al., 1997). However, it is likely that prostacyclin therapy (and perhaps newer agents such as endothelin receptor antagonists or phosphodiesterase V inhibitors such as sildenafil) will improve survival and prevent, or at least delay, the need for lung transplantation in some children with pulmonary hypertension (Rosenzweig et al., 1999; Rubin et al., 2002; Landzberg, 2007; Bush et al., 1986, 1987). Similarly, patients with severe pulmonary venous obstructive disease, which can be a primary phenomenon or follow repair of totally anomalous venous return or other congenital cardiac lesions, may be palliated for prolonged periods with catheter balloon dilations and possibly chemotherapy (Peng et al., 2009). As seen in patients with CF, one consequence is that ventilatory or pulmonary hypertensive complications can be quite significant by the time they are referred for lung transplantation.

Patients with end-stage CF, idiopathic restrictive lung disease, pulmonary venous obstruction, or other lung parenchymal diseases (e.g., alveolar proteinosis) are often hypoxic or hypercarbic (or both) and may be dependent on supplemental oxygen. Their ventilatory effort is at least partially sustained by increased circulating catecholamine concentrations. Deep levels of sedation can reduce ventilatory drive and cause hypotension and are best avoided. If necessary, small increments of midazolam may be titrated until the desired effect is achieved. Although sedative medication may be useful as an adjunct to control pulmonary vascular responses during induction, this should be given only in the immediate preoperative period, with full monitoring in situ. If undertaken, small increments of midazolam are administered until the desired effect is achieved.

The preoperative assessment of the lung transplant recipient is focused on cardiopulmonary status as well as on dysfunction in other organ systems. The CF patient undergoing lung transplantation is usually already on maximal medical therapy. This may include oral or inhaled bronchodilators, supplemental oxygen, nebulized antibiotics, *N*-acetylcysteine or DNase, and chest physiotherapy. These are continued through the time of surgery. It is important to have recent information about right ventricular function and pulmonary artery pressures (both usually with echocardiography). Baseline liver and renal function, as well as coagulation status (potentially compromised by malabsorption in the CF patient), should also be determined.

Monitoring and Vascular Access

Noninvasive monitoring is instituted before induction. An arterial catheter may also be inserted under local anesthesia before induction. However, this is usually performed after induction in young children. Although cannulation of the central venous circulation may be difficult in the patient with severe obstruction or fibrosis because of the large negative intrathoracic pressures generated during spontaneous ventilation, it is usually possible before induction. Pulmonary artery catheterization before pneumonectomy is essential if assessment of the response to pulmonary arterial cross-clamping is required (i.e., single-lung transplantation or bilateral sequential transplantation without CPB). Either the catheter is floated into the appropriate artery using TEE guidance, or the surgeon places the tip by palpation. It is essential to withdraw the catheter tip into the main pulmonary artery before pneumonectomy in patients undergoing bilateral lung transplantation. If available, TEE may be used to visualize the effects of PA occlusion and mechanical ventilation on ventricular function (Triantafillou and Heerdt, 1991). TEE can also provide valuable information about ventricular function and volume status after transplantation.

Intraoperative and postoperative bleeding can be significant. This may be exacerbated by extensive adhesions, especially in patients with longstanding lung inflammation (e.g., CF) or those who have undergone prior thoracic surgery. Thus, it is important to have large-bore vascular access to facilitate rapid volume resuscitation. Often, the use of a rapid infusion device is quite helpful. Almost all pediatric lung transplantations are performed with the patient supine and the patient's arms raised over the head and flexed at the elbows (see Fig. 20-24). This position may occlude catheters placed in the antecubital fossae, and thus other sites are recommended. Epidural catheters can provide excellent postoperative analgesia and facilitate ventilatory effort and pulmonary toilet. Although the use of the lumbar or thoracic approach is adequate, the decision to place the catheter while the child is awake or after induction remains unresolved. In addition, the placement of an epidural catheter in a child who is to undergo lung transplantation using CPB is also contentious. An alternative approach is to place the epidural catheter on the first or second postoperative day, before extubation, when the coagulation status has normalized.

Induction and Maintenance of Anesthesia

A child who is to undergo lung transplantation has precarious physiology and minimal reserve and is usually frightened and thus has elevated levels of circulating endogenous catecholamines. Thus, it is important that the anesthetic induction

have minimal effects on the pulmonary and cardiovascular systems. Myocardial depression and increased pulmonary vascular tone should be avoided, whereas bronchodilation and pulmonary vascular dilation are frequently desirable. Etomidate, ketamine, propofol, and thiopental have all been used successfully for IV induction (Triantafillou and Heerdt, 1991). However, should a rapid sequence induction be required, etomidate may provide the best overall combination of hemodynamic stability and rapid airway control. Ketamine is useful in those patients prone to airway reactivity. The effect of ketamine on PVR is controversial; it probably does not increase PVR if hypoxia and hypercarbia are avoided (Hickey et al., 1985). Ketamine does, however, have some direct negative inotropic effects, and it should be avoided in patients with severe pulmonary hypertension or significant right ventricular dysfunction.

Potent synthetic opioids such as fentanyl are frequently used for both induction and maintenance of anesthesia. In addition to providing relative hemodynamic stability, opioids are effective in attenuating sympathetic stimulation in those patients prone to pulmonary hypertensive crises. To avoid the chest wall rigidity (and limitation to ventilation) that may occur with these agents, it is usually preferable to perform an IV induction with etomidate, establish neuromuscular blockade, and then titrate the opioids to achieve the desired effect. Although the vagolytic effects of pancuronium may be useful in conjunction with synthetic opioid administration, vecuronium or rocuronium also may be used.

There is some evidence that nitrous oxide may increase PVR and impair hypoxic pulmonary vasoconstriction (Sykes et al., 1977; Schulte-Sasse et al., 1982), and thus it is probably best avoided. Inhaled anesthetics are usually used in moderate concentrations as anesthetic adjuncts and to provide amnesia; bronchodilation and perhaps some degree of pulmonary vasodilation secondary to abolishment of pulmonary vascular vasoconstriction may be other benefits. All volatile anesthetics are likely to impair hypoxic pulmonary vasoconstriction to some degree, which may be a particular problem if single-lung ventilation is used and also in patients with significant lung disease, V/Q mismatch, or intrapulmonary shunting (Benumof, 1985). In most situations, a standard single-lumen endotracheal tube of an appropriate size is used for lung transplantation with CPB. An appropriate double-lumen endotracheal tube is inserted after induction for single-lung transplantation or bilateral sequential transplantation without CPB. It is placed to provide differential lung isolation, and its position may be confirmed by flexible bronchoscopic examination (Benumof, 1985, 1991). At all times, the possibility of tube obstruction from inspired secretions and blood clots must be kept in mind. If a double-lumen endotracheal tube is used, it is exchanged for a standard endotracheal tube at the completion of the procedure. Prior to lung replacement, the initial inspiratory oxygen concentration is usually set at 100%. This can then be adjusted according to pulse oximetry and blood gases. Ventilatory parameters are set according to the pathophysiology of the disease involved. The patient with restrictive lung disease is best ventilated with higher rates and lower-than-normal tidal volumes to minimize peak airway pressures, whereas the patient with obstructive lung disease may benefit from longer expiratory times to allow complete expiration and to prevent “stacking” of breaths. In some situations, it may be necessary to manually ventilate the patient to establish the optimal ventilatory pattern. The addition of PEEP may improve gas exchange, but excessive PEEP

may compromise the patient’s cardiovascular status. Volume resuscitation and inotropic support may be necessary to counter the negative hemodynamic effects of PEEP. In patients with CF, frequent suctioning of the endotracheal tube should be performed to keep it clear of copious and tenacious secretions, which in some patients can be voluminous.

Intraoperative Concerns

Patients undergoing lung transplantation have, by definition, severely compromised cardiorespiratory function. If the intention is to conduct either a single-lung or sequential bilateral lung transplantation without using CPB, there needs to be constant reassessment of the patient’s underlying cardiorespiratory status, because single-lung ventilation frequently leads to unacceptable levels of CO₂ and cardiac instability (Triantafillou and Heerdt, 1991). If at any point the situation becomes untenable, the patient is placed on CPB to complete the procedure.

Two events must be critically evaluated. First, with the onset of single-lung ventilation, an immediate increase in airway resistance occurs in all patients. In patients with restrictive lung disease, these changes are more pronounced. High airway pressure will both inhibit venous return and reduce pulmonary blood flow. The initial respiratory management is an adjustment of the ventilatory setting and the possible addition of inotropic agents to augment support for right ventricular function. If gas exchange and hemodynamic status are not improved, then it is important to reinstitute two-lung ventilation while plans for CPB are instituted.

The second intervention that needs to be evaluated is when the pulmonary artery is occluded during single-lung ventilation. Occlusion of the pulmonary artery during one-lung ventilation leads to an improvement in gas exchange. This occurs because the shunt passing through the collapsed lung is removed and the V/Q matching in the perfused lung is improved by minimizing physiologic dead space. However, PAP is increased, with a concomitant increase in afterload. This increased afterload is best treated with pulmonary vasodilation using agents such as prostaglandin, milrinone, or NO. Maintaining coronary perfusion of the hypertensive right ventricle is essential to preserving its function. Thus, adequate preload and inotropic support (alone or in combination with β -adrenergic agonists) may also be necessary. If right ventricular failure cannot be managed with preload and inotropic support, then the pulmonary artery should be unclamped and CPB instituted.

In contrast, double sequential lung transplantation performed on CPB does not have these physiologic difficulties. The lungs are reperfused individually as soon as the anastomoses are complete. After the implantation of the first lung, there is often a “honeymoon” period of excellent gas exchange, but it may be short-lived. Gas exchange may worsen because of factors that include reperfusion injury and pulmonary edema, and reduced compliance. Pulmonary hypertension may also occur as a result of vascular injury triggered by ischemia–reperfusion, and hyperinflation in an open thoracic cavity. These two problems can usually be resolved with ventilatory adjustment and the use of moderate levels of PEEP. Inhaled NO (typically 20 to 40 ppm in oxygen) has become a mainstay of posttransplantation management in many centers (Date et al., 1996; Rea et al., 2005; Baez and Castillo, 2008; Yerebakan et al., 2009) to optimize PVR as well as V/Q matching. Inotropic support is frequently required.

Blood products, including platelets and clotting factors, may be required (occasionally in quite substantial amounts) to correct for ongoing bleeding at surgical sites, adhesions as a result of CPB, and preexisting coagulation abnormalities. The bronchial anastomoses are usually inspected toward the end of the procedure using flexible bronchoscopy, to verify integrity and patency of the airway anastomoses. Patients with “septic lungs” (e.g., CF patients) occasionally develop sepsis or a syndrome resembling septic shock, probably from bacteremia or release of inflammatory mediators during removal of their native lungs, in the early postbypass period. The outcome is frequently poor, despite intensive therapy with inotropes, antibiotics, and so on.

Early Postoperative Complications

Acute Graft Dysfunction

Acute dysfunction of the transplanted lung immediately after implantation or over the ensuing several hours continues to be a significant problem, occurring in up to 30% or 40% of recipients. The primary mechanism is believed to be related to ischemia–reperfusion injury, and in fact its appearance and severity are generally associated with a longer duration of ischemia. The contribution of other factors, such as duration of donor support and occult lung injury (e.g., trauma, infection, multiple transfusions), or recipient factors, such as chronic infection or colonization or use of CPB, is unclear. Acute graft dysfunction typically resembles an acute respiratory distress syndrome or noncardiogenic pulmonary edema, with key features that include markedly decreased lung compliance and impaired gas exchange (especially oxygenation), as well as frequently large amounts of pulmonary edema-like secretions.

The primary treatment is prevention, aiming to keep lung ischemic times to less than 5 to 6 hours whenever possible. The other major focus is on mechanical ventilation, with appropriate use of airway pressures and PEEP. In general, ventilatory parameters should be adjusted to maintain normocarbida or mild hypocarbida with adequate but not excessive lung expansion. Peak and mean airway pressures are kept at the minimum required to maintain gas exchange while protecting the bronchial anastomoses and limiting the possibility of volutrauma. Inspired oxygen concentration is kept as low as practical, so that P_{aO_2} is below 120 mm Hg, to limit oxygen toxicity and reperfusion injury. In the case of single-lung transplantation, the two differing cardiorespiratory requirements make hypoxia due to V/Q mismatch more likely (Triantafyllou and Heerdt, 1991). It may, on occasion, be necessary to use differential lung ventilation to address the ventilatory requirements of the two lungs independently (Todd, 1990; Smiley et al., 1991). Fluid and blood product administration are limited as much as possible. As noted previously, inhaled NO may be beneficial in some circumstances to improve the V/Q matching and to reduce PVR (Rocca et al., 1997). ECMO has been used successfully in some cases of acute graft failure to allow recovery of lung function. As with some cases of acute cardiac allograft rejection, acute antibody-mediated rejection of lung allografts is being recognized with increasing frequency; treatment may include post-transplant plasmapheresis (Morrell et al., 2009). There is also emerging evidence that primary graft dysfunction is a significant risk factor for subsequent immune-mediated graft injury (Bharat et al., 2008).

Infection

Infection is a significant problem in the immediate postoperative period. There are multiple risk factors. In addition to extensive surgical sites and invasive catheters, the patient is often nutritionally compromised and has begun receiving high-potency immunosuppressive agents. The transplanted lung is denervated. The cough reflex is therefore lost below the level of the anastomosis. Airway ciliary function is also likely to be severely impaired in the posttransplantation period. It is essential that chest physiotherapy and tracheobronchial suction be performed routinely to prevent accumulation of blood and secretions, which can obstruct the endotracheal tube or airways and contribute to infection. Bronchoscopy may be necessary at times to clear the airway of the debris. An absence of lymphatic drainage from the donor lung (or lungs) contributes to the tendency to accumulate lung water and develop infection and acute graft dysfunction (Montefusco and Veith, 1986; Todd, 1990). Use of prophylactic antibiotics is routine and guided by the donor's and recipient's colonization status and by subsequent surveillance cultures in the recipient. Ganciclovir (for CMV) and antifungal agents are given when these pathogens exist in either donor or recipient. Infection with parainfluenza, adenovirus, and herpesvirus can be life threatening in pediatric lung transplant recipients (Razonable and Eid, 2009; Liu et al., 2010).

Other Acute Complications

Postoperative hemorrhage is one of the most frequent major complications, with the surgical anastomoses and adhesions in the chest being the most common sites. A high degree of suspicion must be maintained to quickly diagnose anastomotic obstruction or ischemia (bronchial anastomoses). Echocardiography and nuclear medicine perfusion scans can be effective in detecting obstruction of the pulmonary arterial or venous connections (the latter may be a particular problem in lobar transplantation, and in either setting can be heralded by copious amounts of pink, frothy secretions after reperfusion). Airway necrosis and dehiscence are frequently fatal. Increasing scarring and stenosis can also occur. Therefore, regular fiberoptic bronchoscopy is conducted after surgery to screen for these problems (Huddleston, 1996).

Rarely, recurrent laryngeal or phrenic nerve damage can become apparent in the postoperative period, most likely as a consequence of the surgical procedure. These are often transient, although permanent vocal cord or hemidiaphragmatic paralysis can occur; the latter may require plication of the diaphragm.

Later Complications

Although the principal cause of death during the first 30 days after transplantation is graft failure, infection in the setting of sustained immunosuppression is a leading cause of death in the first year, and it continues to be a significant cause of mortality after that (Boucek et al., 2002; Sudan et al., 2007; Kirk et al., 2009; Sweet, 2009). Symptoms of infection in the transplant patient are often difficult to distinguish from those of rejection. Both can involve fever, dyspnea, decreased oxygenation, and pulmonary infiltrates. Definitive diagnosis for most entities requires bronchial lavage and culture; some patients may need

a lung biopsy to rule out infection or rejection. Prevention of infection is a primary goal in the management of lung transplant recipients.

Cytomegalovirus is one of the most frequent causes of infection in the transplantation patient, especially in CMV-negative recipients who received organs from CMV-positive donors. CMV infection may be asymptomatic or symptomatic and may cause pneumonitis (where it is associated with fever, respiratory distress, decreased pulmonary function, hypoxemia, and patchy interstitial infiltrates), gastrointestinal disease (abdominal pain, fevers, and increased liver function enzymes), or viremia. It may also present a sepsis-like picture that can progress to multiple organ failure. CMV infection has been associated with acute cellular rejection and an increased frequency and severity of chronic rejection (Duncan et al., 1992; Razonable and Eid, 2009). Aggressive treatment with antiviral agents, with possible reduction in immunosuppressive therapy, is usually successful. Diagnosis is usually based on positive antibody staining in lung tissue specimens, although newer assays that detect antigenemia may allow earlier and less invasive diagnosis. The use of ganciclovir has decreased the incidence and severity of CMV-related disease in these patients. Prophylactic treatment is usually used in patients where either the donor or recipient is CMV positive.

Overall, patients are constantly at risk for bacterial lung infection. Patients with CF are more susceptible to bacterial infection with agents such as *Pseudomonas aeruginosa* or fungal organisms such as *Aspergillus*. These infectious agents should be actively sought (using bronchoalveolar lavage and transbronchial lung biopsy), especially in patients who do not respond to empirical therapy. Infection with Epstein-Barr virus is of note because of its association with malignancy (see later).

Another significant and often insidious complication is the development of airway obstruction resulting from scarring and granuloma formation, usually at the bronchial anastomosis suture line. The lesion can progress over several months, and the patient typically presents with wheezing and shortness of breath. Flow-volume loops and large-airway flow rates are usually reduced. The diagnosis is confirmed by bronchoscopy and is treated with dilation or stenting (or both).

Delayed gastric emptying and gastroparesis frequently follows lung transplantation, perhaps as a result of surgical injury to the vagus nerve. In addition to the aspiration risk at the time of subsequent surgeries, gastroesophageal reflux has been linked to occult (or overt) aspiration, lung injury, graft failure, and bronchiolitis obliterans (Reid et al., 1990; Huddleston, 1996).

Acute Rejection

Acute rejection is the most frequent in the first year and particularly in the first several months after transplantation, declining substantially thereafter (Sweet et al., 1997; Waltz et al., 2006; Sweet, 2009). It is often initially asymptomatic. Symptoms include fever, dyspnea, and desaturation. Positive laboratory tests can include pleural effusions or perihilar infiltrates on chest radiography, and lower airway obstruction with decreased forced vital capacity and FEV₁ on spirometry. The diagnosis is made (and attempts are made to differentiate it from infection) using bronchoalveolar lavage and transbronchial biopsy. The diagnosis of acute rejection requires the presence of lymphocytic bronchitis or bronchiolitis with associated perivascular mononuclear infiltrates. Acute rejection episodes are most

often treated with high-dosage steroids, to which patients usually respond rapidly with improvements in symptoms and pulmonary function tests. More persistent or severe episodes are typically treated with OKT3 or ATG. Although most lung transplantation patients experience at least one episode of rejection in the first year, additional episodes should prompt reevaluation of the immunosuppressive regimen. Acute rejection episodes are believed to be a major risk factor for the later development of bronchiolitis obliterans (Lawrence, 1990; Theodore et al., 1990).

Bronchiolitis Obliterans

The major manifestation of chronic rejection is obliterative bronchiolitis (bronchiolitis obliterans) (Wilkes et al., 2005; Huang et al., 2008). Bronchiolitis obliterans syndrome affects greater than 50% of all pediatric recipients more than 2 to 5 years after transplantation, and it is the most common cause of death after 1 year. All lung transplant recipients are followed with surveillance transbronchial biopsies, initially every 3 months and then at increasing intervals to evaluate for the presence of rejection. Pulmonary function tests are also performed to rule out, or to follow the progression of, bronchiolitis obliterans. Respiratory symptoms of bronchiolitis obliterans are not dissimilar to those of reactive airways disease involving the small airways; it sometimes responds mildly to bronchodilators. However, as time progresses, the airway obstruction becomes irreversible. Histologic examination confirms the diagnosis, with transbronchial biopsy results showing intraluminal occlusion and granulation of the respiratory and terminal bronchioles; high-resolution computerized tomography of the chest may have some diagnostic usefulness as well (Faro et al., 2007; Sudan et al., 2007). For many groups, progressive reductions in FEV₁ and maximum expiratory flow rates (FEF₂₅₋₇₅, FEF₇₅) are usually sufficient to make the diagnosis without histologic evidence. An association has been shown between bronchiolitis obliterans and increased episodes of acute rejection or infection (particularly CMV) and the onset of chronic rejection (Duncan et al., 1992; Sharples et al., 1996; Liu et al., 2010). The primary therapy is aimed at immunosuppressive prevention of acute rejection and prompt treatment of CMV. Although increased immunosuppressive therapy has been used to attempt to halt the progress of the disease, no solution except retransplantation has been shown to be beneficial.

Immunosuppression for Lung Transplantation

There is substantial variability among pediatric lung transplantation centers in terms of standard immunosuppressive regimens for preventing rejection. Currently, many if not most centers use induction therapy with an IL-2 receptor antagonist, usually in conjunction with one of the antilymphocyte preparations (see earlier) (Hachem et al., 2008a). Most maintenance immunosuppression regimens use MMF, steroids, and tacrolimus (Burch and Aurora, 2004; Waltz et al., 2006; Hachem et al., 2008; Sweet, 2009). Complications arising from the use of these agents were largely summarized earlier, and, as with heart transplantation, significant morbidity is associated with the use of these drugs. Hypertension, hyperlipidemia, diabetes, and renal dysfunction can all occur to varying degrees. Diabetes is a particular problem in CF patients who

have undergone lung transplantation, most likely because of a contribution from pancreatic injury as a result of their underlying disease; as noted earlier, steroids (which cause insulin resistance) and tacrolimus (postulated to have a direct pancreatic effect) are additional risk factors. In addition, PTLD affects up to 15% of patients. Those treated with tacrolimus may have an even higher incidence of PTLD.

Outcome

The overall actuarial survival (adults and children) for single-lung transplantations is approximately 25% to 35% at 5 years, compared with 40% to 60% at 5 years with a double-lung transplantation. This difference reflects the better pulmonary reserve and larger pulmonary vascular bed in double-lung transplantations. Long-term survival in pediatric lung transplant recipients is approximately 50% and, unfortunately, does not appear to have improved significantly in the past decade (Fig. 20-25). When survival is compared by age group, children younger than 1 year of age have an actuarial survival at 7 years of greater than 40%, whereas those older than 1 year have an actuarial 7-year survival of less than 35%. Mortality in the first month after transplantation is usually secondary to graft failure, whereas mortality in the first year beyond the first month is predominantly the result of infection, both from more common organisms and from others such as *Aspergillus*. Interestingly, rejection, bronchiolitis obliterans, and infection may be less common in CF patients transplanted at an older age (Weiss et al., 2009).

■ **FIGURE 20-25.** Kaplan-Meier survival by age group (pediatric versus adult) for lung transplantations performed between January 1990 and June 2007. (From Aurora P, Edwards LB, Christie JD, et al: Registry of the International Society for Heart and Lung Transplantation: twelfth official pediatric heart transplantation report—2009, J Heart Lung Transplant 28:1023, 2009.)

Thereafter, bronchiolitis obliterans affects more than 50% of transplant recipients after the first year and becomes the main cause of death. On a slightly more optimistic note, of those patients who survive without significant bronchiolitis obliterans, more than 80% show no limitation of activity at 1, 3, and 5 years, and most report a markedly improved quality of life (Williams, 1992; Sweet, 2009). Clearly, much further work is needed in this arena to address donor organ insufficiency and preservation, acute and chronic graft failure, improved immunosuppression, and the prevention and treatment of bronchiolitis obliterans (Wilkes et al., 2005).

Limited data exist regarding the indications, contraindications, and success of lung retransplantation. It may be associated with increased risk, depending on donor selection, and it also raises ethical and resource utilization issues. Outcome appears to be worse in the case of emergent retransplantation because of acute graft failure or rejection, and in those less than 2 years removed from their initial transplantation (Shuhaiber et al., 2009); it may be somewhat better in those retransplanted for chronic rejection and obliterative bronchiolitis.

SUMMARY

In major pediatric cardiac centers, essentially every complex cardiac lesion is amenable to surgical intervention with the potential for substantial improvement in longevity and quality of life. At first glance, the complexity and anatomic variations of congenital cardiac lesions appear to present overwhelming challenges to the anesthesiologists caring for these patients in the perioperative period. Guided by the unifying, basic physiologic concepts outlined in this chapter, an individualized management plan can be developed and applied to each patient by an anesthesiologist in possession of solid pediatric anesthesia skills. As the surgical and medical management of CHD continues to rapidly evolve, it is incumbent on the pediatric anesthesia community—in conjunction with colleagues in cardiology, surgery, intensive care, perfusion, and nursing—to be intellectually agile and actively engaged in the process of refining and advancing the care of these patients.

The population of children and adults who has undergone successful repair or palliation of congenital heart disease (CHD) continues to increase (Warnes and Deanfield, 2001; Warnes et al., 2001). Approximately 85% of infants born with CHD can expect to reach adulthood (Moller et al., 1994), and because children of parents with CHD have an increased incidence of CHD (Hoffman et al., 2004), the total incidence and prevalence of CHD are likely to increase generation by generation. Although CHD is synonymous with childhood, the number of adults with CHD currently equals, and is predicted to exceed, the number of children with CHD (Webb and

Williams, 2001); the total number in the United States alone may be approaching 500,000 individuals with significant versions of palliated CHD. The heterogeneous nature of the CHD population is made more so by the use of different treatment strategies for the same or similar lesions, in conjunction with advances in pediatric cardiac surgery, interventional catheterization, and electrophysiologic techniques. For example, in transposition of the great arteries (D-TGA), the majority of adults have had the *atrial* switch operation (the Mustard or Senning procedure), whereas most children have had the *arterial* switch operation (the Jatene). These two operations for the

same underlying condition carry vastly different intermediate and long-term outcomes (Williams and Webb, 2000; Warnes, 2006).

Although it is common to differentiate between corrective and palliative surgery, *total correction or cure is not the rule* for the majority of children with CHD (Stark, 1989). *Cure or definitive repair*, in the strictest sense, means that normal cardiovascular structure and function are achieved and maintained; life expectancy is normal; further medical, surgical, and catheter-based treatments for the CHD are unnecessary; and noncardiovascular (e.g., renal, neurologic) consequences are nonexistent. With *cure*, there are no cardiac or vascular *residua* (abnormalities that were part of the original defect and are still present after repair), *sequelae* (disorders intentionally incurred at the time of reparative surgery and deemed unavoidable), or *complications* (unintentional aftermath) after surgery (Perloff, 1997). *Palliative repair* implies that future procedures are anticipated or necessary to maintain or restore the patient to a state of normal (or at least compensated) physiology and to improve life span. Lesions that lend themselves to cure are uncomplicated closure at an early age of an uncomplicated, nonpulmonary hypertensive patent ductus arteriosus (PDA), atrial septal defect (ASD), ventricular septal defect (VSD) (Talner et al., 1980), and in some instances catheter ablation of tachyarrhythmias (Walsh, 2007). Virtually all other forms of CHD require long-term surveillance. Many carry substantial risk for residual and potentially progressive structural, contractile, hemodynamic, electrophysiologic, and end-organ abnormalities.

CARDIAC FACTORS INFLUENCING OUTCOME AND ANESTHETIC RISK

The factors that determine the natural history and pathophysiologic consequences of congenital cardiovascular malformations also affect perioperative risk. Although the majority of anesthesiologists are not familiar with the natural history of each and every lesion, it is possible to develop a rational approach to the anesthetic management of this group of patients by focusing on the factors listed in [Box 21-1](#). Identification of patients at increased risk, and development of an appropriate strategy to prevent adverse events is the cornerstone of anesthetic management.

Box 21-1 Factors Influencing Outcome and Anesthetic Risk

Defect and type of repair
 Shunting
 Ventricular dysfunction
 Ventricular outflow obstruction
 Hypoxemia and cyanosis
 Rhythm and conduction abnormalities
 Pulmonary hypertension and Eisenmenger's syndrome
 Myocardial ischemia
 Infective endocarditis
 End-organ dysfunction and injury
 Extracardiac anomalies
 Heart transplant recipients

Defect and Type of Repair

In an *anatomic repair*, the morphologic left ventricle is connected to the aorta, the morphologic right ventricle is connected to the pulmonary artery, the circulation is in series, and cyanosis is corrected. An anatomic repair may be categorized as either a *simple* or a *complex* reconstruction. In a *simple anatomic repair*, the heart is structurally normal, and correction for the most part is “curative” without long-term sequelae. Repair of uncomplicated, nonpulmonary hypertensive PDA, ASD, or VSD would fall into this category. In a *complex anatomic repair*, anatomic correction is achieved, but because of the complex nature of the surgical repair there may be significant long-term sequelae. Complex repairs comprise extensive (right and/or left) ventricular outflow tract reconstruction, placement of conduits or baffles, and atrioventricular valve repair. Examples include TGA, tetralogy of Fallot (TOF) with or without pulmonary atresia, severe aortic stenosis (AS), severe pulmonary stenosis (PS), atrioventricular septal defects, mitral stenosis, truncus arteriosus, and interrupted aortic arch. Although patients may report few symptoms or limitations to activities of daily living, significant limitations (e.g., reduced exercise or aerobic capacity, heart rate and blood pressure response to exercise) may be evident on objective testing.

In a *physiologic repair*, the circulation is in series and the cyanosis relieved, but the heart is either univentricular (single ventricle) or biventricular with the morphologic *right* ventricle being the *systemic* ventricle and the morphologic left ventricle being the pulmonary ventricle. Single-ventricle repairs result in connection of the systemic venous return directly to the pulmonary artery, thereby excluding the pulmonary ventricle. By relieving hypoxemia, single-ventricle repairs are “functionally corrective.” A physiologic biventricular repair is seen with the atrial switch operation (Mustard or Senning) for TGA, effectively resulting in a switch at the *atrial* level, with the right ventricle functioning as the systemic ventricle. One major clinical implication of a univentricular heart or systemic right ventricle is significant functional deterioration of the ventricle over time; progressive insufficiency of the systemic atrioventricular valve and dysrhythmias can be additional pathophysiologic features.

Anesthetic considerations: Patients with *simple anatomic repairs* who are asymptomatic have normal to near-normal hemodynamics and can generally be anesthetized in the same manner as patients with a structurally normal heart. *Patients with complex anatomic repairs*, because of the issues discussed later, are at increased perioperative risk. *Physiologic repairs* are always palliative and are associated with progressive ventricular dysfunction and other risk factors. Anesthetic management of patients with *single-ventricle physiologic repairs* is complex and can be associated with significant intraoperative problems if the pathophysiology is not well understood.

Shunting

A shunt is an abnormal communication between the systemic and pulmonary circulations, allowing blood to flow directly from one circulatory system to the other. A left-to-right shunt allows oxygenated pulmonary venous blood to return directly to the lungs rather than being pumped to the body, whereas a right-to-left shunt allows deoxygenated systemic venous blood to bypass the lungs and return to the body (Sommer et al., 2008). An increased

workload is placed on the ventricles, with the degree (volume) of shunting determining the severity of symptoms. Factors influencing the direction and degree of shunting include the size of the shunt orifice, the pressure gradient between the chambers or arteries involved in the shunt, the relative compliance of the right and left ventricles, the ratio of pulmonary vascular resistance (PVR) to systemic vascular resistance (SVR), and the blood viscosity (hematocrit). Total pulmonary blood flow (Q_p) is the sum of effective pulmonary blood flow and recirculated pulmonary blood flow, whereas total systemic blood flow (Q_s) is the sum of effective systemic blood flow and recirculated systemic blood flow. Total Q_p and total Q_s do not have to be equal.

The lesions most likely to be encountered before repair that are associated with the potential for left-to-right shunting include large PDA, VSD, and atrioventricular canal defects; patients palliated with large, unobstructed modified Blalock-Taussig shunts (e.g., stage I repair of hypoplastic left heart syndrome) can behave similarly. Left-to-right shunting results in increased pulmonary blood flow, increased pulmonary vascular resistance, increased pulmonary artery pressures (PAP), increased left atrial volume or pressure, pulmonary edema, and volume overload of both the right and left ventricles leading to biventricular failure. Low aortic diastolic pressure accompanying large systemic-to-pulmonary artery shunts can lead to myocardial ischemia as well as organ hypoperfusion (e.g., bowel ischemia). Pulmonary overcirculation is associated with decreased lung compliance, increased airway resistance (Stayer et al., 2004), and airway compression (Berlinger et al., 1983). Alterations in pulmonary function lead to increased work of breathing (with increased energy expenditure), atelectasis, air trapping, and respiratory infections. The time course for developing pulmonary vascular occlusive disease (PVOD) with shunt reversal (right-to-left) and Eisenmenger's syndrome depends on the size and site of the shunt and age at repair; patients with underlying anatomic or genetic predisposition to the development of pulmonary hypertension—for example, trisomy 21 children—can develop earlier, more severe PVOD for a given shunt (Chi and Krovetz, 1975; Gorenflo et al., 2002).

Right-to-left shunting results in decreased oxygen content of the systemic arterial blood, with the decrease in proportion to the volume of deoxygenated systemic venous blood mixing with the oxygenated pulmonary venous blood. Even with normal cardiac output, the decrease in tissue oxygen delivery limits exercise tolerance (Sommer et al., 2008).

Anesthetic considerations: Avoidance of air bubbles in intravenous catheters to prevent systemic embolization and attention to pulmonary vascular tone and its influence on the PVR-to-SVR ratio are important considerations. Factors influencing PVR are discussed later in the pulmonary hypertension section. In patients with left-to-right shunts, the major perioperative concerns are threats to already limited *systemic* blood flow. Routine clinical monitoring tools are unlikely to indicate an evolving problem in this regard until severe hypotension and evidence of myocardial ischemia ensue; in patients with shunt physiology, it is important both to maintain myocardial pump function (i.e., avoid myocardial depression) and to try to limit decreases in PVR. Such decreases (e.g., those that can be produced by hyperventilation or hyperoxia) can lead to a steal phenomenon with increased pulmonary blood flow (PBF). The major *acute* consequence will be decreased Q_s with increased risk for significant systemic hypotension

and hypoperfusion; in the longer term, the increased Q_p that results can increase pulmonary congestion, lung water, and cardiac volume overload.

In patients who have or who are at risk for significant right-to-left shunting or who are dependent on a systemic-to-pulmonary artery shunt for pulmonary blood flow (e.g., after stage I repair of hypoplastic left heart syndrome [HLHS] or as the initial palliation for reduced blood flow lesions such as tricuspid atresia), primary management considerations are the maintenance of overall pump (cardiac) function and blood pressure and avoidance of factors that further increase PVR or decrease SVR (or both). It is important to note that the resultant arterial oxygen saturation in such patients will be affected by both the magnitude of the right-to-left shunting and the saturation of the shunted (essentially systemic venous return) blood.

Ventricular Dysfunction

Progressive ventricular dysfunction leading to congestive heart failure (CHF) is the most common cause of disability and death in patients with CHD (Warnes and Deanfield, 2001). The etiology is multifactorial and may result from the primary disease, many years of abnormal volume and pressure loading (which cause pathologic remodeling of numerous cardiomyocyte and nonmyocyte functions and processes), chronic hypoxemia, damage during surgical repair (inadequate myocardial preservation, scarring, poor repair, damage to coronary arteries), acquired disease (Graham, 1982), and arrhythmias (Shinbane et al., 1997; Deal, 2001). *Ventricular volume overload* occurs with intracardiac or extracardiac left-to-right shunts, valvular regurgitation, and single-ventricle lesions. The time course over which irreversible ventricular dysfunction develops is variable, but if surgical intervention to correct the volume overload is undertaken within the first year of life, residual dysfunction is uncommon (Cordell et al., 1976; Graham et al., 1976). *Ventricular pressure overload* results from residual or recurrent ventricular outflow obstruction or elevated PAP or PVR. The time to develop significant ventricular dysfunction is longer compared with a chronic volume load, so symptoms are uncommon unless the obstruction is severe and prolonged, or it is combined with a volume load (Graham, 1991). *Chronic hypoxemia and cyanosis* decrease ventricular oxygen supply and increase oxygen demand through increased work related to increases in pulmonary and systemic vascular resistance with associated polycythemia. Myocardial ischemia resulting from coronary artery anomalies or kinking or torsion after reimplantation may also cause ventricular dysfunction.

Anesthetic considerations: The chronic presence or potential to develop or exacerbate low systemic cardiac output is probably the single most important consideration in approaching the care of patients with CHD. Attempts to correlate clinical status and functional myocardial reserve can be unreliable. No single parameter or test is best to assist with this assessment. Rather, one is advised to carefully integrate historical, physical, and diagnostic test information pertaining to myocardial performance to arrive at an integrated assessment of the degree of ventricular dysfunction, as well as the potential for further decompensation that can occur as a result of anesthetic choices and procedural factors. Although there is no

single recipe, key aspects of successful management include appropriate fluid administration, usually with maintenance of normal to modestly increased preload, and selection of suitable anesthetic induction and maintenance techniques most likely to maintain contractile function and hemodynamic stability. These techniques should also be chosen to minimize the possibility of airway obstruction and hypoventilation. Of note, positive pressure ventilation is likely to improve the function of a dysfunctional systemic ventricle according to Laplace's law, by the effect of increased intrathoracic pressure to decrease transmural myocardial pressure and hence decrease ventricular afterload. In instances of significant myocardial dysfunction, prophylactic inotrope administration before or soon after induction and also during the procedure may be beneficial.

Ventricular Outflow Obstruction

Ventricular outflow obstruction may be subvalvar, valvar, supravvalvar, or a combination thereof, isolated or part of more complex malformations, residual or recurrent, and fixed or dynamic. Outflow obstruction results in pressure overload on the ventricle, ventricular hypertrophy, a "stiff" ventricle (diastolic dysfunction), and ultimately systolic ventricular dysfunction (Carabello, 2006). *Left ventricular outflow obstruction* may occur with aortic stenosis, coarctation of the aorta, interrupted aortic arch, and variants of HLHS and Shone's anomaly (Shone et al., 1963). *Right ventricular outflow obstruction* is seen with pulmonary stenosis, TOF, hypoplastic pulmonary arteries, right ventricle-to-pulmonary artery (RV-PA) conduits (performed in repair of pulmonary atresia, truncus arteriosus, TGA with pulmonary stenosis [Rastelli procedure], some double-outlet right ventricle defects), and pulmonary hypertension. Conduits calcify and narrow, and together with the increasing stroke volume that occurs with growth, significant obstruction can develop. The septal shift associated with severe right ventricular pressure overload can compromise left ventricular function via a reduction in left ventricular filling and systemic outflow obstruction.

Anesthetic considerations: Pressure-overloaded ventricles are at significant risk for myocardial ischemia during anesthesia, particularly in association with systemic hypotension and tachycardia. Subendocardial ischemia is a potential risk in patients with systemic or suprasystemic RV pressures as systolic coronary flow may be markedly diminished or absent. The overall goal of anesthetic induction and management is to optimize and maintain the major determinants of ventricular function in the face of a fixed outflow obstruction and often some degree of both diastolic and systolic dysfunction. Thus, dependency on sinus rhythm and preload to maintain cardiac output are increased. Adequate preoperative hydration in accordance with fasting guidelines or a bolus of intravenous fluid prior to induction is recommended. Volume infusion or replacement in the presence of a stiff left ventricle or mitral stenosis must be done judiciously, as it has the potential to cause an inordinate increase in left atrial pressure and consequent pulmonary edema. As severity of ventricular dysfunction increases, an intravenous induction with agents that maintain contractility and systemic blood pressure without significant alterations in heart rate is probably indicated. Although the majority of patients can tolerate at least modest concentrations of inhalational agent, a balanced technique employing a potent opioid

such as fentanyl in combination with low-concentration inhaled agent and muscle relaxant may offer greater hemodynamic stability. When feasible, relief of severe outflow tract obstruction, which can frequently be performed in the catheterization laboratory, should precede all but emergency surgery.

Hypoxemia and Cyanosis

Cyanosis is associated with decreased pulmonary blood flow or intracardiac mixing lesions, or both. Prior to repair, cyanotic lesions include tricuspid atresia, pulmonary atresia, tetralogy of Fallot, transposition of the great arteries, and truncus arteriosus; tricuspid atresia, pulmonary atresia, and TOF are all lesions that typically have reduced PBF. Increased PBF occurs in truncus arteriosus. In lesions with intracardiac mixing (e.g., TGA), cyanosis can occur with decreased or increased PBF depending on whether there is obstruction to the PBF. Cyanosis may also be found in the setting of very low cardiac output, increased arteriovenous oxygen difference, and respiratory disease. With the advent of early infant repair, chronic hypoxemia is now most frequently encountered in the young child undergoing staged repair, and in the adult with unrepaired or palliated CHD. Indeed, one stimulus for early, definitive repair is to eliminate hypoxemia and the compensatory polycythemia, with its rheologic, neurologic, hemostatic, renal, and metabolic consequences. Although the analyses are limited and imperfect for obvious reasons, the data that does exist suggests that chronic hypoxemia during infancy and early childhood is a significant risk factor for reduced cognitive performance. As blood viscosity increases, systemic (including coronary) and pulmonary vascular resistances increase markedly. Hemostatic abnormalities that can result from cyanosis and polycythemia include thrombocytopenia, platelet dysfunction, shortened platelet survival, disseminated intravascular coagulation, decreased production of coagulation factors, and primary fibrinolysis (Tempe and Virmani, 2002; Odegard et al., 2003, 2009). Sludging of red blood cells increases the risk for thromboembolism and stroke, particularly when the hemoglobin approaches or exceeds, 20 g/dL, and in conjunction with dehydration. Phlebotomy regimens are being used less frequently in the absence of symptoms, as they may be associated with an increased risk for cerebrovascular events (Ammash and Warnes, 1996). The duration and degree of hypoxemia and polycythemia are important historical factors in the evaluation of possible long-term residual cardiac muscle blood flow abnormalities.

Anesthetic considerations: It is important to maintain adequate preoperative hydration by encouraging liberal clear fluid intake in accordance with fasting guidelines or placement of an intravenous catheter and administration of maintenance fluids. Although the data are scant, preoperative hydration may be especially important as the hemoglobin concentration exceeds, 20 g/dL, and some consideration should be given to reducing red cell mass (pheresis, normovolemic phlebotomy) at higher hemoglobin values, perhaps particularly before more complicated procedures. There is an increased risk of bleeding in association with increased tissue vascularity, hemostatic abnormalities, and anticoagulants, and the risks of regional anesthesia in the presence of a hemostatic abnormality should be carefully considered. Of note, the effect of anemia on oxygen-carrying capacity is exaggerated as hemoglobin values "within

the normal range” in cyanotic patients may represent a significant deficit. Other aspects of anesthetic management should be based on the underlying pathophysiology, as discussed later.

Rhythm and Conduction Abnormalities

Arrhythmias and conduction defects have a major impact on the prognosis and management of patients who have undergone palliation or repair of CHD (Warnes and Deanfield, 2001). Rhythm disturbances that may be well tolerated in a structurally normal heart may be life threatening in a structurally or functionally abnormal heart. The etiology is multifactorial and includes damage to the arterial supply or direct injury to the sinoatrial node, atrioventricular (AV) node, and conduction system, atrial or ventricular scarring, chamber dilation or hypertrophy with resultant pathologic remodeling, and myocardial ischemia.

Arrhythmias may occur in the postoperative period or many years after surgery, and they tend to vary with the type of underlying heart disease and surgical procedures that have been performed (Vetter, 1991). *Supraventricular tachycardias* (atrial flutter/intraatrial reentrant tachycardia, atrial fibrillation) and *sinoatrial node dysfunction* (bradycardia, tachy-brady syndrome, exit block, sinus arrest) are more common in lesions that required extensive intraatrial surgery or have residual elevations in right atrial pressure, such as the atrial switch (Mustard or Senning) procedure for TGA, the Fontan procedure, and TOF repair. Isolated *right bundle branch block* is frequent after ventriculotomy. The QRS duration may be an independent predictor of arrhythmia, right ventricular dysfunction, and sudden death risk in patients after TOF repair (Gatzoulis et al., 2000a). Whether aberrant conduction and ventricular dyssynchrony are independent causes of ventricular dysfunction and, consequently, whether using biventricular pacing to restore normal activation-contraction patterns can prevent or reverse ventricular function in patients with dyssynchrony is currently under investigation (Cecchin et al., 2009). *Ventricular arrhythmias* are more common in lesions with residual ventricular pressure or volume load, as in aortic stenosis, hypertrophic cardiomyopathy, and TOF repair. Tachyarrhythmias and ventricular dysfunction are a dangerous combination and a cause of late sudden death (Vetter, 1991).

Anesthetic considerations: Any new onset of palpitations or syncope should be investigated before elective surgery. Consultation with a pediatric electrophysiologist can be very helpful to understanding the risk factors and causes for various rhythm disturbances in the CHD population, the need for additional diagnostic procedures, and the preferred pharmacologic and electrical approaches to the rhythm disturbances likely to arise. Such discussions help ensure availability and appropriate use of antiarrhythmic agents and cardioversion/defibrillation devices. The availability of similar expertise consultation during procedures is also advisable. In patients with tachyarrhythmias, there is at least theoretical reason to avoid agents with vagolytic or sympathetic-stimulating properties (e.g., pancuronium). The electrophysiologic impact of most inhaled or intravenous agents is probably modest.

Existing pacemakers should be checked preoperatively and the appropriate precautions taken in patients with *complete AV block*. There is the need for preoperative evaluation and temporary resetting or shutting down of pacemakers and implantable cardioverter defibrillators (Practice advisory, 2005), as well as

backup pacing (transcutaneous pacing) in the event of pacemaker malfunction. For high-risk patients, an external pacing or defibrillator unit should be in the operating room and pads applied around the time of induction of anesthesia. The need for and use of electrocautery (monopolar versus bipolar) in pacemaker-dependent patients should be discussed with both the surgeon and electrophysiologist. Implanted pacemakers and cardioverter defibrillators typically need to be interrogated and reprogrammed after the surgical procedure. The electrophysiologist may also be helpful for patient optimization. For example, consideration should be given to temporary pacing in select unpaced patients with bradycardia, as well as to radiofrequency catheter ablation in patients with amenable tachyarrhythmias, especially before major procedures.

Pulmonary Hypertension

In the unrepaired child, unrestricted left-to-right shunting with increased pulmonary blood flow produces a volume load on the heart and structural changes in the pulmonary vascular bed (medial hypertrophy progressing to necrotizing arteritis [Heath and Edwards, 1958]), leading to decreased myocardial function and pulmonary hypertension (mean PAP greater than 25 mm Hg). The time course for developing PVOD depends on the size and site of the shunt and age at surgery. Progression is more rapid when both the volume and the pressure load on the pulmonary circulation are increased, such as with a large VSD. For the majority of infants with an unrestrictive shunt, repair of the defect in the first year of life is usually associated with regression of the pulmonary vascular changes. Pulmonary hypertension develops more slowly with increased pulmonary blood flow in the absence of elevated pulmonary artery pressures, as with an ASD, where the absence of pulmonary hypertension into the third decade or beyond is not uncommon. Eisenmenger's syndrome is characterized by irreversible PVOD and cyanosis related to reversal of the left-to-right shunt (Wood, 1958).

Pulmonary hypertension and increased PVR can be reactive, fixed, or a combination of the two. The reactivity of the pulmonary vascular bed is determined during cardiac catheterization by the changes in PAP and PVR in response to vasodilators such as oxygen and nitric oxide (NO). Factors increasing PVR include hypoxemia, hypercarbia, acidemia, extremes of lung volume, hypothermia, and sympathetic stimulation associated with stress or light anesthesia. Acute dramatic increases in PAP or PVR result in increased RV afterload with decreased RV stroke volume; in addition, resultant RV dilation can cause a leftward shift of the interventricular septum, with further impairment of left ventricular (LV) function and filling, and decreased cardiac output. The ensuing hypotension can result in myocardial ischemia (particularly of the RV), bradycardia, and cardiac arrest. If an intracardiac communication (patent foramen ovale [PFO], ASD, VSD) is present, increases in PAP lead to right-to-left shunting and desaturation, albeit with better maintenance of LV filling and systemic cardiac output.

Anesthetic considerations: Severe pulmonary hypertension appears to impart major anesthetic risk, even for minor procedures (Ammash and Warnes, 1996; Raines et al., 1996; Daliento et al., 1998; Martin et al., 2002; Carmosino et al., 2007). This topic has been the subject of recent reviews (Subramaniam and Yared, 2007; Friesen and Williams, 2008). Suprasystemic pulmonary artery pressure is a significant predictor of major

complications in children with pulmonary hypertension undergoing noncardiac surgery (Carmosino et al., 2007). It is not possible to recommend a specific anesthetic technique as all anesthetic techniques have been used successfully. Of note, many perioperative deaths occur in the postoperative period (Lyons et al., 1995; Martin et al., 2002). In older patients with Eisenmenger's syndrome, most deaths appear to occur either as a result of the surgical procedure and not of anesthesia, or in the postoperative period because of complications such as atelectasis, pneumonia, worsening hypoxemia, or other end-organ dysfunction (Martin et al., 2002). Preoperative knowledge of the degree of pulmonary hypertension, pulmonary vascular reactivity, right ventricular dysfunction, and the presence of an intracardiac communication is imperative. For example, patients with severe pulmonary arterial hypertension, significant RV dysfunction, and no "pop-off" communication (i.e., right-to-left shunt) are probably the most at risk.

Acute right ventricular dysfunction and resultant low systemic cardiac output are the major pathophysiologic consequences of acute exacerbations in pulmonary artery pressure. The overall goals of anesthesia, therefore, are to provide adequate analgesia and anesthesia while minimizing increases in PVR and depression of myocardial function (Friesen and Williams, 2008). Likely methods include providing adequate preoperative sedation, high inspired oxygen, hyperventilation (respiratory alkalosis) if possible, adequate depth of anesthesia, maintenance of a normal to increased preload, early use of an inotrope to support RV function and systemic blood pressure (i.e., RV perfusion), and use of induction and maintenance agents that do not significantly reduce contractility or systemic blood pressure. Endotracheal intubation as a potential mechanical trigger of pulmonary vasoreactivity should be recognized; this also applies to extubation on emergence from anesthesia. In addition to adequate anesthetic depth, lidocaine spray to the vocal cords and trachea may offer some degree of protection. Noninvasive ventilation may be an attractive alternative to support adequate gas exchange during anesthesia and surgery under some conditions. Although allowing better control of oxygenation and ventilation, positive pressure ventilation increases RV afterload and decreases RV filling so that excessive inspiratory pressures and volumes, and positive end-expiratory pressure (PEEP), should be avoided. It is critical that pulmonary vasodilator therapy not be interrupted perioperatively, particularly prostacyclin (Flolan) infusions, whose discontinuation can result in severe rebound pulmonary hypertension in as little as 10 to 15 minutes. With severe pulmonary hypertension and known responsiveness of the pulmonary vasculature to NO, it is advisable to have NO available for immediate or even prophylactic administration. The use of invasive monitoring (e.g., arterial blood pressure) is usually determined by the nature of the surgical procedure. Because of the significant morbidity and mortality of anesthesia and surgery for the patient with severe pulmonary hypertension, a risk-benefit analysis involving the cardiologist, surgeon, and anesthesiologist is essential before performing elective procedures.

Myocardial Ischemia

Coronary artery anomalies (e.g., intramural coronary, anomalous origin from the other sinus or pulmonary artery) or problems associated with coronary reimplantation in the arterial

switch operation can result in myocardial ischemia. More commonly, in many patients with congenital defects and normal coronary arteries, ischemia is secondary to imbalances in myocardial oxygen supply and demand. There is some evidence, in lesions associated with abnormal load, including ones where the RV is the systemic ventricle, that coronary angiogenesis and capillary supply may not keep pace with increased muscle mass. This creates a relative supply-demand inequity. Subendocardial perfusion is largely determined by coronary perfusion pressure, which is the aortic diastolic pressure minus the ventricular end-diastolic pressure. In addition, the time interval available for perfusion (predominately diastole) is critical. As a result, the relationship between diastolic blood pressure, ventricular end-diastolic pressure, and heart rate determines whether subendocardial ischemia occurs. These three factors place patients with CHD at risk for ischemia in the following situations: (1) the *systolic pressure in the ventricles is abnormally elevated* (in some cases, the pulmonary ventricle may have suprasystemic pressures), thereby requiring elevated perfusion pressure; (2) the *aortic diastolic pressure* is compromised by diastolic runoff of aortic blood into the lower resistance pulmonary circuit in ductal-dependent and systemic-to-pulmonary artery shunts (coronary perfusion is further compromised if the coronary ostia are perfused with desaturated blood, as in patients with HLHS); (3) *elevated ventricular end-diastolic pressure*, which may be the result of impaired systolic function, impaired diastolic function (reduced ventricular compliance and relaxation, as seen with ventricular pressure overload), increased ventricular end-diastolic volume (volume overload), or a combination of these; and (4) *increases in heart rate*, which geometrically reduce the duration of diastole (the duration of systole stays relatively constant) so that the time available for coronary perfusion falls and consequently a higher diastolic pressure is necessary to maintain the same degree of subendocardial perfusion. In particular, the combination of a high heart rate and low diastolic blood pressure can produce significant ischemia.

Anesthetic considerations: Standard principles are followed to ensure that myocardial oxygen supply exceeds demand apply. In particular, maintaining aortic perfusion pressures, in combination with avoiding excessive tachycardia, frequently appears to be critical. With cyanotic lesions, a hemoglobin level above the normal acceptable range may be necessary.

Infective Endocarditis

The most recent guidelines of the American Heart Association concluded that only an extremely small number of cases of infective endocarditis could be prevented by antibiotic prophylaxis for dental procedures (Wilson et al., 2007). As a result, infective endocarditis prophylaxis for dental procedures is recommended only for patients with underlying cardiac conditions (Box 21-2) associated with the highest occurrence and risk for adverse outcome from infective endocarditis. Prophylaxis in this group is recommended for all dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa. The antibiotic is administered in a single dose before the procedure (Table 21-1). Administration of antibiotics solely to prevent endocarditis is not recommended for patients who undergo a genitourinary or gastrointestinal tract procedure.

Box 21-2 Cardiac Conditions Associated with the Highest Risk of Adverse Outcome from Endocarditis for Which Prophylaxis with Dental Procedures Is Recommended

Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
 Previous infective endocarditis
 Congenital heart disease (CHD)*

- Unrepaired cyanotic CHD, including palliative shunts and conduits
- Completely repaired congenital heart defect repaired with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure†
- Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (both of which inhibit endothelialization)

Cardiac transplant recipients with valve regurgitation resulting from a structurally abnormal valve

From Wilson W, Taubert KA, Gewitz M, et al: Prevention of infective endocarditis. Guidelines from the American Heart Association, *Circulation* 116:1736–1754, 2007.

*Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any form of CHD.

†Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after the procedure.

Rarely, patients scheduled for an invasive procedure have endocarditis, in which case the results of blood cultures should guide antibiotic therapy.

End-Organ Dysfunction and Injury

Unrestricted left-to-right shunting, in addition to increasing PAP and PVR, produces alterations in lung mechanics and airway compression. The primary effects on lung mechanics are a decrease in lung compliance and an increase in airway resistance (Bancalari et al., 1977; Stayer et al., 2004). Decreased compliance will necessitate higher than expected airway pressures, with care being taken not to insufflate the stomach during mask ventilation. Airway compression can result from dilated pulmonary arteries, left (or right) atrial dilation, massive cardiomegaly, or intraluminal bronchial obstruction (Berlinger et al., 1983). The pulmonary lymphatics are also compressed in these circumstances, perhaps explaining an increased incidence of pulmonary infectious symptoms in patients with large left-to-right shunts.

Neurologic injury and adverse neurodevelopmental outcome in CHD patients are multifactorial, with various contributions from genetic, lesion, and procedural elements (Newburger and Bellinger, 2006). Relatively pervasive issues include hyperactivity, diminished executive function, and various other neurocognitive abnormalities, especially in areas pertaining to speech and language and executive functions. Less commonly seen in the current era are seizures, stroke, and choreoathetosis. Structural brain abnormalities have been found with magnetic resonance imaging (MRI) in infants with CHD *before* any intervention, as well as after surgery or balloon atrial septostomy (Mahle et al., 2002; McQuillen et al., 2006; McQuillen et al., 2007; Miller et al., 2007; Andropoulos et al., 2010). Complex CHD may have anywhere from a mild to a profound impact on a child's psychosocial development (Horner et al., 2000). These issues necessitate additional sensitivity with the family, altering the amount of detail discussed in front of the child when obtaining informed consent, and precluding certain sedation or regional anesthetic techniques.

Chronic cyanosis, low systemic cardiac output, or high venous pressures (Damman et al., 2009) may over time contribute to the development of renal and hepatic insufficiency. This may not be evident on routine laboratory tests (e.g., serum creatinine or liver enzymes) but may predispose to perioperative dysfunction in response to relatively minor changes in organ perfusion and oxygen delivery, or to otherwise relatively mild toxic stresses (e.g., ketorolac). Cardiac catheterization (contrast nephropathy) increases the risk for perioperative renal dysfunction (Briguori et al., 2007).

Extracardiac Anomalies

Extracardiac anomalies occur in 25% of infants seen during the first year of life in patients with cardiac disease (Greenwood et al., 1975). The anomalies are often multiple and may result from chromosomal, genetic, teratogenic, or unknown causes.

Anesthetic considerations: A focused airway examination and thorough assessment of all organ systems is essential.

TABLE 21-1. Antibiotic Regimens for a Dental Procedure

Situation	Agent	Regimen: Single Dose 30 to 60 min Before Procedure	
		Adults	Children
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin OR cefazolin or ceftriaxone	2 g IM or IV	50 mg/kg IM or IV
		1 g IM or IV	50 mg/kg IM or IV
Allergic to penicillins or ampicillin—oral	Cephalexin* OR clindamycin	2g	50 mg/kg
		600 mg	20 mg/kg
	OR azithromycin or clarithromycin	500 mg	15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone† OR clindamycin	1 g IM or IV	50 mg/kg IM or IV
		600 mg IM or IV	20 mg/kg IM or IV

From Wilson W, Taubert KA, Gewitz M, et al: Prevention of infective endocarditis. Guidelines from the American Heart Association, *Circulation* 116:1736–1754, 2007.

*Or other first- or second-generation oral cephalosporin in equivalent adult or pediatric dosage.

†Cephalosporins should not be used for an individual with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.
 IM, Intramuscular; IV, intravenous.

Heart Transplant Recipients

The worldwide annual transplant rate in children is around 400, with the major indications being cardiomyopathy and congenital heart disease (Kirk et al., 2008). Factors to consider in this population are cardiac physiology and functional status, cardiac allograft vasculopathy, rejection, the side effects of immunosuppressive agents, and the development of renal dysfunction, hypertension, and malignancy. Efferent denervation results in a resting tachycardia (withdrawal of vagal tone) and impaired chronotropic response to stress. Afferent denervation results in lack of angina during myocardial ischemia and alterations in cardiac baroreceptors and mechanoreceptors. Cardiac physiology is restrictive, with mildly elevated filling pressures and a low-normal ejection fraction (Cotts and Oren, 1997). There may be sinus node dysfunction and there is a shift from β_1 to β_2 receptors.

Anesthetic considerations (see Chapter 20, Anesthesia for Congenital Heart Surgery, for a more complete discussion): The response to hemodynamic instability is slower (dependence on circulating catecholamines) and less robust. The denervated heart is preload dependent, with a reduced chronotropic response to hypotension or sympathetic stimulation. Restrictive physiology, particularly with rejection, increases the risk for pulmonary edema when fluid administration is not judicious. Sensitivity is increased to direct-acting catecholamines, β -blockers, adenosine, and verapamil, and it is decreased to digoxin and indirect-acting sympathomimetic agents. Myocardial ischemia is an ever-present threat from coronary artery vasculopathy. A new onset of dysrhythmias or heart block is ominous, suggesting rejection or myocardial ischemia. Immunosuppression requires strict aseptic technique, and the hypertension and nephrotoxicity associated with some agents and possible need for stress-dose corticosteroids need to be addressed.

PREOPERATIVE ASSESSMENT

CHD adds significant risk for morbidity and mortality in patients requiring noncardiac surgery (Warner et al., 1998; Coran et al., 1999; Baum et al., 2000; Martin et al., 2002; Carosino et al., 2007). The preoperative evaluation should be complete enough to provide a clear understanding of the pathophysiology of the cardiac defect, the implications of any corrective or palliative procedures, and the likely interactions with the planned surgical procedure. As a general rule, patients with CHD who are doing well clinically (i.e., have good functional status, few or no medications, and only routine medical examinations) tend to do well with anesthesia and surgery. Not surprisingly, the unrepaired or palliated patient presents a greater risk, as does the more complex and stressful surgical procedure. Broadly speaking, there are three categories of patients with CHD: those who have undergone a reparative (corrective) procedure, those who have undergone a palliative procedure, and those who have not undergone any procedure. The principles of anesthetic management are the same whether the patient is a child or an adult, and whether they have had a procedure or not.

History and Physical Examination

As the history may be incomplete or misleading with complex CHD (Colman, 2003), close collaboration with the patient's cardiologist is valuable. Additionally, the cardiologist can help

identify patients at high risk, clarify pathophysiologic issues, establish if the current clinical status is the best possible, and provide the findings of recent cardiologic studies. The focus of the history should be on the type of lesion and factors listed in **Box 21-1**, prior surgical and catheterization procedures and complications thereof, anesthetic experience, medications, allergies, and current functional status. Specific symptoms that should be sought are feeding difficulties and sweating in infants, poor growth, cyanotic spells, decreased activity level such as inability to keep up with healthy peers, fatigue, dyspnea, palpitations, chest pain, and syncope. New or worsening symptoms require cardiology consultation. Recent respiratory tract infections can cause changes in pulmonary vascular resistance and airway reactivity, increasing anesthetic risk in the setting of decreased pulmonary compliance, pulmonary hypertension, systemic-to-pulmonary artery shunts, and cavopulmonary anastomosis.

The physical examination should include general appearance, level of activity, presence of distress, and vital signs. Arterial oxygen saturation (SpO_2) varies with clinical status, but is expected to be above 94% after definitive procedures and in the range of 75% to 85% after palliative interventions that create shunted or intracardiac mixing circulations. Evidence of tachycardia, cyanosis, tachypnea, labored breathing, congestive heart failure, and poor peripheral perfusion should be sought. Airway assessment is important, because extracardiac anomalies may be present in up to one quarter of patients with CHD (Friedman, 1997). Peripheral pulses and four extremity blood pressures should be assessed in the setting of known or suspected aortic arch obstruction, previous or present Blalock-Taussig shunts, or after multiple cardiac catheterizations.

Special Investigations

The extent of laboratory testing depends on the child's clinical status and the complexity of the planned procedure. General recommendations for blood testing include the following: (1) hematocrit or hemoglobin if the child is pale, cyanotic, or undergoing a procedure with the potential for significant blood loss; (2) serum electrolytes for patients with renal dysfunction or those receiving diuretics, angiotensin-converting enzyme inhibitors, or digoxin (although preoperative electrolyte disturbances in children and young adults presenting for cardiac surgery are uncommon [Hastings et al., 2008]); (3) platelet count and coagulation studies for cyanotic children or those on anticoagulants or antiplatelet agents; and (4) blood typing and cross-matching if significant blood loss is anticipated. A chest radiograph should be obtained with new cardiorespiratory symptoms or abnormal findings on clinical examination, or if dictated by the surgical procedure. Cardiologic studies should be coordinated with the child's cardiologist, because some tests will have been recently completed, and investigations such as cardiac catheterization, Holter monitoring, exercise stress tests, and cardiac MRI mandate the cardiologist's input. The electrocardiogram is reviewed for rhythm abnormalities, impaired conduction, chamber enlargement, and ischemia. Changes from prior studies need to be explained before proceeding. Preoperative consultation with the cardiologist is essential for patients with pacemakers, with evaluation of the pacemaker and a clear plan made for appropriate adjustment on

the day of surgery (see earlier) (Practice advisory, 2005). In all but the simplest lesions, recent echocardiography is probably useful to document the current status of anatomy and ventricular function.

Procedure Scheduling

Institutional practices vary in the provision of anesthetic care for the highest-risk children with CHD. The aging of the CHD population has also resulted in adults with CHD undergoing noncardiac procedures at pediatric institutions (Warnes et al., 2001). In some institutions, anesthesia is provided by those who routinely practice pediatric cardiac anesthesia, and in others (including our own) pediatric anesthesiologists who do not practice cardiac anesthesia provide the care (Walker et al., 2009). The important point is that the case be assigned to an anesthesiologist who will understand the cardiac pathophysiology and know how to prevent and promptly deal with cardiac-related complications.

Ideally, patients with significant CHD should be scheduled for surgery early in the day. Clinical advantages include minimizing the effects of dehydration on hemodynamic function (particularly in infants and in cases of obstructive lesions, shunt-dependent circulations, cyanotic disease, single-ventricle physiology), possible reduction in the increased myocardial oxygen consumption associated with prolonged anxiety, provision of additional time to monitor patients in the postanesthesia care unit if discharge to home is being considered, greater availability of additional support if necessary, and avoidance of multiple care teams.

INTRAOPERATIVE MANAGEMENT

Premedication

The younger child will usually benefit from oral premedication before placement of an intravenous catheter. Premedication is especially beneficial for children with cyanotic CHD, particularly those with hypercyanotic spells, catecholamine-induced arrhythmias, and preexcitation syndromes. Although the potential effects of hypoventilation and hypoxemia on PVR need to be considered in the setting of pulmonary hypertension, sympathetic stimulation in a distressed patient may have a more deleterious effect.

Midazolam, 0.5 to 0.75 mg/kg orally, is usually sufficient, but for patients who have had multiple surgeries and catheterizations and thus are likely to be more anxious and perhaps more tolerant to sedative medications, it is often necessary to increase the dose to 1 mg/kg (Masue et al., 2003); sometimes oral ketamine, 3 to 10 mg/kg, is added as well (Auden et al., 2000; Funk, et al., 2000). Troublesome ketamine-stimulated secretions can usually be controlled with glycopyrrolate once intravenous access is established. If the patient has intravenous access in situ or after placement, a small bolus of midazolam, 0.05 mg/kg, repeated as necessary, will provide anxiolysis and facilitate separation from the parents. Intramuscular sedation with ketamine, 3 to 5 mg/kg, with or without midazolam, 0.05 to 0.1 mg/kg, may be necessary for the uncooperative or combative child who will not accept oral premedication and for whom an intravenous induction is most desirable. A combination of

oral meperidine and pentobarbital for heavy premedication of CHD patients has been used with a substantial track record of safety and success (Nicolson et al., 1989), but insufficient effect and rage-like reactions (most likely attributable to pentobarbital) are known side effects. After any heavy premedication, the anesthesiologist should remain with the patient, and, particularly for patients with cyanotic CHD, oxygen saturation should be monitored and oxygen administered as needed (Stow et al., 1988; DeBock et al., 1990).

Anesthetic Technique

Standard principles of anesthetic management apply to patients with CHD who present for noncardiac surgery. The choice of anesthetic technique (local, regional, or general anesthesia), selection of pharmacologic agents, and requirement for invasive monitoring are determined by the physical (functional) status of the patient and the nature of the planned procedure. Cardiac medications, apart from diuretics, angiotensin-converting enzyme inhibitors, and angiotensin receptor antagonists (which are typically held), are generally administered on the morning of surgery. The patient's cardiologist should discuss with the surgeon the withholding of aspirin or other antiplatelet agents. Depending on the circumstances, the institution of an appropriate perioperative anticoagulation strategy may be necessary for patients on coumadin. In general, patients with prosthetic valves or a history of stroke and other thromboembolic events mandate the greatest degree of concern. Approaches to anticoagulation vary and depend to some extent on both the specific indication and the degree of concern regarding the relative risks. Management strategies vary from temporarily discontinuing coumadin (and usually following the prothrombin time and international normalized ratio [INR] and performing the surgery in the ensuing 24 to 48 hours), or discontinuing coumadin and instituting low-molecular-weight heparin prior to surgery, or discontinuing coumadin and administering periprocedural intravenous heparin.

For *general anesthesia*, an intravenous induction is recommended for patients with limited cardiac reserve, particularly those at risk for a marked decrease in cardiac output or circulatory instability with induction. Such high-risk cases include the more severe presentations of ventricular dysfunction, outflow tract obstruction, and pulmonary hypertension. Patients with cyanotic lesions resulting from right-to-left shunts have a slower inhalation induction because of the effects of reduced Q_p (Tanner et al., 1985). Dependency on a systemic-to-pulmonary artery shunt (and hence maintenance of adequate cardiac output and peripheral resistance) may also be better served by a hemodynamically stable intravenous induction, particularly if there is evidence (e.g., echocardiographic, history of decreasing arterial oxygen saturation or rising hemoglobin) of shunt narrowing or outgrowth over time.

Etomidate lacks significant hemodynamic effects in clinical dosages in children and adults (Gooding et al., 1979; Sarkar et al., 2005), and ketamine provides hemodynamic stability through sympathetically mediated increases in heart rate and systemic vascular resistance, albeit with direct myocardial depressant effects (Murray et al., 1984). There is no technique that guarantees preservation of myocardial function and hemodynamic stability during anesthetic induction at the extreme of ventricular dysfunction (e.g., severe end-stage dilated cardiomyopathy),

valvar obstruction, or pulmonary hypertension; reasons are multiple and include increased aortic impedance (both ketamine and etomidate) in the face of absent myocardial reserve to respond, deleterious effects of institution of positive pressure ventilation, and altered catecholamine tone. Clearly, only absolutely necessary or emergent procedures should be undertaken for such patients. Preoperative treatment with inotropes or inodilators (e.g., milrinone), or both, for patients with severe ventricular dysfunction or balloon dilation of severe valvar stenosis are examples of preoperative optimization techniques that should be considered. In addition to including inotropic support, the ability to rapidly convert to support with extracorporeal membrane oxygenation should be available (Duncan et al., 1998; Thiagarajan et al., 2007).

Although reports of the effect of ketamine on pulmonary vascular resistance are conflicting (Murray et al., 1984; Hickey et al., 1985; Berman et al., 1990; Maruyama et al., 1995), it can be used without risk of major increases in PVR in patients with CHD provided elevations in arterial CO₂ are prevented (Hickey et al., 1985). Opioid-benzodiazepine techniques are also suitable, particularly if postoperative mechanical ventilation is planned (Hickey and Hansen, 1984). Remifentanyl provides profound analgesia with short recovery times, but it can be associated with bradycardia and hypotension in high dosages (Ross et al., 2001) and in association with sevoflurane (0.6 minimum alveolar concentration) (Foubert et al., 2002); bradycardia can be prevented with pretreatment with glycopyrrolate, 0.006 mg/kg (Reyntjens et al., 2005). Propofol use should probably be limited to children with adequate cardiovascular reserve who can tolerate mild to moderate decreases in systemic vascular resistance, contractility, and heart rate (Williams et al., 1999). Sevoflurane is associated with less myocardial depression and better hemodynamic stability than halothane, particularly in infants (Holzman et al., 1996; Wodey et al., 1997; Rivenes et al., 2001; Russell et al., 2001; Laird et al., 2002). Exposing neonates to large amounts of opioids and benzodiazepines can lead to tolerance that may persist (Mao and Mayer, 2001; Suresh and Anand, 2001), whereas inadequate analgesia for infants may lead to specific centrally mediated pain sensitization and thus increased sensitivity to pain and greater fear of painful procedures (Porter et al., 1999; Lowery et al., 2007). This has implications for premedication, opioid-benzodiazepine anesthesia, and postoperative pain control.

Regional anesthesia, alone or in combination with general anesthesia, has been used successfully in patients with CHD (Selsby and Sugden, 1989; Holzman et al., 1992; Martin et al., 2002; Sacrista et al., 2003; Katznelson et al., 2005; Walker et al., 2009), including those with shunt physiology and left-sided obstructive lesions. In infants and young children (<3 to 4 years of age), this success is likely to be at least in part due to minimal effects of regional blockade on α -adrenergic tone and SVR. As complex CHD can have a profound effect on emotional life and psychosocial development (Horner et al., 2000; Reid et al., 2006), substantial persuasion may be necessary in the older child or young adult when primarily regional or local anesthetic techniques are deemed to be indicated to reduce anesthetic risk.

Monitoring and Vascular Access

Standard monitoring according to the guidelines of the American Society of Anesthesiologists is recommended, with the need for invasive monitoring determined by the physical status of the

patient and the complexity of the planned procedure. As discussed earlier, the site of previous Blalock-Taussig (BT) shunts, the presence of aortic arch obstruction, and a history of multiple cardiac catheterizations need to be considered when choosing a site for blood pressure cuff or arterial line placement. Classic BT shunts (subclavian artery-to-pulmonary artery anastomosis with ligation of distal subclavian artery) result in decreased or absent pulses on the side of the shunt. A modified BT shunt (synthetic graft between subclavian or innominate artery and pulmonary artery) may or may not result in stenosis of the subclavian artery with decreased pressure on the side of the shunt. The left subclavian artery is sometimes used as part of a flap in the repair of coarctation of the aorta. Lower limb blood pressures may be lower after narrowing or occlusion of the femoral arteries as a result of cardiac catheterization, or as a result of a technically inadequate repair (e.g., coarctation, arch reconstruction in patients with HLHS). Arterial access may be limited after radial artery cutdowns or femoral artery occlusion from multiple cardiac catheterizations.

Venous access may be limited as the result of multiple surgical procedures, cardiac catheterizations, and intensive care admissions. Multiple cardiac catheterizations can also lead to femoral vein occlusion. It is imperative to avoid the introduction of air into the venous system, leading to systemic air embolization in patients with intracardiac or intravascular communications and the potential for right-to-left shunting. For the more complex surgical procedures, central venous catheters allow monitoring of trends in central venous pressure and oxygen saturation (Dueck et al., 2005), as well as fluid and inotrope administration. Internal jugular or subclavian vein catheters can be quite useful but also carry a risk for thrombosis in the superior vena cava, as well as postoperative catheter-associated infection. The thrombotic complication can be disastrous in patients with a cavopulmonary anastomosis; consideration should be given to placing a femoral venous catheter if central access is necessary in such patients. Central venous catheters should be used for the shortest duration possible, access frequency limited, and special access ports and disinfection techniques employed to reduce the risk for catheter-associated infection. A low-dosage postoperative heparin infusion (10 IU/kg per hr) through the catheter can reduce the risk for thrombosis. Urinary catheters are placed as a guide to the adequacy of cardiac output and renal perfusion if major fluid shifts or blood losses are anticipated or if the procedure will be prolonged.

Transesophageal echocardiography (TEE) has been shown in adults to be useful for intraoperative assessment of ventricular preload and function (Schulmeyer et al., 2006), but the often complex anatomy in patients with CHD mandates additional expertise (Rivenes et al., 2001; Ikemba et al., 2004). TEE is likely to be used with increasing frequency in patients with and without CHD undergoing noncardiac procedures for monitoring of ventricular function and preload, particularly as the technology becomes more available and anesthesiologists become more practiced in its use (Mahmood et al., 2008). Intermittent transthoracic echocardiography is an alternative approach, provided that it is practical, there are adequate acoustic windows, and personnel with expertise are available.

Use of pulmonary artery catheterization (PAC) is controversial (Bernard et al., 2000), as added benefits have not convincingly been demonstrated with acquired heart disease. The risks are increased in the setting of pulmonary hypertension, and correct placement may be more difficult in some patients with

CHD (absence of pulsatile flow, need to traverse atrial baffles). PAC can be placed under fluoroscopic guidance in the cardiac catheterization laboratory before elective, major noncardiac surgery (e.g., spinal fusion) in patients with a Fontan circulation or severe ventricular dysfunction. In these circumstances, PAC can be useful as an indicator of systemic ventricular filling (pulmonary artery capillary wedge pressure) and oxygen delivery (pulmonary artery saturation). In the future, this role may be supplanted by TEE.

POSTOPERATIVE MANAGEMENT

The preoperative clinical status, nature of the surgical procedure, and intraoperative course determine whether postoperative admission will be to a general surgical ward, a cardiology ward, or an intensive care unit. Hemorrhage, hypoxia, hypoventilation, fever, uncontrolled pain, or myocardial ischemia may convert a well-tolerated surgical procedure into a crisis. Day surgery is possible for those patients whose cardiac status is well controlled, who have undergone a minor surgical procedure, and who have attained their baseline status prior to discharge. Higher-risk patients, particularly those undergoing major surgical procedures, are usually best managed in an intensive care setting. It is our practice to admit the child to the cardiology ward if changes in cardiac physiology pose a greater risk than complications from the surgical procedure. The healthier cardiac patient with a more complex surgical procedure is usually admitted to the appropriate surgical ward with cardiology consultation and follow-up. Standard fluid replacement guidelines are employed, and postoperative laboratory testing is guided by intraoperative blood loss, fluid shifts, and the child's preoperative status. Effective pain management is important and can be especially difficult if the patient is tolerant to sedatives and narcotics, or has recently been discharged after prolonged hospitalization and still on a withdrawal regimen. Involvement of colleagues with pediatric pain management expertise is recommended (see Chapter 15, Pain Management). Despite the best-possible anesthetic and procedure, it is in the postoperative period that complications are still likely to develop. In our experience, these are usually in patients with subtle or occult preexisting end-organ dysfunction, occurring as a consequence of chronic cyanosis, low cardiac output, or high venous pressures (or a combination of these). Certainly, the ability of various anesthetic agents, other drugs, and the surgical procedure to compromise organ blood flow or alter organ function plays a role as well.

OUTCOMES OF COMMON CONGENITAL HEART DEFECTS

Tetralogy of Fallot

Tetralogy of Fallot is the most common cyanotic lesion and accounts for approximately 10% of all CHD (Hoffman and Kaplan, 2002; Therrien and Webb, 2003). See related video online at www.expertconsult.com. The defect is characterized by anterocephalad deviation of the outlet septum, resulting in right ventricular outflow tract obstruction, a nonrestrictive VSD, aortic override, and right ventricular hypertrophy. The subpulmonary obstruction may be fixed or dynamic, it is invariably associated

with some degree of pulmonary valve stenosis, and there may be hypoplasia of the main and branch pulmonary arteries as well. Associated cardiac anomalies include a right-sided aortic arch (25%), a second VSD (3%), and coronary artery anomalies (anterior descending coronary artery arising from the right coronary artery and crossing the RV outflow tract [3%]). TOF is frequently associated with a 22q11 deletion, and DiGeorge and velocardiofacial syndromes.

Hypercyanotic episodes ("tet spells") are a hallmark of unrepaired TOF and can be life threatening, with increased cyanosis, syncope, and convulsions. Spells occur more frequently in cyanotic patients, with a peak frequency between 2 and 3 months of age. Infundibular spasm may play a role, and crying, defecation, feeding, fever, and awakening can be precipitating events. Spells are self-aggravating in that hypoxia induces a decrease in SVR, which further increases the right-to-left shunt. Paroxysmal hyperpnea increases oxygen consumption through increased work of breathing. Tet spells are managed as follows:

1. Nonanesthetized children are treated initially with 100% oxygen, knee-chest position, and morphine sulphate (0.05 to 0.1 mg/kg IM or IV) to relieve distress and air hunger. Ketamine is a suitable alternative (Tugrul et al., 2000).
2. Intravenous crystalloid (15 to 30 mL/kg) or colloid is used to increase preload and decrease the dynamic nature of the RV outflow tract spasm.
3. For continuing hypoxemia, an α -agonist (phenylephrine 0.5 to 2 mcg/kg) is used to increase SVR.
4. Judicious use of propranolol (0.1 mg/kg) or esmolol (0.5 mg/kg followed by an infusion of 50 to 300 mcg/kg per minute) slows the heart rate and relaxes the infundibulum. β -Adrenergic agonists are contraindicated.
5. Sodium bicarbonate (1 to 2 mEq/kg) can be administered to correct the metabolic acidosis, increasing the SVR and lowering the PVR.

If the spell persists, the child can be anesthetized, the trachea intubated, and mechanical ventilation instituted with 100% oxygen, low inspiratory pressures, and long expiratory times to promote venous return and antegrade flow across the RV outflow. An inhalation agent may be beneficial to reduce hyperdynamic right ventricular outflow obstruction. Manual compression of the abdominal aorta can be an effective means to temporarily increase SVR and decrease cyanosis in the anesthetized patient. In the operating room, there may be the need to proceed very rapidly to cardiopulmonary bypass (CPB) if the spell is severe and not resolving. Resuscitation with extracorporeal membrane oxygenation (ECMO) should be considered for refractory episodes when immediate operative intervention is not possible (Duncan et al., 1998; Thiagarajan et al., 2007).

Primary complete repair for the neonate or infant has largely replaced the traditional two-stage repair sequence of arterio-pulmonary shunting in early infancy followed by later repair (Pigula et al., 1999). Thus, it is becoming fairly unusual to encounter an unrepaired or shunted infant with TOF. Right ventricular outflow obstruction is relieved by resection of hypertrophied muscle bundles and enlargement of the outflow tract with a pericardial patch. Although pulmonary valve-sparing techniques are increasingly being employed, a very small pulmonary annulus or a very stenotic pulmonary valve dictates placement of the patch across the annulus (transannular patch), resulting in pulmonary insufficiency. The VSD is closed with a Dacron patch. If a major coronary artery crosses the RV outflow

tract (RVOT), or with long-segment pulmonary atresia, a right ventricle-to-pulmonary artery conduit rather than a pericardial patch is placed.

The majority of problems after TOF repair relate to chronic abnormal RV loading—that is, pressure loading from residual or recurrent RVOT obstruction and volume loading primarily from pulmonary regurgitation (issues shared by other lesions that require RVOT reconstruction or RV-PA conduit such as truncus arteriosus, pulmonary atresia, and the Rastelli procedure for TGA). In the long term, there is progressive RV dysfunction and the development of arrhythmias with increased risk for sudden death. Factors that have been associated with reduced long-term survival include older age (>4 years) at repair, initial palliative shunting procedures, significant RV hypertension, and volume loading of the RV (Gatzoulis et al., 2000a; Karamlou et al., 2006). Timely pulmonary valve replacement in children and young adults, before irreversible severe RV dilation and systolic ventricular dysfunction accrue, has become a major consideration (Therrien et al., 2000). Many patients after repair are asymptomatic with normal activity, although right ventricular dysfunction may progress and be evident only on exercise testing (decreased maximal aerobic capacity and endurance), stress echocardiography, or radionuclide techniques. Cardiac MRI is particularly useful to quantify RV systolic function, RV volume, the degree of pulmonary regurgitation, and sites of RVOT obstruction (Geva and Powell, 2008). The presence of tricuspid regurgitation is a likely surrogate for substantial RV dysfunction. Right bundle branch block is commonly seen after repair, whereas atrial tachyarrhythmias (atrial flutter or intra-atrial reentrant tachycardia) arise in about one third of adults. Although the presence of premature ventricular contractions (PVCs) is common in asymptomatic patients (approximately 10% on routine electrocardiogram, 30% on exercise stress testing, and up to 50% during Holter monitoring), it is often of low grade and has not been a predictor of patients at risk for sudden death. Although a QRS duration of 180 msec or greater is a highly sensitive marker for sustained ventricular tachycardia and sudden death, its positive predictive value is low (Gatzoulis et al., 1995). LV dysfunction and dyssynchrony have been observed in patients with TOF and was associated with QRS duration, such that abnormal LV mechanics in combination with RV dysfunction may explain the relation between QRS duration and adverse cardiac outcomes (Tzemos et al., 2009).

However, the presence of monomorphic ventricular tachycardia in a symptomatic patient (syncope and palpitations) is significant and necessitates treatment. Electrophysiologic methods are to assess and ablate atrial or ventricular arrhythmias and for deciding on the need for an implantable cardioverter-defibrillator (Khairy et al., 2008b).

Anesthetic considerations: The degree of RV dysfunction needs to be defined and consideration given to preoperative interventional cardiac catheterization to reduce the impact of significant residual lesions (RVOT or PA obstruction, residual VSD, collaterals causing volume loading, arrhythmias). In the presence of pulmonary regurgitation or RV dysfunction, factors that increase PVR should be avoided, as should factors detrimental to RV myocardial supply-demand relationship (tachycardia, hypotension, anemia, and acidosis are detrimental). The role of pulmonary valve replacement in patients with severe pulmonary regurgitation, RV volume overload, and RV dysfunction (all best assessed by cardiac MRI) remains to be defined. Right ventricular filling should be maintained, understanding

that excessive volume (or dysfunction) can lead to RV dilation and resultant LV dysfunction (ventricular interdependence). Prophylactic administration of an inotrope to improve RV contractile performance should be considered in patients with significant RV dysfunction. (See Pulmonary Hypertension, earlier.) A means for external defibrillation and pacing should be readily available. Late development of LV dysfunction is another consideration in patients with TOF as they age.

Transposition of the Great Arteries

Transposition of the great arteries (D-TGA) accounts for 3% to 10% of all CHD (Hoffman and Kaplan, 2002). See related video online at www.expertconsult.com. Ventriculoarterial discordance results in the aorta arising from the anatomic right ventricle and the pulmonary artery from the left ventricle. Associated defects include a VSD (40% to 45%), VSD with LV outflow tract obstruction (10%), or variability in coronary artery pattern (Mayer et al., 1990). A much less common form of TGA is congenitally (physiologically) “corrected” TGA (L-TGA), in which there is both ventriculoarterial and atrioventricular discordance (i.e., a series circulation in which the right atrium connects via the mitral valve to the LV and then the PA, and the left atrium connects via the tricuspid valve to the RV and then the aorta). Congenitally corrected transposition (without associated cardiac lesions) may go undetected for decades until the RV, which is the systemic ventricle, begins to fail. This group is at increased risk for the spontaneous development of complete heart block.

D-TGA produces two parallel circulations with recirculation of systemic and pulmonary venous blood. Adequate systemic oxygenation and survival are dependent on one or more communications between the two circuits to allow intercirculatory mixing; these communications can be intracardiac (ASD, VSD) or extracardiac (PDA, bronchopulmonary collaterals), or both. For initial palliation, the infant is maintained on a prostaglandin E₁ (PGE₁) infusion to support adequate intercirculatory mixing via the PDA. With adequate mixing and a good-sized PDA, excessive pulmonary blood flow can result, placing a volume load on the ventricle and inducing pulmonary congestion as a result of an increased Q_p:Q_s ratio, and causing decreased systemic perfusion. A general rule of thumb aims for arterial saturations in the 75% to 85% range in the nonintubated, spontaneously ventilating patient. With inadequate intracardiac mixing, frequently manifesting as excessive cyanosis and poor perfusion, a *balloon atrial septostomy* is performed in the catheterization laboratory or at the bedside to improve mixing and to reduce left atrial pressure. This can be an urgent or emergent procedure performed shortly after delivery. In patients with reduced pulmonary blood flow or poor intercirculatory mixing (most often those with an intact ventricular septum) despite PGE₁ and a widely patent atrial communication, volume loading often improves the situation, which at times requires further augmentation by inotropic support to increase overall myocardial function and venous blood saturation. In patients demonstrating significant overcirculation (e.g., tachypnea, pulmonary congestion on chest x-ray, systemic hypoperfusion, acidosis), reduced fraction of inspired oxygen (Fio₂) via blending of atmospheric air with nitrogen, or controlled ventilation with induced hypercarbia via added inspired CO₂, has been used to try to reduce excessive PBF. More frequently now, this situation is managed with circulatory support as needed (e.g., dopamine),

controlled ventilation, and early surgical repair. Infants with evidence of multiple organ dysfunction after severe cyanosis and hypoperfusion are generally better managed with a period of stabilization and recovery, facilitated by the aforementioned measures to improve mixing and oxygen delivery, before undergoing corrective surgery.

D-TGA is currently repaired anatomically by the *arterial switch (Jatene) operation* (ASO) (Jatene et al., 1976). The pulmonary artery and aorta are transected distal to their respective valves. The coronary arteries are excised with a button of surrounding tissue and reimplanted into the proximal pulmonary artery (neoaorta). The great arteries are then switched, with the pulmonary artery brought anterior (Lecompte maneuver) and anastomosed to the proximal aorta (right ventricular outflow) and the aorta anastomosed to the proximal pulmonary artery (left ventricular outflow). Most patients with TGA have coronary anatomy that is suitable for coronary reimplantation. The variant

of D-TGA with VSD and severe LVOT obstruction precludes the ASO. In this setting, the *Rastelli procedure* is performed, in which the VSD is repaired by a patch that directs blood from the left ventricle through the defect into the aorta (and also closes the VSD), and a valved conduit is placed from the right ventricle to the main pulmonary artery. With the Rastelli procedure, the LV functions as the systemic ventricle, but conduit degeneration and stenosis are inevitable (Warnes, 2006).

The *atrial switch procedure* (Mustard, Senning), which revolutionized the management of infants with TGA, is now rarely used. It is a physiologic repair in which a baffle in the atrium directs systemic venous blood to the mitral valve (and consequently to the LV and pulmonary artery) and pulmonary venous blood to the tricuspid valve (and consequently to the RV and aorta) (Fig. 21-1).

The *atrial switch* procedures provide excellent midterm results (15-year survival, 77% to 94%; 20-year survival, 80%)

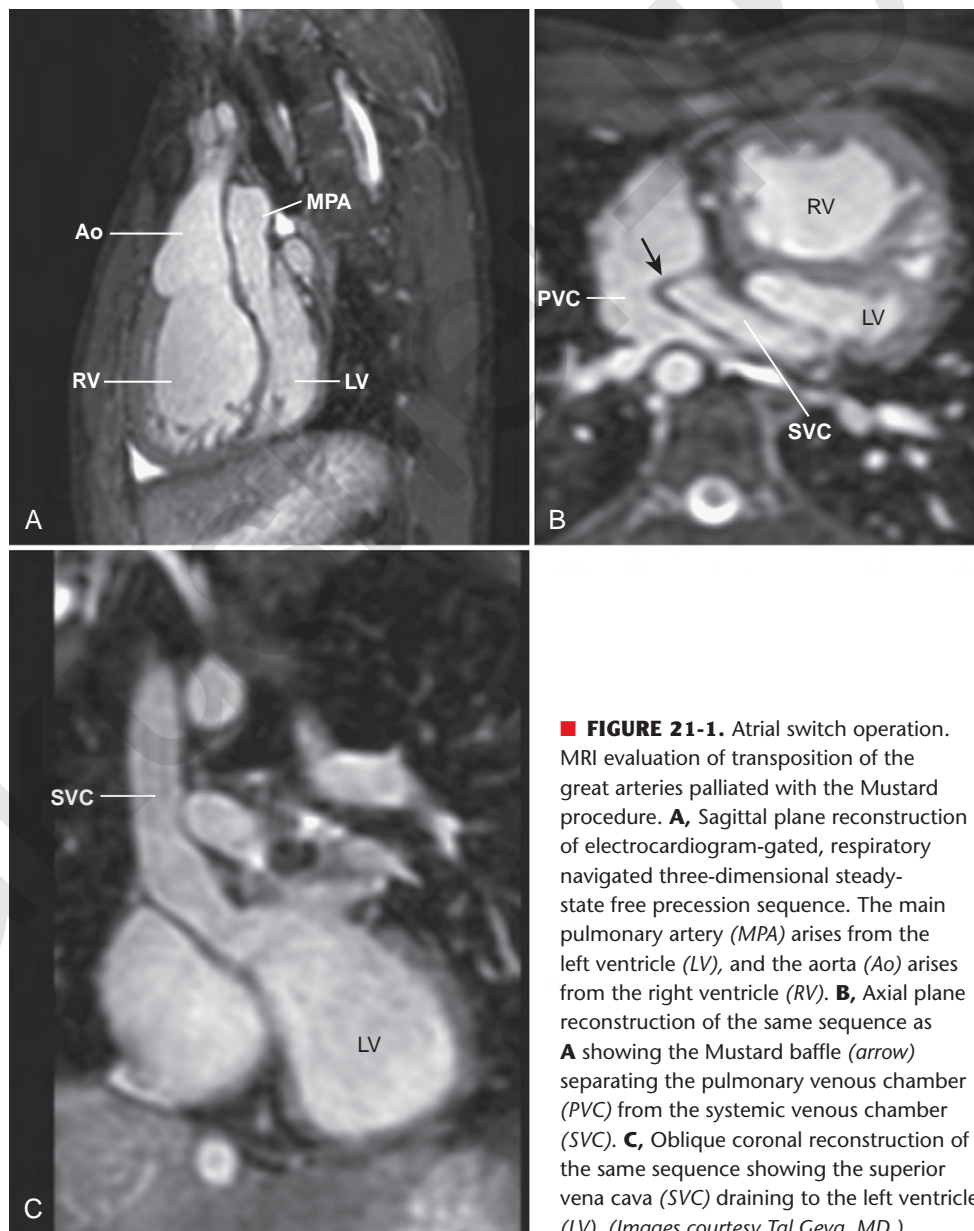

FIGURE 21-1. Atrial switch operation. MRI evaluation of transposition of the great arteries palliated with the Mustard procedure. **A**, Sagittal plane reconstruction of electrocardiogram-gated, respiratory navigated three-dimensional steady-state free precession sequence. The main pulmonary artery (*MPA*) arises from the left ventricle (*LV*), and the aorta (*Ao*) arises from the right ventricle (*RV*). **B**, Axial plane reconstruction of the same sequence as **A** showing the Mustard baffle (*arrow*) separating the pulmonary venous chamber (*PVC*) from the systemic venous chamber (*SVC*). **C**, Oblique coronal reconstruction of the same sequence showing the superior vena cava (*SVC*) draining to the left ventricle (*LV*). (Images courtesy Tal Geva, MD.)

(Merlo et al., 1991; Helbing et al., 1994; Wilson et al., 1998; Sarkar et al., 1999; Williams et al., 2003), with many patients able to lead fairly normal lives into their third and fourth decades. In the long term, there is progressive deterioration in RV function (Piran et al., 2002) and development of tricuspid regurgitation (which is the *systemic* atrioventricular valve in this circulation) with heart failure, arrhythmias, and risk for sudden death (Wilson et al., 1998). Even in asymptomatic patients, exercise testing demonstrates moderate to severe limitations in RV function and maximal aerobic capacity. Sinus rhythm is maintained in only 40% to 50% of patients (Deanfield et al., 1988), with the frequent occurrence of sick sinus syndrome. Atrial flutter parallels the development of ventricular dysfunction (Gatzoulis et al., 2000b) and is experienced in one third or more of patients, 20 years after surgery (Puley et al., 1999). Intraatrial baffle leaks can result in shunting and hypoxemia. Baffle obstruction of the systemic venous return can cause superior vena cava (SVC) syndrome, hepatic congestion, ascites, and peripheral edema, whereas pulmonary venous baffle obstruction can cause pulmonary edema and pulmonary hypertension. Subendocardial perfusion defects of the systemic (right) ventricle have been noted in a significant number of patients.

The ASO is associated with an early hospital mortality of less than 5% in experienced centers (Hutter et al., 2002; Warnes, 2006; Raisyk et al., 2007). At 15 years, good LV function and sinus rhythm are maintained in 96.4% and 98.1% of patients, respectively (Losay et al., 2001). The ongoing risk for death is less than after the atrial switch operation, and it is related to coronary events and arrhythmias. In long-term follow-up, patients remain in good condition, and the majority are New York Heart Association functional class I (Hutter et al., 2002). The most frequent need for reintervention has been the development of supravalvar (anastomotic) pulmonary artery stenosis, less commonly supravalvar aortic stenosis. These are frequently amenable to balloon dilation, although reoperation may occasionally be necessary. Neoaortic insufficiency (i.e., the anatomic pulmonary valve now located in the aortic position) appears to be occurring with increasing frequency as more patients accrue and age. At present, it is usually of mild or lesser severity and thus far has infrequently required reintervention; however, the long-term implications of this problem are concerning. Another potential complication that is being found more frequently and requires ongoing attention is the development of coronary artery stenoses. Coronary obstruction is an infrequent clinical complication outside of the immediate perioperative period, where technical difficulties associated with coronary reimplantation can result in myocardial ischemia and problems related thereto. Overall, the incidence of coronary events has a bimodal pattern, with a high early incidence and low late incidence (Legendre et al., 2003). The arteries display varying degrees of proximal eccentric intimal proliferation (Pedra et al., 2004) and concentric intimal smooth muscle hyperplasia with preserved tunica media (Bartoloni et al., 2006), suggesting the potential for the development of early atherosclerosis in the reimplanted coronary arteries. Noninvasive tests are not sufficiently sensitive to detect delayed coronary artery stenosis, and coronary artery angiography or intracoronary ultrasound is required (or both); it is presently unclear whether such testing should be a mandatory component of surveillance in all patients who have undergone an ASO (Pedra et al., 2004). If needed, coronary revascularization can be achieved using coronary angioplasty in most cases (Raisyk et al., 2007).

Anesthetic considerations: After an uncomplicated ASO, most patients can be managed in the same way as those with a structurally normal heart, but with an index of suspicion for coronary artery disease. Severe pulmonary artery stenosis can be managed with interventional cardiac catheterization prior to elective procedures. Anesthesia for patients after the *atrial switch* operation should be based on the knowledge that this can become an increasingly fragile circulation with limited physiologic reserve as patients age. The potential for decreased ventricular function is substantial, particularly of the systemic right ventricle, as well as for arrhythmias and end-organ dysfunction. Although some volatile anesthetic will be tolerated by most of these patients, many will benefit from the more hemodynamically stable induction and maintenance regimens that have been discussed earlier. As elsewhere, it may be prudent to start an inotrope infusion at the time of or shortly after induction in those with more severe degrees of ventricular dysfunction. A significant number of these patients have a pacemaker, and the appropriate guidelines need to be followed (see earlier) (Practice advisory, 2005). Baffle leaks can result in cyanosis and increase the risk for systemic embolization of air or debris; consideration should be given to device closure in the catheterization laboratory prior to elective procedures associated with a high risk for embolization.

Single-Ventricle Physiology

A single ventricle is defined as the presence of two atrioventricular valves with one ventricular chamber, or a large dominant ventricle with a diminutive opposing ventricle (Keane and Fyler, 2006c). See related video online at www.expertconsult.com. Single ventricle or *univentricular* hearts encompass a wide variety of lesions that include tricuspid atresia or severe tricuspid stenosis, double-inlet single ventricle (usually left), single ventricle with common atrioventricular valve (unbalanced complete AV canal, heterotaxy variants), HLHS, and some forms of double-outlet right ventricle and pulmonary atresia with intact ventricular septum. Initial management is aimed at optimization of systemic oxygen delivery and perfusion pressure. Subsequent management is aimed at reducing the volume load on the ventricle (superior cavopulmonary connection or Glenn procedure) and finally achieving a series circulation with fully saturated systemic arterial blood (Fontan procedure). This is usually achieved through a staged approach. Although, collectively, single-ventricle defects are relatively rare, they account for a disproportionate share of repeated procedures and resultant morbidity and mortality.

Unoperated *single-ventricle physiology* is characterized by complete mixing of systemic and pulmonary venous blood at the atrial or ventricular level (or both). If there is no obstruction to pulmonary or systemic outflow, the amount of flow to each circulation is determined by the relative resistances of the pulmonary and systemic vascular beds. With no obstruction to pulmonary blood flow and the normal postnatal regression in PVR, PBF gradually increases and results in congestive heart failure. Obstruction to PBF will result in progressive cyanosis in the absence of a patent ductus arteriosus. Systemic outflow obstruction will result in increased PBF, CHF, and systemic hypoperfusion. In patients with single-ventricle physiology, an arterial saturation of 75% to 80% is felt to be indicative

of a relatively balanced circulation with a $Q_p:Q_s$ at or near 1:1 (assuming pulmonary venous saturation of 95% to 100% and mixed venous saturation of 50% to 55%) (Rudolph, 1974). However, even with a “balanced” $Q_p:Q_s$ of 1:1, the systemic ventricle is essentially pumping double the normal cardiac output. This gives some appreciation for the even greater degrees of systemic ventricular volume overload that is imposed by increased amounts of PBF.

The initial procedure in the neonatal period varies with the anatomy. In the presence of approximately the right amount of pulmonary obstruction to balance the circulations, no procedure will be required in the newborn period.

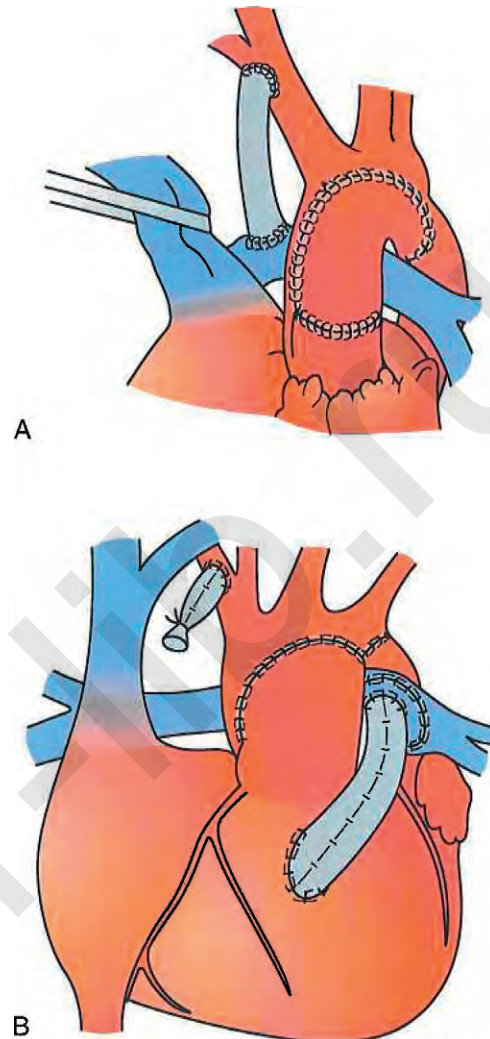

Norwood Operation

The Norwood procedure, also referred to as stage I single-ventricle palliation, is performed for patients with HLHS and its variants (Norwood et al., 1983) or when the pathway to the aorta from the systemic ventricle is obstructed. The pulmonary artery is transected just proximal to its bifurcation, and the pulmonary artery is anastomosed end to side, or side to side, to the ascending aorta, with reconstruction of the ascending and transverse aorta. In the neonatal period, PBF is supplied by a modified BT shunt or RV-to-PA conduit (Sano et al., 2003) (Fig. 21-2). When pulmonary venous blood must cross the atrial septum to reach the systemic ventricle, the atrial septum must be nonrestrictive. Creating a nonrestrictive atrial septum can be achieved in the cardiac catheterization laboratory with a Rashkind-Miller balloon atrial septostomy, or a surgical atrial septectomy can be performed at the time of initial palliation in procedures that require CPB.

Anesthetic Considerations for the Unoperated Neonate

A continuous infusion of PGE₁ is used to maintain ductal patency for lesions associated with ductal-dependent blood flow (either systemic or pulmonary). In right-sided obstructive lesions (e.g., pulmonary atresia), left-to-right flow through the duct is needed for pulmonary perfusion, whereas for left-sided obstructive lesions (e.g., HLHS, critical neonatal coarctation), an adequate amount of right-to-left flow through the duct is needed for systemic perfusion. In both settings, the underlying tendency is for excessive PBF, resulting in pulmonary overcirculation, pulmonary congestion, and systemic hypoperfusion.

Management principles are similar for patients whether they are dependent on the PDA or they have a surgically created shunt. A target arterial partial pressure of oxygen (PaO_2) of 40 to 45 mm Hg and an oxygen saturation of hemoglobin (SaO_2) of 70% to 80% are reasonable starting goals that are likely to approach achieving adequate systemic O_2 delivery and PBF. With unrestricted PBF, control and manipulation of PVR and subsequently of $Q_p:Q_s$ is accomplished most reliably through ventilatory interventions to increase PVR, usually hypercarbia in combination with 21% inspired oxygen to achieve a pH of 7.30 to 7.35; use of hypoxic (17% inspired O_2 achieved by addition of nitrogen to air) or hypercarbic (F_{iCO_2} , 2.7%) are alternatives (Tabbutt et al., 2001). In anesthetized patients, an appropriate degree of hypercarbia can usually be obtained with a tidal volume of 6 to 10 mL/kg, a PEEP of 3 to 5 cm H_2O , and a respiratory rate of 8 to 10 breaths/min. Higher F_{iO_2} is avoided unless the PaO_2 is less than 35 to 40 mm Hg and intrapulmonary \dot{V}/\dot{Q}

■ **FIGURE 21-2.** The Norwood operation for first-stage palliation of hypoplastic left heart syndrome. The pulmonary artery is transected just proximal to its bifurcation, and the pulmonary artery is anastomosed in an end-to-side or side-to-side fashion to the ascending aorta, with reconstruction of the ascending and transverse aorta. Pulmonary blood flow is supplied by a modified Blalock-Taussig shunt (A) or right-ventricle-to-pulmonary artery conduit (B). (Redrawn from Sano S, Ishino K, Kawada M, et al: Right ventricle-pulmonary artery shunt in first-stage palliation of hypoplastic left heart syndrome, *J Thorac Cardiovasc Surg* 126:504–510, 2003.)

mismatch is suspected. Denitrogenation with 100% O_2 is recommended prior to laryngoscopy and tracheal intubation so as to prevent hypoxemia during this interval. Once the airway is secured, the F_{iO_2} can be reduced.

Because ventilatory interventions are usually incapable of reducing $Q_p:Q_s$ much below 2:1, additional measures to increase systemic cardiac output are often necessary to ensure adequate systemic oxygen delivery and coronary perfusion pressure; ensuring adequate preload and inotropic support with dopamine in the range of 3 to 10 $\mu\text{g}/\text{kg}$ per minute is often sufficient to accomplish these goals. It should be noted that the ability to recruit stroke volume with preload augmentation is very limited in neonates, particularly in the presence of already volume-overloaded ventricles. Although cardiac output in these

circumstances has increasing dependency on contractile state and heart rate, increasing heart rate much above normal (~140 to 160 beats/min) can potentially induce myocardial ischemia, particularly when aortic diastolic blood pressure is low (<20 to 30 mm Hg, caused by the large amount of runoff via the PDA).

An intravenous induction with ketamine, etomidate, or high-dosage narcotic (if postoperative ventilation is planned) and muscle relaxant is recommended. Inhalation agents should be used with caution, and a benzodiazepine (usually midazolam) can be added as tolerated. Use of invasive monitoring in shunt-dependent patients is usually determined by the nature of the surgical procedure.

Pulmonary Artery Band

Unrestricted PBF compromises systemic oxygen delivery, results in congestive heart failure, and ultimately leads to pulmonary artery hypertension and the development of pulmonary vascular occlusive disease. In this setting, a pulmonary artery band is placed to limit pulmonary blood flow, thereby controlling congestive heart failure and protecting the pulmonary vascular bed (Heath and Edwards, 1958).

Systemic-to-Pulmonary Artery Shunt

Infants with ductal-dependent pulmonary blood flow will require stabilization with PGE₁ followed by placement of a surgical aortopulmonary shunt (clearly, an intracardiac right-to-left shunt is also required). A *modified Blalock-Taussig shunt* is performed most commonly and involves placement of a Gore-Tex graft between the subclavian or innominate artery and the pulmonary artery on the side opposite to the aortic arch. The aim of this procedure is to establish a stable source of PBF as the PDA closes. In patients with HLHS, a right ventricle-to-pulmonary artery conduit is an alternative to a modified BT shunt (Sano et al., 2003). A superior cavopulmonary shunt cannot be performed in the neonatal period, because the high PVR necessitates a pumping ventricle or systemic blood pressure to drive blood through the lungs.

Anesthetic Considerations after Initial Palliation

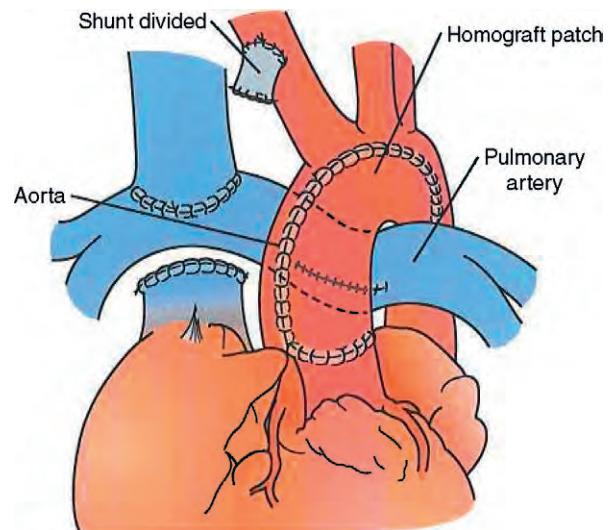

After initial palliation, the same principles apply to balancing systemic and pulmonary blood flow as before (or immediately after) the initial operation. Surgically created shunts early in their course are typically large so as to allow for growth, and hence the major issues are controlling excessive PBF, ensuring adequate systemic perfusion, and managing congestive heart failure (see later). On the other hand, the child can outgrow the shunt or band (both involve fixed diameters) at around 3 to 6 months of age, so that the $Q_p:Q_s$ falls and eventually becomes less than 1:1 with a lower arterial oxygen saturation. Shunt calcification or stenosis also plays a role in limiting shunt flow, can occur at any time, and can result in increasing cyanosis. Clearly, severe or total shunt occlusion (thrombosis) can be catastrophic.

In patients with evidence of shunt flow that is beginning to be critically limited (decreased saturations, increasing hemoglobin, echocardiographic evidence), it is reasonable to assume that the effective resistance to PBF is relatively fixed (i.e., pulmonary overcirculation is unlikely to be possible), and primary attention is therefore directed toward maneuvers that maintain or in fact increase cardiac output and systemic blood pressure

in order to support adequate PBF. It is also reasonable to try to avoid increases in intrinsic and reactive components of PVR by using increased inspired oxygen concentrations and avoiding hypercarbia, acidosis, and other factors that increase PVR. An intravenous induction is generally preferred, as loss of the airway and hypotension can lead to profound hypoxia and cardiac arrest. Vascular access may be difficult, as many of these patients have had prolonged intensive care unit (ICU) stays. Many of these patients are tolerant to opioids and benzodiazepines, and this fact should be considered if premedication is planned prior to placement of an intravenous line. Intramuscular induction with ketamine can be a safe alternative.

Anesthetic Considerations after the Superior Cavopulmonary Connection

In the superior cavopulmonary connection or bidirectional Glenn operation, the SVC is transected and the cranial end is sewn in an end-to-side manner to the right pulmonary artery (which is in continuity with the left pulmonary artery); the distal (cardiac) end is oversewn (Fig. 21-3). Systemic venous return from the head and upper body thus passes directly from the SVC into the pulmonary circulation. The goal is to reduce the volume load on the ventricle and allow cardiac remodeling (compared with the prior shunted circulation) with maintenance of cardiac output at a lower ventricular filling volume. After the Glenn operation, the $Q_p:Q_s$ will be between approximately 0.5:1 and 0.8:1, as the inferior vena cava (IVC) blood does not pass through the lungs but mixes with pulmonary venous blood in a functionally common atrium. The arterial oxygen saturation will still be reduced (75% to 85%), with a typical SVC pressure of 10 to 12 mm Hg and an atrial pressure of 5 to 6 mm Hg. The transpulmonary gradient is thus 4 to 7 mm Hg. The physiology of PBF and anesthetic considerations are similar to the Fontan circulation and discussed later.

■ **FIGURE 21-3.** Bidirectional Glenn operation. The superior vena cava is transected and the cranial end is sewn in an end-to-side fashion to the right pulmonary artery (which is in continuity with the left pulmonary artery). The distal (cardiac) end is oversewn. (Redrawn from Sano S, Ishino K, Kawada M, et al: Right ventricle-pulmonary artery shunt in first-stage palliation of hypoplastic left heart syndrome, J Thorac Cardiovasc Surg 126:504–510, 2003.)

Anesthetic Considerations after the Total Cavopulmonary Connection or Fontan Operation

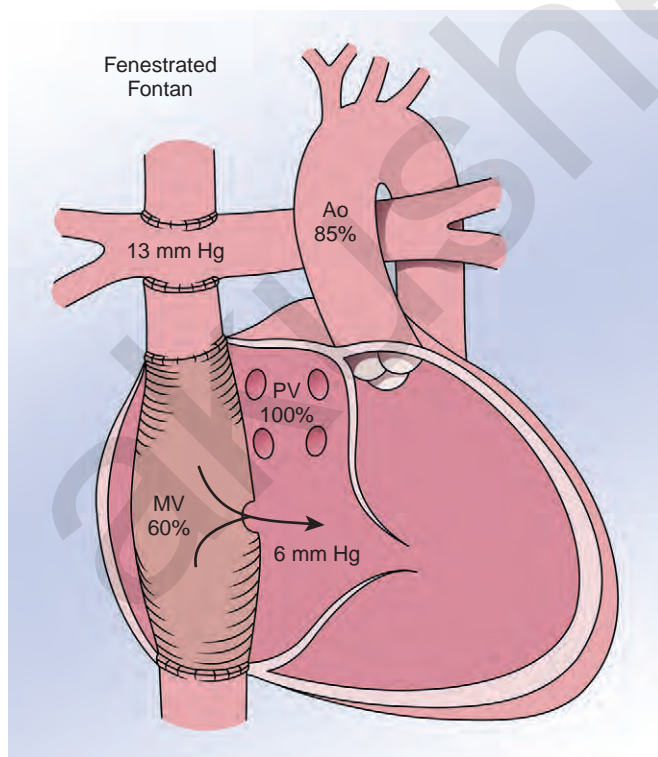

Patients with Fontan circulations are symbolic of how asymptomatic clinical status should not give the anesthesiologist a false sense of security about cardiovascular stability. The Fontan operation is usually performed within 1 to 2 years of a bidirectional Glenn (Jonas, 2004), and thus between 15 months and 2.5 years of age. The operative principle is diversion of the systemic venous return directly to the pulmonary arteries without the need for a subpulmonary ventricle, resulting in a series circulation with relief of cyanosis. Although many modifications of this procedure have been described, the total cavopulmonary connection (lateral tunnel Fontan) is currently the procedure of choice in most centers (Jonas, 2004) (Fig. 21-4). In the presence of a preexisting bidirectional Glenn anastomosis (the situation for most patients coming to Fontan surgery at present), an intraatrial baffle is placed to direct IVC flow from the IVC orifice along the side wall of the atrium up to the SVC orifice, with opening of the cardiac (distal) end of the SVC and anastomosis to the pulmonary artery.

The key physiologic principle in patients with Fontan physiology is maintaining filling and function of the systemic ventricle. In the absence of a pumping pulmonary ventricle, the initial consideration is to maintain an adequate pressure gradient between the systemic venous return circulation and the common atrium (i.e., the atrium that serves the systemic ventricle). The circulation can be viewed, in oversimplified fashion, as a waterfall, with the systemic venous pressure as the top, and the end-diastolic pressure in the systemic ventricle as

the bottom. The ideal Fontan will have a mean systemic venous (pulmonary artery) pressure of approximately 10 to 15 mm Hg and a common atrial pressure of 7 to 10 mm Hg, resulting in a transpulmonary gradient of 3 to 8 mm Hg. Optimal physiology depends on adequate preload, unobstructed systemic venous return, low PVR, low mean intrathoracic pressure, normal lung parenchyma and alveolar ventilation, unobstructed pulmonary venous return, sinus rhythm (resulting primarily from the atrial contribution to ventricular filling [Penny et al., 1991]), atrioventricular valve competency, normal ventricular function, and low ventricular afterload. Any significant departure from these requirements can result in severe compromise. For example, ventricular dysfunction with an end-diastolic pressure of 15 mm Hg mandates a venous pressure of 20 to 25 mm Hg (i.e., the transpulmonary gradient is preserved but venous pressures must be proportionately higher) to achieve comparable pulmonary blood flow, ventricular filling, and cardiac output. Relatively *mild* acute lung disease (e.g., viral pneumonia), if associated with increased PVR, can lead to an acute and severe decrease in systemic ventricular filling and cardiac output unless and until preload is restored sufficiently to restore ventricular filling (here, the transpulmonary gradient is increased)—that is, any downstream problem will necessitate a higher upstream pressure.

Because ventricular dysfunction and elevated PVR can contribute to early mortality after a Fontan operation, a fenestration (hole) is made in the intraatrial baffle at the time of the Fontan operation. This fenestration allows right-to-left shunting from the venous side of the baffle to the common atrial arterial side, and hence a portion of the cardiac output is able to avoid traversing the lungs; in the presence of an elevated PVR or elevated end-diastolic pressures (e.g., after cardiopulmonary bypass), flow through the fenestration maintains filling of the systemic ventricle and preserves cardiac output at lower systemic venous pressures, albeit at the expense of a physiologically acceptable reduction in systemic arterial saturation. The fenestration is a potential site for paradoxical embolism. In time, the fenestration either closes spontaneously or it can electively be closed with a device in the catheterization laboratory when adequate hemodynamics are achieved. Arterial oxygen saturations are usually in the range of 80% to 90% in the presence of a patent fenestration, depending on the magnitude of the shunt and the saturation of the shunted venous blood (and therefore systemic oxygen delivery and extraction). An SpO₂ of approximately 95% is expected with a closed fenestration, but saturations in the 90% to 95% range are common. This reduction from full saturation results in part from the fact that the coronary sinus is usually located on the common atrial side of the repair (causing mixing of highly desaturated coronary venous blood, about 20% of total cardiac output, with oxygenated blood in the systemic ventricle). Greater degrees of desaturation may reflect residual right-to-left shunt across a patent baffle fenestration, baffle suture line leaks, decompressing venous collaterals (typically between the SVC and the atrium or pulmonary veins), pulmonary arteriovenous malformations (can occur as a consequence of Glenn physiology), very low cardiac output, or intrinsic lung disease.

Complications after the Fontan operation are in part dependent on surgical technique and era, and partly on pathophysiologic sequelae of multiple factors such as multiple surgeries, long-standing systemic venous hypertension, cyanosis, and perhaps limited cardiac output as well. One can expect progressive

■ **FIGURE 21-4.** Lateral tunnel Fontan with patent fenestration. Ao, Aortic saturation; MV, mixed venous saturation; PV, pulmonary vein saturation.

decline in the function of the systemic ventricle, an increasing risk for development of arrhythmias, and end-organ dysfunction as these patients age. Recent data suggest that diastolic dysfunction may be an early and persistent feature of Fontan myocardial physiology (Cheung et al., 2000; Olivier et al., 2003). Other specific issues include recurrent pleuropericardial effusions, peripheral edema, ascites, cirrhosis, and protein-losing enteropathy (3.7%) (Mertens et al., 1998; Khairy et al., 2007). Thrombosis in the venous pathway (6% to 33%) may occur early or late and result in both pulmonary and systemic embolic complications, particularly stroke. Sudden total obstruction appears as sudden death. It is unclear whether and to what extent specific hemostatic derangements such as increased factor VIII, dysregulation of other procoagulant and anticoagulant factor synthesis resulting from Fontan physiology, or the superimposition of this physiology on a “normal” background of thrombophilic polymorphisms (e.g., factor V Leiden, prothrombin mutations) might be responsible for the apparent increased thrombotic risk in these patients (Odegard et al., 2003, 2009).

Arrhythmias are associated with serious morbidity (especially the development of atrial thrombi) and can lead to profound hemodynamic deterioration. The combination of atrial incisions, multiple and extensive atrial suture lines, and increased right atrial pressure and size appear to be predisposing factors. The incidence of atrial tachyarrhythmias (atrial flutter or fibrillation, or both) is lower with the lateral tunnel Fontan (Stamm et al., 2001b) than in patients operated on in the 1970s and 1980s with direct atriopulmonary anastomosis (Fishberger et al., 1997). In the current era, freedom from new supraventricular tachyarrhythmia was 98% at 5 years and 95% at 10 years (Brown et al., 2010). A recent study found less atrial arrhythmia with extracardiac conduit than lateral tunnel Fontan (Robbers-Visser et al., 2009). Bradyarrhythmia (heart block and sick sinus syndrome), which may necessitate pacemaker implantation, also appears to be more frequent in the first 10 years than atrial tachyarrhythmias with the lateral tunnel version of the procedure (Stamm et al., 2001b). Freedom from late-onset bradyarrhythmia varies from 89% (Stamm et al., 2001b) to 96% (Brown et al., 2010) at 10 years.

The probability of survival after Fontan surgery has increased in more recent years (93.9% at 8 years in one study [Stamm et al., 2001b] and 95% at 15 years in another [Brown et al., 2010]), largely as a result of improved surgical techniques, patient selection, and perioperative management (Mitchell et al., 2006; Anderson et al., 2008; Khairy et al., 2008a; Robbers-Visser et al., 2009). Progressive deterioration of ventricular function (functional status) and gradual attrition occur, predominantly from thromboembolic, heart failure–related, and sudden (presumed arrhythmic) deaths (Khairy et al., 2008a).

Objective testing of functional status has indicated that patients with stable single-ventricle physiology are able to lead a fairly normal life with moderate exercise tolerance (Robbers-Visser et al., 2010). With exercise, maximal aerobic capacity was reduced, with only 28% of patients having peak oxygen consumption within the normal range (Paridon et al., 2008). Stroke volume reserve is the most important determinant of aerobic capacity, with exercise tolerance limited by peak blood flow in the pulmonary vascular bed. With exercise or other hemodynamic stress, a fall in cardiac index and oxygen saturation may occur because of an inability to increase stroke volume (Robbers-Visser et al., 2008). This inability probably results from multiple factors, including relatively fixed

myocardial contractile reserve and the fact that many Fontan patients are near-maximally venoconstricted, thereby limiting the amount of preload augmentation that can occur to support exercise-stimulated increases in cardiac output; a blunted heart rate response, for reasons discussed previously, may be an additional factor. In sum, the progressive and late decline in survival and functional status implies that these repairs are not curative and should be viewed as palliative at this time (Khairy et al., 2008a). A recent Pediatric Heart Network study found that sinus rhythm was present in 67% of patients; 13% used a pacemaker; semilunar and atrioventricular valve regurgitation was present in 49% and 74% of patients, respectively; 72% had abnormal diastolic function; and pulmonary reserve was below normal in 34% of cases (Anderson et al., 2008).

Anesthetic management: Management of Fontan physiology is summarized in Table 21-2. Hemodynamic goals are to maintain normal to increased preload, normal to slightly increased heart rate, normal to low pulmonary vascular resistance, and sinus rhythm (atrioventricular synchrony); to support ventricular function; and to avoid high ventricular afterload. In the hospitalized patient, maintenance intravenous fluids should be begun while the patient is fasting preoperatively. Particularly in outpatients, volume expansion may be necessary before induction to ensure adequate preload. A technique using sedation with local or regional anesthesia should be considered where feasible (recognizing that some patients will be on anticoagulants).

The use of mechanical ventilation deserves some consideration, as ventilation and acid-base management need to be optimized to keep PVR low. Although spontaneous ventilation enhances pulmonary blood flow (Penny and Redington, 1991), the accompanying hypoventilation likely to occur during anesthesia or procedures associated with abdominal or thoracic compression will increase PVR through atelectasis, hypoxic pulmonary vasoconstriction, and hypercarbia. In fact, increased PVR (and hence acutely reduced cardiac output) is more likely to occur during either relative hypoventilation (resulting primarily from increased P_{CO_2} and also from alveolar hypoxia and collapse) or excessive positive pressure ventilation (resulting from increased intrathoracic and pulmonary pressures that are transmitted to the vasculature, as well as from potential microvascular distention or compression [or both] caused by overinflation). For most surgical situations (all but the shortest of procedures), we believe that the sum of effects favors judicious use of positive pressure ventilation in order to provide an effective anesthetic while maintaining lung volumes and normal gas exchange. This can usually be accomplished with a relatively large tidal volume (~10 mL/kg), slower respiratory rates (10 to 15 breaths/min), and shorter inspiratory times (I:E of 1:3 or 1:4). Similar considerations apply to the use of PEEP: if it is targeted to maintain or improve functional residual capacity and lung compliance and thereby assist with gas exchange, it is likely to be helpful, whereas overdistention will favor deleterious effects. Additional fluid administration can be used to overcome the decrease in venous return associated with mechanical ventilation. Another benefit of positive pressure ventilation can be the decrease in afterload on the systemic ventricle (LaPlace's law) and consequent improvement in its function.

When choosing induction agents, etomidate or ketamine is likely to provide the greatest degree of hemodynamic stability, and either is preferred if functional status is diminished. Thiopental or propofol should be used with considerable caution. An inhalational induction in younger patients with

well-preserved ventricular function and patent Fontan pathways is possible, keeping in mind that airway difficulty (e.g., prolonged obstruction or laryngospasm) is likely to be quite poorly tolerated, as are significant agent-induced negative inotropic effects. For maintenance of anesthesia, a balanced technique with moderate concentrations of inhaled anesthetic agents is usually tolerated. As previously stated, it is common to support patients with preexisting ventricular dysfunction with an inotropic agent (dopamine). Central venous catheters placed in the internal jugular or subclavian vein have a place in managing Fontan patients undergoing procedures associated with major blood loss or fluid shifts, providing information about proximal filling pressures and pulmonary artery pressure (the SVC is of course in direct continuity with the PA). In addition, oxygen delivery (and hence cardiac output) can be inferred from the oxygen saturation of SVC blood. A general guideline (not only in Fontan) is that the likelihood of reduced cardiac output increases (assuming reasonably normal hemoglobin concentration and tissue extraction) as the difference between arterial and SVC O₂ saturation exceeds ~25 (e.g., we would infer at least a component of low cardiac output in a fenestrated Fontan patient with an Sa_o₂ of 84% and an SVC saturation of 50%.) Because of the risk for thrombosis and caval obstruction of the Fontan pathway, a

femoral venous catheter may be preferable when central venous access is needed only for infusions. Elevated venous pressures and coagulation defects may increase the risk of bleeding. For major surgery, especially in the setting of moderate to severely depressed ventricular function, referral to a specialized center with expertise in the care of patients with CHD is warranted.

Coarctation of the Aorta

The anatomy, pathophysiology, and anesthetic management for repair of aortic coarctation are discussed later (see Anesthesia for Closed Cardiac Procedures). The long-term consequences after coarctation repair are related to blood pressure and left ventricular mass. In long-term follow-up studies, persistent arterial hypertension in the absence of re-coarctation and type of repair is present in as many as one third of patients (de Divitiis et al., 2003; Rosenthal, 2005; Hager et al., 2007). Systolic blood pressure is positively associated with LV mass in this cohort, and elevated systolic blood pressure and LV mass are both important risk factors for late morbidity and mortality from heart failure, sudden death, and coronary and cerebrovascular disease (Toro-Salazar et al., 2002). Although it has been suggested that

the risk of developing subsequent hypertension is reduced by repair in the first year of life (Seirafi et al., 1998), some series do not support this contention (de Divitiis et al., 2001). The etiology of this persistent hypertension is multifactorial and includes reduced pulsatility of the post-coarctation descending aorta (Pfammatter et al., 2004), reduced upper body vascular responses to reactive hyperemia and glyceryl trinitrate (possibly abnormal smooth muscle relaxation or structural abnormalities of the arterial wall [Murakami and Takeda, 2005]), aortic arch geometry (Ou et al., 2007, 2008), and abnormalities in baroreceptor reflexes and the renin-angiotensin-aldosterone system (Rosenthal, 2005). There is evidence to suggest that abnormalities in cardiovascular reflexes are already present in neonates with coarctation before repair (Polson et al., 2006).

These patients are at increased risk for premature coronary atherosclerosis, cerebral vascular disease, left ventricular hypertrophy with impaired diastolic function, congestive heart failure, aortic aneurysm and fistula formation, aortic dissections and rupture, and endarteritis at the repair site (Rosenthal, 2005; Hager et al., 2007). Bicuspid aortic valve and advanced age appear to be independent risk factors for aortic complications (Oliver et al., 2004).

Atrial Septal Defects

An atrial septal defect is a communication between the left and right atria, and it may be single or multiple, vary widely in size, be located anywhere in the atrial septum, and be isolated or associated with other congenital heart defects (50%). See related video online at www.expertconsult.com. There are four morphologic types: secundum ASD, primum ASD, sinus venosus ASD, and coronary sinus ASD. Patent foramen ovale is a normal interatrial communication during fetal life and is seen in almost all newborns. A probe-patent foramen ovale, present in up to 25% of adults, is not a true defect in the atrial septum but results from incomplete fusion of the septum primum and the superior limbic band of the fossa ovalis (septum secundum). Paradoxical embolism is a major anesthetic consideration in these patients.

ASDs allow shunts, and the amount of blood that passes through the defect is determined by the size of the defect, the pressure difference between the left and right atria, and the relative compliance of the right and left ventricles. Left-to-right shunting increases as the patient gets older (Campbell, 1970). Early in infancy, the right ventricle is less compliant, so that left-to-right shunting is minimal. With declines in pulmonary artery pressure and remodeling (increased compliance) of the right ventricle, shunting increases as the right atrial pressure becomes lower than left atrial pressure. The normally decreasing left ventricular compliance with age further increases left-to-right shunting. ASDs result in increased pulmonary blood flow and place a volume load on the right atrium, right ventricle, and left atrium.

Isolated ASDs are generally asymptomatic in infancy and childhood, but a few infants develop congestive heart failure as a result of pathophysiology that is incompletely understood. CHF is more common after 40 years of age. The incidence of atrial fibrillation (less commonly atrial flutter) also increases with advancing age (Murphy et al., 1990).

Spontaneous closure of secundum defects is related to defect diameter (<3 mm, 100%; 3 to 8 mm, 87%; 3 to 5 mm, 80%) (Radzik et al., 1993). Indications for closure are a pulmonary to systemic blood flow ratio greater than 2:1, with the second year

of life currently considered the optimal time for surgical closure. Normal ventricular function after repair is the rule, but ventricular dysfunction and atrial arrhythmias can occur with late repair. Pulmonary vascular occlusive disease will develop in approximately 5% to 10% of unrepaired ASDs, most commonly in the second decade or thereafter, and can result in shunt reversal and Eisenmenger's syndrome (Steele et al., 1987). Residua and sequelae are more commonly seen after repair of sinus venosus defects (loss of sinus node function, pulmonary venous obstruction, residual shunt) (Attenhofer Jost et al., 2005) and ostium primum defects (see Atrioventricular Septal Defects, p. 694).

Ventricular Septal Defects

A ventricular septal defect is an opening in the ventricular septum permitting communication between the left and right ventricles, and it is the most common congenital cardiac defect (2.5 per 1000 live births) after bicuspid aortic valve. VSDs are classified by their location in the septum, with multiple classifications existing. The physiologic effects are determined by the degree of shunting, which is influenced by the size of the defect and the relative pulmonary and systemic vascular resistances. Smaller (restrictive) defects limit shunting—there is a large pressure gradient across the defect. Large (nonrestrictive) defects have less pressure difference between the ventricles, so the magnitude and direction of shunting are more dependent on the relative pulmonary and systemic vascular resistances. The high PVR at birth limits left-to-right shunting, but the magnitude of the shunt increases over the first few months of life because of the normal postnatal decline in PVR; there is also a contribution from physiologic anemia of the infant (hematocrit has a disproportionately greater effect on PVR than SVR) (Lister et al., 1982). Excessive left-to-right shunting with increased pulmonary blood flow leads to pulmonary congestion, abnormal pulmonary mechanics (decreased compliance, increased airway resistance, airway compression), increased myocardial work, and pulmonary hypertension (Berlinger et al., 1983; Stayer et al., 2004). Congestive symptoms appear when the $Q_p:Q_s$ exceeds 1.4. Pulmonary hypertension is usually reversible initially but becomes increasingly fixed as PVOD develops; although the timing can be variable, irreversible pulmonary vascular disease is uncommon in infancy.

Most VSDs are small, and many will decrease in size or close spontaneously. Indications for surgical repair in infancy are poor growth, significant CHF, pulmonary artery pressure at or near systemic level, and multiple VSDs (Keane and Fyler, 2006d). Patients with advanced PVOD and pulmonary hypertension (Eisenmenger's complex) are generally not candidates for VSD closure. Device closure of muscular VSDs, particularly difficult-to-reach apical and anterior septal defects, is possible in the catheterization laboratory provided the device will not impinge on the atrioventricular or semilunar valves.

Anesthetic management: For unrepaired VSD, the focus should be on assessing the degree of systemic circulatory compromise and control of pulmonary vascular tone. Signs and symptoms of significant CHF in infants include (1) respiratory: tachypnea, grunting, flaring, retractions; pulmonary congestion on chest x-ray; (2) growth and nutrition: poor feeding, poor growth, failure to thrive; and (3) cardiovascular: tachycardia, diminished pulses, decreased peripheral perfusion, hepatic congestion (hepatomegaly). An inhalational induction should

be reserved for patients with smaller defects, no worse than compensated CHF, well-preserved ventricular function, and no PVOD. The major concern is inducing significant decreases in PVR, resulting in decreased systemic flow and hypotension; less commonly, reactive elevations in PVR can result in right-to-left shunting with desaturation. Myocardial and pulmonary function are likely to be normal if complete repair is done within the first year or two of life (Kidd et al., 1993). Potential sequelae include residual defects, heart block, subaortic obstruction, and aortic regurgitation (Kidd et al., 1993; Chiu et al., 2007). Early and mid-term follow up of VSD closure by device found that complete atrioventricular block is a serious concern (Butera et al., 2007).

Atrioventricular Septal Defects

Atrioventricular septal defects (AVSDs), also referred to as canal defects or endocardial cushion defects, result from abnormal endocardial cushion development. See related video online at www.expertconsult.com. AVSDs may be *complete* (common AV valve with ostium primum ASD and moderate to large inlet VSD), *partial* (two distinct AV valves with ostium primum ASD and usually a cleft in the anterior leaflet of the mitral valve), or *transitional* (ostium primum ASD, restrictive VSD, common AV valve orifice with fused anterior and posterior bridging leaflets dividing the common AV valve into distinct mitral and tricuspid components). AVSDs are commonly associated with extracardiac defects and are present in approximately 60% of children with Down syndrome.

The physiology resembles that of atrial and ventricular septal defects, with the possible added feature of AV valve regurgitation. There is a left-to-right shunt with increased pulmonary blood flow and volume overloading of the right and left ventricles, with the magnitude of shunting largely determined by the size of the VSD component. Surgery for complete AV canal defects is usually undertaken in the first 2 to 3 months of life because of the risk for accelerated pulmonary vascular disease. Surgery is usually done later in infancy for partial and transitional AV canals because the pulmonary vasculature is protected and the normal AV valve tissue is thin and fragile (Jonas, 2004). The repair typically involves dividing the common AV valve and closing the ASD and VSD with either one or two patches, approximation and suspension of the valve apparatus, and suturing any cleft in the mitral valve.

Anesthetic management: For unrepaired canal defects, management is like that for left-to-right shunts. An inhalational induction should be reserved for patients with small defects, preserved ventricular function, no worse than compensated CHF, and no PVOD. Potential sequelae include residual septal defects, AV valve regurgitation or stenosis (especially mitral) (or both), AV block, subaortic obstruction, and occasionally pulmonary hypertension; the last is more likely in patients with Down syndrome.

Aortic Stenosis

Bicuspid aortic valve is the most common congenital cardiac defect. It occurs in 1% to 2% of the population and demonstrates a substantial male predominance (Hoffman and Kaplan, 2002). It may be an isolated lesion or associated with other left-sided obstructive defects (e.g., aortic coarctation), and it may be asymptomatic or become progressively obstructive or regur-

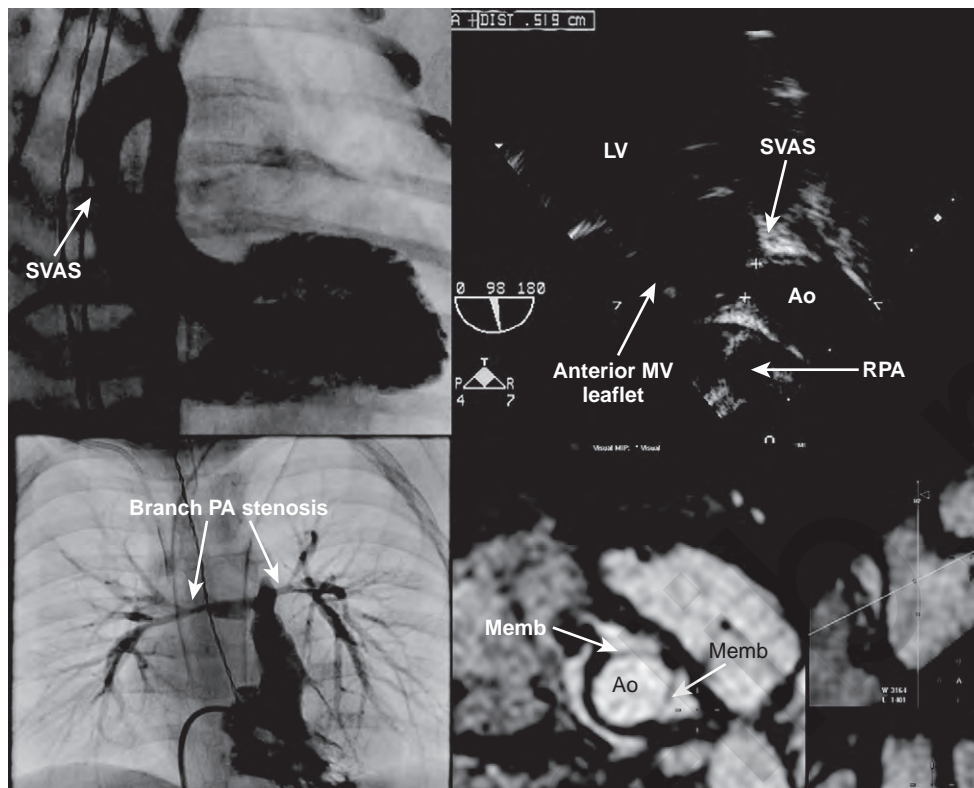

gant. *Critical neonatal aortic stenosis* is frequently a ductal-dependant lesion, with an appearance similar to that of severe aortic coarctation. In its most severe forms, critical neonatal AS is poorly tolerated and produces left ventricular failure with poor systemic perfusion and pulmonary vascular congestion; factors that increase myocardial demand even modestly (e.g., mild fever, anemia) can markedly exacerbate the low cardiac output state and potentially precipitate cardiovascular collapse. In *supravalvar aortic stenosis* (SVAS), there is narrowing at the sinotubular junction, which may be associated with coronary artery stenoses, hypoplasia of the ascending aorta and arch, distal arterial tree, and pulmonary artery stenoses (Stamm et al., 2001a) (Fig. 21-5). *Subaortic stenosis* may comprise a discrete fibromuscular ridge or membrane, a long fibromuscular tunnel, or hypertrophy of the interventricular septum (hypertrophic cardiomyopathy). *Shone's anomaly* consists of aortic coarctation, subaortic stenosis, and mitral stenosis on the basis of both a parachute mitral valve and supravalvar mitral ring (Shone et al., 1963). Although the relief of coarctation is typically straightforward, patients with Shone's anomaly frequently have prolonged and recurrent left-sided obstruction arising from its other components, leading to reduced LV compliance and dysfunction despite one or more attempts at correction. The mitral stenosis (leading to pulmonary hypertension) and reduced ventricular function in particular can make these patients particularly difficult to manage in the perioperative period, because of associated fluid loads and shifts, anemia, fever, and stress response.

Balloon dilation of the aortic valve has replaced surgery as the initial procedure for significant *aortic valve stenosis*, effectively reducing the gradient and promoting growth of the valve annulus (Jonas, 2004). Aortic valvuloplasty or replacement becomes necessary when dilation of the stenosis is no longer effective or aortic regurgitation and consequent LV dilation become significant. *Subaortic stenosis* resulting from a discrete subaortic membrane is repaired by membrane resection. In addition to creating increased pressure within the LV, aortic valve damage and regurgitation caused by a jet arising from flow across the membrane is a common finding and an indication for surgery. Tunnel subaortic stenosis is managed by the modified Konno procedure in which LV septal tissue is excised and a patch placed to enlarge the LV outflow tract.

The pathophysiology and *anesthetic management* of left ventricular outflow obstruction were discussed earlier in this chapter.

Supravalvar aortic stenosis, specifically that associated with Williams (Williams-Beuren) syndrome, merits particular attention. Patients with SVAS are at significantly increased risk for cardiac arrest and death during anesthesia, cardiac catheterization, and surgery (Bird et al., 1996), and the anesthetic management has recently been reviewed (Burch et al., 2008). SVAS is associated with variable-sized deletions in the elastin gene and adjacent segments and can be accompanied by a diffuse and variable arteriopathy (Poer, 2010). Common manifestations of patients with Williams syndrome include SVAS, supravalvar pulmonic stenosis, more distal PA stenoses, and at times renal artery stenosis. The increased risk for sudden death appears to occur by at least two different but potentially interacting pathophysiologic features:

1. Significant ventricular hypertrophy as a consequence of severe outflow obstruction; the presence of severe, bilateral (i.e., supravalvar aortic and pulmonic) obstruction and hypertrophy poses the greatest risk.

■ **FIGURE 21-5.** Supravalvular aortic stenosis (SVAS). *Top left:* Anteroposterior projection of a left ventricular angiogram demonstrating significant SVAS. *Top right:* Inverted transesophageal echocardiography of mid-esophageal aortic valve, long-axis view demonstrating SVAS. *Bottom left:* Anteroposterior projection of a right ventricular angiogram demonstrating significant proximal branch pulmonary artery stenoses. *Bottom right:* Cardiac MRI short-axis view of the ascending aorta demonstrating an obstructive membrane arising from the sinotubular junction and extending in front of both the right and left coronary ostia. (From Burch TM, McGowan FX Jr, Kussman BD, et al: Congenital supravalvular aortic stenosis and sudden death associated with anesthesia: what's the mystery? *Anesth Analg* 107:1848-1854, 2008.)

2. Various forms of coronary artery obstruction. It is noteworthy that the degree of coronary involvement may not be accurately imaged by echocardiography or predicted by the degree of supravalvular aortic obstruction.

Anesthetic management: Key features include avoidance of dehydration, hypotension, and other factors that compromise myocardial perfusion. Thus, minimizing the amount of time that the patient receives nothing by mouth, placing an intravenous catheter (aided by premedication as necessary), administering a fluid bolus, and administering intravenous induction with agents that maintain hemodynamic stability are important anesthetic management principles. Although uneventful inhalational inductions have been reported (Bragg et al., 2005; Medley et al., 2005; Astuto et al., 2007), we would advise against this, because significant hypotension can lead to cardiac arrest (especially when coronary artery obstruction is present) prior to establishing intravenous access; in many instances, resuscitation is unsuccessful (Bird et al., 1996). In the catheterization laboratory, both radiographic contrast injection (perhaps via its transient but significant ability to impair coronary oxygen delivery when injected into the aorta or left side of the heart) and cardiac rhythm disturbances (as might be induced by a wire or catheter) are possible events leading to decompensation. Although not based on evidence, it is our practice to have a norepinephrine infusion available for immediate administration should hypotension ensue or be predicted. The lesion itself is usually repaired

by resection of the stenotic area and patch placement, although more extensive aortic (or supravalvular pulmonary) reconstruction may be necessary (Stamm et al., 2001a).

Truncus Arteriosus

Truncus arteriosus is a single arterial trunk from which the aorta and the pulmonary and coronary arteries arise, with a VSD present beneath the truncal valve. See related video online at www.expertconsult.com. Like tetralogy of Fallot, it is frequently associated with a 22q11 deletion, and with DiGeorge and velocardiofacial syndromes. It is the quintessential parallel circulation, with the $Q_p:Q_s$ ratio determined by the ratio of pulmonary to systemic vascular resistance (Hansen and Hickey, 1986; Wong et al., 1991). Surgical repair involves patch closure of the VSD and detachment of the pulmonary arteries from the truncus with establishment of right ventricle-to-pulmonary artery continuity with a conduit (valved homograft).

Anesthetic management: Control of pulmonary blood flow and support of ventricular function are central management tenets. Unrepaired truncus arteriosus poses a significant anesthetic challenge, because declines in PVR can be associated with increased left-to-right shunting, leading to systemic (in particular, diastolic) hypotension, coronary ischemia, and ventricular fibrillation. Increased PVR can result in right-to-left shunting

with desaturation, systemic (and myocardial) hypoxia, myocardial depression, and cardiovascular collapse. Late sequelae after repair include obstruction of the right ventricle-to-pulmonary artery conduit, conduit regurgitation, truncal (aortic) valve regurgitation, residual VSD, and persistent pulmonary hypertension (for repairs done later in childhood). Anesthetic management for the repaired truncus is similar to that for right ventricular outflow obstruction (the most frequent sequela).

Ebstein's Anomaly

Ebstein's anomaly consists of displacement of the septal and posterior leaflets of the tricuspid valve toward the apex of the right ventricle. See related video online at www.expertconsult.com. The right ventricle between the true annulus and the level of attachment of the septal and posterior leaflets to the ventricular septum is thin and dysplastic ("atrialized") (Fig. 21-6). The anterior tricuspid leaflet at the annulus is larger than normal, whereas the other leaflets may be redundant, contracted, or thickened. The tricuspid valve is usually incompetent, occasionally stenotic. The right ventricular cavity beyond the atrialized portion ranges from small to large, whereas the right atrium is invariably enlarged. There is virtually always a PFO or an ASD, and an accessory AV conduction pathway (e.g., Wolff-Parkinson-White Syndrome) is present in 10% to 25% of cases (Watson, 1974; Smith et al., 1982).

The clinical spectrum of Ebstein's anomaly is extremely variable, ranging from the critically ill neonate with minimal to no anterograde flow out the right ventricle to the pulmonary artery, and with severe tricuspid regurgitation and heart failure, to the child with minimal or no symptoms (Brown et al., 2008). Atrial right-to-left shunting can produce cyanosis. Interventions for significant lesions include tricuspid valve

repair (cone procedure) (da Silva et al., 2007) or replacement, closure of interatrial communications, and ablation of accessory pathways.

ANESTHESIA FOR CLOSED CARDIAC PROCEDURES

Patent Ductus Arteriosus

The ductus arteriosus connects the origin of the left main pulmonary artery to the aorta and is a critical component of the fetal circulation. In utero, most of the blood from the RV bypasses the lungs via flow through the ductus to the descending aorta. In most newborns, the ductus closes within 72 hours of birth through contraction of a smooth muscle layer in response to an increase in postnatal systemic oxygen levels (Hermes-DeSantis and Clyman, 2006). The lumen is obliterated by 2 to 3 months of age, but if not fully obliterated, a connection remains between the systemic and pulmonary circulations. The PDA may be isolated (Fig. 21-7) or associated with almost any other congenital cardiac anomaly, in many instances of which it is lifesaving (ductal-dependent lesions). Isolated PDA is associated with increasing left-to-right shunting as the pulmonary vascular resistance falls.

A tiny or small PDA is asymptomatic and associated with normal life expectancy (Campbell, 1968); its closure may be controversial but is generally recommended because of the risk for endocarditis. With a hemodynamically significant ductus, excessive blood flow to the lungs, left atrium, left ventricle, and ascending aorta results in enlargement of these structures, and in large shunts, congestive heart failure. Elevation of left atrial pressure may cause enlargement of the foramen ovale with additional left-to-right shunting. In premature infants with respiratory distress, hypoxia promotes continued patency of the ductus, with the need for more aggressive ventilation. Runoff from the aorta into the pulmonary circulation during diastole reduces aortic diastolic pressure with decreased coronary, cerebral, and abdominal organ perfusion. Necrotizing enterocolitis and intracerebral and intraventricular hemorrhages are potential complications. Other cardiac anomalies determine the direction of shunting across a PDA. For example, with severe aortic coarctation or hypoplastic left heart syndrome, the shunting is predominantly right to left, and in fact necessary to support systemic perfusion until more definitive interventions are undertaken.

Closure of a PDA can be accomplished medically in the preterm infant with indomethacin, surgically, or in the catheterization laboratory. Surgical division is recommended in preterm infants with inadequate response to indomethacin and those with large communications (Ewert, 2005). Surgical management is typically via a small left posterolateral thoracotomy, but the video-assisted thoracoscopic (VAT) technique has become the surgical standard of care for infants and children with a small to moderate-sized ductus (Laborde et al., 1997; Jonas, 2004). Closure using interventional catheterization techniques has increased in frequency and is an attractive option because it can be done on an outpatient basis, it reduces surgical scarring, and it may be associated with less pain, faster recovery, and reduced risk for late thoracotomy complications (cosmetic defects, rib fusion, and scoliosis). It is best suited for a restrictive ductus with some length and an ampulla at the aortic end (Ewert, 2005; Keane and Fyler, 2006b).

Anesthetic Management

Anesthetic management for PDA ligation depends on patient age and clinical status. Physiologic goals are similar to other patients with left-to-right shunts.

The majority of patients are sick, premature, ventilator-dependent neonates with respiratory distress syndrome and no better than borderline systemic blood pressure and perfusion. The major consideration is manipulations to balance the PVR and SVR. Maneuvers that decrease PVR, in particular, as well as those that reduce myocardial contractility and SVR, should be avoided. Dopamine is often already in use or may need to be added to maintain a blood pressure that is appropriate (one rule of thumb is mean arterial pressure approximately equal to the patient's gestational age). Although direct monitoring of arterial blood pressure can be helpful in the sicker patients, it can be technically challenging and is not part of our routine practice for neonates who arrive from the neonatal ICU without it. An anesthetic technique using high-dosage fentanyl (30 to 50 mcg/kg) and pancuronium is usually well tolerated (Robinson and Gregory, 1981). In the current era, although advisable to supplement this technique with low-dosage inhaled agent or benzodiazepine, the hemodynamics often do not allow for this. Transport of these neonates to the operating room can be hazardous, with the risks of accidental extubation, inadequate attention to ventilation, line disruption, and excessive cooling. Many centers perform PDA ligation in the neonatal ICU, either as routine practice or in cases where transport seems especially risky, but the unfamiliarity of the environment, available personnel, relative lack of surgical equipment should a complication arise, adequacy of lighting, and sterility need to be considered. Surgical dissection and the lung retraction necessary to expose the duct can result in hypoxemia, hypercarbia, and hypotension. If possible, blood pressure should be monitored in an upper and lower extremity; the right arm is preferable, because the surgeon may have to place a clamp on the aorta if control of the aortic end of the ductus is lost during dissection or ligation. A second pulse oximeter on a lower

extremity can provide reassuring information to the surgeon at the time the duct is clipped or ligated (the PDA can be larger than either the PA or the aorta). After ligation, there is an acute increase in blood pressure with an increase in LV afterload, so that increased inotropic support of the severely dysfunctional ventricle may be necessary. Other complications include accidental extubation, profound hemorrhage resulting from disruption or tearing of the ductus, inadvertent ligation of the left pulmonary artery or descending aorta, and recurrent laryngeal nerve (RLN) damage. One needs to be vigilant for plugging of the endotracheal tube, particularly during the surgery or after lung reexpansion, in very small infants with correspondingly small (≤ 3.0 mm) tubes.

Older infants and children with an isolated PDA undergoing surgical or catheterization procedures may be extubated at the end of the procedure, allowing a variety of anesthetic techniques. The incidence of RLN injury may be reduced by using direct intraoperative stimulation and evoked electromyogram monitoring (Odegard et al., 2000).

After repair of PDA, and in the absence of pulmonary hypertension, cardiovascular function should be normal so that anesthetic management is straightforward.

Coarctation of the Aorta

Coarctation of the aorta is a focal narrowing of the descending thoracic aorta consistent with a discrete posterior shelf or invagination just opposite the insertion of the ductus arteriosus (juxtaductal) and distal to the left subclavian artery (Fig. 21-8). In some instances, this shelf may be circumferential. The precise cause is unknown, but it is thought to be caused by extension of ductal tissue into the wall of the aorta or by abnormal fetal blood flow patterns associated with lesions that reduce antegrade flow into the ascending aorta. Not surprisingly, coarctation is associated with aortic valve stenosis or a bicuspid aortic valve (50%), ventricular septal defect (48%), hypoplasia of other left heart structures (mitral valve and left

■ **FIGURE 21-8.** Coarctation of the aorta. Gadolinium-enhanced three-dimensional magnetic resonance angiogram showing coarctation of the aorta (arrow) distal to the left subclavian artery (LSCA). (Image courtesy Tal Geva, MD.)

ventricle), and aortic arch hypoplasia (Quaegebeur et al., 1994; Aboulhosn and Child, 2006).

The pathophysiology is varied and depends on the severity of the coarctation and the associated lesions. The ductus arteriosus plays a critical role as a source of systemic perfusion, so presentation is in infancy for all patients except those capable of tolerating ductal closure without overt hemodynamic compromise. In general, presentation beyond infancy is limited to patients with an isolated coarctation of mild to moderate severity. Critical neonatal coarctation with abrupt ductal closure results in profound circulatory collapse within the first days to a month of life, because perfusion to the lower body is dependent on patency of the ductus arteriosus and relatively high PVR. The presence of poor perfusion, acidosis, oliguria, and other signs and symptoms of acute systemic illness often results in these patients being seen emergently to rule out sepsis. Severe presentations typically involve some degree of acute myocardial dysfunction and can also include evidence of lung, liver, or renal injury. When a large VSD is also present, the aggravated degree of left-to-right shunting and heart failure (with elevated left atrial pressure and additional left-to-right shunting across the foramen ovale) results in presentation within days of birth. The initial treatment involves hemodynamic stabilization by reopening the ductus arteriosus with a PGE₁ infusion. Often, other resuscitative measures such as inotropic support, volume expansion, sodium bicarbonate, and, at times, intubation and controlled ventilation are needed. Of note, once the duct is open, it is possible for blood pressures in the upper and lower limbs to be similar despite severe aortic narrowing. Patients who presented with severe decompensation and evidence of

organ injury benefit from one or more days of restored systemic perfusion prior to surgical repair.

If the coarctation is not severe and closure of the ductus has occurred slowly, or if compensatory collaterals develop rapidly, presentation may be later in infancy, with tachypnea and failure to thrive. In such patients, the degree of coarctation commonly becomes more obstructive as the child grows. Blood pressure is elevated in the upper extremities, with an average gradient between upper and lower extremity sites of 30 to 40 mm Hg at rest (Keane and Fyler, 2006a). Collaterals may originate from the internal thoracic, intercostal, subclavian, or scapular arteries, and with extensive collateral development, patients may be asymptomatic with little difference in blood pressure between the arms and legs. Large collaterals can be a source of an auscultable bruit over the rib cage or elsewhere, as well as rib notching on chest x-ray. Coarctation causes left ventricular hypertension and hypertrophy, as well as systemic hypertension. Symptoms (exercise intolerance, headache, chest pain, lower extremity claudication) are an absolute indication for surgical repair. For the asymptomatic patient, surgical indications include a blood pressure gradient between the upper and lower limbs of greater than 20 mm Hg, upper body blood pressure greater than two standard deviations above normal, or aortic diameter loss of 50% or greater.

The optimal treatment for neonates, infants, and children is currently felt to be complete excision of the area of coarctation and surrounding ductal tissue with end-to-end anastomosis (Dodge-Khatami et al., 2000). With a hypoplastic aortic isthmus, complete excision in conjunction with an extended end-to-end or end-to-side anastomosis is recommended (Backer, 2003). Although balloon angioplasty may be used for primary relief of coarctation (Golden and Hellenbrand, 2007), it is rather regarded as the standard of care for recurrent coarctation after previous surgical repair (Jonas, 2004). Paraplegia secondary to spinal cord ischemia is the most devastating complication associated with surgical repair. The incidence is quite low (0.14% to 0.4%), and several factors are associated with an increased risk of developing paraplegia: hyperthermia, prolonged aortic cross-clamp time, elevated cerebral spinal fluid pressures, low proximal and distal aortic blood pressures, and poorly developed collaterals to the descending aorta. In addition to recoarctation, long-term consequences of coarctation and its repair can include the development of essential hypertension (even in the absence of a residual coarctation gradient) and perhaps increased risk of premature or sudden death.

Anesthetic Management

The newborn with *critical* coarctation requires medical stabilization, as outlined earlier, prior to surgical repair. Anesthetic management includes continuation of PGE₁ infusion (0.01 to 0.05 mcg/kg per minute) to maintain ductal patency, inotropic support of left ventricular function, adequate preload, and preservation of increased PVR, as lower body perfusion is dependent on right-to-left flow across the ductus. Blood pressure above and below the coarctation should be monitored, with the arterial catheter preferentially in the right arm. The proximal aortic clamp may occlude or compromise the origin of the left subclavian artery, or the left subclavian artery may be sacrificed for the repair. A femoral arterial line and right arm cuff can be used if right radial artery cannulation is unsuccessful. Neonates and very young infants are not candidates for volatile-based anesthetics. A technique using high-dosage fentanyl in combination

with a benzodiazepine or low inspired concentration of an inhalation agent is well tolerated by these patients. Ketamine may worsen hemodynamics in neonates with severe LV dysfunction by increasing SVR and should probably be avoided. In older children with only proximal systemic hypertension, intravenous or inhalational techniques are well tolerated. Regardless of the technique chosen, it should be appreciated that proximal blood pressure response to stimulation will be exaggerated.

The increase in proximal aortic pressure with application of the aortic cross-clamp in neonates and infants can usually be managed expectantly or with a volatile agent while continuing any inotropic support. In older children and adolescents, β -blockers and vasodilators may occasionally be necessary. However, a moderate increase in proximal aortic pressure during the cross-clamp period may be beneficial, as it is likely to encourage some degree of lower body perfusion via any existing collaterals. On the other hand, sodium nitroprusside results in further increases in cerebral spinal fluid pressure and further decreases in distal aortic blood pressure, reducing spinal cord blood perfusion pressure (Marini et al., 1998). In sum, we are unlikely to treat hypertension during the cross-clamp period unless it exceeds baseline arterial blood pressures by about 30% or more, or unless it approaches values that raise concern for cerebral toxicity. Spinal cord protection is accomplished with a short cross-clamp time (preferably <20 minutes) and mild induced hypothermia (34° C). Blood pressure is maintained at or a little higher than the preoperative level in the upper limbs. Removal of the cross-clamp will result in reactive hyperemia in distal tissues with vasodilation and transient hypotension, and release of acid metabolites will increase $Paco_2$. Anticipation by decreasing or discontinuing inhaled anesthetics or vasodilators in use, volume expansion, and appropriate ventilation are usually sufficient to limit these effects. Postoperatively, rebound hypertension may occur and persist for some time. Esmolol and sodium nitroprusside infusions are used in the early postoperative period. Older children without coexisting diseases can be additionally managed with lung isolation and may be candidates for early extubation.

Systemic-to-Pulmonary Artery Shunts

Systemic-to-pulmonary artery shunts (extracardiac shunts) are palliative procedures performed in neonates and infants with severely decreased pulmonary blood flow or ductal-dependent pulmonary blood flow when a corrective procedure is not possible (del Nido et al., 1988). With increased neonatal and infant repair of complex defects, fewer systemic-to-pulmonary artery shunts are being performed. The primary indications are single-ventricle, pulmonary atresia with intact ventricular septum, and some variants of TOF with pulmonary atresia.

The classic *Blalock-Taussig* shunt (end-to-side anastomosis of the transected subclavian artery to the branch pulmonary artery) has been abandoned because of resultant interruption of arm blood flow, and it has been replaced by the *modified Blalock-Taussig* (mBT) shunt in which a synthetic tube graft of polytetrafluoroethylene (PTFE; Gore-Tex) is interposed between the subclavian (or innominate) artery and the branch pulmonary artery (Gazzaniga et al., 1976a, 1976b; de Leval et al., 1981). With a median sternotomy approach, the shunt is placed more medially from the innominate artery. The shunt is usually performed on the side opposite the aortic arch, with a 3.5-mm shunt typically used in infants weighing 2 to 3.5 kg.

A *central* shunt, used when prior shunt procedures have failed, consists of a synthetic tube graft between the ascending aorta and the main or a branch pulmonary artery. The *Potts* shunt (side-to-side anastomosis of the descending aorta and left pulmonary artery) and *Waterston* shunt (side-to-side anastomosis of ascending aorta and right pulmonary artery) have largely been abandoned because of the high incidence of pulmonary artery distortion, the risk of too large a shunt, and the difficulty of closing the shunt at the time of subsequent repair.

Anesthetic Management

Anesthetic management for creation of a systemic-to-pulmonary artery shunt, as well as after shunt placement, necessitates control of the factors influencing the ratio of pulmonary to systemic flow across the shunt, usually in opposite directions from a physiologic standpoint. During *creation* of shunts to increase pulmonary blood flow (e.g., tricuspid atresia, and pulmonary atresia and its variants), pulmonary blood flow in most patients is clearly restricted, and concerns about increasing the degree of cyanosis are paramount. Thus, maneuvers to decrease PVR (high inspired oxygen concentration, induced respiratory alkalosis, avoidance of extremes of lung volume), to maintain or increase systemic cardiac output, and perhaps to increase SVR and blood pressure (volume administration, inotropic support) are most likely to be necessary to maintain oxygenation. In the presence of a widely patent PDA, there is the risk for pulmonary overcirculation prior to ligation of the ductus in some of these patients.

After shunt creation, pulmonary overcirculation is frequent. Such patients can be expected to demonstrate significant hemodynamic instability in the immediate postoperative period as they adapt to the shunt-dependent circulation. This situation is managed initially by lowering inspired O_2 to room air (or as low as tolerated based on SpO_2), allowing the $Paco_2$ to rise to at least moderate levels of hypercarbia, and adding PEEP to increase PVR. A major factor is that these shunts are intended to be large and therefore provide “excessive” amounts of PBF to accommodate patient growth (the duct may also be open for some period of time, and furthermore some surgeons do not ligate the duct initially so as to provide a margin of safety against acute shunt thrombosis). Shunts impose a volume load on the systemic ventricle, and together with any preexisting ventricular dysfunction, inotropic support may be necessary to ensure systemic and shunt perfusion after shunt creation. Thus, anticipation of significant hemodynamic instability and invasive monitoring of arterial pressure are required, and the need for significant inotropic support (dopamine, at times supplemented by epinephrine or norepinephrine) in the early postoperative period can be expected. Persistent and severe cyanosis after the shunt is opened should raise suspicions of inadequate shunt flow; arterial blood pressure in this instance may be either high or low, depending in large part on systemic cardiac output and the effect of hypoxia on myocardial function and SVR. Inadequate shunt flow may be caused by shunt occlusion (thrombus, stenosis, or compression), high PVR, low arterial blood pressure or SVR, low cardiac output (causing both decreased shunt flow and reduced venous saturations), or parenchymal lung disease.

The modified BT shunt can be performed via a thoracotomy or median sternotomy, and with or without CPB. Central shunts are usually performed through a median sternotomy. With a thoracotomy approach, unilateral lung retraction is

necessary and the resulting atelectasis may compromise oxygenation and ventilation. The branch pulmonary artery will have to be partially occluded by a clamp to allow creation of the distal anastomosis, increasing physiologic dead space and further compromising oxygenation and CO₂ removal. The arterial-to-end-tidal CO₂ gradient will be further increased. Efforts to increase pulmonary blood flow by reducing PVR with ventilatory interventions and by increasing left-to-right shunting should be initiated before pulmonary artery occlusion. If persistent severe desaturation, bradycardia, or hypotension occurs with cross-clamping of the pulmonary artery, CPB will be required for shunt placement. A narcotic-based technique with muscle relaxant, supplemented with a volatile agent or benzodiazepine (or both) as tolerated, and a period of postoperative ventilation is the rule. Arterial catheter placement should preferably not be on the side of the subclavian artery to be shunted. Central venous access is recommended, but if it is not possible, a right atrial catheter can be placed by the surgeon for monitoring and inotrope administration. Heparin (50 to 100 IU/kg) may be requested by the surgeon to reduce the risk for shunt thrombosis. Complications include bleeding; desaturation during chest closure as a result of alterations in pulmonary mechanics or kinking, distortion, or compression of the shunt or pulmonary arteries; shunt thrombosis and profound hypoxemia; and pulmonary overcirculation with systemic hypotension if the shunt is too large or the PVR too low (see earlier). Postoperative ventilation is usually required to ensure adequate shunt function and attainment of a stable hemodynamic state.

Pulmonary Artery Banding

Pulmonary artery banding (PAB) is used to limit pulmonary blood flow in infants with a large left-to-right shunt not amenable to early corrective surgery, or as part of a staged palliation (Muller and Danimann, 1952). With the increase in early infant repair, PAB is performed less commonly, and it is currently most often indicated for very complex lesions (multiple VSDs, at times referred to as Swiss-cheese septum), in TGA for preparation of the left-ventricle prior to an arterial switch operation (Mee, 1986; Jonas et al., 1989), for double-inlet or double-outlet ventricles in the absence of pulmonary stenosis, or to temporize in neonates who are critically ill with significant noncardiac diseases. As congestive heart failure in the newborn period is atypical because of the high PVR, PAB is sometimes performed in the second or third month of life (del Nido et al., 1988). By reducing the extent of the left-to-right shunt, the band reduces the volume load on the ventricles, improves congestive symptoms, protects the pulmonary vascular bed against the development of pulmonary hypertension and PVOD, and improves respiratory mechanics. PAB may cause distortion of the main pulmonary artery or distortion of the branch pulmonary arteries by migration of the band distally. This distortion may complicate or even preclude subsequent attempts at definitive repair.

Anesthetic Management

The infant is usually in congestive heart failure with reduced systemic perfusion and excessive PBF. General endotracheal anesthesia with full cardiovascular monitoring and postoperative ventilation is usually required. Anesthetic management before band placement is conceptually the same as that for

patients with large left-to-right shunts (i.e., focused on maintaining systemic perfusion and limiting further increases in PBF). It is usually opioid based, with inotropic support of the ventricle and systemic cardiac output as needed. The surgical approach may be via a left thoracotomy or sternotomy without CPB. The band is placed circumferentially around the main pulmonary artery. Techniques for determining the degree of band tightening vary by surgeon and are based on formula, the resultant level of arterial oxygen saturation (above 70% to 80%), the level of Pao₂ (>30 to 35 mm Hg), or the pulmonary artery pressure distal to the band (one third to one half of systemic pressure), the pressure proximal to the band (75% or greater of systemic, particularly when the indication is to “train” the LV prior to arterial switch), or some inexact combination thereof. An excessively tight band will severely reduce pulmonary blood flow, cause an intolerable degree of hypoxemia, and expose the ventricle to high afterload. Pulse oximetry has proved useful during pulmonary artery banding because arterial desaturation usually precedes hypotension and bradycardia when band tightness is excessive. Echocardiography can be valuable in assessing ventricular function and determining the pressure gradient across the band. Ventricular distention may require loosening of the band or initiation of inotropic support, or both. Postoperative ventilation is usually required to allow recovery of lung function.

Vascular Rings and Slings

A vascular ring is an aortic arch anomaly in which the trachea and esophagus are surrounded completely by vascular structures (Fig. 21-9, A). See related video online at www.expertconsult.com. Rings, which need not be composed entirely of patent vascular structures, are formed by abnormal persistence or regression of components of the aortic arch complex, and they can cause compression of the trachea, bronchi, and esophagus. In a vascular sling, the trachea and esophagus are not completely encircled but can be compressed. Although accounting for less than 1% of all congenital heart defects, vascular rings and slings represent an important source of airway and esophageal obstruction. Intracardiac defects are present in approximately 29% of patients with vascular rings (Humphrey et al., 2006).

The vast majority of patients with a vascular ring have either a double aortic arch with right arch dominance (see Fig. 21-9, B), a right aortic arch with mirror-image branching, or a right aortic arch with an aberrant left subclavian artery and left ligamentum arteriosum (Dodge-Khatami et al., 2002; Humphrey et al., 2006). With a double aortic arch with right arch dominance, the anteriorly located left aortic arch gives rise to the left carotid and left subclavian arteries. This left arch is generally atretic or severely hypoplastic beyond the origin of either the left carotid or left subclavian artery. A right aortic arch passes rightward and posterior to the trachea, and a left aortic arch passes leftward and anterior to the trachea. With mirror-image branching, the arch gives off, in order, the common trunk of the left common carotid and left subclavian, the right common carotid, and the right subclavian arteries.

Vascular rings and slings generally appear in childhood, with the most common symptoms being inspiratory stridor, dysphagia, wheezing, dyspnea, cough, and recurrent respiratory tract infections (Humphrey et al., 2006). Feeding problems are common. MRI is the diagnostic technique of choice in many

■ **FIGURE 21-9.** Vascular ring. **A**, Three-dimensional volume reconstruction of gadolinium-enhanced magnetic resonance angiogram showing a double aortic arch with nearly equal-sized left and right arches. **B**, Electrocardiogram-gated fast (turbo) spin-echo MRI in the coronal plane showing a double aortic arch with a large right aortic arch (*RAA*) and a small left aortic arch (*LAA*). Note the severe compression of the trachea by the double aortic arch. (Images courtesy Tal Geva, MD.)

centers (van Son et al., 1994); other diagnostic tools include echocardiography (for evaluation of intracardiac defects), bronchoscopy, and barium swallow.

The goal of *repair* for vascular rings or slings is to divide the compressive ring, relieve the airway or esophageal compression, and maintain normal perfusion of the aortic arch. The surgical approach is typically via a left posterolateral thoracotomy, at times open, but more commonly using a video-assisted thoracoscopic technique (Burke and Chang, 1993). Simultaneous repair of vascular tracheobronchial compression syndromes and intracardiac defects carries a higher risk for morbidity and mortality (Sebening et al., 2000).

Anesthetic Management

Anesthetic management depends on the type of vascular ring, the type and severity of underlying CHD, and the planned surgical procedure. It is not clear how frequently, if ever, these lesions behave like anterior mediastinal masses (Kussman et al., 2004). The majority of these patients are best approached by careful induction, assurance of the ability to ventilate with positive pressure, and then muscle relaxation; the application of positive pressure and removal of respiratory effort usually result in improved airflow. With significant airway narrowing, the endotracheal tube tip should lie proximal to the stenotic segment to avoid edema and granulation tissue formation caused by tube impact on the narrowed area. Alternatively, cases of severe collapse may require stenting with an endotracheal tube or rigid bronchoscope to ensure adequate ventilation. For all of these reasons, previous characterization of tracheal narrowing with respect to mechanism (extrinsic compression, tracheomalacia,

complete tracheal rings), location, severity, and extent (length of segment) can critically inform intubation and other aspects of management in these patients. Airway radiography (plain film, MRI, computed tomography) and bronchoscopy (routine in some centers) (Chapotte et al., 1998) can also provide this information. In patients without a prior bronchoscopy, one can be performed after induction at the time of the ring or sling surgery. In older children, the surgical approach may benefit from single-lung ventilation techniques.

Successful tracheal extubation is possible in most patients with isolated vascular rings at the conclusion of the procedure. However, successful repair of the ring may not immediately relieve airway obstruction, so obstruction may recur immediately on extubation or as a remote problem after surgery. Persistent obstruction may result from residual compression, associated structural anomalies, and secondary airway wall instability (tracheomalacia, bronchomalacia) that can be exacerbated by posttraumatic edema and may persist for months after successful surgery. Bronchoscopy performed at the end of the surgical procedure may be helpful to assess residual airway compression and degree of dynamic airway collapse.

The potential for a variable course and relationship of the RLN to the ligamentum arteriosum and descending aorta makes the RLN susceptible to injury during either type of surgical approach to vascular ring. In the largest reported series, there was a 5.3% incidence of unilateral vocal cord paralysis (Geva et al., 2002). Intraoperative RLN monitoring may be useful (Odegard et al., 2000), in which case muscle relaxants should not be used or allowed to wear off prior to testing. When RLN injury occurs, there is a risk for stridor or hoarseness, and the potential for aspiration.

ANESTHESIA FOR CARDIAC CATHETERIZATION

The cardiac catheterization laboratory is one of the most challenging and unpredictable environments in which to provide anesthesia. Major advances in interventional catheterization techniques and imaging (echocardiography, cardiac MRI, cardiac computed tomography) in pediatric cardiology have led to fewer diagnostic or hemodynamic catheterizations and a concomitant increase in interventional or therapeutic procedures. Evolutions in the surgical management of CHD, together with the expanding role of interventional catheterization, has led to a larger and more complex population of children and adults with CHD undergoing one or repeated catheterizations, radiofrequency ablations, and imaging studies. Many congenital cardiovascular anomalies that previously required surgical management may now be corrected with transcatheter techniques, and some lesions that were previously inoperable can be effectively managed at cardiac catheterization (Lock, 2006). Surgical and interventional catheterization approaches complement one another so that the ability to treat patients with more complex CHD is enhanced (Mayer, 2000).

Anesthesia for cardiac catheterization mandates knowledge and understanding of the catheterization environment, indications for catheterization and procedures performed, the associated risks and complications thereof, and lesion- and procedure-specific principles of anesthetic management.

Catheterization Laboratory Environment

Cardiac catheterization laboratories are usually outside the operating suite, but provision of the same standards of care, patient monitoring, and equipment as in an operating room is mandatory (Stensrud, 2005) (see Chapter 10, Equipment). The development of hybrid procedures involving combined catheter and surgical approaches indicates that the modern catheterization laboratory is also an operating room (Bacha, 2008). Nonetheless, the laboratory is usually configured to accommodate the needs of the cardiologist, resulting in a confined space for the anesthesia machine, monitors, and other essential personnel and equipment. Access to the patient is limited by the radiology equipment, movable leaded-glass screens or partitions, and positioning of the patient's arms around the head (Fig. 21-10). These poor ergonomics are exacerbated by darkening of the room to facilitate viewing of images, repeated obstruction to observing the images by the anteroposterior and lateral cameras, and the relatively heavy lead apron and thyroid shield worn to limit radiation exposure. Extreme movement and positioning of the x-ray cameras to obtain greater magnification or different views are a danger to the patient and anesthesiologist, causing physical (positioning and compression) damage to the patient and anesthetic equipment or dislodgement of the anesthesia circuit, endotracheal tube, laryngeal mask airway, and intravenous catheters. The laboratory is kept cool to prevent overheating of the electronic equipment (and cardiologists), and the cold-flush solutions, wet drapes, exposure during positioning and groin preparation, large surface area-to-body mass ratio in neonates and infants, and general anesthesia additionally predispose to hypothermia.

■ **FIGURE 21-10.** Catheterization laboratory environment showing limited access to the patient and obstruction to viewing the fluoroscopic images.

Indications for Cardiac Catheterization and Procedures Performed

Cardiac catheterization is indicated when precise physiologic measurements are required, when anatomic features are poorly visualized by imaging, when electrophysiologic studies are necessary, and when therapeutic catheterization is planned (Lock, 2006). Interventional procedures now account for greater than 50% of cardiac catheterization procedures at many centers (79% at Children's Hospital Boston) (Qureshi et al., 2000) and may be performed as the primary treatment of a defect, as an interim treatment prior to surgical repair, or for the treatment of a residual defect after surgery. Procedures performed in the catheterization laboratories are shown in Box 21-3. The anesthetic considerations for specific procedures are discussed toward the end of this section.

Box 21-3 Types of Procedures Performed in the Cardiac Catheterization Laboratory

- Diagnostic (hemodynamic) catheterization
- Interventional catheterization
- Endomyocardial biopsy
- Valvotomy
- Angioplasty with or without stent implantation
- Device closure of cardiovascular communications
- Creation of an atrial septal defect
- Transcatheter implantation of pulmonary valves
- Pericardiocentesis
- Electrophysiologic
- Diagnostic electrophysiologic studies
- Catheter ablation of arrhythmias
- Pacemaker implantation (including automatic implantable cardioverter defibrillators and testing)
- Electrical cardioversion
- Other imaging procedures
 - Cardiac magnetic resonance imaging
 - Echocardiography: transthoracic, transesophageal

Diagnostic or Hemodynamic Catheterization

Diagnostic or hemodynamic catheterization measures intracardiac (right and left atrial, ventricular end-diastolic) and intravascular (arterial, pulmonary artery, ventricular outflow gradient) pressures and oxygen saturation (arterial, mixed venous, pulmonary venous), from which the cardiac index (Fick principle with assumed or measured oxygen consumption), systemic and pulmonary blood flows and their ratio ($Q_p:Q_s$), and pulmonary vascular resistance can be calculated. The $Q_p:Q_s$ ratio is calculated according to the following formula: $Q_p:Q_s = (S_{aO_2} - S_{PAO_2}) / (S_{PV O_2} - S_{PAO_2})$; when an intracardiac shunt or intracardiac mixing is present, $S_{SVC O_2}$ is used rather than S_{PAO_2} . The methodology is concisely reviewed elsewhere (Lock, 2006; Bergersen et al., 2009). Arterial blood gas and activated clotting time are measured hourly, with analysis of the blood gas for hematocrit, acid-base status, electrolytes, and glucose. Hemodynamic measurements and calculations are usually performed with the patient breathing air (F_{iO_2} , 0.21) to simulate baseline conditions. Normal hemodynamic data in children vary with age (Table 21-3). Angiography is performed when noninvasive imaging is inconclusive or fine vascular detail is needed. Most catheterizations are carried out percutaneously via the femoral vessels or umbilical vessels (newborns). The subclavian, internal jugular, and hepatic veins (transhepatic approach) may be used in patients with femoral vein occlusion, or as the preferred or necessary site for some procedures or anatomic situations (e.g., in setting of bidirectional cavopulmonary anastomosis).

Interventional Catheterization

Endomyocardial biopsy is used for evaluation of myocarditis or cardiomyopathy and remains the gold standard for detection of cellular rejection after heart transplantation. At least five biopsies of 1 mm or greater in diameter are obtained from the RV septum in all patients. The femoral vein is usually used in patients weighing 15 kg or less, and in bigger patients, the right internal jugular vein is the preferred access site (Lock, 2006).

Balloon valvotomy (valvuloplasty) is used in the management of valvar pulmonary stenosis, aortic stenosis, mitral stenosis, right ventricle-to-pulmonary artery conduits, and recurrent coarctation of the aorta. Indications for dilation are

generally in the following ranges: valvar pulmonary stenosis, peak gradient greater than 50 mm Hg; aortic stenosis, peak gradient greater than 50 mm Hg; mitral stenosis, mean gradient greater than 10 mm Hg, taking into account morphology of valve apparatus and symptoms (poor growth, respiratory symptoms, hemoptysis, severe pulmonary hypertension); right ventricle-to-pulmonary artery conduits, when pressure in the right ventricle reaches three fourths of aortic pressure; aortic coarctation, peak gradient greater than 20 mm Hg. The principle involves placement of a guidewire across the valve, passage of a balloon catheter over the wire so that it straddles the valve, and then inflation of the balloon with resultant tearing of the fused leaflets (Kan et al., 1982). *Pulmonary valvotomy* is the treatment of choice for pulmonary valve stenosis, with excellent long-term results (Jarrar et al., 1999; Gudauskys and Beekman, 2006). The procedure is performed in neonates with critical obstruction, or electively at 3 to 9 months of age when there is moderate obstruction, and it is generally associated with little hemodynamic instability. Although a sedation technique may be used, general anesthesia is recommended for the neonate with critical pulmonary stenosis or when radiofrequency catheterization is planned to perforate platelike pulmonary atresia (Justo et al., 1997), and in the older child with RV dysfunction and systemic or suprasystemic RV pressure. PGE₁ therapy appears to increase the incidence of apnea during procedural sedation of neonates, and hence elective intubation and general anesthesia is done for this subset of patients.

In contrast, *aortic valve dilation* provides short- to intermediate-term palliation (Pedra et al., 2004) of congenital aortic stenosis and is associated with greater risk than pulmonary valve dilation. It is undertaken in children and adolescents with a peak systolic gradient greater than 50 mm Hg without severe aortic regurgitation, and in infants with critical obstruction regardless of the gradient (Lock, 2006). An aim is to delay the need for surgical repair or valve replacement. Balloon inflation is associated with loss of cardiac output, arrhythmias, and the risk for coronary ischemia. Neonates with critical aortic stenosis are frequently hemodynamically unstable, have a ductal-dependent circulation, often have artificially low gradients because of decreased cardiac output, and are prone to ventricular fibrillation. General endotracheal anesthesia with inotropic support, PGE₁ infusion, and postoperative ventilation is frequently necessary. Sedation may be considered for older children with good ventricular function.

Mitral valvotomy, initially described for treatment of rheumatic mitral stenosis, is also now used for palliation of congenital valvar mitral stenosis (McElhinney et al., 2005). Indications include systemic or higher pulmonary artery pressures, failure to thrive, frequent respiratory infections, or mean mitral gradients greater than 15 mm Hg (Lock, 2006). In addition to resulting in arrhythmias and loss of cardiac output, balloon inflation can result in increased pulmonary venous pressure or acute mitral regurgitation, both of which can lead to significant pulmonary edema. Inotropic support is often necessary. For these reasons, general endotracheal anesthesia is recommended for most patients undergoing balloon mitral valve dilation, with consideration for postprocedure mechanical ventilation until resolution of the pulmonary edema. *Dilation of bioprosthetic valves* in right ventricle-to-pulmonary artery conduits is not usually successful, but it will allow postponement of conduit or valve replacement for 6 to 18 months.

TABLE 21-3. Normal Hemodynamic Data in Children

Right atrial pressure	3–5 mm Hg (mean)
Right ventricle pressure	20–30 or 3–5 mm Hg (systolic or end-diastolic)
Pulmonary artery pressure	12–15 mm Hg (mean)
Pulmonary capillary wedge pressure	8 mm Hg (mean)
Left atrial pressure	5–8 mm Hg (mean)
Left ventricular pressure	65–110 or 3–8 mm Hg (systolic or end-diastolic)
Aortic pressure	65–110 or 35–75 mm Hg (systolic or diastolic)
Pulmonary vascular resistance	<2 Wood units (indexed)
Systemic vascular resistance	15–20 Wood units (indexed)

Balloon angioplasty with or without stent implantation is most commonly employed for pulmonary artery stenoses, right ventricle-to-pulmonary artery conduits, and postoperative coarctation of the aorta, but it may also be used for pulmonary vein stenoses and dilation of atrial baffles. The procedure is similar to that of balloon valvotomy (balloon placement over a guide wire), with the goal being to create a controlled tear in the intima so that the vessel can heal in the newly created diameter (Moore and Lock, 2000). If the vessel (waist) is resistant to a conventional angioplasty balloon, a cutting balloon may be employed. *Stent implantation* in the dilated vessel is indicated with elastic recoil after dilation, for creation of an intimal flap, for occurrence of dissection or hematoma that may impair flow, or to control bleeding from a tear in the vessel wall. It is imperative that patients not move during balloon angioplasty and stent placement, as vessel rupture, stent malposition, or stent displacement (embolism) can occur. *Pulmonary artery balloon angioplasty* is the procedure of choice for hypoplastic noncentral pulmonary arteries after repair of tetralogy of Fallot, and in other arteriopathies (Noonan, Williams, Alagille, idiopathic). A successful relief of obstruction by pulmonary artery dilation frequently results in high-flow, high-pressure pulmonary edema, which may necessitate diuretic administration and in some cases a period of postoperative ventilation. Hemoptysis resulting from vessel tear can be brisk and life threatening, resulting in difficulty in securing the airway during a sedation technique and progressive difficulty ventilating and oxygenating once the airway is controlled; an acute respiratory distress syndrome (ARDS)-like process can occur after significant pulmonary hemorrhage (or at times after dilation-induced pulmonary edema, particularly in older patients). Balloon angioplasty has also been used postoperatively to dilate scar tissue at a sutured anastomosis (e.g., for relief of SVC syndrome), at the site of surgically created shunts, or because of vessel kinking or twisting.

Indications for general anesthesia in patients undergoing pulmonary artery dilation include moderate to severe right ventricular dysfunction, the presence of systemic to suprasystemic RV pressures, a previous history of significant pulmonary edema after reperfusion or bleeding from tears, or anticipation of a lengthy procedure. The presence of a “pop off” in the form of a VSD or an ASD confers some protection against acute RV dysfunction and systemic hypotension during PA dilation procedures. Elective creation of an ASD for this purpose via balloon atrial septostomy is done at times, particularly in the presence of systemic or suprasystemic RV pressures and RV dysfunction. Stent placement in bioprosthetic right ventricular conduits can interfere with pulmonary valve function or compress the coronary arteries.

Aortic balloon angioplasty is more useful for arch obstructions that recur or remain after repair of coarctation of the aorta, interrupted aortic arch, or hypoplastic left heart syndrome (Qureshi et al., 2007). Primary catheter therapy of native coarctation may be considered for the older child or adult, with less procedural success in neonates. *Pulmonary vein dilation* for pulmonary vein stenosis, although producing an acute improvement in the degree of obstruction and resultant pulmonary hypertension, almost invariably results in restenosis of the affected pulmonary vein within days or weeks after the procedure. These are some of the sickest children, and as pulmonary vein dilation can initially result in worsening of the pulmonary edema, general endotracheal anesthesia is recommended, and there is frequently the need for postprocedure ventilation.

Device closure of cardiovascular communications may be used for PDA, PFO, secundum ASD, VSD, Fontan fenestrations, periprosthetic valve leaks, and various other vessels (aortopulmonary collaterals, BT shunts, systemic arteriovenous fistulae, pulmonary arteriovenous fistulae, venous malformations). Devices approved by the U. S. Food and Drug Administration (FDA) include the Amplatzer (duct occluder, septal occluder, vascular plug), CardioSEAL, and various coils. Non-FDA approved at this time are the STARFlex (recent modification of CardioSEAL), BioSTAR (bioabsorbable), and HELEX (Fig. 21-11). Placement of devices for PDA, for PFO, for ASD, for Fontan fenestrations, and in vessels is usually associated with minimal hemodynamic instability and can often be done with a procedural sedation technique (Hickey et al., 1992). General endotracheal anesthesia is necessary when TEE will be used to guide device placement (e.g., device closure of a secundum ASD), and it is used because of the hemodynamic instability associated with closure of VSD (Laussen et al., 1995) and perivalvular leaks (Hourihan et al., 1992; Pate et al., 2006). Device closure of muscular VSDs is indicated for defects difficult to reach surgically, residual defects after surgery, and defects related to myocardial infarction or trauma (Lock et al., 1988; Knauth et al., 2004). Device closure for perimembranous defects has recently been reported (Hijazi et al., 2002; Holzer et al., 2006). Aside from preexisting ventricular dysfunction, device closure of VSDs is frequently associated with hemodynamic instability. The causes are multiple and include intracardiac manipulation of large, stiff catheters leading to arrhythmias, atrioventricular or aortic valve regurgitation from the stenting open of valves, blood loss (the result mainly of frequent catheter exchanges in and out of large sheaths), device malposition or displacement, and air embolus.

Creation of an atrial septal defect by balloon atrial septostomy was the first reported pediatric interventional procedure (Rashkind and Miller 1966), and is the procedure of choice to palliate the newborn with transposition of the great arteries. A catheter is passed across the atrial septum, and the balloon is inflated in the left atrium and then rapidly jerked two to three times across the septum to produce a tear in the septum primum of the fossa ovalis. An association with stroke has been reported (McQuillen et al., 2006). Balloon atrial septostomy is also used to facilitate adequate mixing in patients with HLHS and a restrictive atrial communication prior to stage I palliation. Beyond the neonatal period, the septum is too tough, so a blade is necessary. Creation of an ASD is also performed for severe pulmonary hypertension and for left atrial decompression during ECMO.

Transcatheter implantation of a pulmonary valve in a prosthetic RV outflow tract conduit is a relatively recent innovation (Bonhoeffer et al., 2002). The Melody Transcatheter Pulmonary Valve consists of an 18-mm bovine jugular vein valve mounted in a NuMed platinum iridium stent (Fig. 21-12). The valve is delivered via a 22-Fr balloon-in-balloon-sheathed delivery system, in a manner similar to that used for other RVOT stents. The hand-crimped valve is then delivered at a final diameter of approximately 18, 20, or 22 mm. The procedure is performed under general anesthesia with fluoroscopic imaging.

Pericardiocentesis may be diagnostic or performed to treat cardiac tamponade. It is frequently performed on an urgent or semiurgent basis in hemodynamically compromised postoperative patients, or as the result of misadventures in the catheterization laboratory (Zahn et al., 1992; Bergersen et al., 2009)

A subxyphoid approach is used with echocardiographic and fluoroscopic guidance. Following standard management principles for this situation (volume loading as necessary, maintaining myocardial function and blood pressure) and titrating midazolam and ketamine with local anesthetic infiltration of the skin and subcutaneous tissues (while maintaining a natural airway with spontaneous ventilation) generally results in very satisfactory anesthesia and good hemodynamic stability (Morray et al., 1993; Jobeir et al., 2003)

Electrophysiologic Procedures

A *diagnostic electrophysiology study* (EPS) measures electrical activation of the heart in time and space (abnormal tissue has different conduction velocity and refractoriness) to determine the mechanism (automaticity versus reentry) and site of the

arrhythmia generation or propagation. Standard electrode catheter recording sites for an EPS are high right atrium, across the tricuspid valve (bundle of His), the coronary sinus (left atrium and ventricle), and the right ventricular apex. Adenosine may be administered, often without warning to the anesthesiologist, to block the AV node in order to reveal a unidirectional retrograde accessory pathway or cryptic preexcitation during sinus rhythm, whereas an isoproterenol infusion may be used to induce tachycardia (Walsh et al., 2006a).

Catheter ablation of arrhythmias has dramatically altered the standards for clinical management of tachycardias in all age groups, resulting in a significant reduction in the use of pharmacologic antiarrhythmic drugs. Radiofrequency catheter ablation (RFCA) is the most widely used technique, with cryoablation (tissue freezing with a cryocatheter) selectively used for ablation in the vicinity of the AV node (Kirsh et al.,

2005). The majority of patients are otherwise healthy, present with well-tolerated supraventricular tachycardia (atrial flutter, AV nodal reentrant tachycardia, accessory pathways, atrial fibrillation), and have otherwise structurally normal hearts. Increasingly, patients who are to receive an EPS have had surgical repair of CHD, in which suture lines, damage to the conduction system, and pressure and volume overloading predispose to myocardial dysfunction and arrhythmias.

A sedation technique may be suitable for purely diagnostic procedures, but general anesthesia is used when EPS is combined with ablation. An exception to this is ablation of ectopic atrial tachycardia or ventricular tachycardia (automatic tachycardias) in older children and adults in whom the decrease in catecholamines associated with deep sedation or anesthesia may make mapping of the arrhythmia difficult or unachievable (Lai et al., 1999). Despite concerns by some and experimental evidence of various electrophysiologic alterations, propofol, isoflurane, sevoflurane, midazolam, alfentanil and fentanyl have little *clinically significant* effects on electrophysiologic studies (Lau et al., 1993; Sharpe et al., 1992, 1995, 1999; Lavoie et al., 1995; Erb et al., 2002b; Fujii et al., 2009) or the ability to map and ablate most arrhythmias. Interestingly, dexmedetomidine does significantly depress sinus and AV node function to an extent that might be relevant to EPS procedures (Hammer et al., 2008). Additional anesthetic considerations for ablation include prolonged procedures (3 to 9 hours); a need for absolute immobility during application of the ablative lesion, because permanent complete heart block can result if the focus is near or in the AV node or bundle of His; the occasional need for ventilation to be held at end-inspiration or during expiration to ensure adequate contact of the ablation catheter with the arrhythmic focus; and the potential for hemodynamic compromise caused by rhythm disturbances and possible need for electrical or pharmacologic cardioversion. As frequent episodes of tachycardia, even if hemodynamically stable, can produce cardiac remodeling and ventricular dysfunction, a preprocedure echocardiogram is typically done for this reason, as well as to look for structural abnormalities. Patients with structurally normal hearts usually tolerate the periods of rapid heart rate well.

In comparison with patients with structurally normal hearts, those with repaired CHD pose a much greater challenge. Patients following repair of Tetralogy of Fallot, the Mustard or Senning operation for TGA, and those with Fontan anatomy are among those with congenital heart disease that present frequently for ablation procedures. Preexisting ventricular dysfunction can limit the choice of anesthetic agents, the procedures are technically more difficult and thus much longer, and

invasive arterial monitoring and a urinary catheter are usually indicated. Inotropic support may be needed from very early in the procedure (sometimes with induction), and evidence of low cardiac output such as a developing metabolic acidosis should be sought with blood gas investigations. Low or falling SVC or mixed venous oxygen saturations can also indicate poor status or tolerance of the procedure. As induced arrhythmic episodes may be associated with significant hypotension, the duration may need to be short and terminated by pacing, drug, or cardioversion methods.

The incidence of postoperative nausea and vomiting with catheter ablation is high, even with little opioid use, and can be significantly reduced with a propofol-based anesthetic (Erb et al., 2002a). An antiemetic is routinely administered, but dexamethasone is avoided because of the theoretical concern of its antiinflammatory effects on the ablation lesion.

Pacemakers and Implantable Cardioverter Defibrillators

Although no pacemaker is specifically designed for use in children, pacemakers have become much smaller in size and weight. Pacemaker systems consist of a pulse generator and one, two, or three leads, with the functionality of the pacemaker described by a five-letter code (the NBG code) (Table 21-4) (Bernstein et al., 2002). The first letter (position I) refers to the chamber that is paced, the second letter (position II) refers to the chamber sensed, the third letter refers to the pacemaker response to sensing spontaneous cardiac depolarizations (or spurious interference signals), the fourth letter indicates the presence or absence of an adaptive-rate mechanism (rate modulation), and the fifth letter indicates whether multisite pacing is absent or present, and, if present, in which chambers. If adaptive-rate pacing and multisite pacing are absent, use of only the first three positions is sufficient.

Single-chamber atrial or ventricular pacemakers sense myocardial signals emanating from the corresponding cardiac chamber and deliver a pacing stimulus if no signal is sensed at the programmed lower rate (Kaszala et al., 2008). Dual-chamber pacemakers sense and pace both the atrium and the ventricle. Atrial-based pacing (e.g., AAI, DDD, AOO) is superior to simple ventricular-based pacing (such as VVI, VOO), as AV synchrony is preserved (see Table 21-4). Biventricular pacing activates both the right and left ventricles in a nearly simultaneous fashion to eliminate any delay or asynchrony between the two ventricles, and it is used in the setting of CHF and interventricular conduction delays.

The most common indications for permanent pacemaker implantation in children, adolescents, and patients with CHD are

TABLE 21-4. Revised NASPE/BPEG Generic Code for Antibradycardia, Adaptive-Rate, and Multisite Pacing

From Bernstein AD, Daubert JC, Fletcher RD, et al: The revised NASPE/BPEG generic code for antibradycardia, adaptive-rate, and multisite pacing, *PACE* 25:260-264, 2002. BPEG, British Pacing and Electrophysiology Group; NASPE, North American Society of Pacing and Electrophysiology.

symptomatic bradycardia, the bradycardia-tachycardia syndrome, and either congenital or postsurgical advanced second- or third-degree AV block (Epstein et al., 2008). Indications for implantable cardioverter defibrillators (ICD) include aborted sudden death, spontaneous sustained ventricular tachycardia, syncope with a positive ventricular stimulation study, and high-risk patients with hypertrophic cardiomyopathy or congenital long-QT syndrome. The transvenous route is preferred whenever possible, as a thoracotomy is avoided, pacing thresholds are lower, and there is a lower incidence of lead fractures. Disadvantages of transvenous leads are risk for venous occlusion and difficulties with length as the child grows. The primary indications for epicardial placement include small patient size, significant intracardiac shunting in which lead thrombus might impose an embolic risk, or lack of vascular access (Walsh et al., 2006b). Transvenous systems are placed with the patient under general anesthesia, either in the operating room or in the catheterization laboratory. The generator is usually placed in the left or right pectoral area with percutaneous puncture of the subclavian vein to introduce the leads. Miniaturization of ICD systems has led to implantation in smaller children and infants (Berul, 2008). It is standard practice to test the ICD by induction of ventricular fibrillation (defibrillation threshold testing). The patient is preoxygenated, and if the device fails the patient is defibrillated by previously placed external pads. While the device is recharging to administer a higher energy shock, the external defibrillator is charged, so that if the device fails a second time external defibrillation can be immediate (Berul et al., 2008). Clear communication between the anesthesia, cardiology, and nursing teams as to the planned sequence of events is essential.

Electrical cardioversion is usually performed in the catheterization laboratory. Anesthesia usually comprises rehydration with a fluid bolus, midazolam premedication if necessary, and titration of etomidate or propofol (the choice guided largely by underlying ventricular function) until loss of consciousness. The principles followed for anesthesia for noncardiac surgery apply.

Other Imaging Procedures

Cardiovascular Magnetic Resonance Imaging

Cardiovascular magnetic resonance (CMR) imaging is usually performed when echocardiography cannot provide the required diagnostic information, as an alternative to or to complement diagnostic cardiac catheterization, and to obtain diagnostic information for which CMR offers unique advantages (Geva and Powell, 2008). Specifically, CMR can provide high-resolution, three-dimensional images of cardiovascular anatomy and pathology, and can accurately quantify cardiac chamber volumes and mass, regional LV and RV myocardial function, and, with magnetic resonance angiography, determine ejection fraction, stroke volume, regurgitation volume and fraction, and systemic and pulmonary blood flows, as well as regional flow rates (Fogel, 2000; Geva, 2000). MRI-guided interventional cardiology for diagnostic and interventional applications is an emerging field (Lardo, 2000).

Anesthetic considerations for MRI in general are discussed in Chapter 33, Anesthesia and Sedation for Pediatric Procedures Outside the Operating Room; however, anesthesia for CMR has some unique requirements. Patients must remain immobile in the scanner bore for periods of 60 to 90 minutes at a minimum (Dorfman et al., 2007). As respiratory motion can degrade image quality, breath-holding sequences allow faster

data acquisition, shorter scan duration, and perhaps improved image quality. Factors that determine whether an examination can be done without sedation or anesthesia are the child's developmental age and maturity, level of anxiety, and experience with prior procedures; the parent's opinion of the child's ability to cooperate; and the anticipated length and complexity of the examination protocol. General anesthesia is used in neonates, infants, and children less than 6 to 8 years of age, as well as in developmentally delayed older children and adults. It has been shown to be relatively safe despite the complexity of many defects, the frequent breath-holding, and the MRI environment (Odegard et al., 2004). In a subsequent nonrandomized study, the group at highest risk for an adverse event was, not surprisingly the ICU patient undergoing general anesthesia (Dorfman et al., 2007).

Echocardiography

The anesthesiologist is frequently requested to provide sedation or anesthesia for transthoracic or transesophageal echocardiography. See related video online at www.expertconsult.com. A variety of techniques may be used for transthoracic echocardiography, including chloral hydrate (50 to 80 mg/kg), oral midazolam and ketamine, intramuscular ketamine, inhalational anesthesia, or a total intravenous technique, as determined by clinical status. Unlike in adult institutions, general anesthesia with endotracheal intubation is generally used for TEE. The anatomy is frequently more complex, resulting in longer studies, and many older children and adults with CHD strongly prefer general anesthesia to a sedation technique.

Risks and Complications of Cardiac Catheterization

All cardiac catheterizations involve definite risk, with the incidence of adverse events and complications influenced by definition, era, institution, patient, and procedural factors (Agnoletti et al., 2005; Bennett et al., 2005; Bergersen et al., 2008; Mehta et al., 2008). Although not all adverse events are preventable, the primary focus should be on anticipation rather than reaction. The complications frequently associated with cardiac catheterization are listed in [Box 21-4](#). Many complications

Box 21-4 Complications Related to Cardiac Catheterization

- Blood loss
- Arrhythmias
- Low cardiac output, hypotension
- Vascular injury (tear, perforation, avulsion)
- Valvular injury
- Cardiac perforation and tamponade
- Embolism (air, thrombus, device) and arterial or venous thrombosis
- Pulmonary edema
- Contrast toxicity
- Hypothermia
- Central nervous system and peripheral nerve injuries (particularly brachial plexus)
- Apnea and airway obstruction (procedural sedation)
- Cardiac arrest

are nonspecific, whereas others are exclusive to the procedure being performed. The majority of events are minor and either resolve spontaneously or with minimal intervention. Major life-threatening events can be sudden and include hemodynamic deterioration; cardiac arrest; bleeding; balloon or device damage to vessels, valves, and other cardiac structures; cardiac perforation and tamponade; and embolization of devices or thrombus with remote obstruction or damage. In a prospective series from Children's Hospital Boston, adverse events occurred in 19% of the cases performed, 9% being clinically significant, and 2.7% life threatening or catastrophic, with a mortality rate of 0.4% (Bergersen et al., 2008). Risk for any adverse event was associated with age less than 1 year, interventional procedures, procedure type, and the presence of hemodynamic vulnerability (suprasystemic pulmonary artery or right ventricular pressure, mean PAP greater than 30 mm Hg, systemic ventricle end-diastolic pressure greater than 20 mm Hg, cardiac index less than 2 L/min per m², systemic arterial saturation less than 75%, mixed venous saturation less than 50%, or case performed on ECMO). The low mortality rate attests in part to a dedicated anesthesia team working closely with the interventional cardiologists, nursing staff, and catheterization technicians to promptly manage critical events.

Blood loss with resultant hypovolemia and anemia is mostly the result of frequent sampling and ongoing leakage out the sheaths from around the catheters or with catheter exchanges. The amount of blood loss can be concealed by the drapes and darkened environment; although hematocrit is followed regularly as part of routine blood gas level tests, it will not (as is also the case in other operative blood loss settings) reflect the degree of blood loss given the relatively rapid rate at which blood can be lost, the correspondingly brief period for renal compensation, and limited fluid administration. Remote vascular injury, or less commonly injury at the cannulation site, can produce sudden and severe hemorrhage manifesting as blood in the airway or lung parenchyma, hemothorax, cardiac tamponade, or retroperitoneal hemorrhage (Pigula et al., 2000). A second intravenous catheter is placed if significant blood loss is anticipated or inotropic support is likely.

Arrhythmias secondary to catheter manipulation in the heart are extremely common and generally not clinically significant (West et al., 2006). Atrial or ventricular premature beats and sinus bradycardia are typically transient, terminating on their own or with repositioning of the catheter. Progression of ventricular extrasystoles to sustained ventricular tachycardia or fibrillation is more likely in critically ill infants, severe aortic stenosis, severe cardiomyopathy, or during extensive catheter manipulations in a ventricle. Radiolucent electrical defibrillator pads can be placed on every patient with the defibrillator turned on and the energy to be delivered set according to the patient's weight at the beginning of the procedure. Supraventricular tachycardia often terminates spontaneously or with catheter-induced atrial or ventricular extrasystoles, but may require adenosine or electrical cardioversion. Atrioventricular conduction disturbance is associated with direct trauma to the AV node or bundle of His, or balloon valvuloplasty, and is more frequent in patients with L-looped ventricles. The catheter is removed from the area and conduction allowed to recover; atropine may be administered for mild to moderate bradycardia in the presence of preserved cardiac output, and otherwise more aggressive therapy such as cardiopulmonary resuscitation (CPR) and epinephrine is indicated. Complete AV block may not be self-limited, and, as urgent placement of a transvenous pacing

catheter may be necessary, pacing catheters and a temporary pacemaker are standard equipment in each catheterization laboratory. Particularly in patients with poor functional status or depressed myocardial function, early and definitive interventions including CPR and associated therapies (e.g., inotrope infusion, epinephrine, cardioversion) are warranted.

Low cardiac output and/or *hypotension* may result from one or more of the following: (1) preexisting ventricular dysfunction; (2) hypovolemia related to prolonged preoperative fasting, diuretics, and blood loss; (3) anesthetic agents; (4) arrhythmias; (5) stenting open of valves by catheters and stiff guidewires causing temporary valvular regurgitation; (6) obstruction to flow across valves, conduits, or arteries by catheters, guidewires, and balloon inflation; (7) excessive left-to-right shunting resulting from hyperventilation or oxygen administration; (8) cardiac tamponade; (9) coronary emboli; (10) myocardial ischemia; and (11) hypothermia. Rehydration to achieve adequate preload, early administration of an inotropic agent, and attention to the interventions being performed are necessary. Low SVC saturations (see earlier) and metabolic acidosis on arterial blood gases are indications of low cardiac output, particularly in the presence of a normal blood pressure, and preservation of an appropriate intravascular volume, hematocrit, and inotropic support when indicated is important.

Vascular injury can occur at the cannulation site (small vessels, large sheaths, multiple catheter exchanges, previous vessel injury, improper technique) or centrally. Vessel injury, caused by perforation or balloon dilation, is more common with interventional procedures as the guidewires are larger, stiffer, and sharper, and they have relatively hard tips, and because of the intervention being performed. Successful balloon dilation of a stenotic area requires overstretching of the abnormal tissue causing an intimal tear with maintenance of vascular integrity by the adventitia (Moore and Lock, 2000). Damage to the *pulmonary arteries* is more common than to the systemic arteries, as the walls are thinner and there are more lesions that require therapeutic intervention. The initial indication thereof in unintubated patients is often cough and hemoptysis, which can be severe. A small perforation or tear in a pulmonary artery may appear as only a slight extravasation of contrast into the lung parenchyma, and this can often be managed expectantly. Major tears, particularly in the setting of high pulmonary artery pressures and abnormal vessel walls, can result in intrapulmonary hemorrhage, hemoptysis, hemothorax, or hemopericardium, and can lead to shock and cardiac arrest (Baker et al., 2000). Techniques available to the cardiologist to limit the hemorrhage include balloon inflation to occlude the leak and tamponade the bleeding, placement of a covered stent, and vessel occlusion with coils (distal pulmonary arteries); pleurocentesis and catheter drainage may be necessary. Anesthetic management comprises tracheal intubation and airway control (if a sedation technique was being used), administration of increased inspired oxygen concentrations and positive end-expiratory pressure, airway suctioning, avoidance of the patient coughing or bucking against the endotracheal tube, acute resuscitation often including blood, and a discussion with the cardiologist of the following: (1) heparin reversal, (2) need for urgent ECMO, and (3) need to go to the operating room. *Aortic tears* may result in catastrophic hemorrhage and the need for urgent surgical intervention, or they may be associated with extravasation of contrast and aneurysm formation without hemodynamic compromise. In the latter situation, the

patient should be kept immobile and hypertension controlled with infusions of esmolol and sodium nitroprusside.

Valvular injury may occur with leaflet perforation or balloon dilation. Severe acute mitral and aortic regurgitation are not likely to be well tolerated in these patients, and urgent surgery may be indicated.

Cardiac perforation may be caused by or occur during catheter or wire manipulation; planned needle, radiofrequency, or blade transeptal puncture; balloon atrial septostomy; endomyocardial biopsy; mitral and aortic valvuloplasty; and during arrhythmia ablation procedures, especially when access to the left side of the heart is obtained via transeptal puncture. Although not all cardiac perforations lead to cardiac tamponade (Bergersen et al., 2008; Mehta et al., 2008), tamponade is an important cause of mortality (Bennett et al., 2005). Clues to the possibility of a new pericardial effusion are hypotension and an enlarged, less mobile cardiac silhouette on fluoroscopy. A transthoracic echocardiogram should be obtained immediately, and pericardiocentesis performed if necessary. With ongoing bleeding and hemodynamic lability, the cardiac surgeons should be notified early, as urgent surgical repair may become necessary. Anesthetic goals are volume administration, inotropic and vasopressor support, and consideration of the need for additional blood, platelets, and clotting factors, as coagulopathy can develop with reinfusion of pericardial blood and massive transfusion.

Embolism of air or thrombi is a constant threat and, if significant, can result in stroke, myocardial ischemia, cardiac arrest, and death. Predisposing factors are poor technique, large sheath size, indwelling sheaths, suction applied to the side port of the sheath (particularly with guidewire or catheter passing through the back-bleed valve), frequent catheter exchanges, contrast injection, marked negative intrathoracic pressure, balloon rupture, preexisting thrombi, and deployment of devices. The best treatment for air embolism is prevention. Precautions that reduce the risk of air embolism are meticulous technique, including frequent aspiration and flushing of catheters, inflation of catheter balloons with carbon dioxide, the use of a manometer to avoid burst pressures, and avoidance during sedation techniques of the marked negative intrathoracic pressures associated with airway obstruction. With air emboli, the cardiologist will usually ask that the inspired oxygen be increased. A large bolus of air may become trapped and seen as a radiolucent area in the least dependent parts of the heart (right atrial appendage, right ventricular outflow tract). Aspiration of visible air and support of the circulation with volume administration, cardiac massage, and vasoactive agents are likely to be necessary for hemodynamically significant air embolism.

Venous and arterial thrombi can preexist in vessels or cardiac chambers or develop spontaneously around catheters, sheaths, wires, or devices placed in the circulation. The risk for thrombus formation is reduced by systemic heparinization (50 to 100 IU/kg to maintain an activated clotting time of >200 sec) after placement of a sheath or catheter (Grady et al., 1995). Embolized or “displaced” stents, devices, or coils may be retrievable by the cardiologist, reducing the need for surgical intervention (Sheth et al., 2007; Mariano et al., 2008).

Pulmonary edema, apart from excess fluid administration in the susceptible patient, is commonly associated with balloon dilation of multiple peripheral pulmonary arteries. The increase in blood flow and pulmonary capillary hydrostatic pressure after successful angioplasty results in a change in Starling forces and unilateral pulmonary edema (Arnold et al., 1988). Risk factors

are an increase in vessel diameter greater than 70% at the site of the stenosis, a greater than 170% increase in distal pulmonary artery pressure, and mean distal PAP greater than 20 mm Hg immediately after dilation. Edema may be seen on fluoroscopy and accompanied by coughing and respiratory distress in the sedated or inadequately anesthetized patient, as well as hypoxemia, hemoptysis, or florid pulmonary edema that can flood the airway. Management includes securing the airway, controlled ventilation with positive end-expiratory pressure, increased inspired oxygen concentration, and diuretic therapy. Severe cases will require a period of mechanical ventilation until resolution of the edema. Dilation of stenotic pulmonary veins results in pulmonary edema because of increased pulmonary venous pressures, and it is managed similarly.

Contrast agents are water-soluble derivatives of triiodinated benzoic acid, with absorption of radiation attributable to the iodine component. Agents are classified on the basis of their osmolality and ionic strength, with four classes available for clinical use: high-osmolality ionic, low-osmolality ionic, low-osmolality nonionic, and isoosmolality nonionic (Esplugas et al., 2002). Adverse reactions may be idiosyncratic (anaphylactoid) or related to dose and physicochemical characteristics of the agent used (Thomsen and Morcos, 2000). Life-threatening hypersensitivity reactions have an incidence of 0.04% (non-ionic agents) to 0.22% (ionic agents) (Katayama et al., 1990) and are more frequent in patients with an allergic history or a prior severe adverse reaction to contrast (Halpern et al., 1996). Cardiovascular effects are more prominent with the high-osmolality agents and include arteriolar vasodilation, ventricular dysfunction, intravascular volume expansion, pulmonary artery vasospasm, depression of atrioventricular nodal conduction, depression of sinoatrial automaticity, and decreased threshold for ventricular fibrillation or tachycardia (Esplugas et al., 2002). Nonionic low-osmolality agents (ioversol, iohexol, iopamidol) cause less patient discomfort (less warmth because of less arteriolar dilation), are probably safer overall, and are now used routinely for pediatric cardiac catheterization (Bergersen et al., 2009). Contrast-induced nephropathy may lead to increased morbidity and mortality in at-risk populations (preexisting renal dysfunction, dehydration, high-contrast dosing, concurrent nephrotoxic drugs) (Goldfarb et al., 2009). To date, preventive strategies have not been studied in children. Adult studies have found that intravenous volume expansion with a sodium bicarbonate-containing solution is superior than sodium chloride solution alone in reducing nephropathy associated with iopamidol (Merten et al., 2004; Masuda et al., 2007), and sodium bicarbonate plus *N*-acetylcysteine is superior to normal saline plus *N*-acetylcysteine with iodixanol (non-ionic isoosmolar) (Briguori et al., 2007).

Hypothermia is a risk in all patients, especially small infants and debilitated patients. It can result in altered hemodynamics because of low cardiac output and vasoconstriction, pulmonary overcirculation in those at risk, prolonged recovery from general anesthesia or sedation, and increased oxygen consumption during rewarming. Fever during or after cardiac catheterization with no identifiable cause (malignant hyperthermia, bacteremia, overheating) is not uncommon and appears to be directly related to the number of angiocardiograms performed (Gilladoga et al., 1972) and perhaps also to a foreign body-type reaction to implanted coils or stents. The temperature elevation is usually to the range of 38.1° to 38.7° C and returns to normal by 24 hours after catheterization.

Central nervous system injury can result from embolization, low cardiac output states, extreme hypoxia, and reactions to contrast agents. Brachial plexus injury is the most common *peripheral nerve injury* and results from extreme extension or abduction of the arms above the head for long durations to improve visualization with extreme angles of the cameras. As much as possible, the arms should be internally rotated and minimally extended at the shoulder. Low cardiac output states and hypotension may increase the risk, which may be particularly exacerbated by underlying anatomic abnormalities (e.g., cervical rib). If such positioning is required by the cardiologist, it should be for the shortest time possible and noted on the anesthesia record. Although these injuries are usually transient, recovery can take months, and occasionally permanent paralysis results. Neurologic consultation should be obtained, and exercises under the supervision of a physical therapist should be used to reduce muscle atrophy during the disability. The brachial plexus may also be injured if the arm of a heavily sedated or paralyzed patient suddenly and violently falls off the side of the catheterization table.

The incidence of catheterization-related complications requiring emergency cardiac surgery is estimated to be 1.9%, so that presence of an in-house pediatric cardiothoracic surgeon is recommended policy (Schroeder et al., 2002). ECMO has been used successfully for resuscitation in the catheterization laboratory if the patient is unresponsive to conventional CPR (Allan et al., 2006). Occasionally, high-risk patients have been specifically placed on ECMO prior to the catheterization (Booth et al., 2002; Carmichael et al., 2002) or a primed circuit is placed in the laboratory if the planned intervention appears to have a high likelihood of cardiac arrest necessitating resuscitation with extracorporeal support. It is important to remember to use the acquired catheterization data to help guide resuscitation, and that the femoral (or other) sheaths can be used as a source of central venous access.

Anesthetic Technique

The shift from diagnostic catheterization to mostly interventional catheterization has required an increasing level of expertise in the provision of anesthesia care. Institutional practices vary from an anesthesiologist providing care for all procedures, to mixed models in which some patients are managed by anesthesiologists while others are managed by nurses trained in pediatric sedation in the cardiac catheterization laboratory, under supervision of the cardiologist (Andropoulos and Stayer, 2003; Guidelines, 2002; Practice guidelines, 1996, 2002). Whichever the model, it is very important that the anesthesiologist providing care or overseeing sedation have a high level of expertise in the management of children and adults with complex CHD, be immediately available to render assistance to the nonanesthesiologist, and be assigned regularly to the catheterization laboratory to better appreciate the procedures and potential complications.

The choice of technique or agents should be based on the child's functional status, the underlying heart disease, the type of procedure (with consideration of the risk for hemodynamic instability and complications), and the familiarity of the anesthesiologist with a specific technique. Although general endotracheal anesthesia with paralysis and controlled

ventilation (GETA) is the rule in many institutions, the majority of hemodynamic and some interventional procedures can be performed with a spontaneously breathing patient, either with a laryngeal mask airway, a face mask with or without an oral airway, or a natural airway with intravenous anesthesia or sedation. Proximity to the radiation and the length of most procedures limit general anesthesia by face mask to short procedures (e.g., myocardial biopsy) in patients with preserved ventricular function. The major advantages of GETA are a secure airway, more precise control of oxygenation and ventilation (and thus the influence of Pao_2 and $Paco_2$ on pulmonary vascular resistance and shunting), reduced risk of patient movement, the propensity for prolonged procedures, the ability if necessary to suction edema fluid or blood from the trachea and large bronchi, and the degree of comfort for most anesthesiologists. A major disadvantage is the potential for wide fluctuations in hemodynamic parameters resulting from the effects of mechanical ventilation on right ventricular preload and afterload, the negative inotropic and vasodilatory effects of volatile agents, and decreased sympathetic tone. On the other hand, one can construct a convincing argument that a given patient is more likely to be closer to his or her baseline hemodynamic conditions under conditions of a well-conducted general anesthetic (which might include low-dosage inhaled agent and potent opioid, muscle relaxation, and controlled ventilation to normal blood gas values and lung volumes), than with procedural sedation requiring large amounts of opioids and benzodiazepines, with the possibility of the upper airway obstruction, hypoventilation, hypercarbia, and alveolar or arterial hypoxia that might result. GETA is generally indicated for procedures with a known risk for significant hemodynamic instability or complications (placement of VSD devices, balloon dilation of mitral stenosis, dilation of multiple peripheral pulmonary artery stenoses, dilation of severe pulmonary vein stenoses, transcatheter placement of a pulmonary valve), patients with limited cardiovascular reserve in whom the perturbations associated with catheterization place them at risk for severe cardiac compromise or arrest, patients who are unable to lie supine (severe CHF, limited diaphragm excursion secondary to hepatomegaly or ascites), planned intraprocedure transesophageal echocardiography, and the usual contraindications to sedation (difficult airway, obstructive sleep apnea, gastroesophageal reflux, previous adverse reaction to sedation). Some of the sickest patients undergoing diagnostic or minimally interventional procedures will best be served by generous reassurance and comfort maneuvers, appropriate use of local anesthetic infiltration, and low-dosage intravenous anesthesia or sedation with a natural airway.

The painful components of the catheterization procedure are vascular access, sheath changes at the access site, and balloon dilation of arteries and veins; pulmonary artery dilation can also induce coughing. Interspersed are periods of relatively little noxious stimulation. Although infiltration of the access site by the cardiologist with 1% lidocaine at the beginning of the procedure is routine, the child will experience pain when the analgesia has worn off and sheaths are exchanged. Reinfiltration may be necessary, particularly with sedation techniques, and good postprocedure analgesia can be obtained with reinfiltration prior to catheter removal at the conclusion of the procedure. It is important that pressure be applied to the access site during emergence from general anesthesia in order to reduce the risk of bleeding with coughing or straining.

Interventions associated with pain or noxious stimulation can be anticipated with good communication between the cardiologist and anesthesiologist.

Premedication

Premedication is similar to that used for patients with CHD undergoing noncardiac surgery.

Sedation Techniques

The transition from minimal (anxiolysis) to moderate (conscious) to deep (unconscious) sedation to general anesthesia is often difficult to control (Practice guidelines, 2002). Identifying potential patients at risk for sedation-related adverse events prior to the procedure is important. Conscious sedation in younger children is an oxymoron (Cote, 2001); the main considerations are airway maintenance, avoidance of significant respiratory depression, and a calm child. Maintenance of sedation during the procedure can be accomplished with a number of agents. Intermittent bolus doses of a benzodiazepine (usually midazolam) and opioid (fentanyl or morphine) are commonly used, particularly for diagnostic catheterization. Continuous intravenous infusions provide a more consistent and predictable level of sedation, and are especially useful for longer procedures and procedures for which interventions are planned. In patients with limited hemodynamic reserve, a combination of ketamine and midazolam can be very effective in maintaining a deep level of sedation with stable hemodynamic status and limited airway compromise or respiratory depression. A propofol infusion (50 to 100 mcg/kg per minute) provides a faster, better quality recovery, but it is more likely to be associated with hypotension and loss of the airway. A number of studies have examined the use of ketamine alone (Singh et al., 2000) or in combination with propofol (Kogan et al., 2003; Akin et al., 2005; Tosun et al., 2006; Gayatri et al., 2007), midazolam (Jobeir et al., 2003), or dexmedetomidine (Tosun et al., 2006). Combinations of ketamine and propofol tend to produce similar sedation with more stable hemodynamics than propofol alone (Akin et al., 2005). A dexmedetomidine-ketamine combination provided insufficient sedation when compared with a propofol-ketamine combination (Tosun et al., 2006). Remifentanyl infusion has been used for sedation, but in many children supplementation with a hypnotic or amnestic agent is necessary (Donmez et al., 2001). Regardless of technique, hypoventilation, hypercarbia, and acidosis resulting from both peripheral (i.e., airway obstruction) and central respiratory effects can occur and, if of sufficient magnitude, mandate transition to some form of assisted or controlled ventilation. Supplemental oxygen is administered during establishment of sedation, and if possible is discontinued once access is achieved so that hemodynamic measurements can be done as close to baseline conditions as possible. Oxygen can be reinstated if desired after the hemodynamic measurement phase.

General Anesthesia

An intravenous induction is recommended for patients with limited cardiac reserve, particularly those at risk for a marked decrease in cardiac output with induction. Such high-risk cases include patients with severe ventricular dysfunction, severe outflow tract obstruction, and severe pulmonary hypertension. Etomidate lacks clinically significant hemodynamic effects in

children and adults (Gooding et al., 1979; Sarkar et al., 2005), whereas ketamine provides hemodynamic stability through sympathetically mediated increases in heart rate and systemic vascular resistance, albeit with direct myocardial depressant effects (Murray et al., 1984). Although reports of the effect of ketamine on pulmonary vascular resistance are conflicting (Murray et al., 1984; Hickey et al., 1985; Berman et al., 1990; Maruyama et al., 1995), it can be used provided elevations in arterial CO₂ are prevented. Opioid-benzodiazepine techniques are also suitable, particularly if postcatheterization mechanical ventilation is planned (Hickey and Hansen, 1984). Remifentanyl provides profound analgesia with short recovery times, but it can be associated with bradycardia and hypotension in high dosages (Ross et al., 2001) and in association with sevoflurane at 0.6 minimum alveolar concentration (Foubert et al., 2002); the bradycardia can be prevented with pretreatment with glycopyrrolate, 0.006 mg/kg (Reyntjens et al., 2005). Propofol should probably be limited to children with adequate cardiovascular reserve who can tolerate mild decreases in contractility, heart rate, and systemic vascular resistance (Williams et al., 1999). Sevoflurane is associated with less myocardial depression and better hemodynamic stability than halothane, particularly in infants (Holzman et al., 1996; Wodey et al., 1997; Rivenes et al., 2001; Russell et al., 2001; Laird et al., 2002).

Monitoring and Vascular Access

Standard monitoring is used for all cases. Blood pressure cuffs should not be placed on the leg if the corresponding groin is to be used for cannulation; occasionally, noninvasive blood pressure measurements on the upper extremity become unreliable because of positioning. End-tidal CO₂ monitoring is possible in nonintubated patients with use of specifically designed nasal cannulas (or a butterfly cannula—the blunt end, after the needle is cut off, is inserted into a nostril or placed in front of the mouth, and the Luer-Loc end is attached to end-tidal CO₂ tubing) and correlates reasonably well with blood CO₂ values (Friesen and Alswang, 1996; Cote et al., 2007). In addition to respiratory rate and pattern, declines in end-tidal CO₂ could indicate decreases in pulmonary blood flow resulting from pulmonary artery obstruction or low cardiac output. Fluoroscopy allows assessment of endotracheal tube position, lung inflation, pneumothorax, hemothorax, extravasation of contrast, and pulmonary edema or hemorrhage. Arterial catheters are generally placed by the cardiologist in the femoral artery for their use. Because access to and measurements from these will be interrupted frequently during the procedure, consideration should be given to placement of a radial (or similar) arterial catheter in selected patients at risk for severe instability. Urinary catheters should be considered for prolonged procedures, particularly if significant volume administration, large dye loads, or administration of diuretics is anticipated.

A second peripheral intravenous cannula is recommended for most interventional procedures, particularly when administration of large fluid volumes or inotropic or vasoactive agents is anticipated. Groin access by the cardiologist could potentially influence the flow from venous catheters in the lower limbs. Although central administration of inotropic agents is recommended, it is possible to administer these agents peripherally for short durations, provided the peripheral venous site is reliable and accessible for repeated assessment. It can be useful to discuss with the cardiologist the possible need to use the side port of the venous sheath for drug or volume administration,

particularly for rapid resuscitation. It is seldom necessary for the anesthesiologist to place a central venous catheter.

Postprocedure Care

Beside routine care after anesthesia, patients need to be monitored for events such as bleeding from the access sites, vascular occlusion with impaired limb perfusion, pulmonary edema after pulmonary artery dilations, and device displacement or embolization. As is apparent from the preceding discussions, some procedures should not be undertaken for some patients without the availability of a bed in the intensive care unit.

CURRENT AND FUTURE DIRECTIONS

Hybrid Transcatheter and Surgical Palliation

The hybrid strategy for neonates with hypoplastic left heart syndrome is a combined surgical and catheterization procedure (Gibbs et al., 1993). The procedure involves bilateral pulmonary artery banding, stenting of the ductus arteriosus, and atrial septectomy or septostomy when the atrial septum is restrictive (Fig. 21-13). The goals of the procedure are to provide unobstructed systemic cardiac output, unobstructed coronary blood flow, and control of pulmonary blood flow. Aortic arch reconstruction combined with bidirectional cavopulmonary connection is performed later in infancy—in one series, patients were a median age of 4.8 months (Akinturk et al., 2007). The proposed benefit of this approach rests on the assumption that avoiding major neonatal cardiac surgery (Norwood stage I operation)

■ **FIGURE 21-13.** The hybrid stage I palliation. Note pulmonary artery bands on the left and right pulmonary arteries, stent in the patent ductus arteriosus, and balloon atrial septostomy. (From Naguib AN, Winch P, Schwartz L, et al: Anesthetic management of the hybrid stage 1 procedure for hypoplastic left heart syndrome (HLHS), *Paediatr Anaesth* 20(1):38–46, 2010.)

and deferring aortic arch reconstruction will result in improved survival and superior neurologic and cardiac functional outcomes (Caldarone et al., 2007). Although this strategy is still evolving, indications include the need for an alternative to the Norwood operation, stabilization of patients before heart transplantation, and salvage of patients for hemodynamic instability not manageable with standard supportive measures. Other factors that may increase the favorability of neonatal hybrid approaches include ongoing evidence of cerebral injury related to cardiac surgery (Soul et al., 2009), particularly when associated with brain immaturity (Andropoulos et al., 2010), and the potential neurotoxicity of anesthetic agents on the developing brain (Patel and Sun, 2009).

The hybrid procedure may be performed in the catheterization laboratory (retrofitted or built as a hybrid suite), in the operating room (portable digital angiographic system), or with the PAB in the operating room and the ductal stenting in the catheterization laboratory (Galantowicz and Cheatham, 2005; Caldarone et al., 2007). In the largest series, management has evolved to the PAB's being performed prior to ductal stenting. Patient presentation can vary from the unintubated neonate breathing spontaneously on room air to the critically ill infant on mechanical ventilation, inotropic support, and with invasive monitoring catheters in situ. The anesthetic management of neonates undergoing the hybrid procedure has recently been reviewed (Naguib et al., 2010).

MRI-Guided Cardiac Catheterization

Cardiac catheterization guided by MRI has been shown to provide better anatomic visualization, reduced radiation exposure, and improved accuracy of some hemodynamic information (Razavi et al., 2003). The use of an interventional MR scanner and fluoroscopy system in a single suite still results in reduced radiation exposure. The technical and clinical considerations and current limitations have recently been reviewed (Ratnayaka et al., 2008), and increased use of these techniques can probably be eagerly anticipated in the not-too-distant future, especially as current investigations into development of MR-compatible catheters and other devices mature.

SUMMARY

Patients with congenital heart disease frequently require anesthesia for both diagnostic and therapeutic interventions. As survival rates for patients with congenital heart disease improve, these patients frequently have cardiovascular and neurologic sequelae from the reparative surgical process. Consequently, over time, myocardial structure and function undergo a remodeling process. As a result, anesthetic management and concerns change over time. Understanding the patient's underlying pathophysiology and the history of both repaired and unrepaired lesions allows the anesthesiologist to appropriately manage the perioperative needs of the patient.

	Summary 744

The perioperative management of pediatric neurosurgical patients presents many challenges to neurosurgeons and anesthesiologists. Many conditions are unique to small children, and an understanding of age-dependent variables and the interaction of anesthetic and surgical procedures is essential to minimize perioperative morbidity and mortality. This chapter will highlight the age-dependent physiologic and pathophysiologic changes relevant to the neurologic lesion, and their effects on the management of the pediatric neurosurgical patient.

DEVELOPMENTAL CONSIDERATIONS

Differences in cerebrovascular physiology and cranial bone maturation distinguish infants and children from adults. The central nervous system (CNS) undergoes a tremendous amount of structural and physiologic changes during the first 2 years of life, which influence the approach to the pediatric neurosurgical patient.

Intracranial Pressure

Normal intracranial pressure (ICP) is relatively low in premature infants and slightly higher in full-term infants (2 to 6 mm Hg) and children and adults (0 to 15 mm Hg). Intracranial compliance is defined as change in intracranial pressure relative to the intracranial volume (Fig. 22-1). At normal intracranial volumes (*point 1* in Fig. 22-1), ICP is low but compliance is high and remains so despite small increases in volume. As intracranial volume acutely rises, the ability to compensate is rapidly overwhelmed. This occurs even when the ICP is still within normal limits, but the compliance is low (*point 2* in Fig. 22-1). When ICP is already high, a threshold is reached, after which further volume expansion leads to rapid ICP elevation (*point 3* in Fig. 22-1). *Point 4* (see Fig. 22-1) reflects maximal intracranial volume and high ICP. Clinically, intracranial compliance can be assessed by a variety of devices that measure intracranial pressure (Wiegand and Richards, 2007).

The neonatal cranial vault is unique in that it is in a state of flux. Open fontanelles and cranial sutures lead to a compliant

■ **FIGURE 22-1.** Intracranial compliance curve. At normal intracranial volumes (*point 1*), intracranial pressure (ICP) is low but compliance is high and remains so despite small increases in volume. As intracranial volume acutely rises, the ability to compensate is rapidly overwhelmed. This only occurs when the ICP is still within normal limits but compliance is low (*point 2*). When ICP is already high, a threshold is reached where further volume expansion leads to rapid ICP elevation (*point 3*). *Point 4* reflects maximal intracranial volume and high ICP.

intracranial space (Fig. 22-2). The mass effect of a slow-growing tumor or insidious hemorrhage is often masked by a compensatory increase in intracranial volume accompanied by head growth. When ICP increases occur slowly, open fontanelles and cranial sutures separate and enlarge the intracranial space, and thus the mass effect of a slow-growing tumor or insidious intracranial bleeding is often shrouded by a compensatory increase in intracranial volume (widening of the fontanelles and cranial sutures). However, acute increases in cranial volume caused by massive hemorrhage or obstructed cerebrospinal fluid (CSF) flow cannot be attenuated by expansion of the cranial vault and frequently result in life-threatening intracranial hypertension in infants (Shapiro et al., 1980). Once the fontanelles and sutures have closed, children have a smaller cranial volume and lower intracranial compliance than adults. The posterior fontanelle is usually closed by 2 months of age. The anterior fontanelle closes after the posterior fontanelle. By 3 months of age, the anterior fontanelle is closed in 1% of infants. By 1 year it is closed in about 40%, and by 2 years it is closed in 96%. Contributory factors include a higher ratio of brain water content, less CSF volume, and a higher ratio of brain content to intracranial capacity (Arieff et al., 1992). Thus, children are at higher risk of herniation than adults.

Cerebrospinal Fluid Dynamics

Cerebrospinal fluid is produced by the choroid plexus and absorbed through arachnoid villi and the ependymal lining of the ventricles. The ventricular system consists of paired lateral ventricles, which connect to the third ventricle via the foramen of Monro; the third ventricle connects to the fourth ventricle through the aqueduct of Sylvius. The fourth ventricle communicates via the paired foramina of Luschka and the foramen of Magendie to a system of cisterns. The rate of reabsorption of CSF increases as ICP increases. Intracranial hemorrhage, inflammation or infection, tumors, or congenital malformations can lead to decreased CSF absorption with possible elevations in ICP. In the adult, the normal volume of CSF is approximately 150 mL, of which 25% is in the ventricular system. CSF is formed at approximately 20 mL/hr.

■ **FIGURE 22-2.** Effect of cranial sutures and fontanelle in neonates and infants. Initially the compliant skull of the neonate minimizes insidious increases in intracranial volume. However, acute increases in intracranial volume (hemorrhage and obstructed ventriculoperitoneal shunt) lead to rapid rises in intracranial pressure.

Cerebral Blood Flow

The cerebral circulation is tightly regulated by a number of homeostatic mechanisms. The major influences of the cerebral circulation are metabolism, partial pressure of arterial carbon dioxide (P_{aCO_2}), partial pressure of oxygen in arterial blood (P_{aO_2}), blood viscosity, and cerebral autoregulation. Coupling of flow and metabolism is the most significant regulator of the cerebral circulation and is preserved even during sleep (Madsen and Vorstrup, 1991; Lenzi et al., 2000) and during general anesthesia (Lam et al., 1995). Under normal conditions, cerebral blood flow (CBF) is tightly coupled to cerebral metabolism and cerebral metabolic rate of oxygen consumption (CMR_{O_2}) at global as well as regional levels. However, during periods of CNS activation, CBF increases more than CMR_{O_2} , resulting in a decrease in the cerebral oxygen extraction fraction (Fox and Raichle, 1986)

During development, CBF changes with age, mirroring changes in neural development. CBF increases during early childhood, peaking during early-to-mid childhood and plateauing at

7 to 8 years (Wintermark et al., 2004). The healthy brain receives about 15% of cardiac output, and normal adult CBF is approximately 50 mL/100 g per minute (Vavilala et al., 2002a). There are few data available from healthy children. Kennedy and Sokoloff (1957) found CBF to be much higher, in the order of 100 mL/100 g per minute, in conscious healthy children, and a study using arterial spin labeling found similar values in young children (Biagi et al., 2007), which then decreased and approached adult values during the teenage years. Even during low-dosage sevoflurane anesthesia, values for CBF in children are higher than those for adults, whose CBF ranges between 50 and 100 mL/100 g per minute (Settergren et al., 1980).

Transcranial Doppler (TCD) ultrasonography can be used to estimate CBF, assuming that changes in CBF are proportional to changes in cerebral blood flow velocity (CBFV), and that

mean flow velocities are used to represent mean CBF. Systolic and diastolic flow velocity parameters are often used to examine resistance of the cerebral vessels and also brain death. Studies using TCD show that in healthy newborns, CBFV is approximately 24 cm/sec, thereafter increasing with age until 6 to 9 years (97 cm/sec) (Bode and Wais, 1988) (Fig. 22-3). Beyond 10 years of age, CBFV decreases, approximating adult values of about 50 cm/sec (Aaslid et al., 1984; Vavilala et al., 2002a). Sex differences have also been observed and may result from differences in hematocrit, hormones, vessel size, or cerebral metabolism (Kennedy and Sokoloff, 1957; Tontisirin et al., 2007). The mean CBFV estimates for middle cerebral artery (V_{MCA} ; anterior circulation) and basilar artery (V_{BAS} ; posterior circulation) by age and sex are listed in Figure 22-3 and Table 22-1 (Bode and Wais, 1988; Wintermark et al., 2004; Vavilala et al., 2005).

■ **FIGURE 22-3.** Age-related changes in mean flow velocity of middle cerebral artery (V_{MCA}) in both sexes. cerebral blood flow (CBF) and cerebral metabolic rate of glucose (CMRglu) [14,22,27,39,40]. Adult values: V_{MCA} , 50 cm/sec [15,16], CBF, 50 mL/100 g per minute [13], CMRglu, 19 to 33 μmol/100 g per minute [27].

Cerebral Metabolic Rate

Global cerebral metabolic rate (CMR) for oxygen and glucose is higher in children than in adults (oxygen, 5.8 versus 3.5 mL/100 g brain tissue per minute, and glucose, 6.8 versus 5.5 mL/100 g brain tissue per minute, respectively) (Kennedy and Sokoloff, 1957). Like CMR_{O_2} , cerebral metabolic rate for glucose (CMR_{glu}) is lower at birth (13 to 25 $\mu\text{mol}/100\text{ g}$ per minute), increases during childhood, peaks by 3 to 4 years (49 to 65 $\mu\text{mol}/100\text{ g}$ per minute), and remains high until 9 years of age. CMR_{glu} decreases thereafter, approaching adult rates (19 to 33 $\mu\text{mol}/100\text{ g}$ per minute) (Chugani et al., 1987); changes in CMR_{O_2} and CMR_{glu} mirror age-related changes in CBF (see Fig. 22-3).

Adenosine and nitric oxide (NO) are two purported mediators of flow–metabolism coupling and CBF increase with neuronal activation. Although the effect of adenosine on human CBF is controversial (Stange et al., 1997; Sollevi et al., 1987), up-regulation of NO production has been reported to increase CBF (Endres et al., 2004). Antagonists of both adenosine and NO attenuate the rise in CBF associated with neuronal activation, although neither mediator antagonist, alone or in combination, completely abolishes the CBF increase in response to neuronal activation (Gotoh et al., 2001). Therefore, other mediators, such as H^+ ions, adenine nucleotides, potassium, prostaglandins, and vasoactive intestinal peptide, may also be involved in flow–metabolism coupling.

Hypothermia causes a reduction in CMR_{O_2} , thereby decreasing CBF via flow–metabolism coupling. CBF decreases approximately 5% to 7% per degree Celsius, and reduction of the brain temperature to 15° C will reduce CMR_{O_2} to 10% of normothermic values (Vavilala et al., 2002). Hypothermia causes a reduction in both the basal metabolism required for maintenance of cellular integrity and the functional metabolism of the CNS.

Carbon Dioxide Vasoreactivity

Cerebral circulation is exquisitely sensitive to changes in P_{aCO_2} (Harper and Glass, 1965; Padayachee et al., 1986). Like that of CBF and metabolism, the vasoreactivity of CO_2 may be higher in healthy children than in adults (13.8% and 10.3% change in mean CBFV per 1 mm Hg change in end-tidal CO_2) during propofol anesthesia (Leon and Bissonnette, 1991; Rowney et al., 2002; Karsli et al., 2003). The cerebrovascular response to changing CO_2 is attenuated at low blood pressure (Harper and Glass, 1965), increases in the presence of moderate hypoxia, decreases again during severe hypoxia (Quint et al., 1980), and may remain abnormally low after a hypoxic episode. Although there is an overall paucity of information regarding CO_2 reactivity in healthy children and in pediatric disease states, older studies suggest that reactivity to CO_2 is well developed even in healthy preterm infants (Pryds et al., 1990) and that CO_2 reactivity in newborns correlates with the lowest pH and may reflect the severity of perinatal asphyxia (Baenziger et al., 1999).

There are many potential control mechanisms involved in reactivity to carbon dioxide (CO_2R). Although neural regulation of CO_2R may be important (Meyer et al., 1971; Bates et al., 1977; Rovere et al., 1977), the most prominent proposed mechanism is the biochemical/metabolic control of cerebral vasoreactivity.

The brisk response of the cerebral vasculature to CO_2 (*the biochemical mechanism*) is caused by the rapid diffusion of arterial CO_2 across the blood-brain barrier (BBB) into the perivascular fluid and cerebral vascular smooth muscle. Changes in extracellular fluid pH by both CO_2 and bicarbonate ions lead to cerebral vasodilation and increased CBF (Kontos et al., 1977). Although CO_2 is a potent cerebral vasodilator, the role of arterial H^+ ions is more controversial. Although pH is not known to generally affect the cerebral vasculature, because arterial H^+ ions do not readily diffuse across the intact BBB (Harper and Bell, 1963), severe metabolic acidosis may cause vasodilation and increase CBF (Westerlind et al., 1994). Therefore, severe metabolic acidosis and alkalosis may affect cerebral vascular tone, as do respiratory acidosis and alkalosis.

During chronic hypercapnia maintained for 6 hours, an adaptive increase in the pH of the CSF occurs with a decrease in CBF (Warner et al., 1987). A decrease in pH is accompanied by an increase in CSF bicarbonate. Similarly, during chronic hypocapnia, CSF bicarbonate concentration decreases, CSF pH gradually decreases, and CBF increases (Muizelaar et al., 1988).

The mechanism of CO_2R also appears to be regulated by local mediators rather than by chemoreceptors in the periphery. NO is partially responsible for CO_2 -mediated cerebral vasodilation. Schmetterer and coworkers (1997) demonstrated a significant reduction in mean V_{MCA} to hypercapnia in healthy humans after administration of an NO synthase (NOS) inhibitor. However, NOS inhibitors do not completely ablate CO_2R , and NO may be more important in regional than in global regulation of vasoreactivity. The cerebral cortex in primates was the only site in which NOS inhibitor attenuated the CBF response to increasing arterial CO_2 concentration (McPherson et al., 1995). Another putative mediator of CO_2R is prostaglandin (PG) E_2 . In contrast, indomethacin (a cyclooxygenase inhibitor) was shown to inhibit prostanoid synthesis and completely abolished CO_2 -induced cerebral vasodilation (Wagerle and Degiulio, 1994).

Hypoxic and Hyperoxic Control of CBF

Compared with P_{aCO_2} , the influence of P_{aO_2} on the cerebral circulation is of much less clinical significance. There are minimal changes in CBF with changes in P_{aO_2} to greater than 50 mm Hg. Below that threshold of 50 mm Hg, CBF increases to maintain adequate cerebral oxygen delivery. Unlike CO_2R , the equilibration of CBF is longer and takes approximately 6 minutes after the establishment of hypoxemia (Ellingsen et al., 1987).

Hypoxemia may induce cerebral vasodilation via anaerobic glycolysis and lactic acid production, causing decreased extracellular pH and subsequent vasodilation. However, pH changes during hypoxemia are only partially responsible for the increased CBF (Koehler and Traystman, 1982). Adenosine has been shown to be necessary for the vasodilatory response to hypoxemia (Morii et al., 1987; Brian et al., 1996; DiGeronimo et al., 1998). NO has also been implicated as a mediator, because NOS inhibitors attenuate the increase in CBF that occurs during hypoxemia (Hudetz et al., 1998). Opioids such as methionine enkephalin and leucine enkephalin have been observed to contribute to hypoxic pial artery dilation in the piglet. Vasopressin-induced CSF methionine enkephalin and leucine enkephalin release are attenuated in the presence of cyclic

adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) antagonists. These data show that both cAMP and cGMP contribute to vasopressin-induced pial artery dilation and the release of the opioids methionine enkephalin and leucine enkephalin (Rossberg and Armstead, 1997).

Although hypoxemia produces cerebrovasodilation, the influence of increases in P_{aO_2} (hyperoxia) at normal atmospheric pressure is less well characterized and somewhat controversial (Armstead, 1998). Previous reports have documented both decrease in CBF (Kennedy et al., 1972) and no change in CBF (Busija et al., 1980) during hyperoxia. Animal studies demonstrate that hyperoxia elicits pial artery vasoconstriction during normocapnia, and that vasoconstrictor peptide endothelin-1 (ET-1) contributes to that vascular response (Armstead, 1999).

Effects of Viscosity on CBF

Viscosity of blood is primarily a function of hematocrit (Hct), and decrease in viscosity is usually secondary to hemodilution. During anemia, CBF increases as a result of improved rheology of the blood flow in the cerebral vessels and as a compensatory response to decreased oxygen delivery (Tomiyama et al., 1999). Although some data suggest that an Hct of less than 30% is associated with worse Glasgow Outcome Scale scores at discharge for adults with severe traumatic brain injury (TBI) (Carlson et al., 2006), neither the optimal duration for maintaining a specific hemoglobin (Hgb) level nor the relationship between target transfusion and neurologic outcome is fully known (Timmons, 2006). A recent study of critically ill children demonstrated that maintaining a Hgb of 7 g/dL rather than 9.5 g/dL can reduce requirements for blood transfusion, but none of these subjects had TBI (Lacroix et al., 2007).

Cerebral Autoregulation

Cerebral autoregulation is a homeostatic process: arterioles dilate and constrict to maintain CBF nearly constant over a range of blood pressures. In healthy adults, changes in mean arterial pressure (MAP) between 60 and 160 mm Hg result in little or no change in CBF (Fig. 22-4) (Lassen, 1959; Paulson et al., 1990). This adaptive mechanism maintains constant (adequate) CBF by vasodilation or decreasing cerebrovascular resistance. Beyond these limits of autoregulation, hypotension may result in cerebral ischemia, and hypertension may cause cerebral hyperemia.

Healthy infants appear to autoregulate CBF as well as older children during low-dosage sevoflurane anesthesia, but the long-held assumption that the lower limit of autoregulation (LLA) is lower in young than in older children may not be valid (same LLA range for younger and older children, 46 to 76 mm Hg) (Vavilala et al., 2003). There are no data on the LLA in healthy neonates. Because blood pressure increases with age, young children may be at increased risk of cerebral ischemia as a result of lower blood pressure reserve (mean arterial pressure to LLA); however, neonates are especially vulnerable to cerebral ischemia and intraventricular hemorrhage because of this narrow autoregulatory range (Pryds et al., 2005) (Fig. 22-5). Sick premature neonates have CBF pressure-passivity, resulting in a linear correlation between CBF and systemic blood pressure (Boylan et al., 2000). Therefore, tight blood pressure control

FIGURE 22-4. Normal and absent autoregulation curves. The “absent” curve indicates a pressure-passive condition in which cerebral blood flow (CBF) varies in proportion to cerebral perfusion pressure. The curve is drawn to indicate subnormal CBF values during normotension, as have been shown to occur immediately after head injury and subarachnoid hemorrhage. The potential for modest hypotension to cause ischemia is apparent. MAP, mean arterial pressure. (From Miller RD, Eriksson LI, Fleisher LA, et al., editors: *Miller’s anesthesia*, ed 7, Philadelphia, 2010, Churchill Livingstone.)

FIGURE 22-5. Autoregulation of cerebral circulation in neonates (curve B) and adults (curve A). (Redrawn from Harris MM: *Pediatric neuroanesthesia*. In Berry FA, editor: *Anesthetic management of difficult and routine pediatric patients*, ed 2, New York, 1990, Churchill Livingstone, p 341. After data of Hernández MJ, Brennan RW, Vannucci RC, et al: *Cerebral blood flow and oxygen consumption in the newborn dog*, *Am J Physiol* 234:R209, 1978.)

is essential in the management of neonates to minimize both cerebral ischemia during hypotension and intraventricular hemorrhage with increased blood pressure. Techniques such as deliberate hypotension in very young children or infants may not be desirable. Age-related increased latency may also occur in cerebral autoregulatory response in young children (Vavilala et al., 2002a), but no data exist in neonates. Animal data suggest that although CBF pressure autoregulation and reactivity to CO_2 operate in the newborn rat, hypercapnia abolishes cerebral autoregulation (Pryds et al., 2005), that abolished autoregulation is associated with cerebral damage in asphyxiated infants, and that the combination of isoelectric electroencephalograms (EEGs) and cerebral hyperperfusion is an early indicator of very severe brain damage (Pryds et al., 1990).

Despite these clinical observations, the mechanisms of normal cerebral autoregulation in healthy children and adaptations in acute disease are not completely understood, and as occurs with changes in CBF, both anatomic and physiologic maturation might play a role in the development of a fully developed autoregulatory response. The mechanisms of cerebral autoregulation may involve a combination of myogenic, neurogenic, and metabolic processes. The metabolic mechanism stipulates that autoregulation is mediated by the release of a vasodilator substance that regulates the cerebrovascular resistance to maintain CBF constant. Although no specific substance fits all experimental observations, adenosine, a potent cerebral vasodilator, is formed from the breakdown of ATP when neuronal demand of oxygen exceeds supply (Winn et al., 1985). Adenosine can be found in increased concentration in cerebral tissue as systemic blood pressure falls toward the lower limit of autoregulation. In fact, brain adenosine concentration doubles within 5 seconds of decreasing blood pressure (Winn et al., 1980). Cortical activation via contralateral peripheral stimulation is also immediately followed by adenosine release and regional vasodilation (Ngai et al., 1998). It has been suggested that NO exerts an influence on basal and stimuli mediated cerebrovascular tone. The mechanism of NO-induced cerebral vasodilation probably involves cGMP and a decrease in intracellular calcium. It is unclear to what extent NO affects cerebral autoregulation in both healthy patients and in patients with TBI. Although earlier studies suggest that NO has no influence on cerebral autoregulation, Jones and coworkers (1999) described an increase in the lower limit of autoregulation with NOS inhibitors. Other transmitters or substances that have been proposed as mediators of autoregulation include protein kinase C (Jones et al., 1999), melatonin (Régrigny et al., 1999), prostacyclin, activated potassium channels, and intracellular second messengers (Faraci and Heistad, 1998).

Pressure-dependent myogenic tone in the systemic resistance vessels was first proposed by Bayliss in 1902 was not experimentally verified until approximately 50 years later. The myogenic theory states that the basal tone of the vascular smooth muscle is affected by change in perfusion or transmural pressure, and that muscle contracts with increased MAP and relaxes with decreased MAP. Studies suggest that there may be two myogenic mechanisms involved in cerebral autoregulation: a rapid reaction to pressure pulsations and a slower reaction to change in MAP. This adaptive process appears to be initiated within the first 400 msec (rapid and rate-dependent response) and is probably completed in a few minutes by the slower and rate-independent component of the autoregulatory process. The slower secondary component appears to be the dominant force in regulating CBF. Autoregulation might also be invoked by incremental increases in blood pressure. However, constant pressure elevation is probably not a sufficient stimulus to maintain sustained vascular contraction. Some investigators believe the myogenic mechanism sets the limits of autoregulation, whereas the metabolic mediators are responsible for cerebral autoregulation itself.

The Neurogenic Mechanism

Perivascular innervation of the cerebral resistance vessels and the specific neurotransmitter contained in the perivascular nerve fibers may also modulate vascular response to change

in blood pressure. However, the specific mechanisms by which the CNS exerts control on the cerebral vasculature are poorly understood. Although acetylcholine is the most abundant perivascular neurotransmitter, the list of neurotransmitters involved in this neural response includes norepinephrine, neuropeptide Y, cholecystokinin, acetylcholine, vasoactive intestinal peptide, and calcitonin gene-related peptide (Yoon et al., 1997). Experimentally sympathetic stimulation can shift the autoregulatory curve to the right, thus protecting the brain against severe elevation of MAP.

EFFECTS OF DRUGS ON NEUROPHYSIOLOGY

The effects of the commonly used anesthetic agents on CBF, $CMRO_2$, and CSF dynamics are discussed here and summarized in Table 22-2. The data are scant on these effects in infants and children. The responses in children are assumed to be the same as those in adults.

Intravenous anesthetic drugs have varied effects on cerebral hemodynamics. Thiopental and propofol maintain autoregulation and coupling and potently reduce CBF, cerebral blood volume (CBV), and $CMRO_2$. Karsli and associates (2004) found that propofol maintained cerebrovascular reactivity to CO_2 at levels greater than 30 mm Hg end-tidal CO_2 in children. Furthermore, propofol, at high dosages, lowers CBFV and MAP values in children, which may be mediated by its cerebral vasoconstrictive properties (Karsli et al., 2002). Both thiopental and propofol have been touted as having neuroprotective properties, especially in preclinical studies, but their clinical efficacies in neurologically compromised pediatric patients have not been tested. Etomidate and ketamine are frequently used to induce anesthesia in hemodynamically compromised patients, as these drugs are less likely to cause hypotension than thiopental or propofol. However, CNS excitation and increased ICP have been associated with these drugs, respectively, and they may not be appropriate for many neurosurgical patients.

Intravenous Anesthetics

Propofol

Propofol is an intravenous (IV) induction agent with cerebrovascular properties similar to those of thiopental: both may depress systemic blood pressure but both potently decrease $CMRO_2$, CBF, and ICP (Van Hemelrijck et al., 1990). Cerebral autoregulation and cerebral responsiveness to changes in arterial CO_2 tension (Karsli et al., 2004) are well preserved during propofol anesthesia. Propofol is a good alternative to thiopental for induction of anesthesia for neurosurgery. In the presence of nitrous oxide and hypocapnia, propofol results in lower ICP, higher cerebral perfusion pressure (CPP), and less cerebral cortical edema than isoflurane or sevoflurane. In patients with or at risk for intracranial hypertension and decreased cerebral perfusion, maintenance of anesthesia with propofol is superior to inhaled halogenated anesthetics, at least until the dura has been opened.

Barbiturates

Barbiturates decrease CBF, CBV, and $CMRO_2$ in a dosage-dependent manner (Pierce et al., 1962; Michenfelder, 1974; Albrecht et al.,

1977) and therefore reduce ICP. Neither CBF nor cerebral metabolism is significantly altered by subanesthetic dosages of barbiturates. When the EEG becomes isoelectric, CBF and CMR_o₂ decrease to about 50% of normal, and additional doses of barbiturates have little further effect. Barbiturates may also be used to prevent increases in ICP that can occur with laryngoscopy and endotracheal intubation. Autoregulation and the cerebrovascular response to changes in Paco₂ remain intact during barbiturate anesthesia. The rate of CSF formation and the resistance to reabsorption of CSF are not altered by barbiturates (Mann et al., 1979). In dosages that suppress the EEG, barbiturates reduce cerebral damage in animal and human models of focal cerebral ischemia (Smith et al., 1974; Nehls et al., 1987). In animals, barbiturates also reduce the extent of cerebral edema after a cortical freeze injury. This decrease in edema is in contrast to the response observed with the volatile anesthetics (Smith and Marque 1976).

Opioids

Opioids have little effect on CBF, CBV, or ICP unless respiration is depressed and Paco₂ is increased (Miller et al., 1975; Misfeldt et al., 1976; Jobes, 1977; Moss et al., 1978).

Fentanyl

When combined with nitrous oxide, fentanyl decreases CBF by 47% and CMR_o₂ by 18% (Michenfelder, 1974). Autoregulation and CO₂ responsiveness of the cerebral circulation are not altered. Fentanyl does not alter the rate of CSF formation, but it reduces the resistance to CSF reabsorption by 50% (Artru, 1984a, 1984c), the effect of which is to decrease CSF volume to a degree of unknown clinical significance. The neonatal cerebral circulation is also unaffected by fentanyl (Yaster et al., 1987). Sufentanil and alfentanil in high dosages (10 to 20 mcg/kg) reduce both CBF and CMR_o₂ by 25% to 30% (Stephan et al., 1991), whereas at exceedingly high dosages (10 to 200 mcg/kg), sufentanil may transiently increase CBF while reducing CMR_o₂

(Milde et al., 1990). However, at conventional dosages, sufentanil (Herrick et al., 1991; Weinstabl et al., 1991; Mayberg et al., 1993) does not appear to have adverse effects on the cerebral vasculature or on ICP in most patients. In a subset of patients with severe head injuries and very poor intracranial compliance, sufentanil may cause a small (e.g., <10 mm Hg) and transient increase in ICP that may be clinically significant in some settings (Sperry et al., 1992; Weinstabl et al., 1992; Albanese et al., 1993).

Remifentanyl

Remifentanyl is an ultra-short-acting to short-acting opioid that is rapidly metabolized by plasma and tissue esterases. The very short clinical duration of effect of remifentanyl and its context-sensitive half-life, which is independent of the duration of infusion (Minto et al., 1997; Mertens et al., 2003), make it an appealing opioid for lengthy neurosurgical procedures after which rapid return of consciousness is desirable. As is the case with other opioids that have been studied, remifentanyl does not increase CBF or ICP (Hoffman et al., 1993; Baker et al., 1997; Ostapkovich et al., 1998; Klimscha et al., 2003; Engelhard et al., 2004; Lagace et al., 2004). Return of consciousness is very rapid after remifentanyl is discontinued, and the frequency of administration of naloxone to permit neurologic assessment is decreased (Guy et al., 1997). However, because remifentanyl analgesia is very brief after its discontinuation, a long-acting opioid analgesic must be administered to prevent severe pain and rebound hypertension before or soon after remifentanyl is discontinued (Gerlach et al., 2003; Cafiero et al., 2004).

Other Intravenous Anesthetics

Etomidate reduces ICP by decreasing CBF and CMR_o₂ by 34% and 45%, respectively. It, too, preserves the CO₂ responsiveness of the cerebral circulation (Renou et al., 1978; Moss et al., 1979).

A side effect of etomidate administration is myoclonus, which has been reported after prolonged continuous infusion of etomidate (Laughlin and Newberg, 1985). *Lidocaine* in clinical dosages decreases CBF and reduces the increase in ICP associated with endotracheal intubation (Sakabe et al., 1974; Donegan and Bedford, 1980). The *benzodiazepines* (diazepam, lorazepam, and midazolam) decrease CBF and CMR_{O_2} by approximately 25% (Cotev and Shalit, 1975; Rockoff et al., 1980; Tateishi et al., 1981; Forster et al., 1982; Nugent et al., 1982; Nakahashi et al., 1991).

Dexmedetomidine

The neurophysiologic effects of dexmedetomidine (an α_2 -agonist) have not been extensively studied in humans. In animals, it has been noted to decrease CBF but was not associated with a proportional decrease in the cerebral metabolic rate (Zornow et al., 1990). In human studies, CBFV decreases after dexmedetomidine administration (Zornow et al., 1993) and CBF—both global and regional—decreases by 30% at clinically relevant concentrations of dexmedetomidine (Prielipp et al., 2002).

The effect of dexmedetomidine on ICP in patients with space-occupying lesions is unclear. In patients undergoing transphenoidal hypophysectomy, dexmedetomidine had no effect on lumbar CSF pressure (Talke et al., 1997). Its effect on the amplitude and latency of cortical somatosensory evoked potential is minimal.

Ketamine

In contrast to the other IV anesthetic agents, ketamine is a potent cerebrovasodilator. It increases CBF by 60% with little change in CMR_{O_2} (Dawson et al., 1971; Takeshita et al., 1972; Schwedler et al., 1982). The cerebrovascular response to administration of ketamine is thought to be the result of regional cerebral activation induced by the drug (Hougaard et al., 1974). Ketamine produces a marked increase in ICP, which can be reduced, but not prevented, by hyperventilation (Gardner et al., 1972; Takeshita et al., 1972; Wyte et al., 1972). The increase in CBF, and presumably in ICP, can be blocked by previous administration of thiopental (Dawson et al., 1971). Ketamine has been associated with sudden elevation of ICP and clinical deterioration when used in patients with hydrocephalus and other intracranial pathology (List et al., 1972; Lockhart and Jenkins, 1972; Wyte et al., 1972). Although ketamine is not currently used as a general anesthetic in patients with reduced intracranial compliance, a recent study in critically ill children reported a decrease in ICP following ketamine (Bar-Joseph et al., 2009), thereby challenging the notion that ketamine increases ICP.

Inhalational Anesthetics

Volatile anesthetic drugs are potent cerebrovasodilators and may produce uncoupling of CMR_{O_2} and CBF, and different volatile anesthetics may have varying uncoupling profiles (Hansen et al., 1989). Uncoupling may lead to increased CBV and can exacerbate intracranial hypertension. Children have increased sensitivity to the vasodilatory effects of volatile drugs. TCD measurements reveal that the following volatile agents increase CBFV in descending order: halothane, desflurane, isoflurane, and sevoflurane. Autoregulation is also blunted in the presence

of volatile drugs in a dosage-dependent fashion. However, this perturbation is mitigated by hypocapnia. Nitrous oxide has vasodilatory effects alone and in combination with other anesthetics. Because isoflurane and sevoflurane significantly decrease CMR_{O_2} in children and maintain coupling, these two inhaled drugs are ideal anesthetics for the neurologically compromised patient. Sevoflurane does not significantly affect CBFV, and it preserves cerebral autoregulation in children anesthetized with up to a minimum alveolar concentration (MAC) of 1.5 (Fairgrieve et al., 2003; Wong et al., 2006).

Nitrous Oxide

Nitrous oxide is a weak cerebrovasodilator whose effects on CBF are offset by hyperventilation and barbiturate anesthesia (Algotsson et al., 1988). The variability of effects that nitrous oxide has on CBF and ICP in different reports results from differences in experimental species and background anesthesia. In many animals, nitrous oxide in subanesthetic dosages (60% to 70%) causes excitement and cerebral metabolic stimulation, with an accompanying increase in CBF (Theye and Michenfelder, 1968; Sakabe et al., 1978; Pelligrino et al., 1984; Drummond et al., 1987). Because nitrous oxide is not an adequate anesthetic in the absence of other inhalation or IV anesthetics, the modification of its cerebral effects by additional anesthetic drugs is particularly important. Nitrous oxide at 70% does not, for example, cause a change in CBF, but it does reduce CMR_{O_2} by 15% to 20% during barbiturate and narcotic anesthesia (Sakabe et al., 1978). However, when nitrous oxide is added to a volatile anesthetic such as isoflurane (Cucchiara et al., 1974; Manohar and Parks, 1984) or halothane (Sakabe et al., 1976), both CBF and CMR_{O_2} increase. When nitrous oxide is added to sevoflurane, cerebral hyperemia increases and autoregulation is impaired (Iacopino et al., 2003).

The cerebrovascular responses to changes in $Paco_2$ and MAP are preserved during nitrous oxide anesthesia. ICP may increase in response to nitrous oxide in patients with intracranial mass lesions and reduced intracranial compliance (Henriksen and Jørgensen, 1973; Moss and McDowall, 1979; Iacopino et al., 2003). The increase in ICP with nitrous oxide, however, is readily reversible by diazepam and barbiturate anesthesia and simultaneously initiated hyperventilation (Phirman and Shapiro, 1977).

The use of nitrous oxide for pediatric neuroanesthesia remains controversial. Some anesthesiologists prefer to avoid it because of its ability to increase CMR_{O_2} and reduce the cerebroprotective effects of barbiturates. Others are concerned because it readily diffuses into collections of intracranial air and may increase ICP in the presence of pneumocephalus (Artru, 1982; Skahen et al., 1986). Asymptomatic accumulation of intracranial air occurs commonly during craniotomies, especially those associated with posterior fossa surgery and drainage of CSF (Yates et al., 1994). Some anesthesiologists discontinue nitrous oxide before closure of the dura to reduce the incidence of tension pneumocephalus, and others administer nitrous oxide throughout the procedure without any obvious detrimental effects. Indeed, one randomized control trial comparing anesthetic techniques with and without nitrous oxide in patients undergoing sitting craniotomies showed no difference in the incidence or size of pneumocephalus between the three groups (Hernández-Palazón et al., 2003). It may be that nitrous oxide equilibrates with intracranial air before the dura is closed; if so,

ICP would not increase during craniodural closure because air pockets would already contain nitrous oxide. In addition, the discontinuance of nitrous oxide would decrease ICP, as nitrous oxide diffused back into the bloodstream (Skahen et al., 1986). Maintenance with nitrous oxide until the end of the surgery may be advantageous because it permits rapid awakening and may reduce the intracranial gas volume and the likelihood of delayed tension pneumocephalus. Nitrous oxide is generally not contraindicated during sitting craniotomies, even though the volume of a venous air embolus (VAE) expands in the presence of nitrous oxide. In fact, this phenomenon actually increases the sensitivity of monitoring for VAE by capnography, while at the same time nitrous oxide neither increases the risk of VAE (Losasso et al., 1992) nor increases the hemodynamic consequences of VAE, provided that nitrous oxide is discontinued when VAE is first detected (Losasso et al., 1992).

Isoflurane

Isoflurane is frequently used for neuroanesthesia. Its popularity is based on the fact that it affects CBF less than does halothane at equivalent MAC dosages (Todd and Drummond, 1984; Drummond and Todd, 1985; Algotsson et al., 1988), the fact that 1 MAC isoflurane preserves cerebral autoregulation (McPherson and Traystman, 1988) and CO₂ responsiveness (McPherson et al., 1989), and the belief that it may provide cerebral protection (Newberg and Michenfelder, 1983; Verhaegen et al., 1992). Cerebral autoregulation is less affected by isoflurane than by halothane (Todd and Drummond, 1984b). In addition, isoflurane does not change CSF production, and it reduces the resistance to reabsorption of CSF (Artru, 1984b). During hypocapnia, CBF is lower with 1.0 MAC isoflurane (with 75% nitrous oxide) than with nitrous oxide alone (Cucchiara et al., 1974; Drummond and Todd, 1985). In contrast, 1.0 MAC halothane (with 75% nitrous oxide) increases CBF. Despite their dissimilar effects on CBF, isoflurane and halothane increase ICP equally in an animal model of brain injury (Scheller et al., 1987). This is probably because isoflurane and halothane increase CBV to a similar degree (Artru 1984c; Archer et al., 1987). In patients with reduced intracranial compliance, isoflurane increases ICP. This increase can be attenuated by simultaneous initiation of hyperventilation (Adams et al., 1981).

Isoflurane may be safely used in patients with small supratentorial brain tumors (Madsen et al., 1987), but it may cause dangerous increases in ICP in patients with large intracranial mass lesions that are associated with a midline shift evident on a computed tomography (CT) scan (Grosslight et al., 1985). Like halothane, isoflurane should be avoided in patients with reduced intracranial compliance until the dura is open, if ICP is not being monitored. Isoflurane decreases CMRO₂ by 30%, and it causes an isoelectric EEG at concentrations above 2.0 MAC (Newberg and Michenfelder, 1983). It is unique among the volatile agents in that it preserves normal cerebral energy states and aerobic metabolism at very low blood pressure (40 mm Hg), in contrast to the findings observed with hypotension induced by halothane, trimethaphan, or sodium nitropruside (Newberg et al., 1984). In studies of mice exposed to 5% oxygen, isoflurane increased survival time and thus may have provided some degree of cerebral protection. In studies of incomplete global ischemia in isoflurane-anesthetized dogs, cerebral energy stores were increased, presumably through depression of cortical electrical activity and cerebral metabolism (Newberg

and Michenfelder, 1983). Protective effects of isoflurane, however, were not observed in a primate model of regional cerebral ischemia (Nehls et al., 1987).

Sevoflurane

Sevoflurane is a fluorinated ether with a low blood-gas solubility. Studies in rabbits suggest that sevoflurane does not increase CBF at 0.5 to 1.0 MAC. Sevoflurane does cause increases in CBF and ICP and a decrease in cerebral oxygen consumption (Scheller et al., 1988) and CPP, similar to isoflurane (Petersen et al., 2003). Compared with isoflurane, sevoflurane allows more rapid emergence after lengthy neurosurgery, and thus more rapid neurologic assessment (Mönkhoff et al., 2001; Gauthier et al., 2002). Taken together, the available evidence suggests that sevoflurane is a more appropriate inhaled anesthetic than halothane during craniotomy, and that it is equivalent in its cerebrovascular effects to isoflurane, while allowing more rapid recovery after long anesthesia. As is the case with other halogenated agents, if ICP or intracranial compliance is compromised, sevoflurane should be withheld until the dura has been opened (Petersen et al., 2003).

Halothane

Halothane is a cerebral vasodilator that decreases cerebrovascular resistance and increases CBF in a dosage-dependent fashion (Wollman et al., 1964; Albrecht et al., 1977; Todd and Drummond, 1984; Brüssel et al., 1991). The increase in CBF is transient; CBF decreases to baseline levels after 150 minutes of halothane anesthesia (Albrecht et al., 1983). CBV, however, remains elevated by 11% to 12% over a 3-hour period of halothane administration (Artrub, 1983). Halothane reduces CMRO₂ by 17% to 33% (Albrecht et al., 1977). The cerebral vasculature remains responsive to changes in arterial Paco₂ (Alexander et al., 1964; Wollman et al., 1964; Drummond and Todd, 1985). Halothane in high concentrations (2.0 MAC) abolishes autoregulation of the cerebral circulation in response to changes in MAP in both adults (Miletich et al., 1976; Todd and Drummond, 1984) and infants (Messer et al., 1989). Halothane alters blood-brain barrier permeability, promoting the extravasation of plasma proteins into normal brain during periods of acute hypertension (Forster et al., 1978). Halothane reduces CSF formation by 30% in dogs and increases the resistance of reabsorption of CSF (Artru, 1983a, 1984b).

Because ICP is determined by CBV, CSF volume, and brain tissue volume, it is not surprising that ICP increases with halothane (Jennett et al., 1969; DiGiovanni et al., 1974). Peak increases are observed in 3 to 13 minutes, although the increase persists over 3 hours of halothane exposure (Artru, 1983b). The increase in ICP in patients with intracranial mass lesions can be attenuated, but not totally prevented, by establishing hyperventilation for 10 minutes before the introduction of halothane (Adams et al., 1981). If ICP is not being monitored, halothane should not be used in patients with reduced intracranial compliance until the dura is open and its effects on the brain can be seen.

Desflurane

Desflurane is an inhalation agent that is chemically similar to isoflurane. Its physicochemical properties are remarkable,

with a blood-gas partition coefficient even lower than that of nitrous oxide, permitting rapid uptake and washout of the gas. The effects of desflurane on cerebral metabolism and hemodynamics are not as well studied as the effects of the other inhalation agents, but animal studies suggest that its effects are not unique in any way. Desflurane at clinical concentrations is a potent cerebral vasodilator, increasing ICP (Artru, 1994), increasing CBF by 50% at 1.5 MAC, and reducing autoregulation of CBF (Lutz and Milde, 1990). However, cerebrovascular responsiveness to hypocapnia is preserved during desflurane anesthesia in laboratory animals, protecting the animal from increases in ICP if hyperventilation occurs during the anesthesia (Lutz et al., 1991; Young, 1992). In patients with mass lesions, equivalent MAC dosages of desflurane and isoflurane are similar in terms of absolute CBF, the response to increasing dosages, and the preservation of CO₂ reactivity (Ornstein et al., 1993; Fraga et al., 2003). Desflurane effects seen on the EEG are also similar to those of isoflurane. At increasing concentrations, the electroencephalographic frequency decreases and the amplitude increases. Burst suppression appears at about 1.24 MAC (Rampil et al., 1991).

Muscle Relaxants

Succinylcholine

Succinylcholine is very infrequently used in pediatric anesthesia because of its association with life-threatening hyperkalemia and cardiac arrest in children with undiagnosed myopathies. This has led to a black-box warning by the U.S. Food and Drug Administration, reserving its use in children for emergency intubation when securing the airway is necessary. Most often, the use of even high-dosage nondepolarizing neuromuscular blockers is appropriate for emergently securing the airway in children, but in some cases a very rapid and immediate pharmacologic paralysis is required, and succinylcholine remains the drug of choice in these circumstances. Life-threatening hyperkalemia has also been associated with administration of succinylcholine after many types of CNS disorders, including closed-head injury, even without motor deficits (Mazze et al., 1969; Thomas, 1969; Smith and Grenvik, 1970), cerebral hypoxia caused by near-drowning (Tong, 1987), subarachnoid hemorrhage (Iwatsuki et al., 1980), encephalitis (Cowgill et al., 1974), cerebrovascular accidents (Cooperman et al., 1970), and paraplegia (Cooperman, 1970; Tobey, 1970). The onset of the period of vulnerability is not well defined. It may begin as early as 24 to 48 hours after injury and may last up to 1 to 2 years after injury (Cooperman, 1970). Because the period of risk for succinylcholine-induced hyperkalemia after cerebral injury is undefined, succinylcholine should be avoided in these patients, except in the period immediately after injury. Succinylcholine can increase CBF and ICP in patients with reduced intracranial compliance (Cottrell et al., 1983; Minton et al., 1986; Stirt et al., 1987a; Thiagarajah et al., 1988), probably because of cerebral stimulation from succinylcholine-induced increases in afferent-muscle spindle activity (Lanier et al., 1986.). The increases in CBF and ICP can be blunted by deep general anesthesia or by previous paralyzing or “defasciculating” dosages of nondepolarizing muscle relaxants (Minton et al., 1986; Stirt et al., 1987a). In contrast, most nondepolarizing relaxants have little effect on CBV and

ICP (Lanier et al., 1985; Minton et al., 1985; Stirt et al., 1987b; Rosa et al., 1991), unless associated with histamine release (D-tubocurarine, atracurium), which causes transient cerebrovasodilation and increased ICP (Tarkkanen et al., 1974). In dosages that do not release histamine, atracurium does not increase ICP, despite the accumulation of laudanosine, a major metabolic product of atracurium and a potential CNS arousal agent.

Nondepolarizing Muscle Relaxants

The presence of motor deficits or the administration of anticonvulsants may affect the dosage of nondepolarizing muscle relaxant necessary in neurosurgical patients. Hemiplegia from an upper motor neuron lesion (such as a stroke or a brain tumor) is associated with resistance to nondepolarizing relaxants on the paretic side (Graham, 1980; Moorthy and Hilgenberg, 1980; Shayevitz and Matteo, 1985). Excessive dosages of muscle relaxants may be given if the dosage is guided by a nerve stimulator monitoring a hemiplegic extremity. In contrast, an increased response to nondepolarizing muscle relaxants is observed in paretic-muscle lower motor neuron lesions (e.g., paraplegia and quadriplegia) (Brown et al., 1975). Acute administration of several anticonvulsants, including phenytoin, phenobarbital, trimethadione, and ethosuximide, enhances nondepolarizing neuromuscular blockade or delays its reversal (Gandhi et al., 1976; Spacek et al., 1999). Patients receiving chronic phenytoin or carbamazepine therapy are resistant to the effects of nondepolarizing relaxants, including pancuronium, (Roth and Ebrahim, 1987), metocurine (Ornstein et al., 1985), vecuronium (Ornstein et al., 1987; Alloul et al., 1996), and rocuronium (Spacek et al., 1999; Hernández-Palazón et al., 2001) but, interestingly, not mivacurium or atracurium (Ornstein et al., 1987; Spacek et al., 1996). The cause of phenytoin-induced resistance to nondepolarizing muscle relaxants and the reason for the lack of the same effect with mivacurium or atracurium are unclear. Finally, no data have yet been published describing the interactions of anticonvulsants (felbamate, gabapentin, levetiracetam, tiagabine, topiramate, sodium valproate, or valproic acid) with nondepolarizing neuromuscular blocking drugs (Fig. 22-6).

■ **FIGURE 22-6.** Effect of chronic anticonvulsant therapy on the half-life of the muscle relaxant vecuronium. Vecuronium plasma concentrations are plotted against time after a single bolus dose of vecuronium (0.15 mg/kg). Mean \pm SD is plotted for all three groups.

Vasodilators

The direct-acting vasodilators, including sodium nitroprusside, ATP, adenosine, nitroglycerin, diazoxide, and hydralazine, are cerebrovasodilators and may increase CBF and ICP (Stoyka and Schutz, 1975; Turner et al., 1977; Marsh et al., 1979; Cottrell et al., 1980; McDowall, 1985). The calcium channel blockers also raise CBF and ICP (Griffin et al., 1983; Mazzoni et al., 1985). These drugs should therefore be avoided in patients with reduced intracranial compliance, unless the dura is open or ICP is monitored. Indirect-acting antihypertensives, including trimethaphan (a ganglionic blocker), propranolol and esmolol (β -adrenergic blockers), and labetalol (a combined α - and β -blocker), do not increase CBF or ICP (Magness et al., 1973; Turner et al., 1977; McDowall, 1985). These agents are useful for the control of blood pressure in patients with elevated ICP. Trimethaphan may interfere with the neurologic examination by causing mydriasis, cycloplegia, or anisocoria. Sodium nitroprusside lowers the range of cerebral autoregulation. Brain-surface oxygen tension is greater (Maekawa et al., 1977) and metabolic disturbances in brain biochemistry (e.g., lactate, pyruvate, and phosphocreatine levels) are less during nitroprusside-induced hypotension than with trimethaphan- or hemorrhage-induced hypotension (Michenfelder and Theye, 1977). In addition, cortical blood flow and electrical activity are better preserved at lower MAP with sodium nitroprusside (Ishikawa and McDowall, 1981). Nitroprusside, however, induces more pronounced blood-brain barrier dysfunction than does trimethaphan (Ishikawa et al., 1983). Because CBF, brain oxygen tension, neuronal function, and brain metabolism are better maintained with sodium nitroprusside than with trimethaphan at a MAP of 50 mm Hg, sodium nitroprusside is the preferred agent for deliberate hypotension.

Central Nervous System Toxicity of Anesthetic Agents

Preclinical studies have demonstrated that prolonged exposure of fetal and neonatal laboratory animals to anesthetic drugs leads to accelerated neurodegeneration (Ikonomidou et al., 1999; Jevtovic-Todorovic et al., 2003; Slikker et al., 2007). The data generated in these reports have provoked a heated debate on its relevance to the practice of pediatric anesthesia (Anand and Soriano, 2004; Olney et al., 2004). There is no doubt that this phenomenon is valid in the experimental paradigms used in these laboratory investigations. The same model has also implicated dexamethasone and magnesium sulfate in accelerating neuroapoptosis in the development of rat brain (Noguchi et al., 2008; Dribben et al., 2009). However, a number of factors make the extrapolation of these findings to humans in the daily practice of clinical pediatric anesthesiology questionable. For example, these animal and *in vitro* studies have significant limitations in terms of agent dosage and duration of exposure (both absolute and in comparison with human studies) (Loepke and Soriano, 2008). Furthermore, no defined clinical markers or syndromes are associated with neonatal exposure to general anesthetics. Unlike general anesthetic agents, exposure to alcohol or anticonvulsant drugs during gestational development has clearly characterized clinical syndromes. Although histologic evidence of accelerated neurodegeneration has been verified by several investigational groups, discrepancies in neurocognitive

outcomes exist (Loepke et al., 2009). Prospective clinical investigations are underway to verify these observations. Finally, the majority of neonatal and infant surgery is urgent or emergent, and anesthetic care is essential to proceed safely. It has been clearly demonstrated that inadequate anesthesia leads to poor postoperative outcomes in infants (Anand and Hickey, 1987; Anand and Soriano, 2004), and it is crucial to attenuate the stress response associated with surgical stimulation.

Several retrospective reports have positively linked exposure to general anesthesia before the age of 4 with an increased chance of developing learning deficits. Wilder and colleagues (2009) examined the extensive medical and school records of 5358 children in Rochester, Minnesota, and determined that there was an association between learning deficits in school and having more than two surgeries before age 4. A cross-sectional study done by Kalkman and colleagues (2009) in Utrecht, The Netherlands, surveyed a small number of parents of children who had had surgery at a young age and determined that there was a trend toward greater prevalence of learning deficits in children who had had early surgery. However, these reports need to be reconciled with a recent report demonstrating no causal relationship between anesthesia exposure and subsequent learning behavior in twin cohorts (Bartels et al., 2009). Clinicians should be aware of the rapid developments in the area of anesthetic-induced neurodegeneration and keep in mind the degree of necessity of infant surgical procedures and the more significant effects of the hypoxic and cardiovascular mechanisms of brain injury and death during anesthesia and surgery in these patients.

PREOPERATIVE EVALUATION AND PREPARATION

A proper and thorough evaluation and preparation of the pediatric patient for anesthesia and surgery are essential components of minimizing perioperative morbidity and mortality. Because of the urgent nature of many pediatric neurosurgical procedures, a thorough preoperative evaluation may be difficult. The perioperative management of pediatric patients undergoing neurosurgical procedures should be based on the developmental stage of the patient and is discussed in Chapter 8, Psychological Aspects, and Chapter 9, Preoperative Preparation. Given the systemic effects of general anesthesia and the physiologic stress of surgery, an organ system–based approach is optimal for anticipating potential physiologic derangements and coexisting disease states that may increase the risk of perioperative complications (Ferrari, 1999). Many potential perioperative problems can be preemptively addressed with such an approach. Because some children are either preverbal or do not fully understand their medical condition, their parents or primary caregivers should be interviewed carefully to obtain information regarding coexisting medical problems. A thorough review of the patient's history can reveal conditions that may increase the risk of adverse reactions to anesthesia and perioperative morbidity and identify patients who need more extensive evaluation or whose medical condition needs to be optimized before surgery. There are also special perioperative concerns regarding children with neurologic abnormalities. However, certain aspects of this evaluation are of special relevance to neurosurgical patients. Specific concerns in these patients are listed in [Table 22-3](#). Preoperative laboratory testing should be tailored to the proposed neurosurgical procedure.

TABLE 22-3. Common Perioperative Concerns for Infants and Children with Neurologic Lesions

Condition	Anesthetic Implications
Denervation injuries	Hyperkalemia after succinylcholine Resistance to nondepolarizing muscle relaxants Abnormal response to nerve stimulation
Chronic anticonvulsant therapy	Hepatic and hematologic abnormalities Increased metabolism of anesthetic agents
Arteriovenous malformation	Potential congestive heart failure
Neuromuscular disease	Malignant hyperthermia Respiratory failure Sudden cardiac death
Chiari malformation	Apnea Aspiration pneumonia Stridor
Hypothalamic and pituitary lesions	Diabetes insipidus or syndrome of inappropriate antidiuretic hormone Hypothyroidism or hyperthyroidism Adrenal insufficiency or adrenal excess

The chronicity and severity of the patient's neurologic condition vary greatly and should dictate the perioperative management. Special attention should be given to symptoms of allergy to latex products, because anaphylaxis has been reported in a number of children who have undergone multiple previous operations, especially patients with meningomyeloceles (Holzman, 1997). Severe dehydration and electrolyte abnormalities can be the result of protracted vomiting from intracranial hypertension. Patients with diabetes insipidus can develop hypovolemia as a result of polyuria. During the perioperative period, steroids are frequently initiated to palliate cerebral swelling in patients with intracranial tumors. Therapeutic levels of anticonvulsants should be verified preoperatively and maintained perioperatively. Patients on long-term anticonvulsants may develop toxicity, especially if seizures are difficult to control. This reaction frequently manifests with abnormalities in either hematologic or hepatic function, or both. Patients on chronic anticonvulsant therapy may also require increased amounts of sedatives, nondepolarizing muscle relaxants, and narcotics because of enhanced metabolism of these drugs (Soriano et al., 2000b; Soriano et al., 2001; Soriano and Martyn, 2004).

Physical Examination

The physical examination should include a brief neurologic evaluation that includes consciousness level, motor and sensory function, normal and pathologic reflexes, integrity of the cranial nerves, and signs and symptoms of intracranial hypertension (Fig. 22-7 and Table 22-4). It is essential to document these factors in the preoperative examination to be able to gauge postoperative neurologic function. Lesions of the brainstem can manifest with cranial nerve dysfunction such as respiratory distress, impaired gag reflex and swallowing, and pulmonary aspiration. Evidence of muscle atrophy and weakness should be noted, particularly if the patient is hemiparetic, hemiplegic, or bedridden, because up-regulation of acetylcholine receptors may precipitate sudden hyperkalemia after succinylcholine administration and induce resistance to nondepolarizing muscle

■ **FIGURE 22-7.** An infant with hydrocephalus. Note enlarged head and the downward gaze (the setting-sun sign). The latter suggests the presence of intracranial hypertension.

TABLE 22-4. Signs of Intracranial Hypertension in Infants and Children

Infants	Children	Infants and Children
Irritability	Headache	Decreased consciousness
Full fontanelle	Diplopia	Cranial nerve (III and VI) palsies
Widely separated cranial sutures	Papilledema	Loss of upward gaze (setting-sun sign)
Cranial enlargement	Vomiting	Signs of herniation, Cushing's triad, pupillary changes

relaxants in the affected limbs. Body weight should be accurately measured to guide the administration of drugs, fluids, and blood products. Physical signs of dehydration should be noted, especially in patients who have been chronically ill or have received osmotic or diuretic agents.

Radiologic and Laboratory Evaluation

Most neurosurgical patients have a magnetic resonance imaging (MRI) or CT scan of the head as part of the preoperative assessment. These scans should be reviewed with the neurosurgeon to confirm the primary lesion and the presence of evolving neurologic conditions (hydrocephalus, compressed cisterns, midline shifts) (Fig. 22-8). Preoperative laboratory tests should be tailored to the proposed neurosurgical procedure. Given the risk of significant blood loss associated with surgery, the hematocrit, prothrombin time, and partial thromboplastin time should be obtained to uncover any insidious hematologic disorder. Patients with suprasellar pathology should have an endocrinology evaluation. Type- and cross-matched blood should be ordered before all craniotomies. Endocrinologists may be needed to help optimize the patient's condition before surgery and to assist in postoperative management. Liver function tests and a hematologic profile should be obtained if not recently reviewed for children taking long-term anticonvulsants.

■ **FIGURE 22-8. A**, CT scan depicting normal (*left*) and compressed (*right*) basal cisterns. The basal, or perimesencephalic, cerebrospinal fluid space consists of the interpeduncular cistern (anterior), the ambient cisterns (lateral), and the quadrigeminal cisterns (posterior). In the patient (*right*) with diffuse cerebral swelling (caused by sagittal sinus thrombosis), the cisterns have been obliterated. **B**, Hydranencephaly. CT scan demonstrates replacement of the cerebral hemispheres by a large, water-dense cavity with residual islands of brain tissue in regions of the occipital poles and right inferior temporal lobe. (**A**, Courtesy Ivan Petrovitch, MD; **B**, courtesy Division Neuroradiology, University of Health Center of Pittsburgh.)

Premedication

Perioperative anxiety plays a significant role in the care of the pediatric neurosurgical patient. Anxiety issues are related to the cognitive development and age of the child (see Chapter 2, Behavioral Development). Preoperative sedatives given before the induction of anesthesia can ease the transition from the preoperative holding area to the operating room (Kain et al., 2004). Oral midazolam is particularly effective in relieving anxiety and producing amnesia. If an indwelling IV catheter is in place, midazolam can be slowly titrated to achieve sedation. Sedation is usually withheld from pediatric neurosurgical patients until they arrive in the preoperative area to avoid the problem of an oversedated, neurologically impaired patient with inadequate supervision; however, heavy premedication may be warranted to avoid agitation in patients with moyamoya disease or an intracranial aneurysm or arteriovenous malformation that has recently bled. Narcotics are best withheld preoperatively, as they may cause nausea or respiratory depression, especially in patients with increased ICP.

Sedatives are administered in the parents' presence to facilitate a smooth separation and induction. Midazolam (0.5 to 1.0 mg/kg) may be given orally; it usually requires 5 to 20 minutes to take effect. Alternatively, after application of EMLA (eutectic mixture of local anesthetics, 2.5% lidocaine, and 2.5% prilocaine) cream, an IV catheter can be inserted, into which incremental dosages of IV midazolam may then be carefully titrated.

GENERAL PRINCIPLES OF INTRAOPERATIVE MANAGEMENT

Induction of Anesthesia

The patient's preoperative status dictates the appropriate technique and drugs for induction of anesthesia. A modified Glasgow Coma Scale for infants and children is useful for assessing

the mental status of the patient before the administration of anesthesia (Table 22-5). Somnolent patients with intracranial hypertension are at risk for aspiration pneumonitis and require a rapid-sequence induction of anesthesia.

In the presence of intracranial hypertension, the primary goal during induction is to minimize severe increases in ICP. The effects of anesthetic drugs on cerebral hemodynamics were discussed extensively earlier in this chapter and are summarized in Table 22-2. In general, most IV drugs decrease CBF, metabolism, and ICP. Thiopental (4 to 8 mg/kg) and propofol (2 to 5 mg/kg) have similar effects on cerebral hemodynamics and maintain tight coupling of CBF and cerebral metabolic rate. Patients at risk for aspiration pneumonitis (including certain patients with intracranial hypertension) should have rapid-sequence induction of anesthesia using cricoid pressure. An IV hypnotic drug, such as thiopental or propofol, is administered and followed immediately by a rapid-acting muscle relaxant. Rocuronium can be used when succinylcholine is contraindicated, such as for patients with spinal cord injuries or parietic extremities. In instances of preexisting neurologic injury (e.g., in a patient with a history of a stroke resulting in a weak extremity), succinylcholine can result in sudden, catastrophic hyperkalemia. Etomidate and ketamine are frequently used to induce anesthesia in hemodynamically compromised patients, because these drugs are less likely to cause hypotension than thiopental or propofol. However, CNS excitation and increased ICP have been associated with these drugs, respectively, and they may not be appropriate for many neurosurgical patients. Ketamine should be avoided because of its known ability to increase cerebral metabolism, CBF, and ICP.

General anesthesia can be induced with sevoflurane and nitrous oxide in patients who are neurologically stable. Although volatile anesthetic drugs are potent cerebrovasodilators and may produce uncoupling of cerebral metabolic requirement of oxygen, its use for induction of anesthesia is relatively brief. ICP can be lowered during induction by initiating controlled

TABLE 22-5. Glasgow Coma Scale and Modifications for Young Children

Glasgow Coma Scale	Pediatric Coma Scale	Infant Coma Scale	Score
Eyes: Best Response			
Open spontaneously	Open spontaneously	Open spontaneously	4
React to verbal command	React to speech	React to speech	3
React to pain	React to pain	React to pain	2
No response	No response	No response	1
Best Verbal Response			
Oriented and converses	Smiles, oriented, interacts	Coos, babbles, interacts	5
Disoriented and converses	Interacts inappropriately	Irritable	4
Inappropriate words	Moaning	Cries to pain	3
Incomprehensible sounds	Irritable, inconsolable	Moans to pain	2
No response	No response	No response	1
Best Motor Response			
Obeys verbal command	Spontaneous or obeys verbal command	Normal spontaneous movements	6
Localizes pain	Localizes pain	Withdraws to touch	5
Withdraws to pain	Withdraws to pain	Withdraws to pain	4
Abnormal flexion	Abnormal flexion	Abnormal flexion	3
Extension posturing	Extension posturing	Extension posturing	2
No response	No response	No response	1

hyperventilation and administering opioid and barbiturate supplements before laryngoscopy and intubation. A nondepolarizing muscle relaxant may then be administered after IV access has been established to facilitate intubation of the trachea. Pancuronium is an ideal muscle relaxant for neonates and infants because it produces tachycardia that counters the parasympathetic effect of laryngoscopy.

A common problem is an uncooperative toddler who has an intracranial tumor, has moderately decreased intracranial compliance, and is agitated and resistant to parental separation. Some clinicians advocate the use of rectal barbiturates with meticulous attention to airway maintenance to avoid obstruction and resultant hypercarbia and hypoxemia. However, others argue that a crying, agitated child has demonstrated a tolerance to increased ICP and that IV induction is safer. Fortunately (for the anesthesiologist), patients who have severe intracranial hypertension generally have a decreased level of consciousness, and it becomes easier to insert an IV catheter when it is most necessary.

Succinylcholine should be avoided in patients with denerating processes such as stroke, or spinal cord injury, because it can result in life-threatening hyperkalemia.

Airway Management

Developmental changes in airway anatomy have a significant impact on management of the pediatric airway. Nasotracheal tubes may be best suited for situations when the patient will be prone, because orotracheal tubes can kink at the base of the tongue when the head is a flexed and result in airway obstruction. The timing of tracheal extubation may be challenging after neurosurgical procedures. Infants, particularly those with Chiari malformation (Cochrane et al., 1990) or older children after procedures in the posterior fossa (Cochrane et al., 1994), may exhibit intermittent apnea, vocal cord paralysis, or other irregularities before resuming a stable respiratory pattern. Significant airway edema and postoperative obstruction can complicate prone procedures or those involving significant blood losses and large volume replacement. Lingual or supra-glottic swelling may require direct laryngoscopy to assess the airway. Head-up positioning and gentle forced diuresis usually improve airway edema within 24 hours.

Positioning

Patient positioning for surgery requires careful preoperative planning to allow adequate access to the patient for both the neurosurgeon and anesthesiologist. For the patient with altered physiologic states, various surgical positions can predispose to injury (Fig. 22-9 and Table 22-6). The prone position is commonly used for posterior fossa and spinal cord surgery. The sitting position may be more appropriate for obese patients, who may be difficult to ventilate in the prone position because of increased intrathoracic pressure. In addition to the physiologic sequelae of the sitting position, a spectrum of neurovascular compression and stretch injuries can occur. It is important to ensure free abdominal wall motion. Increased intraabdominal pressure can impair ventilation, cause venocaval compression, and increase epidural venous pressure and bleeding. Postoperative visual loss has been linked to surgery in the prone position. Therefore, the eyes must be free of any direct contact with the horseshoe or Mayfield head holder (Lee et al., 2006). Many neurosurgical procedures are performed with the head slightly elevated to facilitate venous and CSF drainage from the surgical site; however, superior sagittal sinus pressure decreases with increasing head elevation, and this increases the likelihood of VAE (Grady et al., 1986). Excessive rotation of the head can impede venous return via compression

FIGURE 22-9. Positioning patients and padding them to prevent injuries is essential, especially for prolonged procedures with the patient in the prone position.

TABLE 22-6. Physiologic Effects of Patient Positioning

Position	Physiologic Effect
Head elevated	Enhanced cerebral venous drainage Decreased cerebral blood flow Increased venous pooling in lower extremities Postural hypotension
Head down	Increased cerebral venous and intracranial pressure Decreased functional residual capacity (lung function) Decreased lung compliance
Prone	Venous congestion of face, tongue, and neck Decreased lung compliance Increased abdominal pressure (can lead to venocaval compression)
Lateral decubitus	Decreased compliance of down-side lung

of the jugular veins and can lead to impaired cerebral perfusion, increased ICP, and venous bleeding. Flexion of the head can cause the tracheal tube to migrate into a main stem bronchus. Extreme head flexion can cause brainstem compression in patients with posterior fossa pathology, such as mass lesions or an Arnold-Chiari malformation and high cervical spinal cord ischemia. Likewise, extreme head extension may result in inadvertent tracheal extubation. Finally, all pressure points should be padded and peripheral pulses checked to prevent peripheral nerve and vascular compression and pressure injury.

Vascular Access

The routine use of central venous catheters in pediatric neurosurgical patients is controversial. The small bore and relatively long length of pediatric central catheters may produce too much resistance to high flow rates. Typically, two large peripheral venous cannulae are sufficient for most craniotomies. Should peripheral IV be difficult to secure, a cannulation of the femoral vein avoids the risk of pneumothorax associated with subclavian catheters, and it does not interfere with cerebral venous return as may be the case with jugular catheters. Because significant blood loss and hemodynamic instability can occur during craniotomies, an arterial catheter provides direct blood pressure monitoring and sampling for blood-gas analysis.

Maintenance of Anesthesia
