Thrombocytopenia and Bleeding Disorders

Elizabeth Helen Horn / Lucy Kean

THROMBOCYTOPENIA

Introduction

The normal range for peripheral blood platelet count in nonpregnant individuals is generally reported as 150 to 400 $\times 10^9$/L. If a low platelet count is seen on an automated complete blood count, spurious thrombocytopenia should be excluded. This condition may occur because of a small clot in the blood sample or because of platelet clumping caused by the addition of the anticoagulant EDTA to the sample. A repeat count for confirmation and examination of the peripheral blood film can ascertain whether the thrombocytopenia is genuine. If the blood film shows platelet clumps, a repeat complete blood count in a sample anticoagulated with citrate may resolve the problem.

Studies of platelet counts during normal pregnancy differed in their conclusions, with some suggesting no overall effect of pregnancy on platelet count[1-3] and others showing a modest reduction in late pregnancy.[4-6] One study of platelet counts in 6715 consecutive patients delivering in a single Canadian center showed that thrombocytopenia (platelet count $<150 \times 10^9$/L) occurred in 7.6% of women, and most (65.1%) had no associated pathology.[7] From a practical point of view, any pregnant woman with a platelet count of less than 100×10^9/L should undergo further clinical and laboratory assessment. No pathology is found in most women with mild thrombocytopenia.[8] Pregnant women with platelet counts between 100 and 150×10^9/L should be evaluated further if there has been a rapid decline in the platelet count.

Causes of Thrombocytopenia in Pregnancy

Causes of thrombocytopenia in pregnancy are summarized in Table 41–1. They can be broadly divided into the following categories:

- Platelet destruction or consumption
- Splenic sequestration of platelets
- Failure of platelet production in the bone marrow

Platelet destruction or consumption is much more common than bone marrow failure in obstetric practice. Causes with management implications in pregnancy are discussed in detail.

Investigation of Thrombocytopenia in Pregnancy

As discussed earlier, spurious thrombocytopenia should be excluded. In assessing pregnant women with genuine thrombocytopenia, close liaison is required between the obstetrician and the hematologist. Patients should be assessed clinically to obtain clues to the diagnosis. In patients with severe thrombocytopenia, the clinical severity of hemorrhagic problems should be assessed. In the history, current or previous bleeding problems or a family history of a hemorrhagic disorder should be noted. Other medical or obstetric problems, a drug and alcohol history, and a recent transfusion history should be noted. For example, a history of recurrent miscarriage suggests antiphospholipid syndrome. On examination, important features include petechiae and signs of mucosal bleeding. Blood pressure should be measured, and the clinician should look for clinical features that suggest underlying autoimmune disease, chronic liver disease, or splenomegaly. Urinalysis should be performed, and proteinuria should be quantified. Careful examination of the blood film is mandatory because it may give important clues to the diagnosis. For example, red cell fragmentation narrows the differential diagnosis to thrombotic microangiopathies (discussed later) (Table 41–2). Hypersegmented neutrophils and oval macrocytes suggest folate deficiency, and other red and white cell

Causes of Thrombocytopenia in Pregnancy

Platelet Consumption or Destruction

Gestational thrombocytopenia
Autoimmune thrombocytopenia
   Primary
   Secondary
      Antiphospholipid syndrome
      Systemic lupus erythematosus and connective tissue
         disorders
      Drug-induced
      HIV-associated
      Other viral infection (e.g., Epstein-Barr virus)
      Lymphoma
   Nonimmune
      Disseminated intravascular coagulation
      Preeclampsia or HELLP syndrome
      Thrombotic thrombocytopenia purpura or hemolytic
         uremic syndrome
      Acute fatty liver of pregnancy
      Heparin-induced thrombocytopenia
      Large vascular malformations

Splenic Sequestration

Splenomegaly
Portal hypertension
Liver disease
Portal or hepatic vein thrombosis
Myeloproliferative disorders
Lymphoproliferative disorders
Storage disease (e.g., Gaucher's disease)
Infection (e.g., tropical splenomegaly or malaria)

Failure of Platelet Production

Bone marrow suppression
   Drug-induced
   Aplastic anemia
   Paroxysmal nocturnal hemoglobinuria
   Infection (e.g., parvovirus B19)
   Bone marrow infiltration
      Hematologic malignancy
      Nonhematologic malignancy
Severe vitamin B_{12} or folate deficiency

abnormalities may suggest underlying bone marrow disease. In gestational thrombocytopenia and autoimmune thrombocytopenia (AITP), the blood film is normal except for the apparent reduction in platelet count. The results of coagulation screening tests and D-dimer may be abnormal in thrombocytopenia associated with consumptive coagulopathy. Renal and liver function should be routinely checked. The serum urate level may be increased in preeclampsia, HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome, or acute fatty liver of pregnancy. The lactate dehydrogenase level is usually elevated in microangiopathic hemolysis. The pattern of development of thrombocytopenia should be determined if previous platelet counts are available. Bone marrow examination is necessary only when the diagnosis is unclear after initial clinical and laboratory assessment or if features suggest underlying bone marrow disease. However, bone marrow examination may be carried out in suspected AITP if thrombocytopenia is severe or if treatment with steroids is contemplated.[8]

After initial assessment, further tests may be indicated, including antinuclear factor, specific tests for lupus anticoagulant and anticardiolipin antibodies, or tests for the diagnosis and typing of von Willebrand's disease (vWD). Platelet antibody testing by standard techniques is of little value both diagnostically and prognostically in suspected cases of AITP.[8–11] In cases of suspected thrombotic thrombocytopenic purpura (TTP), some specialized laboratories carry out von Willebrand factor (vWf) multimer analysis and assay of ADAMTS 13 (a member of the ADAMTS family), a vWf cleaving protease (discussed later), in plasma. These tests can be helpful but are not necessary in the differential diagnosis of thrombotic microangiopathy with typical clinical fea-

Variation in the Features and Management of Thrombotic Microangiopathic Hemolytic Anemia

tures. There is no one diagnostic test for TTP or any microangiopathic syndrome. If specialized tests are considered, they should be discussed with a hematologist.

Gestational Thrombocytopenia

Gestational thrombocytopenia, or incidental thrombocytopenia of pregnancy, accounts for approximately 70% of cases of maternal thrombocytopenia at delivery.[7,12] The cause is unknown. There is evidence of a degree of physiologic platelet activation in vivo during pregnancy; platelet lifespan is reduced, and the site of platelet activation is believed to be the placental circulation.[13,14] These mechanisms may contribute to gestational thrombocytopenia.

Thrombocytopenia usually develops in the third trimester and is usually mild to moderate. Results of other studies are normal. The platelet count is usually greater than 80×10^9/L, and counts of 40 to 50×10^9/L are attributed to gestational thrombocytopenia.[7,15,16] The platelet count rapidly returns to normal after delivery, usually within 7 days.[7,15] Gestational thrombocytopenia is a diagnosis of exclusion. Antenatally, it can be difficult to distinguish from mild AITP. The diagnosis is suggested by a late decrease in platelet count in a patient with no history of this disorder. Certainty often rests on observations of platelet counts in the puerperium.

Maternal and Fetal Risks

Gestational thrombocytopenia has no pathologic significance for the mother or fetus.[7,8,12,15–17] When gestational thrombocytopenia and AITP cannot be distin-

guished, if the diagnosis is AITP, a potential concern is the transfer of antiplatelet antibodies across the placenta, leading to fetal and neonatal thrombocytopenia. However, neonatal thrombocytopenia is uncommon in women in whom thrombocytopenia is incidentally detected in pregnancy and in whom there is no history of AITP. The incidence of neonatal thrombocytopenia in these patients is approximately 4%,[16,18] which is not statistically different from the incidence of thrombocytopenia in infants of non-thrombocytopenic mothers. Further, no infants in these studies had cord platelet counts less than 50×10^9/L, and none had clinical hemostatic impairment.[16,18]

Management Options

PREPREGNANCY AND PRENATAL

If a woman with previous gestational thrombocytopenia seeks prepregnancy counseling, the most important issue is the exclusion of alternative diagnoses. This is also the case when thrombocytopenia is detected incidentally in the antenatal period. The maternal platelet count should be monitored at a frequency determined by the platelet count, rate of decline, and expected date of delivery.[8] No treatment is necessary for gestational thrombocytopenia. Invasive approaches to fetal monitoring, such as fetal blood sampling to determine the fetal platelet count, are not indicated because the risks are not justifiable (discussed later).[8,17]

LABOR AND DELIVERY

Because the fetus is not at risk for hemorrhage, the mode of delivery is determined by obstetric considerations, and

SUMMARY OF MANAGEMENT OPTIONS			
Gestational Thrombocytopenia			
Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy and Prenatal			
Exclude pathologic causes	IV	C	I
Monitor platelet count	IV	C	8
Fetal blood sampling not indicated	III	B	17
Observe if >100 × 10⁹/L	III	B	18
If rapid fall or <50 × 10⁹/L, reevaluate for pathologic causes	III	B	18
Labor and Delivery			
Avoid fetal blood sampling and traumatic vaginal delivery if autoimmune thrombocytopenia purpura not excluded	IV	C	8
Epidural anesthesia is considered safe if platelet count >80 × 10⁹/L	IV	C	8
Obtain cord blood or neonatal blood at delivery to check neonatal platelet count	III	B	18
Postnatal			
Verify that maternal count returns to normal after delivery to confirm the diagnosis	III	B	18

invasive fetal blood sampling to determine the fetal platelet count is not indicated. Epidural anesthesia is considered safe if the maternal platelet count is greater than 80×10^9/L.[8]

If AITP has not been excluded, traumatic delivery, the use of fetal scalp electrodes, and fetal scalp blood sampling for acid–base status should be avoided.[8]

POSTNATAL

If it is difficult to distinguish between gestational thrombocytopenia and AITP, a cord platelet count should be obtained. If this count is low, serial counts should be obtained in the neonate (discussed later). Maternal platelet counts should also be followed postnatally. A rapid return to normal confirms the diagnosis of gestational thrombocytopenia, whereas continued thrombocytopenia after pregnancy should prompt reassessment of the patient.

Autoimmune Thrombocytopenia

AITP is relatively common in women of childbearing age. AITP occurs in approximately 0.14% of pregnant women at delivery and accounts for 3% of cases of thrombocytopenia at that time.[15] AITP is caused by autoantibodies, which are usually directed against platelet surface glycoproteins, particularly glycoprotein IIb/IIIa and glycoprotein Ib/IX.[19,20] These antibodies adhere to the platelet membrane, causing platelet destruction through Fc receptors in the reticuloendothelial system. The major site of platelet destruction is usually the spleen. AITP may cause purpura and self-limited mucosal bleeding. This pattern of acute AITP, often after a viral infection, is most commonly seen in children. On the other hand, AITP in adults is usually chronic. The symptoms are variable and are often insidious. Although fluctuations in the platelet count may occur, the condition is not self-limiting, and continuing thrombocytopenia is the usual course. Chronic AITP may be asymptomatic and may be found by routine testing, such as the testing that is performed during pregnancy.

AITP may be primary or idiopathic or may be secondary to another disorder (see Table 41–1). In primary AITP, the clinical examination may show purpura, bruising, or signs of mucosal bleeding, but findings are otherwise normal. Other than a reduced platelet count, findings on the blood film are normal, and the bone marrow is normal, with normal or increased numbers of megakaryocytes. In primary or idiopathic AITP, all other test results are normal. Secondary causes of AITP may be associated with antinuclear antibodies or increased levels of anticardiolipin antibodies. HIV testing should be carried out if the patient is in an at-risk group, if this testing was not already performed as a routine antenatal check.

Previously, in AITP, the platelet antibody tests that were used depended on the finding of platelet-associated immunoglobulin G. However, this test has a high frequency of false-positive and false-negative results.[20] More recently, glycoprotein-specific antibodies have been detected in AITP by antigen immobilization assays.[20] These assays show improved specificity but are unreliable as diagnostic tools in individual patients.[20] Further, no assay of platelet antibodies has predictive value for maternal or fetal outcome.[8–11]

Maternal Risks

The risk of maternal bleeding relates to the severity of thrombocytopenia. In AITP, clinical bleeding is often less severe for a given platelet count than in conditions in which thrombocytopenia is caused by an underlying bone marrow disorder.

Women with severe thrombocytopenia (platelet count $<20 \times 10^9$/L) are at risk for spontaneous bleeding antenatally as well as at delivery, and they generally require treatment. Women with platelet counts less than 50×10^9/L may be at risk for increased bleeding at delivery[8,21]; therefore, treatment may be required in late pregnancy to ensure a safe platelet count for delivery in asymptomatic women. A platelet count of greater than 80×10^9/L is considered safe for epidural anesthesia.[8] These figures are generally accepted by clinicians but are somewhat arbitrary. There is no evidence that bleeding time is helpful in predicting hemorrhagic problems in AITP.

Fetal Risks

In mothers with AITP, immunoglobulin G antiplatelet antibodies may cross the placenta and cause fetal thrombocytopenia, resulting in fetal or neonatal bleeding. Maternal findings, such as platelet count and platelet-associated immunoglobulin G level, are of no value in predicting fetal thrombocytopenia.[10,22,23]

In the early 1990s, large prospective studies helped to clarify that in maternal AITP, the risk to the fetus and neonate of bleeding as a result of thrombocytopenia is extremely low. In these series, the overall incidence of fetal or neonatal thrombocytopenia was 10% to 30%, but severe thrombocytopenia was less common and intracranial hemorrhage was rare.[9,12,16,23] The largest study,[12] which was conducted over 7 years and included more than 15,000 mothers and infants, showed that among 46 mothers with AITP, 4 (8.7%) had cord platelet counts of 20 to 50×10^9/L. No infant whose mother had AITP had a platelet count of less than 20×10^9/L, and none had an adverse outcome, despite vaginal delivery in three of the four cases.[12] In this study, all of the neonates with clinically severe bleeding had alloimmune thrombocytopenia (see Chapter 15). Another study showed that 18 of 88 neonates (20%) born to women with AITP before the index pregnancy had platelet counts of less than 50×10^9/L. Five had clinically important bleeding, and two of

these had intracranial hemorrhage.[16] In contrast, in this study, no infants born to women with incidentally detected thrombocytopenia in pregnancy had platelet counts of less than 50×10^9/L, and none had clinical bleeding. This study led to the suggestion that the only clear predictor of neonatal thrombocytopenia in pregnant woman with thrombocytopenia is a history of AITP, and even then, the incidence of neonatal bleeding is low. Limited data suggest that in women with AITP, the outcome of a previous pregnancy with respect to neonatal thrombocytopenia is a reasonable guide to the likely outcome of a current pregnancy, if there have been no significant changes in the course or management of AITP in the mother.[9,24] Another salient point is the time course of thrombocytopenia and bleeding complications in the fetus and neonate in a pregnancy affected by AITP. Bleeding in utero in maternal AITP is rare.[25] Other studies concluded that after birth, the platelet count continues to decrease in affected neonates, reaching a nadir 2 to 5 days after delivery.[10]

Management Options

PREPREGNANCY

In women known to have AITP before pregnancy, therapy should be optimized before pregnancy is planned. In patients with chronic AITP, decisions about splenectomy are best made before the patient becomes pregnant. In general, pregnancy does not affect the clinical course of AITP; however, there is anecdotal evidence of worsening of AITP during pregnancy, with improvement after delivery.[26] Some women of childbearing age have refractory AITP. In these women, if thrombocytopenia is severe, pregnancy may be hazardous and should be avoided. However, the potential hazards of pregnancy must be individually assessed, and patients should be counseled carefully. In addition to the risk of bleeding in the mother and fetus, the risks of third-line therapy in pregnancy (discussed later) must be reviewed. There is considerable experience in the use of azathioprine in pregnancy in clinical settings other than AITP.[27,28] When splenectomy is ineffective and ongoing treatment is needed, this may be a suitable third-line agent if pregnancy is a future consideration.

PRENATAL

In the prenatal period, the aims of management are as follows:

- To treat maternal symptoms of hemorrhage at any stage of pregnancy
- To achieve a safe platelet count for delivery

There is no evidence that any available modalities of treatment administered to the mother affect the platelet count in the fetus or neonate. The frequency of monitoring of platelet counts should be based on the initial count and the rate of decline. Closer surveillance is required in the last trimester to ensure a safe count for delivery. Treatment is generally required in symptomatic patients if the maternal platelet count is less than 20×10^9/L. Treatment is also required in late pregnancy, in the absence of symptoms, to raise the platelet count to 50×10^9/L or more for delivery.[8] Discussion about analgesia for labor should take place, preferably in the early part of the third trimester, because some women may consider regional analgesia. Alternatives should be discussed, but in some cases, it may be necessary to aim for a count of 80×10^9/L to allow regional analgesia to proceed. Balancing the risks requires particular assessment in these women, and treatment purely to allow for regional analgesia is discouraged.

Options for the treatment of AITP in pregnancy include corticosteroids and high-dose intravenous immunoglobulin (IVIG). Conventionally, steroids are used by many as the treatment of choice. When steroid therapy is chosen, prednisolone is usually given initially at a dose of 1 mg/kg daily (based on nonpregnant body weight). A response is obtained in most patients, allowing the dose to be tapered gradually to achieve the minimum dose at which a safe platelet count is achieved. Potential disadvantages of steroid therapy during pregnancy are the precipitation or exacerbation of hypertension, excessive weight gain, gestational diabetes, osteoporosis, and psychiatric disorders.[8,21] These considerations are particularly relevant when prolonged therapy is required and when high doses are required to control symptoms. From the fetal point of view, there is no evidence that corticosteroids are teratogenic, and fetal adrenal suppression is unlikely because prednisolone is extensively metabolized in the placenta.[29]

Concerns about potential adverse maternal effects of steroids have led some to use IVIG as first-line therapy in pregnancy.[15] Others reserve this treatment for patients who do not respond to steroids and patients in whom the maintenance dose of steroids is unacceptably high. IVIg is usually given in doses of 0.4 g/kg daily for 3 to 5 days.[30-38] Alternatively, 1 g/kg daily may be given for 1 or 2 days.[34] These regimens increase the platelet count in most cases, but the response to immunoglobulin is temporary in adult AITP. On average, responses are seen by the fifth day of infusion, with a peak response occurring approximately 4 to 5 days after the end of the infusion.[30] Responses tend to be sustained for only 2 to 4 weeks,[21] but the duration of response is extremely variable.[30] When IVIG is used to increase the platelet count before delivery, treatment is initiated approximately 10 days before delivery is planned. In mothers who need treatment for symptomatic AITP, courses of IVIG may be repeated at intervals to prevent symptoms and ensure a safe platelet count for delivery. One study outside the context of pregnancy showed that approximately

one-third of patients who require repeated infusions eventually stop responding to immunoglobulin.[35]

IVIG is a pooled blood product. IVIG preparations that have been virally inactivated have an excellent safety record, but there is a small risk of transmission of infection.[8,33]

Other adverse effects include allergic reactions, and occasional cases of anaphylaxis have occurred in immunoglobulin A-deficient patients. Aseptic meningitis is well documented, and there are a few reports of thrombotic complications, mainly in elderly patients.[33] Renal failure may be precipitated by IVIG preparations with a high sucrose content.[36] IVIG is well tolerated in most patients. Other side effects tend to be mild.[33]

The placenta contains Fc receptors; therefore, immunoglobulins can cross the placenta. This finding led to hopes that maternal treatment with high-dose IVIG would improve the fetal platelet count.[31,32] There are no controlled studies, but fetal and neonatal thrombocytopenia has been reported with maternal use of IVIG.[33] Evidence does not show a substantial effect of IVIG on fetal platelet counts in maternal AITP.

Patients with severe hemorrhage associated with profound thrombocytopenia require aggressive management. In an emergency situation, 1g methylprednisolone given daily for 3 days has been advocated, perhaps combined with IVIG.[8,21] Although platelet transfusion has little efficacy prophylactically in AITP, platelets should be administered in large doses to patients with life-threatening bleeding.[8]

If a pregnant woman with AITP does not respond to standard treatment with steroids and IVIG, decisions about further therapy must be considered. Factors such as gestation and hemorrhagic symptoms should be taken into account. If the woman is not hemorrhagic, an observant approach is the best option. Platelet transfusion may be required at delivery, even if the patient is asymptomatic prenatally. If the patient is hemorrhagic, several options are available, but supporting evidence is anecdotal. Splenectomy was previously considered hazardous in pregnancy, but more recent literature suggests that, with modern supportive care, successful splenectomy may be carried out in pregnancy, preferably in the second trimester.[37] Splenectomy is commonly performed laparoscopically in nonpregnant patients. In pregnancy, the laparoscopic approach may also be preferable, if technically feasible. The enlarging uterus, however, is likely to cause difficulties with laparoscopic splenectomy after 20 weeks' gestation. Conventional splenectomy in the third trimester may precipitate premature labor, but in some cases, when the fetus is mature, splenectomy is combined with cesarean delivery in late pregnancy.[37] Approximately two thirds of patients have a useful response to splenectomy. Prophylaxis against infections with organisms such as pneumococci, *Haemophilus*, and *Neisseria meningitidis* is necessary. When splenectomy is performed during pregnancy, penicillin V prophylaxis should be given in the prenatal period, and vaccination against these organisms should be performed.

Patients in whom splenectomy is unsuccessful are extremely problematic. Several third-line therapies, such as danazol, vincristine, and cyclophosphamide, are unsuitable for use during pregnancy. In very severe refractory cases, when third-line therapy is necessary, azathioprine is probably the safest treatment. Experience with renal transplant recipients suggests that teratogenicity is rare in humans, but intrauterine growth restriction may occur.[27,28]

Collaboration with an obstetric anesthetist is necessary for all women with platelet counts low enough to affect delivery. Alternatives to regional analgesia, such as patient-controlled analgesia, can be offered when epidural analgesia is considered unsafe.

LABOR AND DELIVERY

From the maternal point of view, when possible, vaginal delivery is preferred in mothers affected by AITP. If the maternal platelet count remains low at the time of delivery, despite optimal antenatal treatment, platelet transfusion may be required to treat maternal bleeding. Platelets should be available for women who have a platelet count of less than $50 \times 10^9/L$ at delivery, but platelet transfusion given for purely prophylactic reasons is usually unnecessary and ineffective.

Epidural anesthesia should be avoided if the platelet count is less than $80 \times 10^9/L$,[8] although there is little concrete supporting evidence. The entire clinical scenario as well as the course of the decrease in platelet count should be considered.[8] Thrombocytopenic women are at risk for bleeding from surgical incisions. Judicious administration of platelets during operative procedures is reasonable in women with severe thrombocytopenia. Nonsteroidal anti-inflammatory drugs should be avoided for postpartum analgesia. AITP should not exclude women from consideration for peripartum thrombosis prophylaxis. Risk assessment should be carried out and should consider constitutional and acquired thrombotic risk factors as well as the risk of bleeding. Prophylactic doses of low-molecular-weight heparin are generally safe if the platelet count is greater than $50 \times 10^9/L$.[8] Graduated compression stockings may be used for women who require specific thrombosis prophylaxis if the platelet count is less than $50 \times 10^9/L$.

As discussed earlier, large, well-conducted studies show that the risk to the fetus and neonate of bleeding as a result of thrombocytopenia is low in maternal AITP.[12,16] No maternal findings are of value in predicting fetal thrombocytopenia. There is no role for measuring fetal platelet count in late pregnancy or during labor. Fetal scalp sampling is often inaccurate and can cause significant scalp bleeding or hematoma formation in thrombocytopenic fetuses. Intrauterine fetal blood sampling cannot be justified as a routine practice in maternal AITP because the associated risks outweigh the risk of serious neonatal hemorrhage.[8,9] In contrast, determining the

fetal platelet count by intrauterine fetal blood sampling in the antenatal period has a role in the management of pregnancies potentially affected by neonatal alloimmune thrombocytopenia. In this situation, this sampling allows concomitant administration of therapeutic fetal platelet transfusion (see Chapter 15).[8,9]

In AITP, it was previously assumed that cesarean section may protect the fetus from bleeding as a result of head trauma. However, no difference was seen between vaginal delivery and cesarean section in bleeding complications in 474 infants born to mothers with AITP.[38] As the nadir of the platelet count often occurs several days after delivery,[10] peripartum events may not have a major effect on neonatal bleeding complications.[39]

The low incidence of neonatal bleeding in modern studies and the data on the mode of delivery and time course of thrombocytopenia support a conservative approach to the management of the fetus in pregnancies complicated by AITP, both antenatally and during labor and delivery. Traumatic delivery, delivery by Ventouse extraction, and the use of high-cavity rotational forceps should be avoided. Decisions about cesarean section should be made on obstetric grounds, without determining the fetal platelet count. Most authors recommend avoiding the use of fetal scalp electrodes and scalp blood sampling to determine acid–base status.[8]

POSTNATAL

Mothers with thrombocytopenia are unlikely to bleed from the uterine cavity after the third stage of labor, provided that there are no retained products of conception. However, bleeding may occur from surgical wounds, episiotomies, or perineal tears. Prompt suturing and close observation of these sites are required.

Immediately after delivery, a cord blood sample should be taken. If the infant is thrombocytopenic but not hemorrhagic, a complete blood count should be obtained daily because the platelet count often continues to decrease over the first few days of life. If the infant has signs of skin or mucosal bleeding or has severe thrombocytopenia (platelet count $<20 \times 10^9$/L, or $<50 \times 10^9$/L in a premature sick neonate), cranial ultrasound should be carried out and treatment instituted. IVIG 1 g/kg is the preferred treatment in neonates[8,9] and increases the platelet count in most infants affected by maternal AITP. Platelet transfusion is rarely necessary, but is indicated if bleeding is life-threatening (e.g., intracranial hemorrhage). Products that are known to be cytomegalovirus-negative should be used.[40] Products that are leukodepleted at the source, however (now standard in the United Kingdom), are generally free from cytomegalovirus.[40] Premature infants with very low birth weight (<1.5 kg) are at greater risk for transfusion-transmitted cytomegalovirus infection than are healthy term infants.

SUMMARY OF MANAGEMENT OPTIONS
Autoimmune Thrombocytopenia

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Optimize management and consider splenectomy or azathiprine	–	GPP	–
Discuss risks in pregnancy if the patient is not responsive to all therapy	–	GPP	–
Prenatal			
Monitor platelet count (frequency determined by initial values)	IV	C	8,9
Treat if symptoms occur or platelet count $<20 \times 10^9$/L at any stage in pregnancy	IV	C	21
Treat if $<50 \times 10^9$/L in late pregnancy even if the patient is asymptomatic:			
Treatment option 1: Prednisolone. Debate whether to use as first-line therapy vs. intravenous immunoglobulin G	IV / III	C / B	8,9 / 23
Treatment option 2: High-dose intravenous immunoglobulin G. Debate whether to use as first line vs prednisolone	IV / Ib	C / A	15,21,33 / 34

Administer platelets if bleeding is life-threatening	IV	C	8,9

Special Considerations in Secondary Autoimmune Thrombocytopenia: Risks and Management Options

Antiphospholipid Syndrome (See Chapter 44)

Primary antiphospholipid syndrome includes the reproducible presence of antiphospholipid antibodies (either lupus anticoagulant or anticardiolipin antibody) and one of the following clinical features: venous thrombosis, arterial thrombosis, recurrent fetal loss, or thrombocytopenia.[41,42]

Primary antiphospholipid syndrome is associated with thrombocytopenia in 20% to 40% of cases.[43] In these cases, thrombocytopenia is autoimmune, although antiphospholipid antibodies may not be the cause of the immune platelet destruction. Thrombocytopenia is rarely severe and usually does not require treatment. Outside the context of pregnancy, responses to the treatment of AITP are similar in patients with and without antiphospholipid antibodies.[44] In terms of thrombocytopenia, management options during pregnancy are similar to those for primary AITP. However, a diagnosis of primary antiphospholipid syndrome has other implications for pregnancy. In addition to recurrent spontaneous abortion, women with antiphospholipid syndrome are at risk for other complications, such as intrauterine fetal death, intrauterine fetal growth restriction, preeclampsia, and maternal thrombosis.[41,42,45] The mechanism of fetal loss is complex. Thrombosis in the placental vasculature is a contributory factor, but there is also evidence of inadequate trophoblastic invasion, induced by antiphospholipid antibodies.[46,47]

A combination of low-dose aspirin and low-dose subcutaneous heparin is helpful in preventing recurrent spontaneous abortions in antiphospholipid syndrome.[48]

Close maternal supervision and fetal monitoring are required antenatally. Antenatal and postnatal thrombosis prophylaxis is indicated in women with antiphospholipid syndrome and a history of thrombosis.[49,50] Moderate thrombocytopenia should not alter decisions about antiplatelet or antithrombotic therapy in antiphospholipid syndrome.[43] In unusual patients who have more marked thrombocytopenia, decisions should be made on an individual basis, taking account of the risks and potential benefits of various management options (see Chapter 44).

Systemic Lupus Erythematosus (See Chapter 44)

Immune platelet destruction may occur in systemic lupus erythematosus because of antiplatelet antibodies or immune complexes. Thrombocytopenia is not usually severe, but if treatment is required, management is governed by the principles outlined for primary AITP. Women with systemic lupus erythematosus are also at risk for preeclampsia, which may be complicated by thrombocytopenia. Other management issues are discussed in Chapter 44.

HIV-Associated Thrombocytopenia (See Chapter 29)

Thrombocytopenia may be associated with HIV infection. A survey of HIV-positive pregnant women showed that 3.2% were thrombocytopenic, and in most cases, thrombocytopenia was believed to be directly related to HIV infection.[5] Slightly fewer than half of the thrombo-

cytopenic women in this series had platelet counts of less than 50×10^9/L, and 20% had hemorrhagic complications. Of 28 infants, only 1 had thrombocytopenia.[51]

Thrombocytopenia associated with HIV is multifactorial. In advanced disease, drugs and infection may lead to marrow dysfunction that results in thrombocytopenia. However, thrombocytopenia is relatively common in otherwise asymptomatic HIV-positive individuals. Immune platelet destruction by antiplatelet antibodies or immune complexes is the likely mechanism of thrombocytopenia in these patients.[52] TTP (discussed later) may also be associated with HIV.[53]

Suppression of viral replication by antiretroviral therapy increases the platelet count in HIV-positive patients with thrombocytopenia, but some antiretroviral drugs may also cause thrombocytopenia. Zidovudine improves platelet counts in HIV-positive thrombocytopenic women and reduces vertical transmission of HIV from mother to infant.[54] Combinations of antiretroviral drugs are much more effective at suppressing HIV viral load than monotherapy, and treatment is usually unaltered in pregnancy.[55] Careful evaluation of trends in platelet counts that correspond to changes in therapy and viral load is helpful in assessing thrombocytopenia in HIV-infected patients. Blood film examination (for red cell fragmentation associated with TTP and other cytopenias that may be associated with disease, infection, or therapy) and bone marrow examination to assess whether thrombocytopenia is caused by peripheral consumption are often useful.

When immune destruction is believed to be a significant component of thrombocytopenia, IVIG may be required to treat hemorrhagic symptoms or to increase the platelet count before delivery in thrombocytopenic HIV-positive women.[51] Corticosteroids are also effective in HIV-associated immune thrombocytopenia, but prednisolone is associated with oral candidiasis and reactivation of herpes simplex.[52] Many physicians avoid the use of steroids because of the risk of further immunosuppression and infection. Cesarean delivery reduces the risk of transmission of HIV from mother to fetus, although the benefit is less clear in women with an undetectable viral load.[56]

Drug-Induced Thrombocytopenia

Drugs may cause thrombocytopenia through immune destruction or through suppression of platelet production in the bone marrow. Both are uncommon in pregnancy, but drug-induced causes should be considered and excluded.

One type of drug-induced thrombocytopenia merits further discussion. Heparin-induced thrombocytopenia (HIT) occurs in 1% to 5% of patients receiving unfractionated heparin. HIT is caused by an antibody directed against the heparin–platelet factor 4 complex, which can induce platelet activation and aggregation in vivo.[57] The incidence of HIT in patients treated with low-molecular-weight heparin is considerably lower than that in patients treated with unfractionated heparin.[58] Cross-reactivity of antibodies is common, and low-molecular-weight agents are not suitable once HIT has occurred.[59] The recognition of HIT is important because the condition may be complicated by thrombosis. Thrombosis in HIT may be venous or arterial and may be life-threatening.[57] HIT has been reported in pregnancy,[60,61] although it may be less common in pregnancy than in nonpregnant individuals.[62] Fetal thrombocytopenia does not occur because heparin does not cross the placenta. Heparin should be withdrawn immediately on clinical suspicion of HIT. Laboratory tests are available to confirm the diagnosis. Some tests aid in identification of the cross-reactivity pattern of the antibody.[63] If ongoing anticoagulation is urgently required, the heparinoid danaparoid may be used in most patients.[64] Danaparoid has been used successfully to treat HIT in pregnancy.[61] Hirudin is an alternative in nonpregnant patients, but experience is limited in pregnancy and its use is not recommended unless there is no suitable alternative.[65,66] Ancrod has been used in HIT,[65] but great caution should be used in pregnancy. Platelet transfusion should be avoided in patients with HIT.

Because HIT is potentially life-threatening, all women must have a platelet count before treatment with heparin begins. The count must be repeated 5 to 7 days after the start of therapy and then at least weekly for the first 3 weeks.

Thrombocytopenia with Microangiopathy

Several syndromes are associated with thrombocytopenia as a result of platelet activation, red cell fragmentation, and a variable degree of hemolysis (microangiopathic hemolytic anemia). Some syndromes are unique to obstetric practice. The differential diagnosis is particularly pertinent for obstetricians and is important because management options differ. The differential diagnosis is summarized in Table 41–2.

DISSEMINATED INTRAVASCULAR COAGULATION (See Chapter 79)

Risks and Management Options. Platelet consumption and consequent thrombocytopenia occur as part of the process of disseminated intravascular coagulation (DIC). DIC, particularly if chronic, may also be associated with microangiopathic features on the blood film. DIC is discussed briefly in the section on acquired coagulation disorders.

PREECLAMPSIA AND HELLP SYNDROME (See Chapters 36 and 80)

Risks and Management Options. Preeclampsia is a multisystem disorder unique to pregnancy. Its pathophysiologic basis lies in widespread damage to the vascular endothelium.[67] The platelet count decreases as a result of platelet activation.[13] A decrease in the platelet count often precedes clinical signs of disease,[68] but thrombocytopenia is rarely severe and although there may be evidence of

consumptive coagulopathy, severe DIC is unusual.[69] The extent and rate of the decrease in the platelet count indicate the severity of preeclampsia,[61] and together with other aspects of clinical and laboratory assessment, these findings may be used to guide the timing of delivery. HELLP syndrome is a variant of preeclampsia that is characterized by microangiopathic hemolysis, elevated liver enzyme levels, and a low platelet count.[70] Hypertension may be minimal. HELLP syndrome carries a particularly bad prognosis for pregnancy outcome if delivery is postponed, so recognition is important. Platelet transfusion is infrequently required in preeclampsia or HELLP[71] but may be needed if bleeding occurs or if thrombocytopenia is severe and cesarean delivery is planned.[72] In both preeclampsia and HELLP, delivery of the fetus and placenta is the only effective treatment, and delivery results in resolution of hematologic and other features of the condition. Regional analgesia is an option if the maternal platelet count is greater than 80×10^9/L and the results of coagulation screening tests are normal. If severe thrombocytopenia, hemolysis, or organ dysfunction persists after delivery, plasma exchange may be considered,[73] but the diagnosis should also be reviewed.

THROMBOTIC THROMBOCYTOPENIC PURPURA (See Chapter 80)

TTP is a rare disorder associated with platelet activation that leads to thrombocytopenia and the formation of platelet thrombi in the microcirculation. The clinical features of TTP consist of a classic pentad of thrombocytopenia, microangiopathic hemolysis, renal impairment, neurologic features, and fever.[74] Many patients do not have all of the features. Results of coagulation screening tests are normal, and D-dimer levels are normal or minimally elevated.[74] TTP may be related to infection (including HIV), drugs, underlying malignancy, or pregnancy; may occur after bone marrow transplant; or may have no clear trigger. Chronic relapsing TTP may be congenital.

Ultra-large vWf multimers that are not normally present in plasma have been found in convalescent plasma in patients with TTP who subsequently relapsed.[75] More recently, deficiency of a novel vWf cleaving metalloproteinase was recognized in patients with both congenital and acquired forms of TTP.[76,77] This metalloproteinase is a member of the ADAMTS family (ADAMTS 13)[78] and can cleave ultralarge vWf multimers. ADAMTS 13 deficiency may occur constitutionally[78] or may be caused by an inhibitory autoantibody.[77] Deficiency of ADAMTS 13 does not seem to be specific to TTP and is seen in other conditions, such as DIC, malignancy, and liver and renal impairment.[79] Further, ADAMTS 13 deficiency is not seen in some cases of secondary TTP.[80] Levels of ADAMTS 13 decrease in the third trimester.[79] The diagnostic role of ADAMTS 13 deficiency in microangiopathic syndromes is unclear. When the diagnosis is difficult, measurement of antithrombin may help to differentiate TTP from preeclampsia because the antithrombin level is reduced in preeclampsia but not in TTP.[81]

TTP associated with pregnancy tends to occur in the antenatal period, with more than half of cases occurring before 24 weeks' gestation.[82] In contrast, preeclampsia usually occurs later in pregnancy, and hemolytic uremic syndrome mainly occurs postnatally.[81]

Maternal and Fetal Risks. Untreated TTP is almost uniformly fatal for the mother and fetus. However, treatment with plasma exchange with fresh frozen plasma (FFP) markedly improves the outlook.[83] When treated with plasma exchange, the outlook for patients with TTP in pregnancy is similar to that in nonpregnant individuals.[84] Fetal risks include intrauterine growth restriction and intrauterine fetal death, but normal fetal growth may be sustained if the condition is quickly recognized and treated and there is a good response to plasma exchange. Relapse of TTP may occur in subsequent pregnancies.

Management Options. A randomized controlled study in more than 100 patients with TTP of differing etiologies showed that plasma exchange with FFP produced a better clinical response than infusion of FFP.[83] This improvement in response was still evident after 6 months. Plasma exchange with FFP should be instituted as soon as possible after the diagnosis of TTP (within 24 hours). Daily plasma exchange should continue until at least 48 hours after complete remission is obtained. Exchange is often tapered (e.g., to alternate-day treatments). In pregnancy, repeated plasma exchange cycles are usually maintained until delivery. Cryosupernatant may be superior to FFP as an exchange replacement fluid,[85] but in practice, the use of cryosupernatant is usually reserved for patients with a poor response to exchange with FFP. Steroids are often given concomitantly with plasma exchange in TTP, but there is no firm evidence of their benefit. However, recent guidelines in the United Kingdom recommended the use of adjuvant steroids in idiopathic TTP.[81] Similarly, antiplatelet therapy with aspirin is controversial. The use of low-dose aspirin has been advocated when the platelet count increases to more than 50×10^9/L.[81] Platelet transfusion is contraindicated and may lead to rapid worsening of the condition.[86] Red cell transfusion should be given as required, and folic acid is administered as requirements are increased in hemolytic states. Unlike in preeclampsia, delivery does not necessarily cause rapid resolution, but delivery should be considered in pregnant women with TTP when the response to standard therapy is poor.[81]

HEMOLYTIC UREMIC SYNDROME (See Chapter 80)

Hemolytic uremic syndrome is characterized by microangiopathic hemolytic anemia, renal impairment, and a variable degree of thrombocytopenia. Hemolytic uremic syndrome usually occurs after infection, particularly with verotoxin-producing *Escherichia coli* in children. Pregnancy-associated hemolytic uremic syndrome usually occurs postpartum with acute renal failure.[81,82] Subsequent chronic renal failure is common. Management is supportive and includes renal dialysis and red cell transfusion. Plasma exchange has no proven benefit.

Secondary Autoimmune Thrombocytopenia

COAGULATION DISORDERS

Congenital Coagulation Disorders

Von Willebrand's Disease

The primary function of vWf, which is a large, multimeric protein, is to promote platelet adhesion to the subendothelium. It also binds to and stabilizes plasma factor VIII. A common bleeding disorder that arises as a result of inherited vWf deficiency, vWD is divided into several types and subtypes.[87] Identification of the type of vWD has implications for management. Broadly speaking, patients may have a quantitative (type 1) or qualita-

tive (type 2) defect in vWf. Some patients have little or no vWf in terms of measurable antigen and function, and these patients have associated marked reductions in factor VIII activity (type 3 vWD). Most types of vWD are inherited in an autosomal dominant fashion, but the pattern of inheritance in type 3 disease is autosomal recessive.

Patients with type 1 or 2 vWD usually have a mild to moderate bleeding disorder characterized by skin and mucosal bleeding and bleeding after surgery or trauma. Patients with type 3 disease have severe bleeding diathesis, with deep joint and intramuscular bleeding resembling the pattern seen in hemophilia, in addition to skin and mucosal bleeding.

Laboratory tests in patients with vWD show a long bleeding time and may show a prolonged activated partial thromboplastin time (APTT). More definitive diagnostic tests depend on the finding of reduced plasma vWf activity measured by ristocetin cofactor activity (vWf:RCo) or collagen binding assay (vWf:CB), accompanied by variable reductions (depending on the type) in vWf antigen and factor VIII (FVIII:C).[88] Several further tests that aid in classification include analysis of ristocetin-induced platelet aggregation, vWf multimer analysis, and assay of factor VIII binding to vWf.[88] Stress, inflammation, physical exercise, recent surgery, and pregnancy increase plasma vWf and factor VIII levels, and diagnosis may be difficult in these circumstances. A subtype of type 2 vWD, type 2B vWD, is associated with thrombocytopenia.

MATERNAL RISKS

Levels of vWf and factor VIII tend to increase during pregnancy. This increase results in improvement in the bleeding tendency in most patients with type 1 vWD.[89] In type 2 vWD, vWf antigen and factor VIII levels may increase, but this increase is not accompanied by clinical improvement.[90,91] The platelet count may decrease further in patients with type 2B vWD during pregnancy, causing diagnostic problems.[92,93] In type 3 vWD, no improvement occurs in either laboratory parameters or clinical severity.[94]

The risk of bleeding in patients with vWD is usually greatest postpartum.[91,94,95] Levels of factor VIII and vWf may decrease rapidly after delivery.[96] One series showed an 18.5% incidence of primary postpartum hemorrhage (PPH) and a 20% incidence of secondary PPH in vWD.[97] In type 1 vWD, factor VIII levels are a good predictor of the risk of bleeding at delivery (minimal if the factor VIII level is >0.5 IU/mL).[98] Invasive procedures during the first trimester (e.g., chorionic villus sampling) may also carry a risk of bleeding in all types of vWD because vWf and factor VIII levels do not start to increase until late in the first trimester.[99]

FETAL RISKS

There is very little literature on fetal risk in vWD. Two case series suggest a possible increased rate of spontaneous miscarriage, but others disagree.[95,97,100,101] A recent survey of risk factors for antenatal fetal intracranial hemorrhage listed maternal vWD as a predisposing factor.[102] General experience, however, is that fetal or neonatal hemorrhage is rarely encountered in infants with vWD. This observation is supported by a retrospective case series that showed no neonatal hemorrhagic complications after pregnancies affected by vWD.[97] In infants with type 3 vWD, the risk of bleeding during traumatic delivery is similar to that in those with severe hemophilia A. However, identification of these infants before birth is difficult because there is usually no history and mothers are asymptomatic carriers.

MANAGEMENT OPTIONS

Prepregnancy. One important aspect of pregnancy management in patients with vWD is its recognition. Patients with vWD may have menorrhagia. Recognition and treatment of vWD may allow a more conservative approach.[100,103]

In women diagnosed with vWD, counseling should be given about its inheritance, which is autosomal dominant in most cases. Vaccination against hepatitis A and B should be carried out before pregnancy. The type of vWD should be characterized to plan optimal management of pregnancy and delivery.[99] In patients with type 1 vWD, it is often useful to carry out a trial of therapy with intravenous desmopressin (DDAVP) to determine the patient's response.[99] This agent may help to prevent or control mild to moderate PPH. A synthetic analogue of vasopressin, DDAVP increases factor VIII and vWf levels in plasma.[104] Its major advantage is the avoidance of exposure to pooled blood products. If menorrhagia has been problematic, iron deficiency anemia should be corrected before pregnancy. For women with vWD who stopped using a combined oral contraceptive to become pregnant, alternative therapies to control menorrhagia may be required (e.g., tranexamic acid[99] if pregnancy can be excluded at the time of use).

Prenatal. Close liaison between the obstetrician and hematologist is necessary. Factor VIII, vWf antigen, and vWf:RCo levels should be monitored[99] and management plans determined individually, depending on the patient's hemostatic response to pregnancy. As discussed earlier, in patients with type 1 vWD, hemostatic values are more likely to normalize as pregnancy progresses. If hemostasis has not resolved, treatment may be required to cover invasive procedures (particularly in the first trimester) or episodes of antenatal bleeding. Outside of pregnancy, options for the treatment or prevention of bleeding in vWD include DDAVP (in responsive patients, mainly those with vWD type 1) and factor VIII concentrates that contain sufficient quantities of vWf.[99] The use of DDAVP is controversial in pregnancy. Some consider it to be contraindicated because of concerns that it may cause premature labor and concerns about water retention that may lead to hyponatremia. Others reported the use of DDAVP in pregnancy, particularly early pregnancy, without adverse effect,[104] and a case series reported the use of DDAVP to treat diabetes insipidus in pregnant women, without adverse pregnancy outcome.[105] No data have been reported on the incidence of neonatal hyponatremia, which is a theoretical concern.

DDAVP is contraindicated in type 2B vWD because it may worsen thrombocytopenia.[104] Patients with type 2A vWD have a variable response to DDAVP, and patients with type 3 vWD are unresponsive. When DDAVP is considered unsuitable, patients are treated with a factor VIII concentrate that contains sufficient vWf. Recombinant factor VIII concentrates do not contain vWf; therefore, suitable products are plasma-derived factor VIII concentrates that have undergone viral inactiva-

tion.[104] A high-purity, plasma-derived vWf concentrate is also available, but it must be administered initially with factor VIII.[106]

Labor and Delivery. For patients whose von Willebrand profile has normalized in pregnancy, no specific hemostatic support is required. Regional analgesia may proceed in these patients after discussion with an obstetric anesthetist. Although neonatal bleeding is rare, Ventouse delivery and high-cavity forceps should be avoided. The third stage of labor should be managed to ensure adequate uterine contraction. Careful and prompt repair of episiotomy wounds or perineal tears is advisable.

For patients whose vWf activity (vWf:RCo) has not normalized, decisions about regional analgesia should be individualized.[107] After treatment, laboratory values do not always reflect clinical hemostasis in vWD, and caution should be used in proceeding with epidural or spinal anesthesia. Patient-controlled analgesia with the short-acting opioid remifentanil can be useful when regional analgesia is contraindicated. Hemostatic supportive therapy should be given to cover delivery or cesarean section if the factor VIII level is less than 0.5 IU/mL or if vWf:RCo has not normalized.[99,104] Considerations about the choice of therapy before the umbilical cord is clamped are similar to those described earlier. After the cord is clamped, DDAVP is less controversial and is the treatment of choice for most responsive patients for prophylaxis or treatment of mild to moderate postpartum bleeding.[108] Because of the high incidence of secondary PPH in patients with vWD, effort should be made to ensure that the placenta is complete. A low threshold for antibiotics should be adopted if the uterine cavity is opened or explored.

Postnatal. All patients should be observed closely for PPH. Uncorrected hemostatic defects should be treated after delivery. In suitable responsive patients, DDAVP is the treatment of choice to prevent and treat mild to moderate postpartum bleeding. Factor VIII and vWf:RCo levels should be checked a few days after delivery because they may fall rapidly after delivery.[96] FVIII:C and vWf:RCo levels should be maintained in the normal range for at least 3 to 7 days after cesarean section.[94,104,108] It is difficult and unnecessary to diagnose vWD in the neonate, except when type 3 vWD is suspected. Generally, diagnosis can be postponed until later in childhood.

Carriers of Hemophilia A and B

Hemophilia A (deficiency of factor VIII) is the most common severe heritable bleeding disorder, with a prevalence of approximately 1 in 10,000 in the population. Hemophilia B (deficiency of factor IX) is approximately five times less prevalent. The conditions are inherited in an X-linked fashion and are clinically identical. Affected males have a bleeding disorder that correlates in severity with the reduction in the level of factor VIII or IX.

Severely affected males have spontaneous bleeding into muscles and joints; mildly affected patients may bleed only after surgery or trauma. Females in families with a history of hemophilia may be obligate, potential, or sporadic carriers, depending on the details of the pedigree.[109] An obligate carrier is a woman whose father has hemophilia, a woman who has a family history of hemophilia and who has given birth to a hemophiliac son, or a woman who has more than one child with hemophilia. A potential carrier of hemophilia is a woman who has a maternal relative with the disorder. A woman with one affected child and no family history may be a sporadic carrier.[109] Carriers of hemophilia usually have factor VIII or IX levels that are approximately 50% of normal, because of lyonization. Abnormal bleeding does not occur at this level of factor VIII activity. Some carriers have lower factor VIII or IX levels, and these individuals have a bleeding disorder that varies according to the coagulation factor level.[110]

MATERNAL RISKS

As discussed earlier, factor VIII levels tend to increase during pregnancy.[111] This increase usually, but not invariably, occurs in carriers of hemophilia A. The risk of bleeding in carriers of hemophilia A is greatest in the postpartum period because factor VIII levels may decrease rapidly after delivery.[91,94,112] Invasive procedures during the first trimester, such as chorionic villus sampling, also carry a risk of bleeding. No substantial increase in factor VIII occurs at this early stage in pregnancy.[94]

There is usually no substantial increase in factor IX levels during pregnancy.[94,112,113] Consequently, compared with carriers of hemophilia A, carriers of hemophilia B who have low factor IX levels are more likely to require treatment to prevent bleeding complications during delivery.

Treatment with a coagulation factor concentrate often is not required in pregnancy.[113] However, the possible need for this treatment should be pointed out when counseling women who are carriers of hemophilia. The risks of pregnancy and the safety and potential risks of available treatments should be discussed. This is best carried out by medical and nursing staff with expertise in the management of bleeding disorders.

FETAL RISKS

If the mother is a definite carrier of hemophilia A or B, a male fetus has a 50% chance of being affected. Spontaneous fetal and neonatal bleeding is unusual, even in severe hemophilia, but there are well-documented cases after traumatic delivery.[112,114] The most serious risk is that of intracranial hemorrhage.

Cephalhematoma may also lead to serious bleeding. The incidence of such complications is poorly defined. One retrospective series reported a combined incidence of 3.58% for intracranial hemorrhage and cephalhematoma in newborns with hemophilia A and B.[115,116] Other reported

areas of bleeding in hemophilic neonates are at puncture sites, the umbilical stump, and during circumcision.[116]

If the parents seek a prenatal diagnosis of hemophilia, counseling should cover the fetal risks associated with chorionic villus sampling. This procedure carries a 1% to 2% risk of miscarriage.[117]

MANAGEMENT OPTIONS

Prepregnancy. All women who are potential or obligate carriers of hemophilia require prepregnancy counseling, including genetic counseling. Arrangements for genetic counseling vary from one area to another, but there is general agreement that a genetic counselor and a physician who is responsible for the management of patients with hemophilia should be involved.[118] It should be established that there is truly a history of hemophilia in the family (not, for example, another bleeding disorder). The pedigree should be established and the possibility of hemophilia carriership determined. Counseling of obligate and potential carriers should include a discussion of the nature and management of hemophilia.[118] Carrier identification studies with molecular genetic techniques should be offered to all potential carriers of hemophilia A and B. Informed consent should be obtained before blood samples are collected for molecular analysis.[118] Advances in molecular genetics have made accurate diagnosis of carriership possible in most cases.[118,119] Hemophilia A and B are genetically heterogeneous. The starting point is identification of the mutation responsible for hemophilia in an affected male member of the family (direct mutation detection).[120] Potential carriers may be screened for this mutation. Approximately 20% of cases of severe hemophilia A are caused by an inversion in intron 22 of the factor VIII gene.[120,121] If an affected male is not available and there is a family history of severe hemophilia A, a potential carrier should be screened for this common molecular defect. Direct mutation detection is otherwise extremely difficult if there is no available affected male. Linkage analysis is now less commonly used, but may still be useful if the mutation responsible for hemophilia cannot be identified.[120] Blood from an affected male family member is required, and more extensive family testing is needed for successful linkage analysis. Linkage analysis will be unsuccessful if the potential carrier is homozygous (uninformative) for common intragenic polymorphisms.[120] The availability of a molecular marker in the family is necessary if prenatal diagnosis is required later.

Coagulation studies should also be carried out to identify carriers with low factor VIII or IX levels. Phenotypic data may be helpful in assessing the statistical risk of carriership if molecular diagnosis is not possible. However, normal levels of factor VIII or IX do not exclude carriership.[119] Women with low levels of factor VIII or IX should be offered vaccination against hepatitis A and B. The immunity status should be checked if the patient has

been vaccinated. Women who have low levels of factor VIII may have a useful hemostatic response to DDAVP.[122] To establish whether this response is occurring, a trial of intravenous DDAVP can be attempted, with measurement of the response in factor VIII levels over the next 24 hours. DDAVP is not useful for women with low factor IX levels.

Once carriership has been established, careful planning of pregnancies should be encouraged. Partners of hemophilia carriers should be encouraged to attend prepregnancy counseling sessions.[109,113] Couples should be informed that hemophilia "breeds true" in families. In other words, its severity is predictable by the family history.[113] Couples should be counseled in a nondirective manner about all reproductive options, including the availability of prenatal diagnosis. They should be encouraged to consider the matter in advance of pregnancy,[109,118] although circumstances may change and final decisions must be made given the circumstances in each pregnancy. Prepregnancy counseling may need to be repeated in subsequent pregnancies. Discussion of the techniques and risks associated with prenatal diagnosis is appropriate during preconception counseling sessions.[109] Carriers should be encouraged to seek care early in pregnancy, especially if prenatal diagnosis is being considered or has not been excluded.

A new technique for preimplantation diagnosis is potentially useful for carriers of hemophilia who, after counseling, do not wish to contemplate bringing up a hemophilic child, but would not consider termination. Preimplantation diagnosis is possible only in in vitro fertilization and is available only in a few specialized centers. In the United Kingdom, each new test requires a license from the Human Fertilisation and Embryology Authority.

Prenatal. Identification and counseling of carriers should be carried out before pregnancy, but may be necessary in early pregnancy if a woman with a family history of hemophilia does not seek care until pregnancy is diagnosed. General practitioners, midwives, and obstetricians should refer these patients for specialized counseling as early as possible.[118]

Pregnancies in patients who are carriers of congenital bleeding disorders should be managed in a hospital with hemophilia expertise.[94,112] Close liaison between the obstetrician and the hemophilia team is necessary. Factor VIII or IX levels should be monitored regularly throughout pregnancy. It is particularly important to measure coagulation factor levels toward the end of the third trimester (34–36 weeks) to plan management of delivery.[112,113]

If prenatal diagnosis is requested and a suitable marker exists, testing is usually carried out by chorionic villus sampling at 11 to 14 weeks. Alternatives are amniocentesis from 14 weeks onward and fetal blood sampling by cordocentesis for phenotypic diagnosis of severe deficiencies. Risks associated with these procedures should be

fully discussed with the patient. Chorionic villus sampling and amniocentesis carry a 1% to 2% risk of miscarriage. Fetal bleeding sufficient to result in death is a recognized risk of cordocentesis. This option is rarely used in the developed world because the risks are great, the causative mutation can be identified in most families, and the procedure may produce invalid or indeterminate results.

The use of prenatal diagnosis is decreasing in developed countries. As hemophilia care improves, more couples are willing to contemplate bringing up a child with hemophilia.[113]

If prenatal diagnosis is requested, treatment with a coagulation factor concentrate may be necessary to increase maternal factor VIII or IX levels if they are less than 0.5 IU/mL. Laboratory measurement of coagulation factor levels should be used to monitor treatment. The use of DDAVP is controversial in the prenatal period, although it has been used both prenatally and postpartum for women with reduced factor VIII levels.[104,105,112,113] If coagulation factor concentrates are used, a recombinant factor VIII or IX concentrate should be chosen[123] for a pregnant carrier of hemophilia who needs hemostatic support in the antenatal period. Many patients are previously untreated, and even a minimal risk of transmission of infection from plasma-derived products is unacceptable. Further, parvovirus B19, which can cause fetal hydrops, may be transmitted by plasma-derived concentrate, and no method of viral inactivation seems to be effective in eradicating this virus.[124] In countries where recombinant coagulation factor concentrates are not available, a plasma-derived concentrate that has undergone viricidal treatment, preferably by dual methods, should be used if hemostatic support is required.

When prenatal diagnosis has not been carried out, but there is a risk that the child may have hemophilia, fetal sex should be diagnosed by ultrasonography.[94,112,113] This information is necessary for the obstetrician and hematologist, even if the parents do not wish to know the sex of the infant.

Labor and Delivery. If maternal factor VIII or IX levels remain low at 34 to 36 weeks in hemophilia carriers, treatment to correct maternal hemostasis is necessary for delivery.[94,112,113] A factor VIII or IX plasma level of 0.4 IU/mL is safe for vaginal delivery, and a level of 0.5 IU/mL or greater is safe for cesarean section. Considerations similar to those discussed earlier govern the choice of treatment. Recombinant factor VIII or IX or DDAVP (for carriers of hemophilia A only) should be used. Full laboratory monitoring of hemostatic replacement therapy is necessary. Epidural anesthesia may be used if coagulation defects have been corrected.[112]

If the fetus is a known hemophiliac, is male and of unknown hemophilia status, or is of unknown sex, care should be taken to avoid traumatic vaginal delivery.[112–114,116] When possible, obstetric problems should be identified before the expected date of delivery, and the mode of delivery should be planned. Routine cesarean delivery is unnecessary,[113,114,116] but cesarean delivery should be carried out if obstetric complications are anticipated. Ventouse delivery is absolutely contraindicated because major cephalhematoma and intracranial bleeding have been documented after this procedure.[113,114,116] Midcavity rotational forceps delivery should be avoided, but simple lift-out forceps delivery may be preferable to a difficult cesarean section if the fetal head is impacted.[113] Maternal perineal trauma should be minimized, with suturing performed promptly after delivery. Fetal scalp sampling and scalp electrodes should not be used if the fetus may have hemophilia.[112,113]

Postnatal. Most bleeding problems in carriers of hemophilia occur postpartum. As discussed earlier, replacement therapy should be given immediately after delivery to mothers with an uncorrected hemostatic defect. Coagulation factor levels should be rechecked urgently if postpartum bleeding occurs. Options at this stage include DDAVP for mothers who are carriers of hemophilia A and recombinant coagulation factor concentrates for carriers of hemophilia A or B. Supportive therapy to maintain hemostasis should be continued for 3 to 4 days after vaginal delivery and for 5 to 10 days after cesarean section.[94] All hemostatic parameters must be normal before epidural catheters are removed. All mothers who are carriers, regardless of whether they need peripartum hemostatic support, should be observed for signs of PPH. Coagulation factor levels should be checked a few days after delivery because they may decrease quickly.[113]

In the infant, intramuscular injections (including vitamin K) should be avoided until hemophilia has been excluded.[113] Vitamin K may be given orally.[116] Cord blood should be obtained for appropriate factor assays.[113,116] Except for very mild cases, hemophilia A can be diagnosed easily in the neonatal period. Difficulties may arise with mild or moderate hemophilia B because of the physiologic reduction in factor IX levels that occurs in the newborn.[116,125] However, severe hemophilia B is usually easily identified. There has been debate about the routine administration of coagulation factor concentrates to neonates with hemophilia.[126] The majority view is that this is unnecessary if delivery has been atraumatic and there are no clinical signs of hemorrhage.[126] If a diagnosis of hemophilia has been made and if there has been an instrumental or traumatic delivery, prophylactic recombinant factor VIII or IX should be considered.[126] Prompt coagulation factor support is needed if there is clinical evidence of intracranial hemorrhage or significant bleeding from other sites.[116] Routine cranial ultrasound should be considered in all infants with severe hemophilia to detect intracranial hemorrhage as early as possible.[116]

The hemophilia team should be involved from the outset in counseling parents of infants with newly diagnosed congenital bleeding disorders. A clear follow-up plan should be discussed with the parents at discharge.[116]

Other Congenital Bleeding Disorders

Occasionally women have rare deficiencies of coagulation factors or congenital platelet function disorders. Detailed description is beyond the scope of this chapter. As with all bleeding disorders, close liaison between the obstetrician and hematologist is required. The principles of management revolve around assessment of the risk of bleeding for the mother and infant. The risks of hemostatic supportive therapy must be taken into account.

Many (but not all) disorders are inherited in a recessive manner; therefore, the risk of fetal or neonatal bleeding is often negligible unless there is a consanguineous partnership. For rarer congenital coagulation factor deficiencies, clinical bleeding does not always correlate with coagulation factor levels. Women with coagulation factor deficiencies or abnormalities may have recurrent fetal loss.[127,128] Placental abruption is reported in congenital afibrinogenemia. Appropriate replacement therapy can help to maintain pregnancy.[127,128]

SUMMARY OF MANAGEMENT OPTIONS
Congenital Coagulation Disorders

Management Options	Quality of Evidence	Strength of Recommendation	References
Von Willebrand's Disease			
Prepregnancy			
Establish type of von Willebrand's disease	IV	C	87
Genetic counseling (usually dominant)	III	B	97,99
Hepatitis A and B immunization	III	B	97,99
For type I von Willebrand's disease, perform a DDAVP trial to establish efficacy (contraindicated in type 2B von Willebrand's disease)	III	B	105
Prenatal			
Combined or interdisciplinary team approach (obstetric and hemophilia team)	III	B	97,99
Monitor vWf:Ag, vWf:RCO, FVIII:C, platelet count (in many cases, parameters improve)	III	B	97,99
Treatment is unlikely to be required unless invasive procedures are performed or an episode of antenatal bleeding	III	B	97,99
Labor and Delivery			
Maternal hemostatic support is needed if FVIII:C <0.5 Iu/mL or if vWf:RCO significantly reduced	III	B	97,99
DDAVP is used in responsive patient (except in type 2B von Willebrand's disease), or a plasma-derived concentrate containing vWf may be used	III	B	94,105,106
Aim for atraumatic delivery (vaginal delivery if uncomplicated delivery is anticipated, but avoid fetal scalp electrode's and fetal scalp sampling)	III	B	97,99,103
Active management of the third stage	–	GPP	–
Prompt repair of perineal trauma	–	GPP	–
Postnatal			
Vigilance for postpartum hemorrhage	–	GPP	–
Cord samples are not indicated unless type 3 von Willebrand's disease is suspected in the newborn	III	B	97,99,103
Avoid neonatal intramuscular injections until status is known	III	B	97,99
Recheck maternal FVIII:C, vWf:Ag, and vWf:RCO for a few days after delivery. If parameters fall or if the patient is bleeding, give hemostatic supportive therapy. Maintain support for an operative delivery	III	B	94

SUMMARY OF MANAGEMENT OPTIONS
Congenital Coagulation Disorders *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Carriers of Hemophilia A or B			
Prepregnancy			
Genetic evaluation and counseling	III	B	109
Establish mutation, if possible; if not, define whether linkage analysis is of use	III	B	120
If maternal factor VIII or IX is reduced, obtain baseline virology (including hepatitis B and C, HIV, and immunity vs. hepatitis A and parvovirus)	III	B	97,99
Hepatitis A and B immunization if the patient is not immune	III	B	97,99
For carriers of hemophilia A with low factor VIII levels, perform a trial of DDAVP to establish efficacy	III	B	105
Prenatal			
Combined or interdisciplinary team approach (obstetric and hemophilia team)	III	B	97,99
Offer prenatal diagnosis (chorionic villus sampling) at 11 to 14 weeks (cover with factor concentrate if level of factor VIII or IX <0.5 iu/mL); use recombinant products, if available, or DDAVP	III	B	104,105,112, 113,123
Obtain maternal serial clotting factor levels, especially in the third trimester	III	B	112,113
Perform fetal sexing by ultrasonography at 16 to 20 weeks if invasive prenatal diagnosis is not requested	III	B	94,112,113
Labor and Delivery			
Consider further concentrate cover for labor and delivery if factor VIII or IX level is <0.5 iu/mL	III	B	94,112,113
For hemophilia A carriers, consider DDAVP alone if the patient is known to be responsive, if normal vaginal delivery is anticipated, and if the coagulation defect is mild	III	B	94,112,113
If high risk fetus, aim for atraumatic unassisted (no ventouse or forceps) delivery (vaginal delivery if uncomplicated delivery is anticipated, but avoid fetal scalp electrodes and fetal scalp sampling)	III	B	112–114,116
Postnatal			
Obtain cord blood for neonatal evaluation if risk of hemophilia A or B	III	B	116
Avoid neonatal intramuscular injections until status is known	III	B	116
Give vitamin K orally if status of neonate is unknown	III	B	116
Obtain cranial ultrasound if neonate has severe hemophilia	III	B	116
A clear follow-up plan is needed for the parents and child	III	B	116
Vigilance for postpartum hemorrhage	–	GPP	–
Provide maternal hemostatic support for 3 to 4 days if vaginal delivery and for 5 to 10 days if cesarean delivery	III	B	94

Acquired Coagulation Disorders

Disseminated Intravascular Coagulation (DIC) (See Chapter 79)

DIC occurs in a wide variety of obstetric complications. It is triggered by vascular endothelial damage, release of procoagulant substances as a result of tissue damage or liquor entering the circulation, or cytokine-mediated up-regulation of tissue factor expression on monocytes and endothelial cells.[129,130] These triggers lead to the generation of thrombin, cause defects in inhibitors of coagulation, and suppress fibrinolysis. These hemostatic changes result in deposition of fibrin in the microcirculation and consumption of coagulation factors and platelets, leading

to a bleeding tendency. In obstetrics, DIC often develops acutely, for example, in placental abruption that results in rapid defibrination with hemostatic failure. Very long clotting times and marked thrombocytopenia usually occur. At the other end of the spectrum, chronic DIC may cause minimal or no abnormality on standard coagulation screening tests. No single test is diagnostic of DIC; the diagnosis depends on a combination of clinical findings and laboratory test results.[130] Thrombocytopenia and a decreasing platelet count are sensitive indicators. In most cases of DIC, whether acute or chronic, the plasma D-dimer level is elevated. In interpreting the results of coagulation screening tests in suspected DIC in pregnant women, it is prudent to note that normal baseline values are altered by physiologic changes. The plasma fibrinogen level is elevated and factor VIII levels increase in pregnancy, leading to an acceleration of APTT.[111,131] Normal fibrinogen levels and APTT in late pregnancy should be regarded suspiciously.

MATERNAL RISKS

Maternal risks arise as a result of the underlying disorder, but there are also risks of bleeding and small vessel occlusion as a direct result of DIC.

FETAL RISKS

Fetal risks in DIC are associated with the underlying cause.

MANAGEMENT OPTIONS

Management of DIC includes treatment of the underlying cause and appropriate resuscitative measures to maintain tissue perfusion. Hemostatic replacement therapy is indicated if there is significant hemorrhage or if invasive procedures are required. When clinically indicated, replacement therapy with FFP, platelet transfusions, and in some cases, a source of fibrinogen, such as cryoprecipitate, is based on the results of laboratory tests and clinical findings.[132] Prothrombin time and APTT provide a guide for FFP usage, and fibrinogen level can be used to guide the use of both FFP and cryoprecipitate. The goal is to increase the fibrinogen level to 1 g/L. Platelet transfusion is required if the platelet count is less than 20×10^9/L or if bleeding occurs in a patient with a platelet count of less than 50×10^9/L. However, the goal is not simply to correct laboratory defects. Important concerns include addressing the clinical features and treating the underlying cause.[129]

The use of heparin is controversial, but it should be reserved for cases in which microvascular occlusion rather than hemorrhage is the predominant clinical problem. The cautious use of heparin may also have a place alongside replacement therapy in the management of amniotic fluid embolism. The rationale is that the underlying cause cannot be removed, and because of the rate of consumption, it is difficult to keep pace with replacement therapy unless thrombin generation is inhibited concomitantly.[129,130]

Concentrates of anticoagulant proteins, such as antithrombin, protein C, and activated protein C, have been used mainly in DIC that is caused by severe sepsis. Promising results in improvement in hemostatic parameters have been obtained, particularly with the use of activated protein C in patients with severe sepsis.[133] Recombinant activated protein C reduced mortality rates in a large clinical trial of patients with severe sepsis.[134] There are only preliminary data on DIC associated with complications of pregnancy.[135] Antithrombin concentrates are used in amniotic fluid embolism and may have a role.[136]

Massive Blood Loss (See Chapters 59 and 79)

Causes of massive obstetric hemorrhage are discussed elsewhere (see Chapters 59 and 79). Massive bleeding in obstetric practice (e.g., as a result of placental abruption) is often accompanied by DIC. Bleeding as a result of placenta previa is not necessarily associated with DIC, but may be massive. Resuscitative measures and red cell transfusion are the first considerations. However, dilutional effects on coagulation and platelets occur, and bank blood does not provide platelets and labile clotting factors, such as factors V and VIII.

MANAGEMENT OPTIONS

The underlying cause should be treated. Resuscitative measures and red cell transfusion are paramount concerns. Blood should be warmed when rapid transfusion is required.

Coagulation defects should be corrected with FFP, and thrombocytopenia is treated with platelet transfusion. Treatment should be guided by the findings on complete blood count, coagulation screening tests, and fibrinogen measurements. Reasonable aims are to keep the platelet count above 50×10^9/L and to keep the fibrinogen level above 0.8 g/L.[94,132] In some cases, cryoprecipitate may be required as a source of fibrinogen.

In intractable major hemorrhage, recombinant factor VIIa may be used to stem bleeding when all other measures have failed. This treatment, which was originally developed for the management of bleeding in hemophiliac patients with inhibitors, has been used successfully in a variety of clinical situations associated with major bleeding and is becoming viewed as a "universal" hemostatic agent.[137] DIC is not a contraindication to the use of recombinant factor VIIa if massive bleeding is occurring. However, caution should be used in patients with major DIC because there are occasional reports of thrombosis and DIC after the use of recombinant factor VIIa.[138] There are several reports of the successful use of recombinant factor VIIa to control massive hemorrhage in obstetric patients.[139,140]

Liver Disease (See Chapter 48)

MATERNAL RISKS AND MANAGEMENT OPTIONS

Patients with liver disease, especially if it is advanced, often have significant hemostatic impairment. Several mechanisms contribute to this impairment, including thrombocy-

topenia as a result of splenic enlargement or alcohol use, impaired production of coagulation factors in the liver, impaired polymerization of fibrin, platelet dysfunction, and hyperfibrinolysis.[141] In pregnant women with liver disease, a complete blood count should be obtained and coagulation parameters monitored. Coagulation screening tests and measurement of fibrinogen levels are indicated. In some cases, screening for DIC or coagulation factor assays is helpful. The risk of bleeding is greatest during and after surgery or invasive procedures. Hemostatic supportive therapy may be required in these situations or if bleeding occurs during labor or delivery. Standard therapy is with FFP and platelets. Efficacy may be limited in patients with liver disease, and large volumes of FFP may be required.

Acquired Inhibitors of Coagulation (Acquired Factor VIII Inhibitor)

MATERNAL RISKS

Rarely, pregnancy is associated with the development of an antibody that inhibits factor VIII activity. Most reported cases occur postpartum.[142,143] This antibody may lead to postpartum hemorrhage or postsurgical bleeding. The timing of the development of these inhibitors is highly variable. One series reported identification of acquired hemophilia between 3 and 150 days postpartum.[142] Postpartum factor VIII inhibitors may disappear spontaneously, but the usual pattern is persistent for months or even years.[142,143] The more common pattern seems to be that inhibitors do not recur in subsequent pregnancies.[142] In the laboratory, a factor VIII inhibitor is associated with prolonged APTT, with nor-

mal prothrombin time and fibrinogen levels. The addition of normal plasma in vitro does not correct APTT. Factor VIII inhibitors must be differentiated from a lupus inhibitor by specific tests because the clinical implications are profoundly different.

FETAL RISKS

Most inhibitors occur postpartum, so there are generally no fetal risks. However, inhibitors that arise antenatally have been reported. These antibodies may cross the placenta and persist for up to 3 months in the neonate.[143] Bleeding complications have not usually occurred, but intracranial hemorrhage has been reported.[143] The management of these pregnancies should be based on the assumption that the fetus potentially is phenotypically hemophiliac, regardless of the sex. Delivery plans and immediate neonatal management are as described earlier.

MANAGEMENT OPTIONS

Specialized management by a hematologist with expertise in hemophilia is required. Various coagulation factor concentrates are available for immediate control of bleeding in patients with factor VIII inhibitors. Detailed discussion is outside the scope of this chapter. In a young woman with bleeding as a result of acquired hemophilia, recombinant factor VIIa offers many advantages over other preparations. Disadvantages include the cost and the need for administration every 2 hours. In the longer term, therapy is given to encourage disappearance of the inhibitor. Steroids and immunosuppressive therapy have been used. Combination therapy is more efficacious in reducing the time to disappearance of the inhibitor.[142]

SUMMARY OF MANAGEMENT OPTIONS
Acquired Coagulation Disorders

Management Options	Quality of Evidence	Strength of Recommendation	References
Disseminated Intravascular Coagulation (DIC)

Immunosuppressive therapy (better in combination)	III	B	142

CONCLUSIONS

Thrombocytopenia

- Thrombocytopenia requires further testing if the platelet count decreases to less than 100×10^9/L.
- Autoimmune thrombocytopenia does not substantially increase the risk of neonatal bleeding.
- A safe maternal platelet count for delivery is 50×10^9/L or greater.
- A safe maternal platelet count for regional analgesia is 80×10^9/L or greater.
- The neonatal platelet count should be obtained on cord blood in women with autoimmune thrombocytopenia. If the initial count is low, the count should be repeated daily.
- All women who receive heparin should have a complete blood count weekly for 3 weeks after the start of therapy.

Coagulation Disorders

- Coagulation disorders should be managed by a team of obstetricians and hematologists.
- Genetic diagnosis of hemophilia may require extensive workup before pregnancy to offer the best chance for prenatal testing.
- Women who may benefit from DDAVP should undergo a trial before pregnancy.
- Coagulation must be optimized before delivery in women with bleeding disorders. Support may need to be continued for approximately 1 week postnatally.
- Women with von Willebrand's Disease have an increased risk of secondary postpartum hemorrhage. They should report abnormal bleeding early.

CONCLUSIONS (Continued)

Disseminated Intravascular Coagulation

- Disseminated intravascular coagulation has several obstetric causes, but the management principles of replacement of blood volume, coagulation factors, and platelets remain the same, regardless of the cause.
- Laboratory test results and clinical findings should guide replacement therapy.
- Simultaneous treatment of the underlying cause is of paramount importance.
- When large volumes of blood are replaced, they must be warmed.

Clotting Disorders

Robert D. Auerbach / Charles J. Lockwood

INTRODUCTION

Disorders of coagulation are a major cause of maternal morbidity and mortality. Pregnancy and the puerperium present a significant challenge to the hemostatic system. Maintaining an intact vascular compartment requires coordination of platelet function, soluble coagulation and fibrinolytic products, and the vascular endothelium. Pregnancy poses paradoxical challenges to the hemostatic system. During implantation and early placentation, syncytiotrophoblasts penetrate the endothelium of uterine vessels to establish the primordial or lacunar-type uteroplacental circulation. High-volume, low-resistance flow is established in the intervillous space after endovascular cytotrophoblast invasion of the uterine spiral arteries. As this process progresses, thrombosis must be avoided to maintain normal fetal growth and viability, and hemorrhage must be avoided to ensure maternal and fetal well-being. During the third stage of labor, 140 placental bed spiral arteries, denuded of their muscular layer, must quickly thrombose during puerperal contractions to avoid fatal maternal hemorrhage. Dramatic changes in local and systemic clotting and fibrinolytic factors are needed to meet this complex hemostatic challenge.

Because both thrombosis and hemorrhage are more common in pregnancy, the physician must understand the normal homeostatic mechanisms involved in the coagulation system and how they are affected by pregnancy and specific pathologic conditions. Stasis, hypercoagulability, and vascular trauma (Virchow's triad) occur in pregnancy, enhancing the risk of thrombosis. Stasis of the lower extremities is a direct result of compression through the enlarging uterus and a hormone-mediated increase in deep vascular capacitance. Estrogen drives endothelium-derived nitric oxide production, inducing vessel dilation.[1] In addition, positional uterine compression (which is greatest in the supine position and least in the left lateral decubitus position) can lead to varying degrees of progressive deep vein dilation.[2] Associated hypercoagulability is a result of increases in the levels of fibrinogen, prothrombin, and clotting factors VII, VIII, IX, and X; a decrease in the level of protein S[3-5]; a progressive increase in resistance to activated protein C[6]; and an increase in the levels of antifibrinolytic types 1 and 2 plasminogen activator inhibitor (PAI-1 and PAI-2).[7,8] This hemostatic change likely reduces the risk of antepartum, intrapartum, and postpartum hemorrhage, but is responsible for the dramatic 10-fold increase in pregnancy-associated venous thromboembolic disease (VTE). The risk of VTE is further increased in patients with acquired or inherited thrombophilias.[9,10] Delivery, especially operative vaginal and cesarean delivery, and puerperal infections are associated with vascular damage.[4] This chapter discusses the regulation of hemostasis, the associated pregnancy-induced changes, and various coagulation abnormalities and their diagnosis, clinical consequences, and treatment.

CLOTTING SYSTEM

Tissue factor (TF) is a cell-membrane-bound glycoprotein that is responsible for initiating hemostasis.[11,12] After vascular disruption, perivascular cell TF comes into contact with plasma factor VII. The TF–factor VII complex either directly activates factor X or generates factor Xa by initially activating factor IX, which complexes with its cofactor (factor VIIIa) to activate factor X. The conversion of factor VII to factor VIIa by thrombin or factor IXa, Xa, or XIIa results in a 100-fold increase in activity. Once activated, factor Xa complexes with factor Va to convert factor II (prothrombin) to factor IIa (thrombin). Thrombin then cleaves fibrinogen to produce fibrin. A stable hemostatic plug is formed as fibrin monomers self-polymerize and are cross-linked by thrombin-activated factor XIIIa. Thrombin induces platelets to aggregate in the fibrin clot. Factor XI binds to the surface of activated platelets, is activated by factor XIIa, and in turn, activates factor IX.[12]

Thrombin cleaves fibrinogen to fibrin and amplifies the hemostatic system by activating factors V, VII, and XIII as well as platelets.[13] Thrombotic disease is caused by excess thrombin generation. To prevent this action, the endogenous anticoagulant system inhibits thrombin and factor Xa activity. This system is composed of heparin cofactor II, α_2-macroglobulin, and antithrombin. The thrombin–factor Xa complex binds to each of the inhibitors and to vitronectin.[14] The result is a conformational change that facilitates binding to heparin, augmenting the rate of thrombin inactivation several 1000-fold.[15–17] Thrombin–antithrombin is the most physiologically active complex of this group. The increase in thrombin generation in normal pregnancy is mirrored by the increase in thrombin–antithrombin complexes.[18]

Thrombin also binds to thrombomodulin, and the resultant complex activates protein C, which binds to protein S to inactivate factors VIIIa and Va.[19] Levels of free protein S and protein S activity decrease 40% during pregnancy, in part because of increases in the complement 4b binding protein, which acts as a protein S carrier protein.[20]

Fibrinolysis aids in the prevention of pathologic thrombosis. Fibrin degradation products are the result of the ability of plasmin to cleave fibrin. Plasmin is created by its conversion from plasminogen by tissue-type plasminogen activator (tPA) embedded in fibrin. Because it inactivates tPA, PAI-1 is the primary inhibitor of fibrinolysis. Sources of PAI-1 and PAI-2, respectively, include epithelium decidua[21] and the placenta.[22] Thrombin-activatable fibrinolysis inhibitor is another inhibitor of fibrinolysis. This inhibitor is also activated by the thrombin–thrombomodulin complex.[23] Thus, thrombomodulin inhibits both excessive clotting (through the generation of activated protein C) and premature fibrinolysis (by generating an inhibitor of tPA).

RISK FACTORS FOR VENOUS THROMBOEMBOLIC DISEASE IN PREGNANCY (See Chapter 43)

Pregnancy-associated changes in hemostatic and fibrinolytic proteins establish a hypercoagulable state. Endogenous anticoagulant levels increase minimally (tissue factor pathway inhibitor [TFPI] α_2-macroglobulin), remain constant (antithrombin, heparin cofactor II, and protein C), or decrease significantly (protein S) in pregnancy. In addition, levels of fibrinogen and factors II, VII, VIII, X, and XII increase.[18] A twofold to threefold increase in PAI-1 concentrations is noted.[24] The result is the promotion of clot formation and stability. Clinical risk factors for VTE include increased parity (which is associated with venous valvular insufficiency), cesarean delivery, and postpartum endomyometritis (which are associated with increases in the complement 4b binding

protein). Independent risk factors include trauma, infection, obesity, nephrotic syndrome, age older than 35 years, bed rest, orthopedic surgery, and a history of VTE.

ACQUIRED THROMBOPHILIAS

Pregnant patients with acquired or inherited thrombophilia are at increased risk for VTE. Antiphospholipid antibodies constitute the acquired thrombophilias, accounting for 14% of VTE events in pregnancy.[9,10] In addition, these antibodies are associated with thrombocytopenia and various adverse obstetric outcomes. Two distinct classes are described: lupus anticoagulants and anticardiolipin antibodies.[25–27] Although antiphospholipid antibodies may arise from conditions associated with VTE and poor pregnancy outcomes (e.g., systemic lupus erythematosus), the antibodies directly promote placental and vascular thrombosis by interfering with a variety of anionic phospholipid-associated anticoagulant proteins, such as annexin V.[28,29] For a more detailed discussion of acquired thrombophilias, see Chapter 44.

INHERITED THROMBOPHILIAS

Maternal and Fetal Risks

Inherited thrombophilias also predispose pregnant women to VTE.[30] In addition to maternal deep vein thrombosis and pulmonary embolism, inherited thrombophilias are implicated in fetal loss (spontaneous abortion and stillbirth), intrauterine growth restriction, placental abruption, and preeclampsia.[31,32] Some studies also report an increased frequency of ischemic cerebrovascular events.[33] In addition to the variable risk of individual inherited thrombophilias, modifying factors (surgery, age >35 years, parity >4, obesity, smoking, immobility, and oral contraceptive use) contribute significantly to the overall risk of VTE.[34] The following are the most common inherited thrombophilias:

Heterozygosity for the following:

- Activated protein C resistance as a result of factor V Leiden (FVL) mutation
- G20210A mutation of the prothrombin gene
  Homozygosity for the following:
- The thermolabile variant of methylenetetrahydrofolate reductase (MTHFR) that increases homocysteine levels, particularly in folate-deficient patients
- 4G/4G polymorphism in the promoter region of the PAI-1 gene that causes an increase in this antifibrinolytic agent

Rarer causes of inherited thrombophilias include autosomal dominant antithrombin, protein S, and protein C deficiencies. More than 70% of cases of pregnancy-associated VTE are related to these conditions, even

though they are present in only approximately 10% to 15% of the population.[34,35] This chapter describes several individual inherited thrombophilias and discusses their clinical manifestations and treatment options.

Activated Protein C Resistance and Factor V Leiden Mutation

Present in 5% to 9% of the European population and 3% of African Americans and virtually absent in African blacks and the Chinese and Japanese populations, FVL is the most common heritable coagulopathy.[36] The condition arises from a point mutation in factor V at its site of inactivation by protein C (substitution of glutamine for arginine at position 506). This abnormality is inherited in an autosomal dominant fashion.[37] Patients with a single mutation have a 5- to 10-fold increased risk of VTE. Homozygous patients have a greater than 100-fold increased risk of VTE.[31,38] Although FVL is present in 40% of pregnant patients with VTE, given the low incidence of thrombosis in pregnancy (1 in 1400) and the high incidence of the mutation in the European-derived population, the estimated risk of VTE among heterozygous pregnant patients is only 0.2%.[32] As in pregnancy, the risk of VTE increases several-fold in women with FVL who take oral contraceptives.[40] Although clinical laboratories can screen for activated protein C resistance in pregnancy, polymerase chain reaction is the optimal method to confirm the presence of the FVL mutation in pregnancy.

Other adverse pregnancy outcomes have been reported in FVL carriers. Particularly at risk are homozygous patients and patients with a combined defect. Associated conditions include severe preeclampsia,[41] placental abruption,[42] fetal thrombosis as a result of fetal thrombophilia,[43] and fetal loss.[44] In a meta-analysis, both heterozygous and homozygous patients with a FVL mutation were at increased risk for recurrent first-trimester loss (odds ratio [OR], 2.01; 95% confidence interval [CI], 1.13–3.58), recurrent loss (>22 weeks) (OR, 7.83; 95% CI, 2.83–21.67), and nonrecurrent loss after 19 weeks' gestation (OR, 3.26; 95% CI, 1.82–5.83).[44]

Prothrombin Gene Mutation

A mutation in the promoter of the prothrombin gene (G20210A) leads to overexpression of prothrombin. Although it is present in only 2% to 3% of the European population, it accounts for 13% to 17% of women with an initial VTE.[31,32] Because of the low incidence of VTE in pregnancy, the actual risk of clotting in a carrier of this mutation is 0.5%.[31] Patients who are homozygous for the prothrombin gene mutation are at increased risk for VTE in pregnancy. A 4.6% risk of VTE occurs with compound heterozygotes for FVL and the prothrombin gene mutation.[32] Data suggest that placental dysfunction and pregnancy loss may be related to the prothrombin gene mutation. A meta-analysis that included women with the prothrombin gene mutation reported an

increased risk of fetal loss prior to 28 weeks (OR, 2.56; 95% CI, 1.04–6.29), recurrent first-trimester loss (OR, 2.32; 95% CI, 1.12–4.79), and late nonrecurrent fetal loss (OR, 2.30; 95% CI, 1.09–4.87).[44]

Hyperhomocysteinemia

Homozygosity for the thermolabile variant of MTHFR results in hyperhomocysteinemia, particularly in folate-deficient patients. An increased prevalence of the thermolabile variant of MTHFR is seen in women with certain complications (VTE, recurrent abortion, fetal neural tube defects, preeclampsia, placental abruption, fetal growth restriction, stillbirth).[45–48] Little or no increase in early fetal loss was noted in three meta-analyses in carriers of the MTHFR mutation.[44,47,49] It is unknown whether folate supplementation reduces or prevents any complications except neural tube defects.

Protein C and Protein S Deficiencies

Protein C and protein S deficiencies occur with a frequency of 0.2% to 0.5% in the general population and account for 10% to 25% of VTE in pregnancy.[50] Protein C or protein S deficiency carries a less than 5% risk of VTE during pregnancy but a 10% to 20% risk in the puerperium.[51] Pregnancy loss also appears to be increased in this population. In one study, loss rates were 28% for protein C deficiency and 17% for protein S deficiency. The control group had a loss rate of 11%.[52] A meta-analysis found that women with protein S deficiency had an odds ratio of 7.39 (95% CI, 1.28–42.83) for fetal loss.[44]

Antithrombin Deficiency

An autosomal dominant condition, antithrombin deficiency is the most thrombogenic heritable coagulopathy. Antepartum VTE rates are 12% to 60%, with puerperium rates of 11% to 33%.[50] Antithrombin deficiency is associated with a twofold risk of miscarriage and a fivefold risk of stillbirth.[53]

Other Heritable Coagulopathies

In patients who are homozygous for the 4G/4G allele in PAI-1, the presence of four instead of five consecutive guanine nucleotides in the PAI-1 promoter produces a site that is too small to allow binding of repressors. As a result, gene transcription and circulating levels of PAI-1 are increased.[54] A modest increase in VTE occurs as well as an increased risk of preeclampsia, fetal growth restriction, fetal loss, and premature delivery.[55] Several reports link VTE with elevated levels of factors VII, VIII, IX, and XI.[56–59] Dysfibrinogenemia may be associated with VTE as well as hemorrhage. Other inherited abnormalities, including decreased tPA, factor XII deficiency, hypoplasminogenemia or dysplasminogenemia, and heparin cofactor II deficiency, are not associated with adverse pregnancy outcomes.[60]

Management Options

Diagnosis

Patients with a history of VTE, a strong family history of VTE, or a history of adverse pregnancy outcomes may be candidates for evaluation of acquired and heritable thrombophilias. Adverse pregnancy outcomes include stillbirth associated with intrauterine growth restriction and placental infarction or abruption and severe or recurrent preeclampsia in the second or early third trimester. Screening of an unselected population is not recommended.[61]

Laboratory evaluation of activated protein C resistance can be obtained; however, antiphospholipid antibodies, low levels of protein S, and elevated levels of factor VIII may produce a false-positive report in pregnancy.[10] Therefore, the FVL mutation should be determined by polymerase chain reaction. Other studies include evaluation for the following:

- Polymerase chain reaction to detect prothrombin 20210A and MTHFR mutations
- Activity assays for antithrombin, protein C, and protein S (with consideration of the normally reduced protein S levels in pregnancy)
- Fasting homocysteine levels
- Thrombocythemia (discussed later; see Chapter 40)
- Antiphospholipid studies (see Chapter 44)

Although genotyping for the 4G/4G PAI-1 mutation is not widely available, assays for plasma PAI-1 protein with a greater than threefold elevation is presumptive evidence of homozygosity. Laboratory evaluation of these disorders is best performed in the nonpregnant patient who is not receiving hormonal or anticoagulation therapy and is remote (>6 months) from a history of VTE.[34]

Treatment

Several small observational studies suggest a benefit of anticoagulation to prevent adverse pregnancy outcomes in patients with thrombophilia.[62,63] Gris et al. randomized 160 patients with FVL, prothrombin 20210A, or protein S deficiency and a history of one unexplained loss after 10 weeks to either low dose asprin or enoxaparin (40 mg SQgd).[64] They observed a significant increase in live born rates in the enoxaparin group (86.2% vs. 28.8%) (OR 1515; 95% CI, 7–34). Women with VTE during a current pregnancy should receive therapeutic anticoagulation for at least 4 months during the pregnancy, followed by prophylactic therapy for at least 6 weeks postpartum. Women with a history of VTE associated with nonrecurrent risk factors (e.g., surgery, orthopedic immobilization), but without acquired or inherited thrombophilia, appear to be at very low risk for a repeat event. Although anticoagulation during the antepartum period

appears unnecessary in these patients, prophylaxis should be used during the higher-risk postpartum period.[65] Women with high-risk (more thrombogenic) thrombophilias (antithrombin deficiency and homozygosity for the FVL and prothrombin G20210A mutations) should be treated with full therapeutic anticoagulation during pregnancy and for at least 6 weeks postpartum, regardless of the history.

Pregnant women who have low-risk (less thrombogenic) thrombophilias (e.g., those who are heterozygous for the FVL and prothrombin G20210A mutations as well as protein C or protein S deficiency or those with hyperhomocysteinemia that does not respond to folate and vitamin B_{12} therapy) and no personal history of VTE have a low incidence of VTE in pregnancy (<5%). These patients do not appear to need antepartum anticoagulation.[66] However, they should receive postpartum prophylaxis if they require a cesarean section because most fatal pulmonary emboli occur during this period.[67] Some experts also recommend postpartum prophylaxis if the patient has an affected first-degree relative or another thrombotic risk factor (e.g., obesity or immobilization). In contrast, patients with these less thrombogenic thrombophilias and a history of VTE require prophylactic anticoagulation, as indicated, during the antepartum and postpartum periods.

Given the lack of consistent evidence of an association between maternal thrombophilia and recurrent early first-trimester loss (<10 weeks), anticoagulant therapy does not appear justified.[68] Women with less thrombogenic thrombophilias and a history of fetal loss (>10 weeks), unexplained abruption, severe early-onset preeclampsia, or severe fetal growth restriction pose a therapeutic conundrum. Definitive recommendations await further clinical trials of anticoagulation in this population.[64,69,70] As discussed earlier, patients in the high-risk thrombophilia group require therapy, regardless of their obstetric history. Vitamin B_{12} and folic acid should be supplemented if hyperhomocysteinemia is diagnosed.

HEPARIN (See Chapter 43)

During pregnancy, unfractionated heparin and low-molecular-weight heparin (LMWH) are the anticoagulants of choice, given their efficacy and safety profile.[71,72] Postpartum, oral anticoagulation with warfarin may be used and is considered safe in breast-feeding mothers.

Heparin enhances antithrombin activity, increases the level of factor Xa inhibitor,[73] and inhibits platelet aggregation.[74] Heparin does not cross the placenta or enter breast milk.[75,76] Side effects include hemorrhage, osteoporosis, and thrombocytopenia. Osteoporosis is more common with doses of heparin greater than 15,000 U daily for longer than 6 months.[77] All patients who are treated with heparin should receive calcium supplementation of

1500 mg daily. Heparin-induced thrombocytopenia occurs in 3% of patients. An early-onset, transient form of platelet aggregation does not require interruption of therapy. However, the immunoglobulin G-mediated thrombotic thrombocytopenia form requires cessation of therapy.[78] Platelet counts should be followed within 3 days of the initiation of therapy, and then weekly for 3 weeks. Heparin-induced thrombocytopenia appears to be far less common with LMWH, and LMWH also exerts lesser osteopenic effects.[79,80] The goals of therapy for a patient with acute VTE are to maintain anti-factor Xa activity between 0.6 and 1.0 U/mL or activated partial thromboplastin time (aPTT) between 1.5 and 2.5 times the control value. The dose required may vary as a result of differences in heparin-binding proteins in pregnancy.[78] During the initial phase of therapy, aPTT, the heparin level, or the anti-factor Xa level should be evaluated every 4 hours, with adjustments made in dosage as needed. Intravenous therapeutic unfractionated heparin administration should be continued for at least 5 days or until clinical improvement is seen.[81] Unfractionated heparin may then be administered subcutaneously every 8 to 12 hours to maintain aPTT at 1.5 to 2 times the control value 6 hours after the injection.[82]

As an alternative, LMWH (dalteparin, enoxaparin) is effective and safe when used during pregnancy.[83] For therapeutic dosing, the anti-factor Xa level should be 0.6 to 1.0 U/mL 4 to 6 hours after injection. Because regional anesthesia is contraindicated within 18 to 24 hours of LMWH administration, the recommendation is to switch to unfractionated heparin at 36 weeks' gestation, or earlier, if preterm delivery is expected. Patients with antithrombin deficiency and those who are homozygous for the FVL or prothrombin G20210A mutation require therapeutic anticoagulation throughout pregnancy. When only prophylactic therapy is required, unfractionated heparin or LMWH should be titrated to maintain the anti-factor Xa level at 0.1 to 0.2 U/mL 6 (unfractionated heparin) and 4 (LMWH) hours after injection. Administration of LMWH should be discontinued at 36 weeks, and treatment with unfractionated heparin at a prophylactic dose should be initiated, as indicated.

If vaginal or cesarean delivery occurs more than 4 hours after a prophylactic dose of unfractionated heparin, the patient is not at significant risk for hemorrhagic complications. Protamine sulfate may be administered to patients with increased aPTT who are receiving prophylactic or therapeutic unfractionated heparin and are about to deliver vaginally or by cesarean section. Anticoagulation-related problems with delivery are unlikely to occur 12 hours from prophylactic or 24 hours from therapeutic doses of LMWH. Antithrombin concentrates can be used in antithrombin-deficient patients in the peripartum period. Unfractionated heparin or LMWH can be used 6 hours after vaginal delivery or 8 to 12 hours after cesarean delivery. In patients who require therapy in the postpartum period, unfractionated heparin, LMWH, or warfarin (discussed later) may be prescribed.

WARFARIN

The anticoagulant activity of warfarin is a result of its inhibition of vitamin K, which is a cofactor in the synthesis of factors VII, IX, and X, and prothrombin II. Carrying a 33% risk of embryopathy (i.e., nasal hypoplasia, stippled epiphyses, central nervous system abnormalities) when exposure occurs between 7 and 12 weeks' gestation, it is loosely bound to albumin and crosses the placenta. Fetal and placental bleeding is also a serious complication of warfarin use throughout pregnancy. Vitamin K or fresh frozen plasma can be used to reverse its effect. Although its use during pregnancy is normally contraindicated,[84] warfarin use during the second trimester may be warranted in patients with mechanical heart valves because current studies suggest an increase in thrombogenic complications with heparin (unfractionated or LMWH).[85,86] Because the risk of fatal maternal valve thrombosis may outweigh the risk of warfarin exposure between 12 and 36 weeks' gestation, the risks and benefits should be discussed with these patients. Warfarin does not accumulate in breast milk or have an anticoagulant effect on the infant and is not contraindicated in breastfeeding mothers. Heparin should be continued for the initial 4 days of warfarin therapy and until a therapeutic international normalized ratio is achieved to avoid skin necrosis and paradoxical thromboembolus.

Maternal and Fetal Surveillance

Inherited thrombophilias present significant risk of maternal VTE and possibly adverse pregnancy outcomes after 10 weeks' gestation. Initiation of therapy, when indicated, and close maternal and fetal surveillance are mandated in this population. Patients with inherited thrombophilias should be educated about the signs and symptoms of thromboembolic disease. Standard screening for preeclampsia should continue (e.g., maternal weight, blood pressure, urine protein), and renal function, liver function, and platelet counts should be monitored with evolving signs or symptoms of preeclampsia. Fetal growth may be followed by establishing a definitive estimated date of confinement by first-trimester ultrasound and serial ultrasound examinations (every 4–6 weeks), beginning at 20 weeks' gestation. Doppler flow examination of the umbilical artery and middle cerebral artery may be used for assessment in fetal growth restriction. Nonstress testing and biophysical profiles may begin at 36 weeks or earlier, as clinically indicated. Taking into consideration gestational age, early delivery may be indicated if the maternal or fetal condition is deteriorating.

SUMMARY OF MANAGEMENT OPTIONS
Inherited Thrombophilias

Management Options (See also Chapter 43)	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Consider evaluation in patients with venous thromboembolic disease, a strong family history of venous thromboembolic disease, and adverse pregnancy outcomes (fetal loss, intrauterine growth restriction, severe or recurrent preeclampsia).	III	B	132
Prenatal

Folate and vitamin B_{12} supplementation for hyperhomocysteinemia	III	B	66
Labor and Delivery			
Reduce or stop heparin for labor and delivery; restart after 6 hours.	III	B	134
Postnatal			
Switching to warfarin postpartum is an option.	III	B	135

ESSENTIAL THROMBOCYTHEMIA (See Chapter 40)

Maternal and Fetal Risks

Essential thrombocythemia is a nonreactive chronic myeloproliferative disorder. As a result of the effect of this process on the hemopoietic stem cells, patients show excessive proliferation of megakaryocytes and sustained elevation of the platelet count.[87] Although previously considered a malady of middle age, increasingly, elevated platelet counts are noted in the younger population. A slight female preponderance is noted, especially in the younger population, with 20% of those affected younger than 40 years of age. Mesa and colleagues[88] reported a prevalence rate of 2.38 patients per 100,000 population in southern Minnesota.

Typical criteria used in the diagnosis of essential thrombocythemia include the following:

- Platelet count greater than $600,000/mm^3$
- Megakaryocyte hyperplasia
- Splenomegaly
- Clinical course complicated by hemorrhagic or thrombotic episodes

Although the cause of increased platelet production by megakaryocytes is unclear, the result is thrombocytosis. Proposed theories include increased sensitivity to cytokines, decreased inhibition of platelet inhibitory factors, and decreased accessory cell microenvironment or autonomous production.[89] The major cause of morbidity and mortality is complications of VTE. Complications are more common in the older population and in those with a history of thrombosis. Hemorrhagic complica-

tions are seen in patients with very high platelet counts. The evolution of essential thrombocythemia into leukemia is rare, but the incidence may be increased by some chemotherapeutic agents.[90]

Patients with essential thrombocythemia may have occlusive disease in the microvascular or macrovascular system (arterial or venous). Microvascular disease may involve transient cerebral ischemia, migraine, visual dysfunction, digital ischemia, and erythromelalgia.[91,92] Arterial thrombosis may include occlusion of the lower extremity, coronary, or renal arteries. Venous thrombosis of the splenic, hepatic, or pelvic veins may occur. Pulmonary hypertension may result from pulmonary vascular occlusion.[93,94] Hemorrhagic complications may include bruising of the skin and bleeding of the mucous membranes or digestive tract. These complications are most common in patients with platelet counts greater than $1,000,000/mm^3$ and are considered a result of acquired deficiency of von Willebrand factor.[95,96] The elevated platelet count may affect the concentration of von Willebrand multimers and thus compromise hemostasis.

Essential thrombocythemia in pregnancy is associated with a 50% risk of obstetric complications, including recurrent abortion, premature delivery, intrauterine fetal growth restriction, and placental abruption. The proposed mechanism of pathogenesis is placental infarction.

Management Options

Diagnosis

Weight loss, sweating, low-grade fever, and pruritus may occur in up to 20% of patients. Although 40% to 50% of patients have splenomegaly and 20% have hepatomegaly, most patients have unremarkable findings on physical examination. Ultrasound or computed tomography scan may be used if splenomegaly is undetectable on physical examination.

The hallmark of essential thrombocythemia is sustained unexplained thrombocytosis. A complete blood count may show leukocytosis, erythrocytosis, and anemia (associated with hemorrhagic complications). Large platelets are typically identified on a peripheral blood smear. Some patients have spontaneous platelet aggregation. Typically, prothrombin time and aPTT are unaffected. One-fourth of patients have elevated uric acid and vitamin B_{12} levels. Levels of potassium, phosphorus, and acid phosphatase may be falsely elevated. Elevated levels of acute-phase reactant C-reactive protein, fibrinogen, and interleukin-6 suggest secondary thombocytosis.[97]

Polymerase chain reaction or Southern genomic blotting may be used to exclude chronic myelogenous leukemia. A normal red cell mass can be used to exclude polycythemia vera. In affected patients, the results of platelet aggregation studies are abnormal and show impaired aggregation to epinephrine, adenosine diphosphate, and collagen, but not to ristocetin and arachidonic acid. Bone marrow aspirate and biopsy may be useful, and most patients show increased bone marrow cellularity and megakaryocytic hyperplasia. Hyperplasia of the granulocytes and reticulocytes is also common. The level of bone marrow reticulin is usually increased, but collagen fibrosis is uncommon.[98]

General Management Guidelines

The risk of thrombotic or hemorrhagic complications as a result of essential thrombocythemia has been categorized into low risk and high risk populations, as follows[99]:

LOW RISK

- Age younger than 60 years
- No history of thrombosis
- Platelet count less than 1.5 million/μL

HIGH RISK

- Age older than 60 years
- History of thrombosis
- Platelet count greater than 1.5 million/μL

Most authorities recommend that myelosuppressive therapy for essential thrombocythemia should be reserved for high risk patients (defined earlier) because the risk of fatal thrombotic complications in low risk patients is rare and cytotoxic drugs have the potential for developing leukemia.[100] Aspirin may be used in both subsets of patients to reduce the microvascular symptoms of erythromelalgia and transient cerebral or ocular ischemia.[91,92] Acute management of these conditions usually requires 100 to 300 mg aspirin daily. In patients with high risk essential thrombocythemia, cytoreductive agents often relieve these symptoms; however, aspirin may be indicated for patients who have a normal platelet count and continue to be symptomatic. In addition, a dose of 75 to 100 mg aspirin daily may provide prophylaxis against major arterial thrombosis. A slightly increased risk of bleeding complications may be associated with this disorder.[101,102]

High risk patients with essential thrombocythemia are candidates for therapy with cytoreductive agents. Although a complete discussion of this therapeutic category is beyond the scope of this chapter, representative agents are discussed briefly. Hydroxyurea emerged as the treatment of choice because of its efficacy and limited toxicity. Neutropenia and macrocytic anemia are the major short-term toxic effects. Long-term follow-up studies show an increased rate of acute leukemia.[100] Busulfan is an alkylating agent that controls megakaryocyte proliferation. Intermittent doses can be given after initial normalization of the platelet count is achieved. Although busulfan was not found to induce leukemia, concerns continue about its possible relation to malignancy because other alkylating agents are associated with malignant transformation.[103,104] Interferon-α is a cytoreductive agent with little mutagenic potential. It antagonizes platelet-derived growth factor and is associated with a dose-dependent reduction in platelet count.

A 90% reduction in the platelet count (<600,000/μL) has been obtained after 3 months of therapy, with an average dose of 3 million IU daily. Interferon-α does not cross the placenta and is listed as a *Physician's Desk Reference* category C drug. It has been used in some pregnant patients without apparent harm.[105,106] If cytoreductive therapy is required before or during pregnancy, interferon-α is the agent of choice. Anagrelide is an imidazoquinolin that causes the suppression of megakaryocytes and thus decreases platelet counts without affecting other hematopoietic cell lines. No association with leukemia is noted. Significant complications include palpitations, tachycardia, cardiac arrhythmias, and congestive heart failure. Although it is listed as a category C drug, its use in pregnancy is not defined.[106]

Treatment in Pregnancy

Some authors recommend treatment during pregnancy with aspirin or subcutaneous heparin.[107,108] Current recommendations for treatment have yet to be defined, as illustrated by a Mayo Clinic study that showed no therapeutic benefit of treatment in 18 women (34 pregnancies) with essential thrombocythemia.[109] In this study, 45% of pregnancies ended in spontaneous abortion. The authors also could not predict the occurrence of spontaneous abortion based on the platelet count or course of disease. No other significant adverse events were noted. Because the outcome was the same in patients who received no therapy and in those treated with aspirin, treatment is not recommended in asymptomatic low risk patients with essential thrombocythemia. Thus, the use of aspirin or interferon-α in these low risk patients is of unproven benefit. Interferon-α has been used successfully in pregnant patients with essential thrombocythemia who are at increased risk for thrombosis.[110] Given the limited experience with this drug in pregnancy, its use is limited to patients in whom the potential benefits outweigh the theoretical risks. Appropriate counseling should be provided.

SUMMARY OF MANAGEMENT OPTIONS

Essential Thrombocythemia

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal			
Interdisciplinary approach	III	B	100
Expectant approach in symptomatic patients with only moderate elevation of platelets	III	B	38
In symptomatic patients (thrombosis or bleeding), consider plasmapheresis in first instance	III	B	38
Low-dose aspirin and heparin if thrombosis occurs; evidence does not support use in all cases	III	B	39, 40
Hydroxyurea has been used, but most experience is with chronic myelogenous leukemia	III	B	39
Limited experience with α-interferon	III	B	42, 43
No experience with anagrelide; avoid	III	B	106

THROMBOTIC THROMBOCYTOPENIC PURPURA-HEMOLYTIC UREMIC SYNDROME (See Chapter 80)

Maternal and Fetal Risks

Although they were previously described as distinct entities, thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) are now considered a single syndrome.[115] Historically, the diagnosis of TTP-HUS was made only if the patient had the classic pentad of thrombocytopenia, hemolytic anemia, neurologic abnormalities, renal abnormalities, and fever. Because of the ability of plasma exchange to improve the survival rate from less than 10% to approximately 80%, the diagnostic criteria have been eased.[116,117] Thrombocytopenia

coupled with microangiopathic hemolytic anemia without an alternative diagnosis is sufficient to define TTP-HUS and possibly begin plasma exchange.[117] Because the diagnosis of TTP-HUS is not precise, an alternative diagnosis may become apparent later in the clinical course. Relapse and chronic renal failure are long-term risks after recovery.

Damage to the microvascular endothelial cell is the current hypothesis to explain the pathogenesis of TTP-HUS.[118] Plasma from patients diagnosed with TTP can cause apoptosis of microvascular endothelial cells.[119] After endothelial damage occurs, release of unusually large von Willebrand factor occurs.[120] Typically, these large multimers are cleaved to a normal size by a plasma protease specific to von Willebrand factor.[121] Patients with TTP may have an inherited or acquired deficiency of this cleaving protease. Although this deficiency is clinically indistinguishable, it could differentiate TTP from HUS. Accumulation of these multimers is associated with the promotion of platelet aggregation.[122] Because these multimers may be noted in patients with disseminated malignancy without the clinical manifestations of TTP, they are not specific to this disease.[123] Less pronounced reductions in protease levels are also noted in patients with disseminated intravascular coagulation, idiopathic thrombocytopenic purpura, severe sepsis, systemic lupus erythematosus, cirrhosis, or heparin-induced thrombocytopenia. On occasion, this deficiency is noted in a patient without disease. In pregnancy, these protease levels decline with advancing gestation. Thus, an asymptomatic pregnant patient with decreased baseline levels of cleaving protease may not seek care until the peripartum period. This delay may account for the increased frequency of TTP-HUS in late pregnancy.[124]

Most patients with TTP-HUS are women, and a significant number are pregnant at the time of diagnosis. This tendency was shown by Hayward and associates, who reported that 69% (36 of 52) patients with TTP-HUS were women and 25% (9 of 36) were pregnant at the time of diagnosis.[124]

Management

Diagnosis

As discussed earlier, the diagnostic criteria for TTP-HUS are thrombocytopenia (typically <30,000 × 10^9/L) and microangiopathic hemolytic anemia (evidence of increased red cell production and destruction, red cell fragmentation, and negative findings on an antiglobulin test) in a patient with no other apparent clinical diagnosis. Other features that support the diagnosis of TTP-HUS, but are not required to make this diagnosis, include renal abnormalities (proteinuria and hematuria), changes in mental status, and abdominal symptoms (pain, nausea, diarrhea, and vomiting). In contrast, acute renal failure, seizures, fever with chills, and extensive purpura

suggest an alternative diagnosis.[125] Patients with this syndrome have various clinical presentations, some of which may make the diagnosis suspect. TTP-HUS may be triggered by pregnancy, bloody diarrhea as a result of pathogenic bacteria, autoimmune disease, drugs (allergic reaction or dose-related toxicity), allogenic bone marrow transplantation, HIV, disseminated malignancy, or malignant hypertension. It may also occur without another current diagnosis.

Preeclampsia and HELLP syndrome (hemolysis, elevated liver function test results, low platelet count) may make the diagnosis of TTP-HUS difficult because both conditions may have associated thrombocytopenia, microangiopathic hemolytic anemia, and neurologic symptoms (visual changes or seizures). The criteria that are most often used to distinguish these processes are clinical recovery and lack of recovery after delivery. In preeclampsia and HELLP syndrome, thrombocytopenia may occur before or after delivery and typically reaches a nadir soon after delivery. Postpartum, the platelet count returns to normal. Hemolytic anemia is much less common in patients with preeclampsia (2%).[126] In contrast, patients with HELLP syndrome may have hemolytic anemia that is significantly slower to recover than thrombocytopenia.[127] The changes in mental status that are typical in TTP-HUS are rarely seen in patients with preeclampsia or HELLP syndrome. In these patients, neurologic symptoms usually include blurred vision, headache, visual scotomata, and rarely, eclamptic seizures. Although proteinuria is a diagnostic hallmark of preeclampsia, renal failure is rare unless the process is complicated by severe hypertension, disseminated intravascular coagulation, hypotension, or sepsis.[128]

Treatment

Plasma exchange is an empirical and effective treatment for TTP-HUS. With this procedure, the patient's blood is withdrawn through a large-bore central venous catheter. Initially, the plasma is separated from the cells, which are then retransfused with fresh plasma. The response to treatment is varied. Changes in mental status may be the first to resolve, with slower recovery of more severe neurologic symptoms, thrombocytopenia, hemolytic anemia, and renal failure. Increasing the frequency of plasma exchange may be required in patients who show a poor response. If plasma exchange is not available, plasma infusion and platelet transfusion have been advocated. This therapy is considered inferior to plasma exchange.[129] Although controversial, occasional supplemental treatment with glucocorticoids, vincristine, splenectomy, intravenous immunoglobulin, immunosuppressive agents, and antiplatelet drugs have been anecdotally recommended.[130] The number of treatments required to achieve a lasting remission is variable (days to months). To reduce the risk of relapse, plasma exchange is usually tapered. Complications of plasma exchange

include those related to central venous catheter placement and the administration of large volumes of plasma.

When TTP-HUS occurs early in pregnancy, it is easily distinguished from preeclampsia or HELLP syndrome. With plasma exchange, pregnancy may be uninterrupted.[130] When the diagnosis is made later in pregnancy, the distinction from preeclampsia or HELLP syndrome becomes more difficult and the timing of delivery becomes more important. Observation may be appropriate in a clinically stable patient who is remote from term. Deterioration of clinical status should prompt treatment (plasma exchange) or delivery. If the patient's symptoms do not resolve after delivery, the clinician must consider the diagnosis of TTP-HUS, especially if symptoms persist beyond the third postpartum day. In patients with severe thrombocytopenia and microangiopathic anemia, possibly coupled with renal failure or changes in mental status, plasma exchange should be considered. TTP-HUS may recur in subsequent pregnancies; however, at least 50% have an uncomplicated pregnancy.[131]

SUMMARY OF MANAGEMENT OPTIONS
Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

Management Options	Quality of Evidence	Strength of Recommendation	References
Plasmapheresis is the treatment of choice	IV	C	130

Critical care setting and interdisciplinary approach	III	B	117

CONCLUSIONS

- Clotting disorders remain a leading cause of maternal morbidity and mortality.
- In addition to maternal disease, thrombosis may have a direct effect on fetal health.
- Pregnancy-associated changes in the hemostatic and antifibrinolytic systems predispose women to pathologic clotting disorders.
- In addition, various pregnancy-dependent and independent risk factors contribute to the overall risk of venous thromboembolic disease.
- Acquired and inherited thrombophilias augment this baseline risk.
- The principal clinical consequence is thrombosis. In some cases, thrombosis may cause adverse pregnancy outcomes, including fetal loss, severe preeclampsia, placental abruption, and fetal growth restriction.
- An interdisciplinary approach is advisable.
- Heparin is the anticoagulant of choice in pregnancy.
- Surveillance of fetal health is mandatory in these pregnancies.

Thromboembolic Disease

Roy G. Farquharson / Michael Greaves

INTRODUCTION

Venous thromboembolism (VTE) is the most common cause of maternal death in the United Kingdom. From 1997 to 1999, 31 women died during pregnancy or soon after delivery.[1] This figure equates to a rate of 1.45 deaths per 100,000 pregnancies. Pulmonary embolism remains the leading direct cause of maternal mortality, and the total number is still disappointingly similar to numbers reported in previous 3-year periods, with the exception of 1994 to 1996, when the total peaked at 46 deaths. The encouraging news is that after cesarean delivery, the number of fatal VTE events decreased dramatically for the first time, from a total of 15 to 4, after the introduction of the Royal College of Obstetricians and Gynaecologists (RCOG) guidelines on thromboprophylaxis, which were published in 1995.[2] Even early pregnancy is a significant risk period for VTE; eight cases (25%) occurred at 8 weeks' gestation. Fatal VTE may occur before the first prenatal visit. Even if the risk of VTE could be predicted accurately, it would not be possible to prevent all fatalities caused by pulmonary embolism in pregnancy.

An accurate measure of the total incidence of VTE in the United Kingdom is difficult to determine because there is no national registry. The Swedish national register suggests an overall incidence of 1.3 events per 1000 deliveries[3] for all types of VTE, including deep venous thrombosis and fatal and nonfatal pulmonary embolism. This rate corresponds closely to the incidence reported in a large, unselected cohort of pregnant women in Glasgow, Scotland.[4]

MATERNAL RISKS

Pregnancy introduces a significant risk of VTE events. Many important changes in the coagulation and vascular systems occur during pregnancy, and these changes support the accepted orthodoxy that pregnancy is a state of hypercoagulation. Each element of Virchow's triad is present: venous stasis, hypercoagulability, and vascular damage. Table 43–1 summarizes additional features in pregnancy that add to the risk of VTE, based on individual case analysis reporting.[1]

Inherited thrombophilia carries an increased risk of thrombosis for both the nonpregnant (Table 43–2) and pregnant populations. In patients with a strong family history of VTE in a first-degree relative, screening for thrombophilia has been suggested as part of the first prenatal visit. Unfortunately, this approach identifies few susceptible carriers of thrombophilia.[5] Further, screening for the most common heritable thrombophilia, heterozygosity for factor V Leiden, is not considered a cost-effective method for the prevention of pregnancy-related VTE.[6] The clinical value of testing for heritable thrombophilia is questioned in most clinical situations.[7] Testing in this context represents screening for what is usually a late-onset, nonfatal clinical disorder of low penetrance. Pretest counseling is mandatory, and non-evidence-based interventions determined by the results of testing must be avoided.[8]

The maternal risks of a VTE event are considerable (discussed earlier). An untreated pulmonary embolism has an estimated mortality rate of 13%. Although recovery from a nonfatal pulmonary embolism is considered complete, subtle residual effects may be detected by pulmonary function testing. The recurrence risk is difficult to quantify, particularly with modern-day aggressive recognition and treatment, but may be as high as 26% in untreated cases. Deep venous thrombosis is associated with valvular damage. Despite recanalization, many patients have postphlebitic syndrome (swelling, pain, skin ulceration) as a long-term consequence. The risks of treatment with anticoagulants include bleeding, thrombocytopenia, and osteoporosis (discussed later).

TABLE 43–1

Risk Factors Identified from Individual Case Analysis of 31 Maternal Deaths as a Result of Venous Thromboembolism (1997–1999)

RISK FACTOR	NUMBER OF CASES	COMMENT
Age	31	The rate of death is doubled in women older than 30 years.
Obesity	13	Body mass index >30. All patients diagnosed in the third trimester were overweight. Increased dosage of low-molecular-weight heparin is recommended for the treatment of venous thromboembolism (VTE).
Immobility	5	All patients had prolonged bed rest.
Family history of VTE	4	Strong history of VTE. All deaths occurred in the antenatal period.
Cesarean delivery	4	The number of events decreased dramatically from the previous report after the 1995 Royal College of Obstetricians and Gynaecologists guideline.
History of VTE	3	Two patients were obese.
Air travel	2	Both cases occurred antenatally.

From Why Mothers Die 1997–1999: The confidential enquiries into maternal deaths in the United Kingdom. London, RCOG Press, 2001, pp 49–71.

FETAL RISKS

Most fetal risk relates to maternal decompensation as a result of the acute VTE event and therapeutic interventions. Hypoxia and cardiovascular collapse are not uncommon in pulmonary embolus. These systemic injuries may directly affect placental and fetal homeostasis. Although heparin does not cross the placenta, its use to treat VTE can precipitate adverse pregnancy outcomes by causing maternal hemorrhage. Warfarin crosses the placenta and is associated with specific teratogenic effects. Except under unusual circumstances, or

TABLE 43–2

when given inadvertently when early pregnancy is not suspected, warfarin is not used in pregnancy (discussed later).

Underlying causes of VTE, such as inherited and acquired thrombophilias, are being actively explored for their relationship to poor pregnancy outcomes, such as early and late fetal loss, growth restriction, and early-onset preeclampsia.[9,10] These conditions are discussed in the chapters on clotting disorders and autoimmune disease in pregnancy (Chapters 42 and 44).

THROMBOEMBOLISM IN PREGNANCY

General

The key elements of the management of VTE in pregnancy are a high index of clinical suspicion, objective confirmation by imaging, and administration of heparin for the rest of the pregnancy followed by heparin or warfarin for at least 6 weeks postpartum and 6 months in total.

Diagnosis

The typical clinical features of deep vein thrombosis in pregnancy differ somewhat from those in the nonpregnant patient in relation to lateralization and extent. In up to 90% of cases, thrombosis affects the left leg, and in most patients, the proximal veins are affected. Deep venous thrombosis restricted to the calf veins is uncommon during pregnancy, although it may complicate the postpartum period.

The differential diagnosis of a painful, swollen leg in this situation is narrow. Alternative causes, such as ruptured Baker's cyst and hematoma, are rare in this age group, and cellulitis is uncommon. Symptoms may be subtle and may be confused with common benign changes in pregnancy, such as lower extremity edema or muscle cramping. The unilateral nature of VTE is a useful distinguishing characteristic. Generalized and point tenderness are common features. Dorsiflexion of the calf causes pain (Homan's sign) if the clot is in that region. Tender, indurated veins may be palpable on careful inspection of the popliteal fossa. Asymmetry of the legs is usually seen below the level of the venous obstruction. Localized erythema suggests concomitant superficial thrombosis.

The clinical features of pulmonary embolism are no different from those in the nonpregnant patient, but may be masked by the physiologic dyspnea seen in pregnancy. In most cases, the features are those of pulmonary infarction, with pleuritic chest pain of acute or subacute onset, with or without dyspnea. Patients may have hemoptysis and low-grade fever. The differential diagnosis includes chest infection with pleurisy and pneumothorax, but in the face of the symptoms described earlier, pulmonary infarction should be considered the most likely cause until

it has been excluded or an alternative diagnosis is identified. Atypical patients have increasing dyspnea only and present a diagnostic challenge. Less commonly, patients may have a submassive or massive pulmonary embolism. Patients with a submassive pulmonary embolism have increasing severe dyspnea that develops over a few days, with evidence of arterial oxygen desaturation. They may also have increased jugular venous pressure and other evidence of right heart strain. In massive pulmonary embolism, patients have acute severe dyspnea, cyanosis, and collapse, often with hypotension. They may have no chest pain or central chest pain as a result of myocardial ischemia from increased right ventricular work in the face of low arterial oxygen tension. Clinical and electrocardiographic evidence of increased right heart pressure and right ventricular strain are often evident.

Clinical risk factors in addition to pregnancy should be considered because they support the clinical suspicion of the diagnosis. Approximately two thirds of patients have a recognizable risk factor, for example, increased parity, age older than 35 years, obesity, recent immobilization, and operative delivery.[4]

Confirmation of the Diagnosis

A diagnosis of VTE means a commitment to full anticoagulant therapy for several months, with its attendant risks of iatrogenic injury and its effect on the management of delivery. VTE also affects the management of future pregnancies, contraceptive choices, and the use of hormone replacement therapy as well as the perceived level of risk of VTE in first-degree relatives. Objective confirmation is essential to establish the diagnosis.

In lower limb deep venous thrombosis, compression ultrasonography is the test of choice because it is noninvasive and sensitive to thrombi in the proximal veins. The typical criteria for diagnosis are lack of vessel compressibility, absence of blood flow, and vessel dilation or visualization of the thrombus. The principal limitation is reduced sensitivity for thrombi confined to the distal calf veins. Other sources of diagnostic error relate to diminished flow in a patent femoral or iliac vein as a result of extrinsic compression from the gravid uterus and persistent flow in the face of a nonocclusive thrombus in the iliac vein. When the diagnosis is in doubt, additional imaging is needed. Contrast venography with shielding of the uterus is most commonly used. Although it is invasive, causes some discomfort, and inevitably involves radiation exposure, the diagnostic sensitivity is high. An alternative that is under development is direct thrombus magnetic resonance imaging, although this technique is not readily accessible in many centers.

When there is clinical suspicion of a venous thrombosis restricted to the calf veins (most commonly postpartum), an alternative strategy to contrast venography is to withhold anticoagulant therapy after a first negative ultrasound examination and then to repeat the study in 3 to 5 days to exclude progression to the popliteal vein. However, this is an extrapolation from nonpregnant subjects with deep vein thrombosis. Anticoagulant therapy is introduced only if progression is seen. This approach is based on the observations that progression occurs in only approximately 30% of cases and that pulmonary embolism is uncommon in deep venous thrombosis restricted to the calf veins.

When pulmonary embolism is suspected based on the clinical features, imaging is essential to confirm the diagnosis or establish an alternative. Although it is usually performed, electrocardiography is insensitive and insufficiently specific. Arterial blood gas analysis is useful to indicate the degree of hypoxia, but does not exclude other causes. A chest x-ray should be obtained with lead apron shielding of the fetus. Although the findings are often normal at presentation with pulmonary embolism and are rarely diagnostic in isolation, they may indicate an alternative cause of the symptoms (e.g., pneumothorax, pneumonia). A chest x-ray is also required for interpretation of the results of a ventilation-perfusion scan. Concomitant ultrasonography examination of the lower extremities is of value because anticoagulation therapy is indicated for an asymptomatic thrombus in this setting. However, a negative finding on ultrasound study of the legs does not exclude pulmonary embolism because the clot already may have embolized or an alternative source of the thrombus (e.g., pelvic veins) may be present. Isotopic scanning is indicated when a pulmonary embolism is suspected. The unavoidable radiation exposure has been calculated to be acceptable in pregnancy and can be minimized by performing the perfusion scan first and proceeding to the ventilation scan only if perfusion is abnormal. The principal limitation of this technique is a lack of specificity. Although a normal scan reasonably excludes pulmonary embolism and a scan showing unmatched perfusion defects at the segmental level or greater can be considered diagnostic, many scans are interpreted as intermediate probability. Because the level of diagnostic precision is inadequate in this category, additional imaging is indicated. Until recently, pulmonary angiography was required. Spiral computed axial tomography is the preferred approach, and in some centers, it is the first-line study. Radiation scatter to the abdomen is sufficiently low for this method to be considered for use in pregnancy. Magnetic resonance imaging techniques are also being developed to confirm the presence of pulmonary embolism.

There has been increasing interest in the use of D-dimer assay alongside a clinical algorithm to assess patients with suspected deep venous thrombosis. D-dimer is a product of the fibrinolytic digestion of cross-linked fibrin. An increased concentration in plasma is a marker for thrombus formation. Although this test is sensitive, it is not specific and is insufficient to confirm the diagnosis. Further, diagnostic algorithms that use a

D-dimer assay were validated only in previously healthy, nonpregnant, nonhospitalized subjects.[11] The use of this laboratory parameter in pregnancy requires the establishment of gestation-specific laboratory ranges. Plasma products of fibrin dissolution increase in concentration from approximately 10 weeks' gestation in healthy pregnancy and increase further and abruptly immediately postpartum. This diagnostic strategy is impractical and is not recommended.

Pharmacologic and Nonpharmacologic Approaches

Interventions to prevent and treat VTE are pharmacologic antithrombotics, thrombolytics, and mechanical measures (Table 43–3). Among the pharmacologic agents, heparins and warfarin are the principal drugs. The efficacy of aspirin in preventing VTE is debated. A meta-analysis[12] and a randomized study of thromboprophylaxis in lower limb orthopedic surgery[13] showed evidence of an antithrombotic effect, but the use of aspirin for this purpose in pregnancy cannot be supported. Novel oral anticoagulants are under investigation, including an oral direct thrombin inhibitor, ximelagatran. The role of these agents has not been established, and there are no data on their use in pregnancy. In VTE, thrombolytic therapy is restricted to emergency management of massive pulmonary embolism and limb salvage in rare cases of massive lower limb deep venous thrombosis with venous gangrene. Thrombolytic agents are associated with miscarriage or fetal death and maternal bleeding. Their use is relatively contraindicated in pregnancy. Similarly, these agents would likely induce massive uterine hemorrhage soon after delivery and therefore empirically should not be used. Under these circumstances, massive pulmonary embolism has been treated with

heparin anticoagulation and emergency pulmonary embolectomy. A recent review of anecdotal reports of thrombolytic therapy in pregnancy implied that the risks to the mother and fetus may be lower than previously suggested.[14]

Heparins

Unfractionated heparin (UH) is manufactured from mammalian intestinal mucosa. It consists of a heterogeneous mixture of highly sulfated polysaccharide chains. The molecular weight ranges from 5000 to 35,000 daltons. Its anticoagulant action is principally the result of binding, through a specific pentasaccharide sequence, to antithrombin III, with a resultant profound acceleration in the rate of inhibition of coagulation enzymes, particularly thrombin and factor Xa.

Although UH is an effective antithrombotic agent, laboratory monitoring of the anticoagulant effect is necessary when it is used to treat established thrombosis. Activated partial thromboplastin time (aPTT) is typically used, but there is marked variation in reagent sensitivity to heparin, and laboratory standardization of heparin dosage control has not been achieved.

Low-molecular-weight heparin (LMWH) is prepared from UH. These products, with an average molecular weight of approximately 5000 daltons, contain a high concentration of molecules with fewer than 18 saccharides. These molecules cannot bind to antithrombin III and thrombin simultaneously, a feature necessary for thrombin inhibition. However, the anti-Xa effect is preserved because there is no requirement for direct binding to factor Xa for the acceleration of inhibition by the heparin–antithrombin III complex. The anti-Xa effect, in relation to the antithrombin effect, is greater in LMWH compared with UH. In addition, the bioavailability from subcutaneous tissues is greater and the plasma half-life is longer than that of UH, permitting effective anticoagulation by once- or twice-daily subcutaneous administration without a requirement for laboratory monitoring. The attributes of LMWH have led to the replacement of UH for many clinical indications. This development is supported by clinical trials in nonpregnant subjects that show at least equivalence to UH in safety and efficacy in the prevention and treatment of VTE. Deep venous thrombosis can be treated safely in the community setting with LMWH,[15] although data on pregnant patients are limited. The efficacy, ease of administration, and possible greater safety of LMWH suggest that these agents are preferable to UH in pregnancy. However, the pharmacokinetics of LMWH may be altered in pregnancy. This consideration is important because the dosing of LMWH has been extrapolated from data on nonpregnant subjects. Some early observational studies of LMWH in pregnancy have design flaws, including nonstandardized gestation intervals, a nonhomogenous case mix, and small numbers of patients with few serial obser-

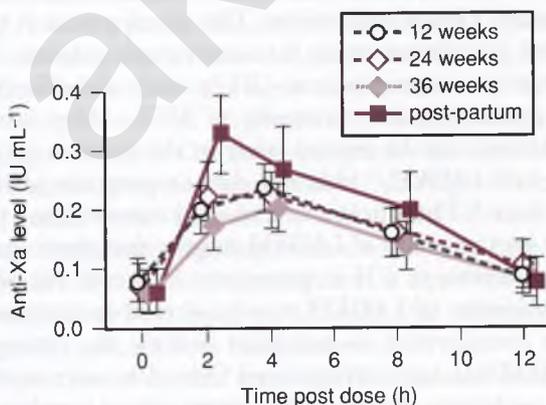
vation points.[16] A systematic review reported 40 citations of LMWH use in 728 pregnant and postpartum women. However, only 2 articles were categorized as level I with regard to the quality of evidence,[17] and 19 of the articles were less than level III. Variations in dosage regimens were marked and ranged from 2500 to 22,000 units daily, which included fixed dosages, increasing dosages as pregnancy progressed, dosages based on body weight, and dosages titrated according to anti-Xa levels. The wide variation in dosage regimens highlights the uncertainty about the pharmacokinetics of heparin in pregnancy.

However, useful data are emerging. In a longitudinal study of LMWH prophylaxis in pregnancy the group mean peak anti-Xa level occurred later, at 4 hours, compared with 2 hours in the nonpregnant state.[18] Group mean peak values showed significant differences at 12 and 36 weeks' gestation, compared with the nonpregnant state, at the 2-hour time point. The threshold for thromboprophylaxis was reached at the 4-hour peak assessment (Fig. 43–1).[18] A previous study in a smaller cohort with nonstandardized gestation intervals supports this trend.[19] Compared with the nonpregnant state, the area under the anti-Xa curve (AUC) is less in pregnancy, with the lowest median reading occurring at 36 weeks' gestation (Fig. 43–2).[18] The AUC reflects LMWH activity and therefore reduced plasma activity with advancing gestation. Renal excretion is the principal route of clearance of LMWH. In contrast, UH is cleared in part by the reticuloendothelial system. Pregnancy-related physiologic adaptations in renal function probably account for the altered pharmacokinetics of LMWH. Renal clearance for LMWH may increase, accounting for the lower AUC of anti-Xa in pregnancy. This observation is supported by higher AUC values in 12 healthy, nonpregnant volunteers who were given LMWH.[20] Conversely, in renal failure, the biologic half-life of LMWH is increased.[21] These issues highlight the unresolved question as to whether dosing regimens based on trials in nonpregnant individuals can be used in pregnancy. Hunt et al.[22] recommended dose escalation after 20 weeks' gestation to


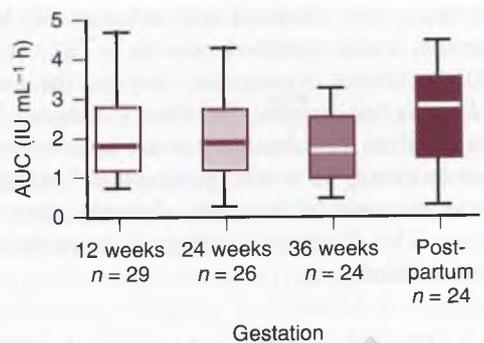


FIGURE 43–2

overcome these altered heparin pharmacokinetics in pregnancy.

The principal side effect of heparin therapy is bleeding. Heparin-induced thrombocytopenia with paradoxical thrombosis is a less common, but potentially lethal side effect. It is caused by platelet consumption and activation by a heparin-induced antibody. Typically, the platelet count begins to decrease 5 to 10 days after exposure to heparin, even at a low dose, and in many cases, new or worsening thrombosis is noted. This decrease is 10-fold more likely to occur with UH than with LMWH,[23] and fortunately, it has been reported only rarely in pregnant patients treated with heparin.

Clinically significant osteoporosis is a rare consequence of pregnancy and also of long-term (>3 months) exposure to heparin. Evidence is accumulating that it is less likely to occur with LMWH than with UH. The potential threat of osteoporosis was addressed by several prospective studies that showed that the physiologic effect of pregnancy-induced bone loss is probably greater than that seen with long-term heparin use (Table 43–4). During pregnancy, bone remodeling is uncoupled, with a marked increase in early bone resorption followed by late bone formation[24] and alteration of bone architecture.[25] Osteoporotic fracture in pregnancy is an alarming condition. Fortunately, it is rare and sporadic.

A novel synthetic pentasaccharide factor Xa inhibitor (fondaparinux) is undergoing clinical investigation.[26] Early results suggest that it may be even less likely to cause thrombocytopenia and osteoporosis than currently available antithrombotics. No data on pregnancy are available.

Warfarin (Coumarins)

Warfarins, prescribed by oral tablet, are vitamin K antagonists. They inhibit the complete synthesis of the vitamin K-dependent procoagulants (prothrombin, factors VII, IX, and X) as well as the anticoagulant proteins C and S. Because a degree of inhibition of coagulation is required for efficacy, but excessive warfarin use causes bleeding, close laboratory monitoring is critical. The adoption of

FIGURE 43–I
Anti-Xa levels in the first 12 hours after dalteparin administration, expressed as mean and 95% confidence intervals (12 weeks, $n = 29$; 24 weeks, $n = 26$; 36 weeks, $n = 24$; postpartum, $n = 24$).

the international normalized ratio (INR) system to express prothrombin time has ensured uniformity between laboratories. Prospective clinical trials established the appropriate target INR in a variety of clinical situations. However, there is a substantial risk of hemorrhage. In unselected series, the prevalence of life-threatening bleeding in subjects treated with warfarin was approximately 1 event per 100 treatment-years.[27] The risk is greatest in subjects with peripheral or cerebrovascular disease and in older patients. The risk may be lower in women of childbearing age. Bleeding is most likely to occur during the first weeks of warfarin therapy. The bleeding risk increases markedly when the INR is greater than 4.5, but approximately 25% of bleeds occur when the INR is less than 3.0. The principal cause of unexpected fluctuation in the INR is drug interaction.

Warfarin is teratogenic. Up to 30% of fetuses exposed between 6 and 10 weeks' gestation are affected. The developing skeleton is the principal target, with abnormalities ranging from subclinical stippling of the epiphyses on x-ray, to nasal deformity, to severe phocomelia. Because heparin is a safer alternative, warfarin is never used to manage VTE during the first trimester. Further, because of reports of intracranial abnormalities and developmental problems attributed to maternally derived inadvertent anticoagulation, warfarin is rarely the anticoagulant of choice to treat or prevent VTE in pregnancy. Commonly, anticoagulation with heparin that was instituted during pregnancy is switched to warfarin postpartum because of the ease of administration.

Mechanical Measures

Well-fitted graduated compression hosiery is widely used to prevent VTE. Although there are few data in pregnancy, there is evidence of efficacy perioperatively in nonpregnant patients. There is also evidence that symptoms of postphlebitic syndrome are less likely to develop if compression stockings are worn regularly for 2 years after an episode of lower limb deep vein thrombosis.[28] Whether below-the-knee stockings are as effective as full-length hosiery is the subject of debate.

Mechanical devices that stimulate calf muscle contraction have been used perioperatively to prevent deep vein thrombosis. They may be indicated in subjects who are not candidates for pharmacologic thromboprophylaxis because of a high risk of bleeding.

Filters that can be located in the inferior vena cava, either temporarily or permanently, have been used in subjects with proximal lower limb deep vein thrombosis who are considered to be at high risk for pulmonary embolism. The frequency of their use varies substantially between nations and is low in the United Kingdom. Risks include inferior vena cava thrombosis and migration of the filter. Their principal use is in patients in whom anticoagulant therapy is contraindicated (e.g., those with recent cerebral hemorrhage). Specific difficulties are associated with their use in pregnancy, in particular, the need to use radiologic screening to ensure safe placement and the possibility of compression of the inferior vena cava by the gravid uterus. Successful use has been reported,[14] however, and these devices may be helpful in some postpartum patients.

Management Options: Established VTE in Pregnancy

Treatment protocols with heparin have been based largely on those used in nonpregnant individuals and seem safe and effective. Treatment with heparin should be initiated when there is clinical suspicion of deep vein thrombosis and continued after the diagnosis is confirmed. Because of the advantages of LMWH (described earlier), most clinicians consider LMWH the anticoagulant of choice. LMWH should be administered by subcutaneous injection at the recommended dose for the particular product, based on prepregnancy body weight. Although there is evidence of more rapid clearance of LMWH in later pregnancy, once-daily administration appears to be satisfactory. Laboratory monitoring for the anticoagulant effect is not essential, although many clinicians prefer to ascertain that the plasma concentration of LMWH is within the therapeutic range on at least one occasion once treatment is established. Coagulation times, such as aPTT, are not of value for this purpose. The aPTT may remain within the nontherapeutic range, even in patients who are given full doses of LMWH. The anti-Xa assay gives an indication of the pharmacologic

response, but is a poor predictor of further thrombosis and provides limited information on bleeding risk.[29] A peak (3–4 hours after injection) plasma anti-Xa concentration of 0.4 to 1.0 anti-Xa units appears to be acceptable. A level greater than 1.0 suggests that the daily dose could be reduced.

Treatment with UH is initiated by intravenous bolus injection of at least 5000 units, followed by continuous intravenous infusion at an initial rate of 1000 units hourly, with adjustment to maintain the aPTT ratio to control of 1.5 to 2.5. This value is often difficult to achieve, especially in late pregnancy. Once the patient's condition is stabilized, the dose of heparin can be delivered in 12-hourly divided doses by subcutaneous injection.

Whether UH or LMWH is administered, the platelet count should be monitored from day 5 until at least day 20. A progressive, unexplained decrease in the platelet count suggests heparin-induced thrombocytopenia, although this complication is rare in this patient group. Heparin should be discontinued and alternative strategies considered until the diagnosis can be reasonably excluded. Although lepirudin is the alternative anticoagulant of choice in the nonpregnant patient with heparin-induced thrombocytopenia, there is no information on its use in pregnancy. The heparin-like preparation danaparoid may be a better choice.

The anticoagulant effect of UH can be reversed rapidly with protamine. However, protamine is of limited efficacy in reversing the effect of LMWH. If bleeding occurs, treatment is supportive, with red cell transfusion if indicated. Plasma infusion is of no value.

The initial management of most cases of pulmonary embolism is comparable to that of deep vein thrombosis. The exception is life-threatening massive pulmonary embolism, in which the relative risks of surgical embolectomy and thrombolytic therapy must be considered urgently.

Additional management issues should be considered. Elevating the affected limb helps to relieve symptoms, but analgesia is frequently necessary because of the considerable swelling and discomfort caused by proximal venous occlusion or pulmonary infarction. Bed rest is not indicated. Compression stockings should be used as soon as resolution of swelling allows them to be worn without discomfort.

Full-dose heparin treatment should be maintained to term. Once labor has begun, the patient should be advised to withhold the next dose of heparin. A recent concern has arisen about the safety of spinal or epidural anesthesia in laboring women who are receiving anticoagulants.[30] For this reason, some clinicians opt to switch from LMWH to UH at approximately 36 weeks' gestation, taking advantage of the shorter half-life of UH. Insertion and withdrawal of a spinal catheter should be avoided within 12 hours of a therapeutic dose. Whether risk is increased after this period is unclear, but the potential risk must be balanced against the needs for analgesia and anesthesia during labor.

If no abnormal bleeding occurs during delivery, heparin is reintroduced 12 to 24 hours postpartum. Alternatively, warfarin may be introduced (along with heparin) and continued postpartum. In this case, heparin is discontinued only when an INR of 2.0 or greater is achieved with warfarin therapy. Treatment is continued with a target INR of 2.5 for 6 weeks postpartum or a total of 6 months from the initial diagnosis of VTE, whichever is longer. Although warfarin is secreted in breast milk, the breast-fed neonate of a treated mother is not adversely affected. However, warfarin is best avoided when the mother is expressing milk to feed to a severely premature neonate.

SUMMARY OF MANAGEMENT OPTIONS
Established Thromboembolism in Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Initial Management	Ia/Ib	A	32–36
Give unfractionated heparin (UH) 5000–10,000 units IV loading dose then continuous IV 1000–2000 U/hr or low-molecular-weight heparin (LMWH) [for example, dalteparin 5000 units three times daily SC].			
Monitor activated partial thromboplastin time (UH) or peak heparin level (anti-Xa) [LMWH]; obtain serial platelet counts.			
Maintenance	Ia	A	36–38
Give UH (10,000 units SC twice daily) or LMWH (dalteparin 5000 three times daily).			
Monitor activated partial thromboplastin time (1.5–2.5 times control) [UH] or peak anti-Xa(>0.2 Us/mL) [LMWH]; obtain platelet counts.			

SUMMARY OF MANAGEMENT OPTIONS
Established Thromboembolism in Pregnancy *(Continued)*

Management Option	Quality of Evidence	Strength of Recommendation	References
Intrapartum	IIa	B	39,40
Temporarily discontinue therapy with onset of labor.			
Epidural block and operative delivery are not contraindicated if clotting is normal.			
Reinitiate treatment with UH or LMWH approximately 12 hours after delivery if no active bleeding occurs.			
Postpartum	IIa	B	34,39,41,42
Continue LMWH, UH, or warfarin (with monitoring) for 6 weeks or at least 6 months after an acute event.			
Measure bone density of the maternal spine and hip if long-term therapy is anticipated.			
Graduated elastic compression stockings should be worn for 2 years. Breast-feeding is not contraindicated.	III	B	43

Management Options: Thromboprophylaxis in Pregnancy

Thromboprophylaxis should not be offered to all pregnant women. Routine population screening for hereditary thrombophilias is not justified. In assessing thrombotic risk, acquired factors are at least as important as genetic predisposition. A history of VTE is an important consideration for thromboprophylaxis in pregnancy. In addition, patient age, parity, and weight are associated with venous thrombotic risk during pregnancy and in the puerperium. Immobilization and serious medical disorders are other important risk factors. In the postpartum period, the risk of venous thrombosis is increased in women who have had cesarean delivery, especially as an emergency procedure.

The risk of VTE in women with a history of thrombosis may be lower than previously considered. In a persuasive prospective study of 125 women who had a history of venous thrombosis and in whom antenatal thromboprophylaxis was withheld, the overall rate of recurrence was only 2.4%. No recurrence was reported in the subgroup of women who had a temporary risk factor at the time of the first event.[31] This study also suggested that the recurrence rate may be higher in heritable thrombophilia, but was too small to allow firm conclusions to be drawn. The risk of pregnancy-associated first occurrence of VTE in women with heritable thrombophilia has been overstated. The best available data show a substantial risk of approximately 1 in 3 in women with antithrombin deficiency. The risk is probably approximately 1 in 100 in asymptomatic patients with protein C deficiency and lower still in asymptomatic women with factor V Leiden.[4] Based on these observations, an attempt to stratify risk has been made, with recommendations for thromboprophylaxis of graded intensity, depending on these factors. Table 43–5 is modified from the recommendations of the British Committee for Standards in Haematology.[8] In deciding on the use of pharmacologic thromboprophylaxis based on the diagnosis of asymptomatic heritable thrombophilia (slightly increased risk), it must be borne in mind that this therapy is invasive, that approximately 5% of the healthy female population will be so classified, and that most do not have pregnancy-related VTE. The recommendations are pragmatic because there are no randomized controlled trials.

The use of compression stockings antenatally and postpartum is a reasonable precaution at all levels of increased risk. In general, for the reasons discussed earlier, LMWH is preferable to UH for pharmacologic thromboprophylaxis. The use of preloaded syringes is convenient and increases safety. The platelet count must be monitored. If anti-Xa levels are used to guide dosing of LMWH, the factors discussed earlier should be considered in the interpretation of the results. Warfarin can be used for postpartum prophylaxis, with a target INR of 2.5. Recently updated thromboprophylaxis recommendations have been published by the Royal College of Obstetricians and Gynaecologists.[53]

TABLE 43–5

Recommendations for Thromboprophylaxis in Pregnancy

RISK CATEGORY	MANAGEMENT
Slight Women who have no personal history of venous thrombosis, but a positive family history and who are heterozygous for protein S deficiency, heterozygous for factor V Leiden, or heterozygous for prothrombin G20210A Women with a history of venous thrombosis in association with a temporary risk factor that is no longer present	In general, pharmacologic thromboprophylaxis is not required antenatally, but anticoagulant prophylaxis may be considered after delivery in those with previous venous thromboembolism and others who have an additional risk factor.
Intermediate Women who have a personal history of apparently spontaneous venous thromboembolism who are no longer receiving anticoagulant prophylaxis Women who have no personal history of venous thrombosis, but a positive family history of venous thrombosis and who are heterozygous for protein C deficiency, are homozygous for factor V Leiden or the prothrombin G20210A mutation, or have combinations of defects	Postpartum thromboprophylaxis with heparin or warfarin should be given. Antenatal thromboprophylaxis should be considered, such as fixed prophylactic doses of unfractionated or low-molecular-weight heparin (e.g., 4000–5000 units dalteparin once daily SC or unfractionated heparin 7500 IU every 8–12 hours SC).
High Women who are receiving long-term anticoagulant therapy for venous thromboembolism Women who have type I antithrombin deficiency or a type II reactive site antithrombin defect (regardless of whether they have had a thrombotic episode)	Adjusted doses of low-molecular-weight or unfractionated heparin, higher than those usually used to prevent venous thrombosis, should be administered (e.g., low-molecular-weight heparin introduced at approximately dalteparin 75 units/kg early pregnancy weight every 12 hours SC; the dose may be adjusted to give a peak anti-Xa level of 0.35 to 0.5 units 3–4 hours after injection). The use of fixed prophylactic doses of unfractionated or low-molecular-weight heparin (e.g., heparin 7500 IU every 12 hours SC or dalteparin 4000–5000 units once daily SC, respectively) is an alternative strategy.

From Walker ID, Greaves M, Preston PE: Investigation and management of inherited thrombophilia. Br J Haematol 2001;114:512–528.

SUMMARY OF MANAGEMENT OPTIONS

Thromboprophylaxis in Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Low Risk Patients	Ia	A	38,44,45,53
Initiate low-molecular-weight heparin (LMWH) (dalteparin 5000 units daily SC) or unfractionated heparin (UH) 7500 units twice daily SC after delivery.			
Continue LMWH or UH for 6 weeks postpartum or convert to oral warfarin after 1 week of heparin treatment.			
Breastfeeding is not contraindicated.			
High Risk Patients	III	B	38,46–48,53
Initiate LMWH (dalteparin enoxaprim, tinzaparin—see reference for dosage), increasing to twice daily after 20 weeks' gestation, or UH 10,000 units twice daily SC on diagnosis.			
Give UH or LMWH for 1 week postpartum, then continue heparin, LMWH, or warfarin for 5 weeks.			
Breastfeeding is not contraindicated.

CONCLUSIONS

- Thromboembolism is an important cause of maternal death, and effective preventative measures are available.
- Pregnancy increases the risk of thromboembolism. Additional risk factors include maternal age, obesity, a family history of thromboembolism, a previous thromboembolic event, immobility, cesarean delivery, and air travel.
- Women with a personal or family history of recurrent thromboembolism may be tested for an inherited thrombophilia.
- Key management strategies for a woman with a thromboembolic event are as follows:
  - Induction of intravenous or subcutaneous heparin, followed by maintenance therapy, with brief suspension of therapy for labor and delivery
  - Continuation of treatment for at least 6 weeks after delivery
- Thromboprophylaxis is the key management strategy for a woman with a previous thromboembolic event. The extent and type of thromboprophylaxis are determined by the nature of the risk.
- Anticoagulation is not a contraindication to breastfeeding.

Autoimmune Diseases

T. Flint Porter / D. Ware Branch

INTRODUCTION

The immune system's remarkable ability to protect the body from invasion by foreign pathogens stems from its capacity to distinguish biologic "self" from "nonself." An aberration in this normally well-regulated process leads to a state of so-called *autoimmunity*, in which immune effector cells are directed against "self" tissues. Persistent immunologic activation results in an *autoimmune disease*, characterized by a typical pattern of clinical signs and symptoms of disease and confirmed by the serologic presence of immune effector cells, usually autoantibodies. For many autoimmune conditions, serologically detected autoantibodies play an active role in tissue damage. In others, their presence may serve only to confirm the existence of an autoimmune process.

The pathophysiologic mechanisms that lead to autoimmune diseases have been studied extensively. The earliest theory held that autoimmunity resulted from a failure in the normal deletion of lymphocytes that recognized self-antigens. More recently, investigators have suggested that autoimmunity results from a failure of the normal regulation of the immune system (which contains many immune cells that recognize self-antigens but are normally suppressed). Regardless of what fundamental immunologic disturbance allows autoimmunity, it appears that a combination of environmental, genetic, and host factors must be present for the full expression of an autoimmune disease.

Autoimmune diseases have a predilection for reproductive-age women and are frequently encountered during pregnancy. Indeed, more than 70% of patients with autoimmune disease are women of reproductive age.[1] Studies in both animal models and humans support the role that sex hormones play in the development of autoimmunity; estrogens accelerate disease while androgens are protective.[2-6] It should come as no surprise that pregnancy-associated fluctuations in sex hormones substantially influence disease severity. Interestingly, the effect of pregnancy depends on whether the autoimmune disease is innate (cellular) or adaptive (humoral) in nature. Diseases with strong cellular pathophysiology, such as rheumatoid arthritis (RA) and multiple sclerosis, are associated with remission during pregnancy, whereas diseases characterized by autoantibody production, such as systemic lupus erythematosus (SLE) and Graves' disease, tend toward increased severity in pregnancy. Still others are unique to pregnancy or have unique features associated with pregnancy. Thus, the obstetrician should be familiar with the more common autoimmune diseases, how they influence and are influenced by pregnancy, and what special medical risks may be in store for mother or the conceptus.

SYSTEMIC LUPUS ERYTHEMATOSUS

General

Systemic lupus erythematosus is an idiopathic chronic inflammatory disease that affects skin, joints, kidneys, lungs, serous membranes, nervous system, liver, and other organs of the body. Like other autoimmune diseases its course is characterized by periods of remission and relapse. The most common complaint among patients with SLE is extreme fatigue (Table 44–1). Fever, weight loss, myalgia, and arthralgia are also particularly common symptoms.

The prevalence of SLE is 5 to 100 per 100,000 individuals, depending on the population studied. The disease is at least 5, and probably closer to 10 times, more common among adult women than adult men.[1] The lifetime risk of developing SLE for a white woman is 1 in

TABLE 44-1

Approximate Frequency of Clinical Symptoms in SLE

SYMPTOMS	PATIENTS (%)
Fatigue	80–100
Fever	80–100
Arthralgia, arthritis	95
Myalgia	70
Weight loss	>60
Skin	
Butterfly rash	50
Photosensitivity	60
Mucous membrane lesions	35
Renal involvement	50
Pulmonary	
Pleurisy	50
Effusion	25
Pneumonitis	5–10
Cardiac (pericarditis)	10–50
Lymphadenopathy	50
CNS	
Seizures	15–20
Psychosis	<25

700,[7] with an overall incidence of 1 in 2000 in the United States. The incidence varies among populations and is approximately two to four times higher in African Americans and Hispanic Americans.[7] A genetic predisposition to SLE is likely, given that approximately 10% of patients with SLE also have an affected relative[8]; concordance between twins is reportedly greater than 50%.[9] Several alterations in the human leukocyte antigen (HLA) system have been linked to the development of SLE, and homozygous carriers of mutations responsible for complement deficiency disorders also appear to be predisposed to development of the disease.

Diagnosis

Serologic Markers

The diagnosis of SLE, suspected by the clinical presentation, is confirmed by demonstrating the presence of circulating autoantibodies. Patients are initially screened for nonspecific antibodies directed against nuclear antigens. Cumbersome biologic assays of antibodies directed against nucleoprotein (nucleohistone) commonly referred to as the *LE phenomenon*, have been replaced by immunofluorescent assays for nonspecific antinuclear antibodies (ANA). Findings are interpreted according to antibody titer and to some degree on the pattern of antibody binding. The *homogeneous* pattern is found most commonly in patients with SLE (65%), though its specificity is low. A peripheral pattern is the most specific for SLE, even if it is not very sensitive. The speckled and nucleolar patterns are more specific for other autoimmune diseases.

Immunofluorescent assays that identify specific nuclear antigen-antibody reactions are better for confirming the diagnosis of SLE, monitoring disease activity, and guiding immunotherapy. Particularly useful are anti-double-stranded DNA (anti-dsDNA) antibodies, present in 80% to 90% of patients with newly diagnosed SLE, elevations of which precede symptomatic flare in 80% of SLE patients followed prospectively.[10,11] In one randomized, placebo-controlled trial, glucocorticoid treatment in patients with elevated anti-dsDNA titers resulted in fewer relapses of disease. In pregnancy, anti-dsDNA antibodies correlate with flare and preterm delivery.[11,12]

Antibodies to single-stranded DNA (anti-ssDNA) are also found in a large number of untreated SLE patients, but are less specific for SLE than anti-dsDNA. Patients with SLE may also have antibodies to RNA-protein conjugates, often referred to as *soluble or extractable antigens*, since they can be separated from tissue extracts. These antigens include the Sm antigen, nuclear ribonucleoprotein (nRNP), the Ro/SS-A antigen, and the La/SS-B antigen. The Sm and nRNP antigens are nuclear in origin, and the presence of anti-Sm, found in about 30% to 40% of patients with SLE, is highly specific for the disease. Anti-Ro/SS-A and anti-La/SS-B, found in the sera of both SLE patients and patients with Sjögren's syndrome, are of particular importance to obstetricians, because they are associated with neonatal lupus.

Diagnostic Criteria

In 1971, the American Rheumatism Association devised criteria for SLE as a framework for comparing studies of patients with SLE. These were revised in 1982[13] and again in 1997[14] (Table 44–2). To be classified as having SLE, an individual must have at least 4 of 11 clinical and laboratory criteria at one time or serially. These criteria are very sensitive and specific for SLE, but were never intended to form the *sine qua non* for the diagnosis of SLE. Many patients have less than four clinical or laboratory features of SLE and do not meet strict diagnostic criteria. Exclusion of patients with an autoimmune diathesis from the diagnosis of SLE by the dogmatic use of strict diagnostic criteria can result in patients being confused and frustrated. Although these patients should not be considered to have SLE, they are often referred to as having lupus-like disease. Such individuals may benefit from therapies for SLE and often require special care during pregnancy. A subset of these patients will ultimately develop the clinical syndrome.

Lupus Nephritis

Clinically obvious renal disease is a relatively common complication of SLE, eventually occurring in about 50% of patients with SLE. Lupus nephropathy probably results from immune complex deposition leading to complement activation and inflammatory tissue damage in

TABLE 44–2

Revised American College of Rheumatology Classification Criteria for SLE

CRITERION	DEFINITION
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring possible in older lesions
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	a) Pleuritis—convincing history of pleuritic pain or rubbing heard by a physician, or evidence of pleural effusion
	b) Pericarditis—documented by ECG or rub or evidence of effusion
7. Renal	a) Persistent proteinuria >0.5 g/day or >3+ if quantitation not performed
	b) Cellular casts—red cell, hemoglobin, granular, tubular, or mixed
8. Neurologic	a) Seizures—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance)
	b) Psychosis—in the absence of drugs or metabolic derangements
9. Hematologic	a) Hemolytic anemia—with reticulocytosis
	b) Leukopenia—<4,000/μL on 2 or more occasions
	c) Lymphopenia—<1,500/μL on 2 or more occasions
	d) Thrombocytopenia—<100,000/μL in absence of drugs
10. Immunologic	a) Anti-DNA—antibody to native DNA in abnormal titer
	b) Anti-Sm—presence of antibody to Sm nuclear antigen
	c) Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis for 6 months
11. Antinuclear antibody	An abnormal ANA titer by immunofluorescence or an equivalent assay at any time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome

From Tan EM, Cohen AS, Fries JF, et al: The 1982 revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum 1982;25:1271–1277 and Hochberg MC: Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum 1997;40:1725.

the kidney. The most common presentation is proteinuria, which occurs at some time in up to 75% of patients. About 40% of patients will have hematuria or pyuria, and about a third will have urinary casts.

Renal biopsy is necessary to confirm the diagnosis of lupus nephropathy and is important for determining the prognosis and providing appropriate treatment. Renal biopsy findings are used to group lupus nephropathy into four basic histologic and clinical categories. Of these, *diffuse proliferative glomerulonephritis* (DPGN) is the most common (40%) and most severe, with 10-year survival around 60%. Patients with DPGN typically present with hypertension, moderate to heavy proteinuria and nephrotic syndrome, hematuria, pyuria, casts, hypocomplementemia, and circulating immune complexes. *Focal proliferative glomerulonephritis* is usually associated with mild hypertension and proteinuria; serious renal insufficiency is uncommon. *Membranous glomerulonephritis* typically presents with moderate to heavy proteinuria but lacks the active urinary sediment and does not cause renal insufficiency. *Mesangial glomerulonephritis* appears to be the least clinically severe lesion and carries the best long-term prognosis.

The first line of therapy in patients with active lupus nephropathy has traditionally been glucocorticoids, usually given as oral prednisone, 40 to 50 mg/day for several weeks to several months. Thereafter, the dose is tapered while carefully watching the patient for evidence of signs and symptoms of worsening disease. Severe proliferative lesions, such as seen in moderate to severe DPGN, have been shown to respond best to cytotoxic agents. Cyclophosphamide, in a divided monthly dose of 0.5 to 1.0 g/m^2, is now generally used.

Lupus Cerebritis

Up to 20% of patients with SLE develop CNS manifestations of their disease, also referred to as lupus cerebritis. Patients most often present with new onset seizures, although peripheral neuropathy, headaches, chorea, stroke, mood disorders, transverse myelitis, and psychosis are also reported. The severity of lupus cerebritis may also be influenced by other problems commonly encountered in patients with SLE, including metabolic abnormalities, infection, and chronic steroid use. An evaluation for lupus cerebritis should include an assessment for the presence of infection, including lumber puncture if necessary, radiologic imaging, and electroencephalogram. Patients with lupus cerebritis who present with chorea, transverse myelitis, or stroke should be tested for antiphospholipid antibodies. Empiric therapy for lupus cerebritis typically includes glucocorticoids as a first-line therapy, with cyclophosphamide and intravenous immune globulin (IVIG) reserved for refractory cases.

Risks of SLE and Pregnancy

The Risk of SLE Exacerbation (Flare)

Whether pregnancy is associated with a higher rate of SLE exacerbation is a matter of considerable debate.

Early studies on the subject were hampered by poor study design, not to mention the difficulty differentiating between normal manifestations of pregnancy and the signs and symptoms typically associated with SLE. At the same time, common complications of pregnancy such as preeclampsia may mimic exacerbations of SLE.

Between the early 1950s and the early 1970s, the findings of several small retrospective series suggested that women with SLE were placing themselves at substantial risk for severe morbidity and even mortality during pregnancy.[15] Many also reported relatively high rates of pregnancy wastage among women with SLE.[16] These concerns led many practitioners to the opinion that SLE patients should not become pregnant. However, these early studies were plagued by several problems, and their conclusions should not be the basis of clinical decision making today. All were retrospective, relatively small, and, because of the lack of generally agreed-upon criteria for the classification of SLE, were predisposed to include a disproportionate number of more severe cases. In addition, without standardized diagnostic criteria for SLE exacerbation, early investigators may have incorrectly diagnosed preeclampsia and other obstetric complications as SLE exacerbations.

Studies done since 1980 have done much to clarify the relationship of pregnancy to the rate and nature of SLE exacerbations. Overall, the rate of flare during pregnancy or the postpartum period varies between 15% to 60% of women.[8,17–29] Several prospective studies deserve special consideration. Lockshin and colleagues[17] matched nonpregnant SLE patients with 28 SLE patients undertaking 33 pregnancies and used a previously published scoring system to define SLE exacerbations. There was no difference in the flare score between the cases and controls, and a similar number in both groups required a change in their medication. The same investigators have now followed 80 consecutive pregnancies in women with SLE and conclude that exacerbations occur in less than 25% of cases and that most are mild in nature. If only signs or symptoms specific for SLE are included, exacerbations occurred in only 13% of cases.

Mintz and colleagues[19] prospectively studied 92 pregnancies in women with SLE and used a similar group of nonpregnant SLE patients on oral contraceptives derived from a previous study as controls. Exacerbations were defined by criteria different from those used by Lockshin and colleagues. As a matter of policy, all pregnant women were started on 10 mg prednisone daily, even if there was no evidence of SLE activity. The rate of SLE flares per month at risk was similar in both groups. As in Lockshin's studies, most of the exacerbations tended to be easily controlled with low to moderate doses of glucocorticoids, but seven patients (8%) had severe exacerbations requiring more aggressive therapies. Interestingly, the majority (54%) of the exacerbations occurred in the first trimester.

Using criteria for SLE flare that differed from either of the other two studies, Petri and colleagues[8] found SLE flares (flares per person-years) to be more common among pregnant women than among controls. Fortunately, over three quarters of the flares were mild to moderate in nature.

Urowitz and colleagues[21] reported their experience comparing 79 pregnancies in patients with active SLE to a matched control group of 59 nonpregnant women with active SLE. They also compared these women to 216 women with inactive disease. Using a previously defined SLE exacerbation score, they found no significant differences in disease activity between the three groups. Only inactive patients at the onset of pregnancy showed a significant reduction in SLE activity (41%).

Ruiz-Irastorza and colleagues[22] analyzed the course of SLE in 78 pregnancies in 68 patients and a matched control group of 50 nonpregnant women. Sixty-five percent of the patients experienced an exacerbation of SLE during pregnancy, for a flare rate of 0.082 per patient-month. In the control group, 42% of the patients experienced a flare, with a flare rate of 0.039 per patient-month, representing a statistically significant difference.

Georgiou and colleagues[27] prospectively evaluated the frequency of SLE exacerbation during 59 pregnancies in 47 women with SLE and 59 nonpregnant women matched for parameters other than disease activity and duration. Using accepted clinical criteria, they reported SLE exacerbation in 8 (13.5%) of pregnant patients compared to 13 (22%) of nonpregnant women. More than half of the exacerbations in the pregnant group occurred during the first trimester. As in the previous studies, all exacerbations were mild and easily treated with glucocorticoids.

Preexisting disease activity undoubtedly plays a large role in risk of SLE flare during pregnancy. Derksen and colleagues[25] reported that SLE exacerbation occurred in fewer than 20% of women with sustained remission prior to pregnancy. More recently, Cortez-Hernandez and colleagues[28] studied 60 women with 103 pregnancies and found that SLE exacerbations during pregnancy were more likely in women who discontinued maintenance therapy before pregnancy and/or had a history of more than three severe flares prior to pregnancy. The findings of several other studies support the notion that women with active disease should postpone pregnancy until sustained remission can be achieved.[26,27,29]

In summary, the question of whether pregnancy predisposes to SLE exacerbation is not yet settled. At most, the predisposition to SLE flare during pregnancy is modest. Importantly, in a majority of studies of pregnant women with SLE, flares have been mild to moderate in nature and easily treated with glucocorticoids.[17,19,21,22,26,27,29] Moreover, the routine use of glucocorticoids or antimalarial agents in all pregnant SLE patients, as suggested by some investigators, seems

unwarranted in view of the excellent results achieved by others without routine prophylactic immunosuppression.

The Risk of Lupus Nephritis Exacerbation

Women with lupus nephropathy face several challenges during pregnancy. Not only is there some evidence suggesting that pregnancy may worsen renal function. In turn, underlying renal disease presages increased risks of maternal and fetal complications. In addition, those with chronic renal disease are likely to have worsening proteinuria during gestation as renal perfusion increases. In turn, this inevitably poses the question of whether the increased proteinuria represents an exacerbation of underlying renal disease, preeclampsia, or both.

Whether renal flares are more common in pregnancy in all women with SLE remains controversial. Two studies reported high frequencies of renal flares (43% to 46%) during pregnancy,[30,31] whereas others have reported lower figures (9% to 28%).[19,22,32,33] Three studies describe the patients' status during pregnancy in terms of whether the SLE was active or in remission prior to conception.[34-36] In all three, the rate of SLE exacerbation was lower among pregnancies in which the patient was in remission prior to conception.

Studies on pregnancy outcome in women with past or current SLE nephritis are scarce. This may be explained, in part, by (1) the reduced fertility associated with long-term cyclophosphamide or impaired renal function, or both, and (2) the classical assumption that pregnancy should be discouraged in women with a history of lupus nephritis. The earliest reports suggested that lupus nephropathy was a major contributor to serious maternal morbidity or death.[15,16,37] However, larger, more recent series suggest that the outlook for pregnancy in women with lupus nephropathy is usually favorable if the disease is well-controlled and renal function preserved.[38] Oviasu and colleagues[39] reviewed eight studies (151 pregnancies) published between 1973 and 1991 on the effect of completed pregnancy on maternal renal function in established lupus nephritis, and reported that transient deterioration of renal function occurred in only 17% of pregnancies and permanent deterioration in 8%.

Even better outcomes were reported in three studies published in the 1990s.[39-41] Out of 143 patients with lupus nephropathy, only 1 developed irreversible loss of renal function after pregnancy. Importantly, the majority of women in these studies had normal renal function, mild proteinuria, and well-controlled hypertension *before* conception. Petri and colleagues at the Hopkins Lupus Pregnancy Center reported that only women who began pregnancy with nephrotic syndrome went on to renal failure after delivery.[32] Hayslett and Lynn[34] and Bobrie and colleagues[36] also found that the rate of renal deterioration was somewhat lower among pregnancies in which the patient was in remission prior to conception. Most recently, Moroni and colleagues[42] reported that renal flare occurred in 5% (1/20) of pregnancies in women with inactive lupus nephropathy prior to conception compared to 39% (12/31) in women with active lupus nephropathy prior to conception ($P < 0.01$). The sole predictors for renal flare were a plasma creatinine greater than 1.2 mg/dL or proteinuria ≥500 mg in 24-hour collection. Permanent deterioration occurred in two women with active lupus nephropathy prior to conception, one of whom eventually died.

Based on the published data summarized in Table 44-3, approximately one third of women with lupus nephropathy experience SLE exacerbation during pregnancy and 21% experience some form of renal deterioration. The median rate for permanent deterioration is 7%. Women with inactive lupus nephropathy prior to conception rarely suffer permanent deterioration during pregnancy.

Medical prudence would strongly suggest that pregnancy is contraindicated in patients with active lupus nephropathy (especially DPGN), nephrotic syndrome, and severe hypertension. Pregnancy should only be attempted if immunosuppressive therapy is effective in reducing disease activity, and antihypertensive therapy reduces blood pressure to acceptable levels. Moderate renal failure (creatinine 1.5 to 2.0 mg/dL) is a relative contraindication to pregnancy, and advanced renal failure (creatinine >2.0 mg/dL) should be considered an absolute contraindication to pregnancy.

Problems of Detection of SLE Exacerbation (Flare) in Pregnancy

Thorough and frequent clinical assessment remains essential for the timely and accurate detection of SLE exacerbation. However, detection of flare during pregnancy is hampered by the fact that many of the typical signs and symptoms associated with flare are considered normal manifestations of pregnancy. In addition, common complications of pregnancy such as preeclampsia may be mistaken for SLE exacerbation. Nevertheless, criteria for measuring SLE flare during pregnancy have been recently tested and have been found valid.[46] As in all patients with SLE, the most common presenting symptom of flare during pregnancy is extreme fatigue (see Table 44-1). In addition, skin lesions occur in >90% and arthritis/arthralgias >80% SLE exacerbations during pregnancy.[27,31]

Serologic evaluation of SLE disease activity may be beneficial in confirming flare in confusing cases. Most specific are elevations in anti-dsDNA titers that precede lupus flare in more than 80% of patients.[10,11] In pregnancy, elevated anti-dsDNA titers have also been shown to correlate with the need for preterm delivery.[12] In combination with anticardiolipin antibodies, elevated levels of anti-dsDNA are associated with an increased risk of fetal loss.

Early reports suggested that serial serologic evaluation of complement components and activation products were

PTC, prior to conception.

beneficial in predicting SLE flare during pregnancy. In two studies, Devoe and colleagues[45,47] found that SLE exacerbation was signaled by a decline of C3 and C4 into the subnormal range. More recently, Buyon and colleagues[48] found that SLE exacerbation was associated with an absence of the usual increase in C3 and C4 levels during normal pregnancies. However, the practical utility of serial determinations of complement components or their activation products during pregnancy remains unproven. Lockshin and colleagues[49] reported that low-grade activation of the classical pathway may be attributed to pregnancy alone. Wong and colleagues[30] prospectively studied 19 continuing SLE pregnancies and found that neither ANA, C3 nor C4 levels predicted which patients were going to have a flare; Nossent and Swaak[50] observed that fewer than half of the pregnancies with decreased serum C3 levels were associated with a clinical SLE flare. Finally, although some have found that hypocomplementemia has been reported to correlate with poor pregnancy outcomes,[51-53] there is also evidence that hypocomplementemia may occur in pregnant patients without SLE and no adverse pregnancy outcomes.[54]

Laboratory confirmation of SLE flare is probably most helpful in women with active lupus nephropathy in whom proteinuria, hypertension, and evidence of multiorgan dysfunction may easily be confused with preeclampsia. Table 44-4 outlines features that may prove helpful in distinguishing between the two conditions. Preeclampsia is more likely in women with decreased levels of antithrombin III.[55,56] Complement concentrations are not always helpful because activation may also occur in women with preeclampsia.[57] In the most severe and confusing cases, the correct diagnosis is

possible only by renal biopsy. However, in reality, concerns about maternal and fetal well-being often prompt delivery, rendering the distinction between SLE flare and preeclampsia clinically moot.

Risks of Immunosuppressive Agents in Pregnancy

GLUCOCORTICOIDS

The group of drugs most commonly given to pregnant women with SLE is the glucocorticoid preparations, both as maintenance therapy and in "bursts" to treat suspected SLE flares. The doses used in pregnancy are the

same as those used in nonpregnant patients. Pregnancy per se is not an indication to reduce the dose of glucocorticoids, though a carefully monitored reduction in dosage may be reasonable in appropriately selected women whose disease appears to be in remission.

Some groups have recommended prophylactic glucocorticoid therapy during pregnancy,[19,29,33] but there are no controlled studies to show this practice to be prudent or necessary in the face of inactive SLE. Moreover, good maternal and fetal outcomes are achieved without prophylactic treatment of women with stable disease.[25] In contrast, glucocorticoid treatment of women with active disease and/or elevated anti-dsDNA titers has been shown to result in fewer relapses and better pregnancy outcomes.[11,27]

Although glucocorticoids have a low potential for teratogenesis, they are not without risk during pregnancy. Patients requiring chronic maintenance therapy are best treated with prednisolone or methylprednisolone because of their conversion to relatively inactive forms by the abundance of 11-β-ol dehydrogenase found in the human placenta. Glucocorticoids with fluorine at the 9-α position (dexamethasone, betamethasone) are considerably less well metabolized by the placenta, and chronic use during pregnancy should be avoided. Both have been associated with untoward fetal effects. Maternal side effects of chronic glucocorticoid therapy are the same as in nonpregnant patients and include weight gain, striae, acne, hirsutism, immunosuppression, osteonecrosis, and gastrointestinal ulceration. During pregnancy, chronic glucocorticoid therapy has also been associated with an increased risk of preeclampsia,[58-60] uteroplacental insufficiency and intrauterine growth restriction (IUGR),[61] and glucose intolerance.[59,60] Women undergoing chronic treatment with glucocorticoids should be screened for gestational diabetes at 22 to 24 weeks', 28 to 30 weeks', and 32 to 34 weeks' gestation.

ANTIMALARIALS

An accumulating body of evidence suggests that antimalarial drugs, such as hydroxychloroquine, may be used safely for the treatment of SLE during pregnancy.[52-66] In the past, many patients and their physicians have discontinued antimalarials during pregnancy because of concerns about teratogenicity, including ototoxicity[67] and eye damage.[68] The latter was of particular concern because of the affinity of antimalarials for melanin containing tissues found in the eye. However, hydroxychloroquine has been used in women considered at risk for malaria for years without any reported adverse fetal effects. This experience has been confirmed in recent large series showing hydroxychloroquine to be relatively safe during pregnancy.[62-65] Furthermore, they may be more beneficial than glucocorticoids for women who need maintenance therapy during pregnancy. In a recent randomized controlled trial, women who continued hydroxychloroquine during pregnancy experienced a significant reduction in

SLE disease activity compared to women who changed to glucocorticoid therapy.[69] The findings of a recent case-control trial, which compared the effects of in utero exposure to hydroxychloroquine, were very reassuring.[66] There were no differences between 122 infants with in utero exposure to hydroxychloroquine and 70 control infants in the number and type of defects identified at birth or in the proportion of infants with visual, hearing, growth, or developmental abnormalities at follow-up (median, 24 months).

CYTOTOXIC AGENTS

Cytotoxic agents, including azathioprine, methotrexate, and cyclophosphamide, are used to treat only the most severely affected patients with SLE. Limited data suggest that azathioprine, a derivative of 6-mercaptopurine, is not a teratogen in humans but has been associated with IUGR[70,71] and evidence of impaired neonatal immunity.[72] Women who require azathioprine to control SLE disease activity should not necessarily be discouraged from becoming pregnant, though potential fetal risks should be carefully weighed against the benefits of the medication. Cyclophosphamide has been reported to be teratogenic in both animal[73] and human studies[74,75] and should be avoided during the first trimester. Thereafter, cyclophosphamide should be used only in unusual circumstances such as in women with severe, progressive proliferative glomerulonephritis.[76] Methotrexate is known to kill chorionic villi and cause fetal death, and its use should be scrupulously avoided.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

The most common types of analgesics used in the treatment of SLE outside of pregnancy are nonsteroidal anti-inflammatory drugs (NSAIDs). Unfortunately, they readily cross the placenta and block prostaglandin synthesis in a wide variety of fetal tissues. Maternal ingestion of normal adult doses of aspirin in the week before delivery has been associated with intracranial hemorrhage in preterm neonates.[77] Although short-term tocolytic therapy with indomethacin appears to be safe,[78,79] chronic use has been associated with a number of untoward fetal effects; when used after 32 weeks' gestation, chronic indomethacin therapy may result in constriction or closure of the fetal ductus arteriosus.[80] Long-term use of all NSAIDs has been associated with decreased fetal urine output and oligohydramnios as well as neonatal renal insufficiency.[81] Given these risks, chronic use of adult dosages of aspirin and other NSAIDs should be avoided during pregnancy, especially after the first trimester. Acetaminophen and narcotic-containing preparations are acceptable alternatives if analgesia is needed during pregnancy.

OTHER IMMUNOSUPPRESSIVE AGENTS

Several new treatment regimens including cyclosporine, high-dose IVIG, mycophenolate mofetil, and thalidomide, have been studied in the treatment of nonpregnant

patients with SLE.[76] Only IVIG has been used during pregnancy without reports of adverse fetal effects. Obviously, thalidomide is strictly contraindicated during pregnancy because of its known potent teratogenicity. Complete immunoablative therapy followed by bone marrow stem cell transplantation has also been studied in patients with the most severe, unresponsive SLE.[76]

TREATMENT OF SLE EXACERBATION IN PREGNANCY

Mild to moderate symptomatic exacerbations of SLE without CNS or renal involvement may be treated with initiation of glucocorticoids or an increase in the dose of glucocorticoids. Relatively small doses of prednisone (e.g., 15 to 30 mg/day) will result in improvement in most cases. For severe exacerbations without CNS or renal involvement, doses of 1.0 to 1.5 mg/kg/day of prednisone in divided doses should be used, and a good clinical response can be expected in 5 to 10 days. Thereafter, glucocorticoids may be tapered by several different approaches (Table 44–5).

Severe exacerbations, especially those involving the CNS or kidneys, are treated more aggressively. In recent years, an intravenous pulse glucocorticoid approach has become popular. The initial regimen involves a daily intravenous dose of methylprednisolone at 10 to 30 mg/kg (about 500 to 1000 mg) for 3 to 6 days. Thereafter, the patient is treated with 1.0 to 1.5 mg/kg/day of prednisone in divided doses and rapidly tapered over the course of 1 month. One can expect that 75% of patients will respond favorably to this approach.[82] This regimen may be repeated every 1 to 3 months in severe cases as an alternative to cytotoxic drugs.

In nonpregnant patients, both azathioprine and cyclophosphamide may be used in severe SLE exacerbations to control disease, reduce irreversible tissue damage, and reduce glucocorticoid doses.[83–85] In particular, severe proliferative lupus nephritis may be treated more effectively with cyclophosphamide, usually in combination with glucocorticoids.[85] The drug may be given either orally or intravenously, but the most effective cyclophosphamide regimen is uncertain. Cyclophosphamide appears to be useful in the treatment of severe cerebral lupus as well.

TABLE 44–5

Suggested Methods for Tapering Prednisone

1. Consolidate to a single morning dose of prednisone. Reduce the daily dose by 10% per week, as tolerated. When a dose of 20 to 30 mg/day is reached, reduce by 2.5-mg increments per week. If the patient remains asymptomatic at a dose of 15 mg/day, reduce the dose by 1-mg increments per week to a dose of 5 to 10 mg/day.
2. Consolidate to a single morning dose of prednisone. Taper to 50 to 60 mg/day by reducing the dose 10% per week. Thereafter eliminate the alternate-day dose by tapering it 10% per week, as tolerated. Thereafter, taper the remaining every other day dose by 10% per week, as tolerated.

Plasmapheresis and IVIG have been used to treat severe cases of SLE flare unresponsive to standard treatments. Plasmapheresis should be considered in life-threatening disease that is unresponsive to other treatments. A cytotoxic agent should also be administered soon after plasmapheresis is initiated (days 5 through 10 of therapy) if the patient is no longer pregnant. IVIG has been used for salvage treatment of recalcitrant SLE flare with neuropsychiatric or renal involvement.[86]

Obstetric Complications in Women with SLE

GESTATIONAL HYPERTENSION AND PREECLAMPSIA

The exact incidence of pregnancy-related hypertension associated with SLE is difficult to estimate due to inconsistencies in the definition and classification of these disorders, as well as the inclusion of patients with lupus nephropathy in the various studies. Nevertheless, it appears that between 20% and 30% of women with SLE develop either gestational hypertension or preeclampsia (gestational hypertension with proteinuria) sometime during pregnancy.[23,34,58,87–89] Women with lupus nephropathy are undoubtedly most vulnerable given the known association between preeclampsia and underlying renal disease of any origin.[90] In one prospective series, preeclampsia occurred in 7 of 19 (37%) women with lupus nephritis, compared with 15 of 106 (14%) without.[17] Other important predisposing factors include chronic hypertension, secondary antiphospholipid syndrome, and chronic steroid use.[23,34,40,41,43,91,92]

PREGNANCY LOSS

Women with SLE are probably more likely to have an unsuccessful pregnancy than women in the general obstetric population. The exact physiologic mechanisms responsible for pregnancy loss in women with SLE and other immunologic diseases remain uncertain, though a clear relationship between pregnancy failure and histologic evidence of inflammation has been well documented. Recent experimental observations suggest that altered complement regulation causes and may perpetuate pregnancy loss.[54]

In most retrospective studies, the rate of pregnancy loss appears to be higher in women with SLE than in the general obstetric population, ranging between 8% and 41%, with a median of 22%.[15,18,34,43,89,93–98] In one case-control trial comparing obstetric outcomes between 481 pregnancies in 203 lupus patients and 566 pregnancies in 177 healthy relatives and 356 pregnancies in 166 healthy unrelated women, investigators found that pregnancy loss occurred significantly more often in women with SLE (21%) than in either their healthy relatives (8%) or unrelated healthy controls (14%).[99] In the group of women with SLE and prior pregnancy, those whose diagnosis was made with SLE onset *after* their first pregnancy had a higher rate of loss once the diagnosis was made

(27% vs. 19%). The pregnancy loss rates observed in most prospective trials of lupus pregnancies have been better than those found in retrospective trials, possibly because of careful monitoring of SLE activity and routine antenatal surveillance. Still, from the data summarized in Table 44–6, between 11% and 34% of women with SLE experienced pregnancy loss, with a median of 24%. A disproportionate number of these occur in the second or third trimester. In the most recent, well-detailed prospective trials, fetal deaths in the second or third trimester accounted for between 10% and 40% of the total number of losses.[27,28]

Control of disease activity appears to have a salutary effect on the rate of pregnancy loss,[24] with one early study reporting live births in 64% of women with active disease within 6 months of conception, compared to 88% in women with quiescent disease.[34] In a more recent prospective study of pregnancy in SLE patients, pregnancy loss occurred in 75% of women with active disease compared to 14% of women with inactive disease.[27] Not surprisingly, pregnancy loss is more likely if SLE is diagnosed during the index pregnancy.[44,96,97]

Preexisting renal disease increases the rate of pregnancy loss in women with SLE. Table 44–7 summarizes obstetric outcomes in 411 pregnancies in 261 women with a diagnosis of lupus nephropathy prior to conception. Excluding therapeutic abortions, the median rates of miscarriage, fetal and neonatal death, and live birth were 13%, 7%, and 75%, respectively, figures not remarkably different from those for all patients with SLE shown in Table 44–6. Pregnancy loss rates in individual studies vary widely, probably because of variations in the degree of renal impairment of included patients, as well as definitions of pregnancy loss.

The degree of renal impairment no doubt influences the likelihood of pregnancy loss in women with lupus nephropathy. In a recent study of lupus nephropathy in

pregnancy that included only women with inactive disease and normal renal function (serum creatinine <0.8 mg/dL), the overall fetal survival rate was >90%, after exclusion of embryonic losses (losses <10 weeks' gestation).[102] These results contrast markedly to those of another study in which the rate of fetal loss was 50% in pregnant women with lupus nephropathy and moderate to severe renal insufficiency (serum creatinine ≥1.5 mg/dL).[34] In a study comparing obstetric outcomes according to the degree of renal impairment in women with lupus nephropathy, spontaneous abortion occurred in 26% of women with minimally impaired renal function (serum creatinine <1 mg/dL, creatinine clearance >80 mL/min, and proteinuria <1 g/day) and 36% in women with mild impairment (creatinine clearance 50–80 mL/min, proteinuria 1–3 g/day).[43]

Among SLE patients, fetal deaths are associated with the presence of antiphospholipid antibodies (see Antiphospholipid Syndrome). In several studies, the presence of antiphospholipid (aPL) antibodies has been the single most sensitive predictor of fetal death.[103] The positive predictive value of aPL antibodies for fetal death is over 50%[58]; for women with SLE and a prior fetal death, the predictive value is over 85%.[104] In the most recent prospective trial, the presence of any aPL was the single strongest predictor of subsequent pregnancy loss, even in women with active disease and underlying renal impairment.[105]

PRETERM BIRTH

Preterm birth has been reported in as few as 3% and as many as 73% of pregnancies complicated by SLE.[19,30,34,35,43,44,97,103–107] Not surprisingly, the presence of aPL antibodies, chronic hypertension, and disease activity have all been reported to increase the likelihood of preterm birth in women with SLE.[27,105] Only a handful of studies have compared preterm birth rates in

PTC, prior to conception.

women with SLE and healthy controls. In one retrospective case-control study, preterm birth occurred more commonly in a group of women with SLE than in a group of matched controls (12% vs. 4%).[100] This was not the case in a more recent prospective trial, in which the rates of preterm birth in women with SLE and healthy controls were statistically similar (8% vs. 15%).[27] Interestingly, preterm birth was more common among women with active SLE compared to those with inactive disease (12.5% vs. 4%).

A substantial proportion of preterm birth associated with SLE is undoubtedly a result of iatrogenic delivery for obstetric and medical indications, rather than idiopathic preterm labor. From the few studies that provide sufficient detail, between 28% and 66% of preterm deliveries are indicated because of preeclampsia and another 12% to 33% because of suspected or confirmed fetal compromise.[8,97,100,104–106] An association between SLE and preterm premature rupture of membranes (PPROM) has also been reported, occurring in 39% of pregnancies delivered at 24 to 36 weeks' gestation.[104]

INTRAUTERINE FETAL GROWTH RESTRICTION

Uteroplacental insufficiency resulting in IUGR or small-for-gestational-age neonates has been reported in between 12% and 40% of pregnancies complicated by SLE.[22,24,26,41,89,105] Mintz and colleagues[19] reported higher rates of IUGR in pregnancies complicated by SLE than in pregnancies in normal controls (23% vs. 4%). However, the higher rate of IUGR associated with SLE may have been due to all the women with SLE receiving prophylactic glucocorticoid therapy during pregnancy. In a more recent prospective trial during which glucocorticoids were given only for symptomatic SLE flare, Georgiou and colleagues[27] reported no significant differences in the rate of IUGR between SLE pregnancies and healthy controls. Factors that have been associated with a higher rate of IUGR in SLE pregnancies include renal insufficiency and/or hypertension.[61,89]

NEONATAL LUPUS ERYTHEMATOSUS

Neonatal lupus erythematosus is a rare condition of the fetus and neonate, occurring in 1 in 20,000 of all live births and in fewer than 5% of all women with SLE.[105] Dermatologic manifestations are the most common manifestation of neonatal lupus and are described as erythematous, scaling annular or elliptical plaques occurring on the face or scalp, analogous to the subacute cutaneous lesions in adults. Lesions appear in the first weeks of life, probably induced by exposure of the skin to ultraviolet light, and may last for up to 6 months.[110] Hypopigmentation may persist for up to 2 years. A small percentage of affected infants will go on to have other autoimmune diseases later in life.[110] Hematologic neonatal lupus is rare and may be manifest as autoimmune hemolytic anemia, leukopenia, thrombocytopenia, and hepatosplenomegaly.

Cardiac neonatal lupus lesions include congenital complete heart block and the less frequently reported endocardial fibroelastosis. Congenital complete heart block is due to disruption of the cardiac conduction system, especially in the area of the atrioventricular node. The diagnosis of congenital complete heart block is typically made around 23 weeks' gestation,[111] when a fixed

bradycardia, in the range of 60 to 80 beats/minute, is detected during a routine prenatal visit. Fetal echocardiography reveals complete atrioventricular dissociation with a structurally normal heart. Confirmation of neonatal lupus is based on the presence of autoantibodies in maternal circulation. Endomyocardial damage is irreversible; in the most severely affected cases, cardiac failure leads to hydrops fetalis and fetal death. In less severely affected neonates, pacemaker placement is not uncommonly necessary to ensure survival. In the largest series of prenatally diagnosed congenital complete heart block, the 3-year survival was only 79%; the majority of deaths occurred before 90 days of life.[111] Cutaneous manifestations of neonatal lupus have also been reported in infants with congenital complete heart block.[110]

Not all women who give birth to babies with neonatal lupus have been previously diagnosed with an autoimmune disorder.[106,108] However, in one study, 7 of 13 previously asymptomatic mothers who delivered infants with dermatologic neonatal lupus were later diagnosed with one of several autoimmune disorders.[110] Surprisingly, asymptomatic women who deliver infants with congenital complete heart block were less likely to develop an autoimmune disorder than those who delivered infants with dermatologic manifestations.[112]

A model of passively acquired autoimmunity, neonatal lupus manifestations are presumed to arise from the transplacental passage of autoantibodies directed against Ro/SS-A and La/SS-B ribonucleoprotein antigens.[111,113–116] Anti-Ro/SS-A antibodies are found in 75% to 95% of mothers who deliver babies with neonatal lupus.[111,117,118] A smaller percentage have anti-La/SS-B, and some have both.[118] Dermatologic neonatal lupus has also been associated with anti-U1RNP without anti-Ro/SS-A or anti-La/SS-B.[118] Among all mothers with SLE, the risk of neonatal lupus is less than 5%.[109] Of mothers with SLE who are serologically positive for anti-Ro/SS-A antibodies, 15% will have infants affected with dermatologic neonatal lupus; the proportion that delivers infants with congenital complete heart block is much smaller. However, once a women with SLE and anti-Ro/SS-A antibodies delivers one infant with congenital complete heart block, her risk for recurrence is at least two to threefold higher than women with anti-Ro/SS-A or anti-La/SS-B antibodies who have never had an affected child.[111] Recurrence of dermatologic neonatal lupus is approximately 25%.[89,119]

There is no known in utero therapy that completely reverses fetal congenital complete heart block secondary to SLE. However, some evidence suggests that glucocorticoids, plasmapheresis, and IVIG, or some combination thereof, may slow the progression of prenatally diagnosed congenital complete heart block or prevent recurrence in a future pregnancy.[120,121] In utero treatment with dexamethasone was felt to slow disease progression in one case report of hydrops secondary to congenital complete heart block.[122] In one retrospective study,

maternally administered dexamethasone appeared to prevent progression from second-degree block to third-degree block.[123] In a large series of 87 pregnancies at risk for neonatal lupus, mothers who received corticosteroids before 16 weeks' gestation were less likely to deliver infants with congenital complete heart block compared to mothers who received no therapy.[124] However, there was no benefit to treatment when congenital complete heart block was diagnosed in utero. In utero treatment with digoxin is not beneficial for prenatally diagnosed congenital complete heart block.[125]

Taken together, the currently available data indicate that newly discovered cases of congenital complete heart block in utero should be evaluated by sonographic examination of the fetal heart and determination of maternal anti-Ro/SS-A and anti-La/SS-B status. If the diagnosis of congenital complete heart block due to neonatal lupus is made, experts currently recommend administration of a glucocorticoid that crosses the placenta (e.g., dexamethasone, 4 mg/day) to limit further immunologic damage to the fetal heart. The efficacy of this approach is being examined in a registry of cases collected by Dr. J.P. Buyon at the Hospital for Joint Diseases, in New York City (212-598-6283).

Management Options

Prepregnancy

Women with SLE who are contemplating pregnancy should be counseled before conception about potential obstetric problems, including pregnancy loss, preterm birth, gestational hypertension/preeclampsia, and IUGR. They should also be informed of the risk of SLE flare as well as special concerns related to antiphospholipid syndrome and neonatal lupus. Preconceptional laboratory evaluation should include an assessment for anemia and thrombocytopenia, underlying renal disease (urinalysis, serum creatinine, and 24-hour urine for creatinine clearance and total protein), and aPL antibodies (lupus anticoagulant and anticardiolipin). It is also common practice to obtain anti-Ro/SS-A and anti-La/SS-B antibodies on all patients with SLE, but the cost-effectiveness of these tests is not proven.

Women with active SLE should be discouraged from embarking on pregnancy until remission can be attained. Cytotoxic drugs and NSAIDs should be stopped before pregnancy. However, maintenance therapy with hydroxychloroquine or glucocorticoids need not be discontinued.

Prenatal

The obstetric management of the patient with SLE is guided by the potential risks to the mother and fetus. As mentioned, prenatal visits should occur every 1 to 2 weeks in the first and second trimesters and every week thereafter. A primary goal of the antenatal visits after 20 weeks gestation is the detection of hypertension and/or

proteinuria. Because of the risk of uteroplacental insufficiency, fetal ultrasonography should be performed every 4 to 6 weeks starting at 18 to 20 weeks' gestation. In the usual case, fetal surveillance (daily fetal movement counts and once weekly nonstress tests and amniotic fluid volume measurements) should be instituted at 30 to 32 weeks' gestation. More frequent ultrasonography and fetal testing is indicated in patients with SLE flare, hypertension, proteinuria, clinical evidence of IUGR, or antiphospholipid syndrome. In the patients with antiphospholipid syndrome, fetal surveillance as early as 24 to 25 weeks' gestation may be justified.[126]

Labor and Delivery

The management of the gravida with SLE during labor and delivery represents a continuation of her antenatal care. Exacerbations of SLE can occur during labor and may require the acute administration of steroids. Regardless, stress doses of glucocorticoids should be given during labor or at the time of cesarean delivery to all patients who have been treated with chronic steroids within the previous year. This compensates for the anticipated

endogenous adrenal insufficiency in these patients. Intravenous hydrocortisone, given in three doses of 100 mg every 8 hours is an acceptable regimen. Complications such as preeclampsia and IUGR should be dealt with based on obstetric concerns; their management is not specifically altered by the presence of SLE. Neonatology support may be needed at delivery for problems associated with congenital complete heart block and other manifestations of neonatal lupus.

Postnatal

The true predisposition for SLE exacerbation following delivery is uncertain. Regardless, care should be taken to examine for these flares in the symptomatic parturient. If gestational hypertension complicates the intrapartum process, it should be anticipated that the patient will clear these acute effects in a manner similar to otherwise normal women with this condition. Maintenance medications should be restarted immediately after delivery, at similar doses as during the pregnancy. Further dose adjustments can be handled in the outpatient setting.

SUMMARY OF MANAGEMENT OPTIONS
Systemic Lupus Erythematosus

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Establish good control of SLE; adjust maintenance medications.	—	GPP	—
Discontinue azathioprine, methotrexate, and cyclophosphamide if possible and only under careful supervision.	IIb	B	72,74,75,78, 79,82,84
It is not necessary to discontinue hydroxychloroquine.	IIa	B	62–66
Perform laboratory assessment for anemia, thrombocytopenia, renal disease, antibodies (anti-phospholipid, anti-Ro/SS-A, anti-La/SS-B).	—	GPP	—
Counsel patient regarding risks (exacerbations, preeclampsia, fetal/neonatal).	—	GPP	—
Prenatal			
Provide multidisciplinary care.	—	GPP	—
Encourage early prenatal care.	—	GPP	—
Perform dating scan.	—	GPP	—
Perform frequent antenatal checks: every 2 weeks in the 1st and 2nd trimesters, weekly in 3rd.	—	GPP	—
Maintain vigilance for SLE flare, preeclampsia, IUGR.	—	GPP	—
For SLE patients with renal involvement, perform monthly 24-hr urine collections for creatinine clearance and total protein.	—	GPP	—
Possible drugs:			
• Antimalarials	IIa	B	62–66
• Glucocorticoids	IIb	B	72,82

SUMMARY OF MANAGEMENT OPTIONS

Systemic Lupus Erythematosus *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal *(Continued)*			
• Azathioprine (if steroids are ineffective)	III	B	72,84
• Methotrexate/cyclophosphamide as third choice	III	B	74,75
• Avoid full-dose NSAIDs	III	B	78,79
Perform serial biometry, Doppler studies, and amniotic fluid volume every 3–4 wks.	–	GPP	–
Begin prenatal testing at 30–32 weeks' gestation (earlier in patients with worsening disease, evidence of fetal compromise, or history of poor pregnancy outcome).	III	B	118
Consider low-dose aspirin, especially if history of recurrent miscarriages or early-onset severe preeclampsia.	Ib	A	59,60
Labor and Delivery			
Deliver at term. Avoid postdates.	–	GPP	–
Maintain continuous fetal heart rate monitoring.	–	GPP	–
Intravenous glucocorticoids for delivery in patients who have received maintenance or steroid bursts during pregnancy.	IIb	B	82
Postnatal			
Monitor for SLE exacerbation.	–	GPP	–
Restart maintenance therapy.	–	GPP	–
Check neonate for SLE manifestations.	–	GPP	–

ANTIPHOSPHOLIPID SYNDROME

Antiphospholipid antibodies are a family of autoantibodies that bind to negatively charged phospholipids, phospholipid-binding proteins, or a combination of the two. The association between aPL antibodies and hypercoagulability was first reported 50 years ago; a link with pregnancy loss was not established until the mid-1970s. Since then, collaboration between international laboratory researchers and clinicians from various specialties has led to the development of definitive diagnostic criteria for so-called *antiphospholipid syndrome* (APS).[127] However, the obstetric aspects of APS continue to generate considerable controversy, and refining the diagnostic criteria for APS is an ongoing process.

The first aPL detected was the false-positive Wassermann test. The key antigenic component was later found to be cardiolipin, a phospholipid found in mitochondrial membranes. Lupus anticoagulant was first described in the early 1950s and was later found to be associated with false-positive tests for syphilis and (paradoxically) with thrombosis. Anticardiolipin antibodies eventually were found to be strongly associated with lupus anticoagulant and thrombosis. Most recently, investigators reported that anticardiolipin binding some-

times requires the presence of a phospholipid-binding protein known as β_2-glycoprotein I (GPI).[128] As a result, APS research has become more focused on phospholipid-binding proteins, rather than the phospholipids themselves.

The association between aPL antibodies and thrombosis and pregnancy loss is now well established. Correctly identifying patients with APS is important given the efficacy of heparin treatment in reducing the recurrence risk of thromboembolism and improvement in pregnancy outcomes.[101,129,130] Nevertheless, aPL antibodies are found in up to 5% of apparently healthy controls and up to 35% of patients with SLE.[131] The prospective risks of a positive test for aPL antibodies in otherwise healthy subjects are unknown.

The Pathogenesis of Antiphospholipid Syndrome

The mechanism(s) by which aPL antibodies cause thrombosis most likely involves interference with normal hemostasis by interaction with phospholipids or phospholipid-binding protein components such as β_2-GPI (which has anticoagulant properties), prostacyclin, prothrombin, protein C, annexin V, and tissue factor.[127]

Antiphospholipid antibodies also appear to activate endothelial cells, indicated by increased expression of adhesion molecules, secretion of cytokines, and production of arachidonic acid metabolites.[132] The findings that some anticardiolipin antibodies cross-react with oxidized low-density lipoprotein[133] and that human anticardiolipin antibodies bind to oxidized, but not reduced, cardiolipin[134] imply that aPL may participate in oxidant-mediated injury of the vascular endothelium. However, aPL do bind perturbed cells, such as activated platelets[135] or apoptotic cells,[136] which typically lose normal membrane symmetry and express anionic phospholipids on their surface.

Whether aPL per se are the cause of adverse obstetric outcomes is also a matter of debate. Investigators working with murine models have found that passive transfer of aPL results in clinical manifestations of APS, including fetal loss and thrombocytopenia.[137,138] One group has used a murine pinch-induced venous thrombosis model to demonstrate that human polyclonal and murine monoclonal aPL are associated with larger and more persistent thrombi than in mice treated with control antibodies.[139] Recent work points to the complement system as having a major role in APS-related pregnancy loss, showing that C3 activation is required for fetal loss in a murine model.[140] In humans, APS-related pregnancy complications are probably related to abnormal placental function. Some authorities have focused on abnormalities in the decidual spiral arteries as the immediate cause of fetal loss in APS pregnancies. Some investigators have found narrowing of the spiral arterioles, intimal thickening, acute athetosis, and fibrinoid necrosis.[141-143] In addition, placental histopathology demonstrates extensive necrosis, infarction, and thrombosis.[141] These abnormalities might result from thrombosis during the development of normal maternoplacental circulation via interference with trophoblastic annexin V[143] or by impairing trophoblastic hormone production or invasion.[144]

Diagnostic Evaluation of Antiphospholipid Syndrome

Diagnostic Criteria

The 1999 International Consensus Statement provides simplified criteria for the diagnosis of APS.[127] Patients with bona fide APS must manifest at least one of two clinical criteria (vascular thrombosis or pregnancy morbidity) and at least one of two laboratory criteria (positive lupus anticoagulant or medium to high titers of β_2-GPI-dependent IgG or IgM isotype anticardiolipin antibodies), confirmed on two separate occasions, at least 6 weeks apart. Thrombosis may be either arterial or venous and must be confirmed by an imaging or Doppler study or by histopathology. Pregnancy morbidity is divided into three categories: (1) otherwise unexplained fetal death (10 weeks' gestation), (2) preterm birth (34 weeks'

gestation) for severe preeclampsia or placental insufficiency, or (3) otherwise unexplained recurrent preembryonic or embryonic pregnancy loss. Autoimmune thrombocytopenia and amaurosis fugax are often associated with APS but are not considered sufficient diagnostic criteria. Antiphospholipid syndrome may exist as an isolated immunologic derangement (primary APS) or in combination with other autoimmune diseases (secondary APS), most commonly SLE.

Laboratory Testing

Patients suspected of having APS should be tested using at least two aPL assays for several reasons. First, there is no definitive association between any of the clinical manifestations of APS and a particular aPL antibody. Second, there is substantial interlaboratory variation in assay performance and interpretation. Currently, the most commonly performed aPL antibody assays are for lupus anticoagulant and anticardiolipin antibodies (IgG and IgM isotypes). These are also the most commonly detected aPL antibodies and the only two currently recognized by the 1999 International Consensus Statement. Testing for lupus anticoagulant utilizes an in vitro coagulation assay in which the antibodies prolong clotting times, and the test for anticardiolipin antibodies is a standardized enzyme-linked immunosorbent assay. Lupus anticoagulant tests are reported as being positive or negative, whereas anticardiolipin antibodies are reported in terms of international units (designated GPL for IgG binding and MPL for IgM binding). Approximately 70% of patients with bona fide APS have both LAC and anticardiolipin antibodies.

The assay for anticardiolipin antibodies is a more sensitive test for detection of APS; the assay for lupus anticoagulant is more specific. Low titers of anticardiolipin antibodies are present in up to 5% of normal individuals and should not be used to make the diagnosis of APS. Medium to high titers of anticardiolipin antibodies are more specific for the diagnosis of APS, as is the specificity of the IgG isotype compared to the IgM isotype.

Several areas of controversy surround laboratory testing for aPL. First, relevance of low positive IgG anticardiolipin antibodies is questionable. Many of the studies reporting a relationship between aPL antibodies and recurrent pregnancy loss have included patients who test positive solely for low levels of IgG anticardiolipin antibodies.[145-147] Yet, marked differences have been reported in low levels of IgG anticardiolipin antibodies in women with recurrent first-trimester miscarriage and the much higher levels found in women with APS characterized by fetal death or thrombosis.[148] In addition, women with low levels of IgG anticardiolipin antibodies have been found to have no greater risk for aPL antibody-related events than women who tested negative.[149]

The presence of isolated IgM or IgA aPL antibody levels is also of questionable clinical significance. Women

with isolated IgM aCL antibodies are no more likely to suffer aPL-related morbidity than women who tested negative for all aPL antibodies.[149] Although the 1999 International Consensus Statement considers medium to high titers of IgM anticardiolipin antibodies as diagnostic criteria for APS, clinicians should exercise caution when the diagnosis is based on their presence alone. Several treatment trials have included women with isolated IgM anticardiolipin antibodies, but have failed to analyze their outcomes separately.[145–147,150] Isolated IgA anticardiolipin antibodies should also be viewed with suspicion. Testing for IgA anticardiolipin antibodies appears to add little diagnostic benefit compared with IgG and IgM anticardiolipin antibodies; IgA anticardiolipin antibodies are not considered criteria in the 1999 International Consensus Statement.

Some investigators have attempted to link poor obstetric outcomes to aPL antibodies other than lupus anticoagulant and anticardiolipin antibodies. These include antibodies to phosphatidylserine, phosphatidylethanolamine, phosphatidylinositol, phosphatidylglycerol, phosphatidylcholine, and phosphatidic acid.[151,152] However, such antibodies do appear to be associated with poor obstetric outcomes once women who are positive for lupus anticoagulant and anticardiolipin antibodies are excluded.[153] In addition, multiple aPL antibody tests do not increase the diagnostic yield for APS.[154] Indeed, substituting negatively charged phospholipids, such as phosphatidylserine or phosphatidylinositol, for cardiolipin in the immunoassay system yields comparable results. The most persuasive argument against using alternative phospholipid assays for the diagnosis of APS is undoubtedly the fact that none of them have been standardized in the same fashion as the assay for anticardiolipin antibodies.

The demonstration that antibodies to cardiolipin are directed against β_2-GPI or an epitope formed by the interaction of phospholipids and β_2-GPI, has led to the development of anti-β_2-GPI antibody assays. Although they are not considered criteria in the 1999 International Consensus Statement, their presence is strongly associated with clinical features of APS and they are sometimes the only aPL antibody detected in patients who are suspected of having the syndrome.[155] Some authorities predict that internationally standardized anti-β_2-GPI assays will replace lupus anticoagulant and anticardiolipin antibody assays for the diagnosis of APS. Current recommendations are to reserve the use of anti-β_2-GPI assays for patients who are strongly suspected of having APS but in whom standard aPL antibody assays are negative.[131,155]

As a final note, the 1999 International Consensus Statement criteria were developed primarily for research purposes to ensure more uniform patient characterization as well as disease subcategorization in APS studies. Not unlike the situation with autoimmune conditions such as SLE, some patients will present with one or more clinical or laboratory features suggestive but not diagnostic of APS. In such cases, the decision to proceed with therapies generally reserved for patients with APS should be based on experienced clinical judgment.

Risks of APS and Pregnancy

Thrombotic Complications of APS in Pregnancy

Numerous retrospective studies confirm a link between aPL and venous or arterial thrombosis.[156,157] Approximately 70% of thrombotic events occur in the venous system, although arterial thromboses and cerebrovascular accidents are also common.[158] Transient CNS manifestations of ischemia also are common in APS patients.[148] Antiphospholipid antibodies are present in approximately 2% of individuals with unexplained thrombosis[159] and are the only identifiable predisposing factor in 4% to 28% of cases of stroke in otherwise healthy patients younger than age 50.[160–162]

In the only prospective study of untreated APS patients (who also had SLE), 50% of those with lupus anticoagulant had a thrombotic episode during the study period; the annual risk of venous thrombosis and arterial thrombosis was 13.7% and 6.7%, respectively.[163] The lifetime risk of thromboembolism in women with APS is unknown. However, over half occur in relation to pregnancy or the use of combination oral contraceptives.[164] In the two largest series of prospectively followed APS pregnancies, the rates of thrombosis and stroke were 5% and 12%, respectively.[101,130]

Obstetric Complications of APS in Pregnancy

GESTATIONAL HYPERTENSION/PREECLAMPSIA

The median rate of gestational hypertension/preeclampsia in pregnancies complicated by APS is 32%, with a range up to 50%.[101,130,165,166] Preeclampsia may develop as early as 15 to 17 weeks' gestation.[101] The rate of gestational hypertension/preeclampsia does not appear to be markedly diminished by treatment with either glucocorticoids and low-dose aspirin or heparin and low-dose aspirin. In contrast to the high rate of preeclampsia observed in some case series of women previously diagnosed with APS, aPL antibodies are not found in a statistically significant proportion of a general obstetric population presenting with preeclampsia[167] or in women at moderate risk to develop preeclampsia because of conditions such as underlying chronic hypertension or preeclampsia in a prior pregnancy.[168] However, two groups of investigators have reported that women with early-onset, severe preeclampsia are more likely to test positive for aPL antibodies compared to healthy controls.[169,170] Based on these findings, testing for aPL antibodies should only be considered in early-onset, severe preeclampsia.

UTEROPLACENTAL INSUFFICIENCY AND PRETERM BIRTH

Several investigators have found relatively high rates of IUGR in association with aPL antibodies.[101,130,169,171,172]

Even with currently used treatment protocols, the rate of IUGR approaches 30%.[101,130] Pregnancies complicated by APS are also more likely to exhibit nonreassuring fetal heart rate patterns during antenatal tests of fetal well-being and intrapartum monitoring.[101,103,130] Not surprisingly, the rate of preterm birth in these series ranges from 32% to 65%.[101,130,166]

PREGNANCY LOSS

In the original description of APS, the sole obstetric criterion for diagnosis was fetal loss (>10 menstrual weeks of gestation).[156] At least 40% of pregnancy losses reported by women with lupus anticoagulant or medium to high positive IgG anticardiolipin antibodies occur in the fetal period.[130,146,173,174,176] More recently, APS-related pregnancy loss has been extended to include women with early recurrent pregnancy loss, recurrent pregnancy loss including those occurring in the preembryonic (<6 menstrual weeks of gestation) and embryonic periods (6 through 9 menstrual weeks of gestation).[127] In serologic evaluation of women with recurrent pregnancy loss, 10% to 20% have detectable aPL antibodies.[145,150–152,170,177]

Fetal death and early recurrent pregnancy loss are seen by some as two points along the same continuum of APS-related pregnancy loss. However, women with APS identified because of a prior fetal death and/or thromboembolism seem to have more serious complications in subsequent pregnancies than those with early recurrent pregnancy loss.[176] Recent prospective treatment trials of APS during pregnancy have been comprised mainly of women with early recurrent pregnancy loss and no other APS-related medical problems.[145,151,177–180] Accordingly, the rates of obstetric complications were relatively low, with fetal death, preeclampsia, and preterm birth occurring in 4.5% (0% to 15%), 10.5% (0% to 15%), and 10.5% (5% to 40%), respectively. Only 1 of 300 women suffered a thrombotic event, and no neonatal deaths due to complications of prematurity were reported. Based on these data, it seems unlikely that early recurrent pregnancy loss, fetal death, and preterm birth resulting from severe preeclampsia or placental insufficiency result from the same pathophysiologic mechanism. Certainly, hypercoagulability causing defective uteroplacental circulation that results in diminished intervillous blood flow might be responsible for later pregnancy complications. Women with early recurrent pregnancy loss probably represent a different patient population with pregnancy losses due to different mechanisms, perhaps relating to different aPL specificities or aPL operating on a fundamentally different pathophysiologic background.

Postpartum and Catastrophic Antiphospholipid Syndrome

Catastrophic APS is a rare but devastating syndrome characterized by multiple simultaneous vascular occlusions throughout the body, often resulting in death. The diagnosis should be suspected if at least three organ systems are affected and confirmed if there is histopathologic evidence of acute thrombotic microangiopathy affecting small vessels. Renal involvement occurs in 78% of patients. Most have hypertension; 25% eventually require dialysis. Other common manifestations described by Asherson[181] include adult respiratory distress syndrome (66%), cerebral microthrombi and microinfarctions (56%), myocardial microthrombi (50%), dermatologic abnormalities (50%), and disseminated intravascular coagulation (25%). Death from multiorgan failure occurs in 50% of patients.[181] The pathophysiology of catastrophic APS is poorly understood. However, the onset may be presaged by several factors, including infection, surgical procedures, discontinuation of anticoagulant therapy, and the use of drugs such as oral contraceptives.[181–183]

Early and aggressive treatment of catastrophic APS appears prudent. Patients should be transferred to an intensive care unit where supportive care can be provided. Hypertension should be aggressively treated with appropriate antihypertensive medication. Although no treatment has been shown to be superior to another, a combination of anticoagulants (usually heparin) and steroids plus either plasmapheresis or IVIG has been successful in some patients.[181,182] Streptokinase and urokinase have also been used to treat acute vascular thrombosis.[181] Women suspected of catastrophic APS during pregnancy should probably be delivered.

Management Options (General Considerations)

Treatment for Antiphospholipid Syndrome during Pregnancy

The ideal treatment for APS during pregnancy should include: (1) improvement in maternal and fetal-neonatal outcome by preventing pregnancy loss, preeclampsia, placental insufficiency, and preterm birth, and (2) reduction or elimination of the risk of thromboembolism. Early enthusiasm for treatment with glucocorticoids to reduce the risk of pregnancy loss waned after publication of a small, randomized trial found maternally administered heparin to be as effective as prednisone.[179] At present, maternally administered heparin is considered the treatment of choice (Table 44–8); it is usually initiated in the early first trimester after ultrasonographic demonstration of a live embryo. In most case series and trials, daily low-dose aspirin is included in the treatment regimen.[145,150,177–180,184] In a recent meta-analysis of treatment trials, the live-birth rate was improved by 54%.[184]

The decision to use one of the currently recommended anticoagulation regimens should be based on individual clinical and laboratory characteristics (see Table 44–8). Women with APS and a history of thromboembolism should probably receive full anticoagulation with heparin during pregnancy because of their substantial risk of recurrent thromboembolism.[129,185,186] Most authorities recommend full, adjusted-dose anticoagulation.[187,201]

TABLE 44–8

Subcutaneous Heparin Regimens Used for Antiphospholipid Syndrome during Pregnancy

Prophylactic Regimens

Recommended in women with no history of thrombotic events—diagnosis of recurrent preembryonic and embryonic loss or prior fetal death or early delivery because of severe preeclampsia or severe placental insufficiency

Standard Heparin
7,500-10,000 U q12h in the first trimester, 10,000 U q12h in the second and third trimesters

Low Molecular Weight Heparin
1) Enoxaparin 40 mg once daily or dalteparin 5000 U once daily
2) Enoxaparin 30 mg q12h or dalteparin 5000 U q12h

Anticoagulation Regimens

Recommended in women with a history of thrombotic events

Standard Heparin
Every 8-12 hours, adjusted to maintain the midinterval heparin levels* in the therapeutic range

Low Molecular Weight Heparin
1) Weight-adjusted (enoxaparin 1/mg/kg q12h or dalteparin 200 U/kg q12h)
2) Intermediate dose (enoxaparin 40 mg once daily or dalteparin 5000 U once daily until 16 weeks of gestation and q12h from 16 weeks on

*Heparin levels, anti-factor Xa levels. Women without a lupus anticoagulant in whom the activated partial thromboplastin time (aPTT) is normal can be observed using the aPTT.

In contrast, women diagnosed with APS *without* a history of thromboembolic disease may have less risk of thromboembolism during pregnancy. Women with early recurrent pregnancy loss alone, without a history of thromboembolism, have been treated with both low-dose prophylaxis and adjusted-dose anticoagulation regimens.[186] Live-birth rates have exceeded 70% using either strategy.[145,151,179] In one trial of nearly 100 women, two thirds of whom had recurrent preembryonic and embryonic pregnancy loss and none of whom had a history of thromboembolic disease, an unfractionated heparin dose of 5000 U twice daily was associated with a 71% live-birth rate.[145] Another study of women with aPL antibodies and predominantly preembryonic and embryonic pregnancy loss, none of whom had a history of thromboembolic disease, with heparin administered in a twice-daily regimen and adjusted to keep the midinterval activated partial thromboplastin time (aPTT) approximately 1.5 times the control mean, was associated with an 80% live-birth rate.[151] In most case series and trials, daily low-dose aspirin is included in the treatment regimen.

Women with a history of fetal death or neonatal death after delivery at less than 34 weeks' gestation for severe preeclampsia or placental insufficiency, without prior thromboembolism, may be at higher risk for thromboembolism during pregnancy.[188] It is our practice to treat such women with generous thromboprophylaxis (e.g., 15,000 to 20,000 units of standard unfractionated heparin or 60 mg of enoxaparin [low molecular weight heparin, or LMWH] in divided doses daily).[130,179,189]

Women with APS should be counseled about the potential risks of heparin therapy during pregnancy, including heparin-induced osteoporosis and heparin-induced thrombocytopenia (HIT). Osteoporosis resulting in fracture occurs in 1% to 2% of women treated during pregnancy.[190] Women treated with heparin should be encouraged to take daily supplemental calcium and vitamin D (e.g., prenatal vitamins). It also seems prudent to encourage daily axial skeleton weight-bearing exercise (e.g., walking). Immune-mediated HIT is much less common but potentially more serious. Most cases have their onset 3 to 21 days after heparin initiation and are relatively mild in nature.[191] A more severe form of HIT paradoxically involves venous and arterial thromboses, resulting in limb ischemia, cerebrovascular accidents, and myocardial infarctions, as well as venous thromboses.[192] It may occur in up to 0.5% of patients treated with unfractionated sodium heparin.[191] LMWH is much less likely to be associated with HIT, compared with unfractionated sodium heparin.[193]

Other pregnancy complications associated with APS occur in spite of appropriate treatment.[130,194] In a recent observational study of 107 pregnancies complicated by APS, preeclampsia occurred in 20%, preterm birth in 24%, and IUGR in 15% of treated women.[194]

Pregnancy losses continue to occur in 20% to 30% of cases, even when heparin prophylaxis is given.[131,179,184] Several alternative therapies have been tried in so-called refractory cases. Glucocorticoids, often in high doses, have sometimes been added to regimens of heparin and low-dose aspirin. Although there are anecdotal reports of success, this practice has never been studied in appropriately designed trials; the combination of glucocorticoids and heparin may increase the risk of osteoporotic fracture.[195] IVIG has also been used in pregnancies complicated by APS, especially in women with particularly poor past histories or recurrent pregnancy loss during heparin treatment.[196] However, a small randomized, controlled, pilot study of IVIG treatment found no benefit to this expensive therapy compared to heparin and low-dose aspirin.[197] Hydroxychloroquine has been shown to diminish the thrombogenic properties of aPL antibodies in a murine thrombosis model.[198] There are few case reports and no trials of APS patients being treated during pregnancy with hydroxychloroquine. Finally, women with particularly egregious thrombotic histories, such as recurrent thrombotic events or cerebral thrombotic events, are understandably viewed as being at very high risk for thrombosis during pregnancy. In selected such cases, some authorities recommend the judicious use of warfarin anticoagulation rather than heparin.

Healthy women with recurrent embryonic and preembryonic loss and low titers of aPL do not require treatment.[199] The controlled trial of Pattison and colleagues included a majority of such women and found no difference in live-birth rates using either low-dose aspirin or placebo.[177]

Prepregnancy

Women with APS will preferably seek preconception counseling. At that time, the presence of clinically significant levels of aPL antibody should be confirmed and potential maternal and obstetric complications discussed, including thrombosis, pregnancy loss, preterm delivery, gestational hypertension/preeclampsia, and uteroplacental insufficiency. Primary APS patients, like patients with SLE, should be assessed for evidence of anemia, thrombocytopenia, and underlying renal disease (urinalysis, serum creatinine, 24-hour urine for creatinine clearance, and total protein).

The various anticoagulation prophylaxis regimens should be discussed, along with their risks and limitations. Patients should also be informed about the risks of heparin-induced osteoporosis and HIT, and recommendations for appropriate protective measures should be provided. Some authorities recommend instituting daily low-dose aspirin (81 mg) prior to conception.

Prenatal

Women with APS who suspect they are pregnant should be evaluated immediately. An early transvaginal ultrasound is useful to confirm an intrauterine pregnancy as well as provide accurate dating of the pregnancy. One of the anticoagulation prophylaxis regimens discussed previously (see Table 44–8) should be instituted, and appropriate precautions against heparin-induced osteoporosis and HIT should be taken. Calcium supplementation is encouraged, as well as the performance of daily weight-bearing exercise.

Prenatal visits should occur every 2 to 4 weeks until 20 to 24 weeks' gestation and every 1 to 2 weeks thereafter. Patient visits should be specifically designed to monitor for the development of preeclampsia and thrombosis and to monitor fetal well-being. Because of the risk of IUGR and oligohydramnios secondary to uteroplacental insufficiency, serial ultrasound examinations should be performed every 3 to 4 weeks after 17 to 18 weeks' gestation. Antenatal surveillance (daily fetal movement counts and at least once-weekly nonstress tests with amniotic fluid volume measurements) should be initiated at 30 to 32 weeks' gestation (or earlier if uteroplacental insufficiency is suspected). More frequent ultrasound examinations and more frequent or earlier fetal testing may be indicated in selected cases.

Labor and Delivery

Labor and delivery in women with APS should be managed in the same way as in any patient who is considered at high risk for preeclampsia and uteroplacental insufficiency. Most authorities recommend continuous electronic fetal monitoring throughout labor, given the increased risk of nonreassuring fetal heart rate tracings noted in women with APS.

The most common management dilemma in women with APS probably involves the need to alter anticoagulation regimens in a way that minimizes the risk of bleeding at the time of delivery without placing the patient at a prohibitively high risk of thromboembolism. Treatment approaches vary and there is no evidence that one method is better than another. Patients receiving prophylactic anticoagulation with heparin can be instructed to withhold their injections at the onset of labor. Alternatively, injections can be discontinued 12 hours before a planned induction. The most common practice in women with APS on full-dose anticoagulation (unfractionated heparin or LMWH) is to hold the last injection 24 hours prior to a planned induction of labor or cesarean delivery. As an alternative for women deemed at extremely high risk for thromboembolism, including those with an event within 2 weeks of delivery, intravenous heparin can be started in labor and discontinued 2 to 4 hours prior to anticipated delivery. Intravenous heparin can be resumed 4 to 6 hours after vaginal delivery and 12 hours after cesarean.

Spontaneous labor is problematic for women who are fully anticoagulated, particularly those receiving LMWH preparations. Anti-factor Xa levels might be helpful but have been found to underestimate the risk of bleeding in some patients. Protamine sulfate may be necessary in the event of surgical intervention. For those on adjusted-dose unfractionated heparin, careful monitoring of the aPTT (or heparin level) is required. If the aPTT is prolonged near delivery, protamine sulfate may be necessary to reduce the risk of bleeding.

Many anesthesiologists are particularly concerned that anticoagulation in any form increases the risk of spinal hematoma formation in women receiving regional anesthesia in labor or for cesarean delivery. The American Society of Regional Anesthesia (ASRA) recommends that neuraxial blockade should be withheld until 24 hours after the last injection in women on full anticoagulation with LMWH.[200] The same recommendation has been made for women receiving adjusted-dose anticoagulation with unfractionated heparin.[201] For women receiving low-dose thromboprophylaxis (low-dose twice-daily unfractionated heparin or once-daily LMWH), ASRA has recommended that needle placement be delayed until 10 to 12 hours after the last dose.

Postpartum

Anticoagulant coverage of the postpartum period in women with APS and prior thrombosis is critical.[201] We prefer initiating warfarin thromboprophylaxis as soon as possible after delivery, with doses adjusted to achieve an

International Normalized Ratio of 3.0. There is no consensus regarding the postpartum management of APS patients without prior thrombosis, although most is diagnosed because of prior fetal loss or neonatal death after delivery at or before 34 weeks' gestation for severe preeclampsia or placental insufficiency, though experts agree that there is an increased risk of thrombosis. The recommendation in the United States is to treat with anticoagulant therapy for 6 weeks after delivery. The need for postpartum anticoagulation in women with APS diagnosed solely on the basis of recurrent preembryonic or embryonic losses is uncertain. Both heparin and warfarin are safe for breast-feeding mothers. Finally, oral contraceptives containing estrogen are absolutely contraindicated.

SUMMARY OF MANAGEMENT OPTIONS

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a debilitating disease, the hallmark feature of which is chronic symmetrical inflammatory arthritis of the synovial joints. RA is more common than SLE, with an incidence of from 2.5 to 7 per 10,000 per year and a prevalence of approximately 1% in the adult U.S. population. Although found in virtually all populations, it is more common in some populations (Native American) and less common in others (Native African). Although it is often said to peak in the 40s or 50s, RA can appear at any age of life (including in children), and the prevalence increases with age into the 60s or 70s in both females and males. As with virtually all autoimmune conditions, RA is more common in women than men with a ratio of 2:1 to 3:1 women to men.[202]

Pathogenesis of Rheumatoid Arthritis

Histologic features of RA are described as symmetrical inflammatory synovitis marked by cellular hyperplasia, accumulation of inflammatory leukocytes, and angiogenesis with membrane thickening, edema, and fibrin deposition as common early findings. Inflammatory damage at the synovium eventually leads to typical joint erosion involving a locally invasive synovial tissue called *pannus.*

The characteristic autoantibody in patients with RA is rheumatoid factor (RF), an autoantibody made by oligoclonal activated B cells in the peripheral circulation and synovium of RA patients. This group of autoantibodies, which reacts with antigens on the Fc portion of IgG, is composed of a heterogeneous group of antibodies containing light and heavy chains distributed among all the variable region subgroups. It is unknown whether RF autoantibodies are simply markers for RA or whether they are directly responsible for tissue damage. There is some evidence that RF autoantibodies form IgG aggregates in synovial fluid, resulting in complement activation and local inflammation and eventual joint erosion.

Concordance for RA is found in approximately 15% of monozygotic twins and 5% of dizygotic twins. It is estimated that heritable factors account for approximately 60% of the predisposition to RA.[203] The human leukocyte antigen (HLA) region (HLA class II gene locus DRB1, encoding HLA-DR), is of primary importance in RA susceptibility. Variant forms of DRB1 have been identified in association with RA, including DRB1*0401, *0404, *0405, *0101, *1402 and *1001. These alleles encode for similar amino acid sequences (*shared epitopes*) that are suspected of bestowing susceptibility to RA. Other suspect HLA complex genes are located on chromosomes 1p and 1q, 9, 12p, 16cen, and 18q.[204,205]

Juvenile rheumatoid arthritis (JRA) is a somewhat different, but related arthritis. It is probably a heterogeneous group of diseases. By definition, JRA has its onset in individuals younger than age 16 years; males and females are equally represented. One prominent subgroup is comprised of individuals with Still's disease. This condition is initially systemic in nature and includes fever, skin rash, serositis, and lymphadenopathy. Arthritis occurs late in the course of disease and tends not to be as destructive or chronic as classic RA. Nearly three quarters of children with JRA have spontaneous, permanent remission by the time they reach adulthood.

Diagnostic Evaluation of Rheumatoid Arthritis

Clinical Presentation

The symptoms of RA develop insidiously over several months; the clinical course is variable. Less commonly, disease onset is acute and somewhat rapid. Twice as many patients present during winter months compared to summer months, and trauma (including surgery) is a frequent precursor. Morning stiffness, pain, and swelling of peripheral joints are the most common initial features. The disease tends to involve primarily the joints of the wrists, knees, shoulders, and metacarpophalangeal joints in an erosive arthritis that typically follows a slowly progressive course marked by exacerbations and remissions. Eventually, joint deformities may occur; these are especially obvious at the metacarpophalangeal joint and proximal and distal interphalangeal joints of the hands. Fatigue, weakness, weight loss, and malaise are also common.

Rheumatoid nodules, present in 20% to 30% of affected patients, are made up of a local proliferation of small vessels, histiocytes, fibroblasts, and other cells, and are usually located in the subcutaneous tissues of the extensor surfaces of the forearm. Uncommonly, extra-articular tissues may also be affected, including the lung (pleuritis, pleural effusions, interstitial fibrosis, pulmonary nodules, pneumonitis, and airway disease) and heart (pericarditis, effusion, myocarditis, endocardial inflammation, conduction defects, and arteritis leading to myocardial infarction).

Diagnostic Criteria

The classification criteria published by the American College of Rheumatology are shown in Table 44-9. Physical examination should reveal evidence of joint inflammation, including joint tenderness, synovial thickening, joint effusion, erythema, and decreased range of motion. Symmetric involvement should be noted. Radiographic evidence of RA includes joint space narrowing and erosion; although too expensive for routine use, magnetic resonance imaging may detect synovial hypertrophy, edema, and early erosive changes.

TABLE 44–9

Classification Criteria for the Diagnosis of Rheumatoid Arthritis

CRITERIA*	DEFINITION
Morning stiffness	Morning stiffness in and around the joints, lasting at least 1 hour before maximal improvement
Arthritis of ≥3 joint areas	At least 3 joint areas simultaneously have had soft tissue swelling or fluid (not bony overgrowth alone) observed by a physician. The 14 possible areas are right or left proximal interphalangeal, metacarpophalangeal, wrist, elbow, knee, ankle, and metatarsophalangeal joints
Arthritis of hand joints	At least 1 area swollen (as defined above) in a wrist, metacarpophalangeal, a proximal interphalangeal joint
Symmetric arthritis	Simultaneous involvement of the same joint areas (as defined above) on both sides of the body (bilateral involvement of proximal interphalangeals, metacarpophalangeals, and metatarsophalangeals is acceptable without absolute symmetry)
Rheumatoid nodules	Subcutaneous nodules, over bony prominences or extensor surfaces, or in juxta-articular regions, observed by a physician
Serum rheumatoid	Demonstration of abnormal amounts of serum rheumatoid factor by any method for which the result has been positive in <5% of normal control subjects
Radiographic changes	Radiographic changes typical of rheumatoid arthritis on posteroanterior hand and wrist radiographs, which must include erosions or unequivocal bony decalcification localized in or most marked adjacent to the involved joints (osteoarthritis changes alone do not qualify)

*For classification purposes, a patient shall be said to have rheumatoid arthritis if he/she has satisfied at least 4 of these 7 criteria. Criteria 1 through 4 must have been present for at least 6 weeks. Patients with 2 clinical diagnoses are not excluded. Designation as classic, definite, or probable rheumatoid arthritis is *not* to be made.

Laboratory Criteria

More than 70% of patients with clinical features of RA are also seropositive for RF. In addition, some of those who are initially seronegative will eventually convert, leaving only 10% of RA patients without a positive RF. Approximately 5% of the general population also test positive for RF, as do many patients with other autoimmune conditions (e.g., SLE, scleroderma, and mixed connective tissue disease), viral infections, parasitic infections, chronic bacterial infections, and after irradiation or chemotherapy.

Rheumatoid Arthritis in Pregnancy

The relationship between RA and pregnancy is fascinating even if the basic scientific understanding of the relationship remains elusive. The observation that in many patients RA dramatically improves during pregnancy[199] eventually led Philip Hench to discover cortisone. Numerous studies (Table 44-10) show that at least 50% of patients with RA demonstrate improvement in their disease in at least 50% of their pregnancies.[206–212] In addition, Hazes and colleagues[213] reported a protective effect of pregnancy in development of RA.

For a majority of patients, the improvement in RA starts in the first trimester heralded by a reduction in joint stiffness and pain.[208] The peak improvement in symptoms generally occurs in the second or third trimester. Other aspects of the disease may also improve during pregnancy, with studies indicating that the subcutaneous nodules associated with RA may disappear during pregnancy.[210] Even with the overall improvement in symptoms, the clinical course of RA during pregnancy is characterized by short-term fluctuations in symptoms, as in the nonpregnant state. Most patients who experience an improvement in RA during pregnancy will have a similar improvement in subsequent pregnancies. However, this is not a given, and some patients will have relatively less improvement in a second or third pregnancy. There are no laboratory or clinical features that predict improvement of RA in pregnancy.

A quarter of RA patients have no improvement in their disease during pregnancy, and in a small number of cases the disease may actually worsen. Unfortunately, nearly

three quarters of patients whose disease has improved during pregnancy will suffer a relapse in the first several postnatal months.[208,210] The level of disease during the first postnatal year generally returns to that of a year before conception, but may be worse.[212]

In contrast to SLE, there are no data to suggest that RA in remission is likely to have a better course during pregnancy than active RA. The long-term prognosis for RA patients undertaking pregnancy appears to be similar to those that avoid pregnancy. Oka and Vainio[212] compared 100 consecutive pregnant RA patients with age- and disease-matched controls and found no significant differences between the groups in terms of the severity of their disease. There are few studies of JRA, but one study found that only 1 case in 20 had a worsening or reactivation of their disease associated with pregnancy.[214]

The mechanism(s) by which pregnancy favorably affects RA is unknown. Plasma cortisol, which rises during pregnancy to peak at term, was initially thought to be important to the amelioration of RA.[206] However, there is no correlation between cortisol concentrations and disease state.[215] Some studies suggest that estrogens or estrogens and progestagens favorably affect arthritis,[216] but there are conflicting studies,[217] and a double-blind crossover trial found that estrogen did not benefit RA.[218] Sex hormones may interfere with immunoregulation and interactions with the cytokine system.[219] Promising data suggest that certain proteins circulating in higher concentrations during pregnancy or unique to pregnancy are associated with improvement of RA. These include pregnancy-associated α_2-glycoprotein[220] and gamma globulins eluted from the placenta.[221] Other investigators feel that the placenta may modify RA by clearing immune complexes[222] or that modification of immune globulins during pregnancy alters their inflammatory activity.[223] Nelson and coworkers suggested that amelioration of disease was associated with a disparity in HLA class II antigens between mother and fetus. Thus, the maternal immune response to paternal HLA antigens may have a role in pregnancy-induced remission of arthritis.[224]

Risks of Rheumatoid Arthritis in Pregnancy

Obstetric Complications and Rheumatoid Arthritis

About 15% to 25% of pregnancies in women with RA end in miscarriage,[225,226] a figure that may or may not be slightly higher than in normal women. One controlled study found that women with RA have a significantly higher frequency of miscarriage than normal women, even before the onset of their disease (25% vs. 17% before disease, 27% vs. 17% after disease).[225] Another controlled study did not find that women with RA have a higher proportion of miscarriage prior to the onset of disease.[211] Interestingly, this same study found that the

frequency of fetal death was higher in patients who later develop RA than in nonaffected relatives. There are scant data available, but women with RA do not appear to be at significant risk for preterm birth, preeclampsia, or IUGR.

Management Options

Prepregnancy

The prepregnancy management of RA is similar to that of any of the other autoimmune disorders. This includes stabilization of the underlying disease process, reducing maintenance medications to minimize early fetal risks, and avoidance of known teratogenic agents.

Prenatal

As with SLE, a physician should see a woman with RA every 2 to 4 weeks throughout the pregnancy, especially if the patient is having trouble with her disease. Rest is an important part of the management of RA, and the patient should be counseled to plan adequately for this. Physical therapy can be helpful in patients whose disease does not improve with pregnancy.

ANTIRHEUMATIC DRUGS AND PREGNANCY

It is best to use acetaminophen for simple analgesia. If possible, the patient should avoid NSAIDs and aspirin (see discussion in SLE). Glucocorticoids should be considered for patients whose RA does not improve during pregnancy. Relatively low doses of prednisone are usually adequate for RA during pregnancy and are not often necessary for maintenance therapy. Intra-articular steroids can also be used if necessary in pregnancy. If NSAIDs prove necessary, the minimum dose necessary to control inflammation should be used. Methotrexate is absolutely contraindicated during the first trimester and relatively contraindicated thereafter. The anti-tumor necrosis factor-α (TNF-α) agents are of unknown safety in pregnancy and probably should avoided. Leflunomide is teratogenic in animals.

Labor and Delivery

Because RA has little, if any, adverse effect on pregnancy outcome, there are no special prenatal obstetric concerns. In a rare case, severe deforming RA can pose a problem to the mechanics of vaginal delivery; such cases are obvious and require individualized care.

Postnatal

Postpartum management of the RA parturient is similar to that of patients with other autoimmune disorders (see SLE).

SUMMARY OF MANAGEMENT OPTIONS

Consult with rheumatology subspecialist.	–	GPP	–

SYSTEMIC SCLEROSIS

The term *scleroderma* is derived from words referring to hardening *(scleros)* and skin *(derma)*, the hallmark feature of this disease. Systemic sclerosis (SSc) refers to internal organ involvement, characterized histologically by a marked increase in collagen, mostly in the dermis with hyalinization and often obliteration of small blood vessels. Early in the disease process, the dermis contains mononuclear cell infiltrates and sometimes calcium, due to the deposition of calcium hydroxyapatite. Pathologic changes also include thinning of the epidermis and loss of normal dermal appendages. Most patients with SSc report Raynaud's phenomenon, and vascular features are evident in biopsies from SSc patients. Small arteries and arterioles exhibit characteristic endothelial cell proliferation and intimal thickening as well as increased amounts of fibrinogen and fibrin, with lumina often occluded by fibrosis. Remaining vessels become dilated, visible through the skin as telangiectases.

Internal organs have similar histologic changes. Fibromucoid intimal thickening in the kidney results in narrowing and thinning of the lumen. Cortical glomerular involvement is usually focal and includes endothelial cell proliferation and thickening of the basement membrane. In the lung, the most common finding is interstitial fibrosis with increased numbers of fibroblasts, capillary congestion, and thickening and occlusion of

alveolar walls and arteriolar intima. Densely hyalinized fibrosis is found in the gastrointestinal tract and random focal fibrosis in the myocardium.

The disease is uncommon, occurring in no more than 10 to 15 individuals per million per year. The ratio of females to males is 10:1 in the 15- to 44-year age-group. The mean age of onset is in the early 40s, when many affected women may potentially become pregnant.[227]

Pathogenesis of Systemic Sclerosis

The pathophysiologic changes of SSc include vascular abnormalities, immunologic abnormalities, and disordered collagen synthesis. The initial event most likely occurs in small blood vessels with early proliferation of intimal layer endothelial cells that produce cytokines, growth factors, adhesion proteins, vasoactive proteins, coagulation factors, and extracellular matrix. Aberrant production of factors such as von Willebrand factor also occurs. A hallmark feature of SSc is clearly increased fibroblast activity with an accelerated rate of fibroblast collagen synthesis.

An association between an increase of HLA-DR11 (whites) and HLA-DR15 (Asians) in patients with diffuse SSc has been described. Associations have also been described with the SSc-associated autoantibodies topoisomerase I and anticentromere antibody although results have varied in different ethnic and racial groups.[228]

A number of different non-HLA genes have most recently been identified in association with SSc. Genes encoding for extracellular matrix proteins have been identified, notably C0L1A1 and C0L1A2, genes encoding type I collagen. Other interesting studies have identified a candidate gene near the fibrillin 1 gene on chromosome 15q in studies of a Native American population with a particularly high prevalence of SSc. Polymorphisms in transforming growth factor-β 1, 2, and 3 genes have also been identified in association with SSc, as have polymorphisms in TNF-α, TNF-β, CXCR2, tissue inhibitor of metalloproteinase-1, and interleukin-4 receptor-α.[229]

Diagnostic Evaluation of Systemic Sclerosis

Clinically, the expression of SSc varies considerably; the morbidity depends on the extent of skin or internal organ involvement. Raynaud's phenomenon is common, especially in patients with CREST syndrome (calcinosis of involved skin, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias), a more limited form of scleroderma. Patients who eventually develop diffuse disease involving the internal organs are more likely to present with arthritis, finger and hand swelling, and skin thickening. The skin thickening, which usually starts on the fingers and hands, eventually involves the neck and face. In severe, progressive disease, much of the skin may be involved and marked deformities of the hands and fingers may occur. Raynaud's phenomenon and internal organ damage are attributed to fibrosis of arterioles and small arteries. In these circumstances, the normal vasoconstrictor response to various stimuli, including cold, causes near-complete obliteration of the vessel. As a result, digital ischemia may occur. A similar vasculopathy is probably responsible for internal organ involvement. Lower esophageal dysfunction is most common. Other portions of the gastrointestinal tract may be involved, producing malabsorption, diarrhea, and/or constipation.

A variety of pulmonary lesions may occur, with the most common being progressive interstitial fibrosis. Pulmonary hypertension, a problem of special interest to the obstetrician, may also occur in longstanding disease. Nearly half of the patients with well-established SSc have evidence of myocardial involvement. Arrhythmias are probably the most common sign encountered. Renal disease occurs to some extent in many patients and is a major cause of mortality among patients with SSc. Severely involved cases may present with proteinuria and renal insufficiency, hypertension, or both. Sudden onset of severe hypertension and progressive renal insufficiency with microangiopathic hemolysis is known as *scleroderma renal crisis*. These crises usually occur in cold weather, suggesting that the pathophysiology is similar to that of Raynaud's phenomenon.

Antinuclear antibodies are present in most patients with SSc, but anti-DNA antibodies are not. About half of patients have serum cryoglobulins. Antibodies to centromere detected by indirect immunofluorescence are common among patients with limited scleroderma (CREST syndrome), but not among those with diffuse disease. Up to 40% of patients have antibody to an extractable nuclear antigen designated ScI. The biologic significance of these autoantibodies is unclear.

Risks of Systemic Sclerosis in Pregnancy

Complications of Systemic Sclerosis in Pregnancy

Pregnancy in women with SSc is uncommon, with fewer than 200 reports in the published literature. Early reports suggested that fertility was impaired in women with SSc, although this has not been confirmed in more recent studies.[230] Rather, women in the SSc group were older and had either waited to have children or had not desired pregnancy.[227] The effect that pregnancy might have on the course of SSc depends to some extent on the degree of preexisting disease involvement. Published data regarding the risks of pregnancy in women with SSc are scarce, and the findings of case reports and small series that suggest pregnancy should be avoided in women with SSc should be regarded with caution. The findings of the largest and most complete studies suggest that overall maternal outcomes are more salubrious, with worsening of disease in pregnancy in no more than 20% of

cases.[227,230,231] Postpartum, approximately one third of women with SSc have exacerbations of Raynaud's phenomenon, arthritis, and skin thickening.[231]

Pregnancy is probably safest in SSc patients without obvious renal, cardiac, or pulmonary disease. Although data are scant, women with SSc with moderate to severe cardiac or pulmonary involvement likely face increased risks of substantial morbidity or mortality and should not undertake pregnancy. In addition, SSc patients with moderate to severe renal disease and hypertension probably face a substantial risk for preeclampsia and perhaps mortality due to renal crisis. Pregnancy should be discouraged in these women as well. Finally, there may be an increased risk of renal crisis in patients with early diffuse SSc[231]; therefore, some authorities suggest that these patients delay pregnancy.

Obstetric Complications in Women with Systemic Sclerosis

PREGNANCY LOSS

Fetal outcomes in SSc pregnancies are mixed, with half or more ending in term live births and another quarter ending in liveborn premature infants.[230,232–238] Preterm birth is particularly prominent in women with early, diffuse disease. Women with late, diffuse scleroderma may be at increased risk for miscarriage, reported at 65% in one case series. There has been some suggestion that a predisposition to pregnancy loss predates the onset of SSc in some women. Of 154 patients who eventually developed SSc and 115 matched controls, a significantly greater number of women with SSc had a history of miscarriage (29% vs. 17%).[238] However, only 3 met the definition for recurrent miscarriage (three or more consecutive losses). The most recent large case-control trial failed to find any association between a history of pregnancy loss and the subsequent development of SSc.[231]

GESTATIONAL HYPERTENSION/PREECLAMPSIA AND IUGR

Given the microvascular nature of the condition and the relative frequency of renal involvement in SSc, one might speculate that preeclampsia and IUGR would occur significantly more often in SSc pregnancies. This is supported by high rates of preeclampsia in case reports but not by case series. In one case series, 10% of pregnancies were complicated by IUGR.[230] Neonatal involvement with skin sclerosis possibly attributable to SSc have been reported in a few cases. The risks of this condition, as well as its relationship to SSc itself, remain unclear. Among the 29 pregnancies accumulated in case reports, there were 2 miscarriages (7%), 2 fetal deaths (7%), and 1 neonatal death attributable to prematurity. Two other infants died because of multiple anomalies. Among the 103 pregnancies in the small series,[233–236] there were 24 miscarriages (23%), 3 fetal deaths (3%), and 2 neonatal deaths due to prematurity. Thus, noncontrolled reports suggest that 72% to 83% of pregnancies among women with SSc are successful (excluding perinatal deaths due to anomalies).

In the case-control study by Giordano and colleagues,[237] 80 SSc patients had 299 pregnancies. Of these, 50 ended in miscarriage (17%), significantly higher than the rate of miscarriage in the matched controls (10%). There was no difference in the miscarriage rate between patients with diffuse versus limited SSc. The retrospective study of Steen and colleagues[232] included 86 pregnancies after the onset of SSc. Of these, 15% ended in miscarriage and 2% ended in midtrimester fetal deaths. These percentages were not significantly different from those in RA controls or neighborhood controls. The later prospective study by this same group found that 18% of 67 SSc pregnancies ended in miscarriage, compared to 158 control pregnancies. Taken together, the available data suggest that the rate of miscarriages and fetal deaths in patients with SSc might be slightly increased compared with controls.

Management Options

Prepregnancy

Before pregnancy, management of SSc follows the basic guidelines set out for the other autoimmune disorders. Patients with early diffuse scleroderma and with significant cardiopulmonary involvement or severe renal disease should be counseled against getting pregnant.

Prenatal

Systemic sclerosis patients considering pregnancy and any patient with SSc who presents for medical care already pregnant should have her clinical situation thoroughly investigated. Special attention should be given to the evaluation of possible renal or cardiopulmonary involvement. It is prudent to recommend pregnancy termination in patients with diffuse SSc and cardiopulmonary involvement or moderate to severe renal involvement.

Even in the nonpregnant state, there is no satisfactory therapy for SSc. Patients with limited disease are usually managed with vasodilators and anti-inflammatory agents. As discussed previously, NSAIDs should be avoided if at all possible during pregnancy. Oral vasodilators for the prevention and treatment of Raynaud's phenomenon may be continued, although substantial data to prove fetal safety are not available. Patients with diffuse SSc may be taking glucocorticoids; see Systemic Lupus Erythematosus in this chapter. Other immunosuppressive or cytotoxic agents should be avoided.

Angiotensin-converting enzyme inhibitors appear to be particularly efficacious in treating SSc-related hypertension and renal crises. These drugs have been associated with fetal/neonatal renal insufficiency in a small number of cases. However, in SSc-related hypertension, the benefits of these medications probably outweigh the risks of discontinuing them.[239]

Patients with continuing pregnancies should be seen by a physician every 1 to 2 weeks in the first half of pregnancy

and once weekly thereafter. Although serial laboratory testing is not necessary, laboratory assessment of unusual or suspicious symptoms or signs may be helpful. The possible risk of IUGR and fetal death requires serial examination of the fetus by sonography. Fetal surveillance should be instituted by 30 to 32 weeks' gestation, or sooner if the clinical situation demands.

Labor and Delivery

In patients with mild to moderate disease, few additional precautions are needed during the labor and delivery process. Again, signs of preeclampsia should be sought, since this complication may be more likely with sclero-

derma.[224] Wound healing may be a problem in patients with advanced disease or those on steroids. Therefore, operative interventions require meticulous attention to this issue. In patients with significant pulmonary, cardiac, or renal impairment, intensive care management may be needed.

Postnatal

Postpartum care represents a continuation of the intrapartum management plan. Most often, reinstitution of maintenance medication is all that is required. Complications of scleroderma, as previously outlined, require individualization of care.

SUMMARY OF MANAGEMENT OPTIONS
Systemic Sclerosis

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Counsel regarding risk of exacerbation during pregnancy and risk of medication exposure.	IIa	B	230
Establish good control of SSc and adjust maintenance medications.	III	B	231
If possible, discontinue cytotoxic medications before conception. This should be done only under careful supervision.	–	GPP	–
Assess cardiopulmonary and renal function (advise against conception if significantly compromised?).	III	B	231
Prenatal			
Institute joint obstetrician and physician surveillance.	III	B	231
Prenatal visits should occur every 2 to 4 weeks until 20 to 24 weeks' gestation and every 1 to 2 weeks thereafter.	III IV	B C	227 231
Monitor cardiopulmonary and renal function (consider termination of pregnancy if severe compromise).	IV	C	227
Possible drugs:			
• Anti-inflammatory for moderate joint problems	–	GPP	–
• Vasodilators for pulmonary problems	–	GPP	–
• Steroids for worsening disease	–	GPP	–
Be vigilant for preeclampsia.	IV	C	227
Use of ACE inhibitors a dilemma if hypertension is present; avoid if possible.	III	B	231
Check fetal growth (every 3 to 4 weeks after 17 to 18 weeks) and health.	IIa	B	230
Initiate antenatal surveillance initiated at 30 to 32 weeks' gestation or earlier if uteroplacental insufficiency is suspected.	–	GPP	–
Labor and Delivery			
Deliver near term. Avoid postdates.	–	GPP	–
Intensive/high dependency care may be necessary.	–	GPP	–
Take special precautions to ensure would healing if cesarean section delivery.	–	GPP	–
Postnatal			
Provide initial care in intensive/high dependency care setting.	–	GPP	–
Review dosage of drugs and resume maintenance medications.	–	GPP	–

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is an autoimmune disorder affecting neuromuscular transmission, resulting in variable weakness and fatigability of skeletal muscle. Increasing weakness with repetitive use of the muscle(s) is the characteristic feature. Occurring in only 2 to 10 per 100,000 individuals, MG affects twice as many women as men, with an onset usually in the second or third decade in women.[240,241] The immediate cause of the disease is probably an autoimmune attack on the acetylcholine receptor complex of the neuromuscular junction. Serum autoantibodies against acetylcholine receptors (anti-AChR) are found in the serum of 85% of patients with MG.[242] The disease can be transferred passively to laboratory animals by the injection of IgG from affected individuals.[243] Accordingly, 10% to 20% of infants born to women with MG show signs of neonatal MG, thought to be caused by the transplacental passive transfer of antibodies from mother to child.[244,245]

Ocular muscle weakness resulting in diplopia or eyelid ptosis is the usual presenting problem. Some patients have difficulty with chewing or talking. In a large majority of patients, MG progresses from ocular to generalized skeletal muscle involvement over a 1- to 2-year period. Any trunk or limb muscle may be involved, but the neck flexors, deltoids, and wrist extensors are notable. Death results from severe respiratory muscle fatigue. Muscle weakness varies throughout the day but is usually worse toward the end of the day. The long-term course of disease is likewise variable and is characterized by periodic fluctuations in severity. For unclear reasons, MG tends to be worsened by emotional distress, systemic illness, and increased temperature (fever, hot weather).

Pathogenesis of Myasthenia Gravis

It is apparent that the pathophysiology of disease is not simply the blockade of AChR by antibody. The muscle endplate, wherein the AChR resides, is misshapen and bears a reduced number of AChR.[246] This is presumed to be due to autoimmune damage, perhaps mediated through complement destruction. The net result is a diminished depolarization response to a normal amount of released acetylcholine at the postsynaptic membrane.

Abnormalities of the thymus are found in most patients with MG. In total, 75% have lymph follicle hyperplasia and 10% to 15% have lymphoblastic or epithelial thymic tumors. Thymectomy results in remission in 35% and improvement in 50% of patients.[247] These observations suggest that MG may be due to (1) an autoimmune attack on the antigens common to the thymus and motor endplate, or (2) abnormal clone(s) of immune cells in the thymus.

Treatment of Myasthenia Gravis

Myasthenia gravis is treatable but not curable. The use of anticholinesterase drugs is reportedly safe during pregnancy. Pyridostigmine, an analogue of neostigmine, is the most commonly used anticholinesterase medication. These medications impede degradation of acetylcholine and bring about improvement in muscle function. Some patients with MG may only respond to immunosuppressive therapy with corticosteroids, azathioprine, and cyclosporine.[247] In the occasional patient with refractory MG, IVIG and plasmapheresis have been used with some success.[240]

Diagnostic Evaluation of Myasthenia Gravis

The diagnosis of MG rests on the clinical presentation, physical examination, and confirmatory diagnostic procedures. Repetitive use of the muscle under study results in apparent exhaustion. The muscle vigor can be dramatically restored with short-acting anticholinesterase drugs, such as edrophonium in doses of 210 mg given by intravenous injection. More sophisticated tests are now available, including single-fiber electromyography and repetitive nerve stimulation studies.

Risks of Myasthenia Gravis in Pregnancy

Complications of Myasthenia Gravis in Pregnancy

Several pregnancy-related physiologic changes may have detrimental effects on MG. Nausea, vomiting, altered gastrointestinal absorption, expanded plasma volume, and increased renal clearance require adjustment of anticholinesterase throughout pregnancy. Elevation of the maternal diaphragm by the gravid uterus causes hypoventilation of the lower portions of the lungs, which exacerbates respiratory compromise in some women with MG. Maternal predisposition to infections such as pyelonephritis can precipitate an exacerbation of MG. Increased physical exertion in the second and third trimesters and the emotional stress of pregnancy itself may also result in MG exacerbation.

The course of MG during pregnancy is highly variable. Cartlidge[248] recommends postponement of pregnancy in women recently diagnosed with MG because this period represents the time of greatest risk. In an extensive review, approximately 40% of women with MG had exacerbation of their disease during pregnancy; approximately 30% had no change and 30% had postpartum exacerbations that were frequently sudden and serious in nature.[249] Moreover, of the approximately 30% of MG patients whose disease remained unchanged during pregnancy, several had significant postpartum exacerbations. In the most recent review that included both patients who were in remission prior to pregnancy and patients who were taking therapy, exacerbations occurred in 10 of 54 pregnancies (19%), improvement in

12 (22%), and no change in 32 (59%).[242] Plauche found an overall maternal mortality of 4% (9 of 225 reported cases).[249] The majority of these (7 of 9) were due to refractory MG.

Obstetric Complications in Myasthenia Gravis

The rates of miscarriage and fetal death in pregnancies complicated by MG do not appear to be significantly different from those of the normal population.[240,250] However, early series suggested preterm birth in up to two thirds of patients with MG,[250–253] and anticholinesterase drugs are thought to have an oxytocic action.[254] However, in the most recent and largest series to date, there was a difference in the prevalence of preterm birth and low birth weight in 54 MG patients compared to the general population.[240]

The transplacental passage of anti-AChR antibodies can lead to fetal or neonatal MG. Only about 10% to 15% of infants born to mothers with MG show signs of MG.[255] The relative infrequency of fetal involvement was due to alpha-fetoprotein, which has been shown to inhibit the binding of anti-AChR to AchR.[256,257] Most infants with neonatal MG have high concentrations of anti-AChR in their circulation.

The diagnosis of neonatal MG is made by observation of poor sucking, feeble cry, and respiratory difficulties that respond to edrophonium. Neonatal MG is transient, usually abating over a period of 1 to 4 weeks. The symptoms usually develop within the first several days of life, but are often absent initially, perhaps because of the presence of alpha-fetoprotein.[257] When properly recognized, the disease is easily managed with supportive care and anticholinesterase drugs. There does not appear to be any correlation between the risk of neonatal MG and severity of maternal MG manifestations[242] or the level of maternal anti-AChR antibodies.[258,259] However, there does appear to be a relationship between neonatal levels and the severity of neonatal MG.[242] Arthrogryposis multiplex congenita (AMC), a nonprogressive congenital contraction disorder thought to result from poor fetal movement, has rarely been reported in infants born to women with MG.[255,260,261] There is some evidence that plasmapheresis and immunosuppressive therapy may reduce the recurrence of AMC in MG patients with a prior neonatal death presumably due to AMC.

Management Options

Prepregnancy

Adjustment of medication to establish quiescence/control of the disease process is vital before pregnancy. Patients should be appropriately educated regarding the need for close supervision, the expected increase in fatigue, and the potential for respiratory compromise (especially late in pregnancy); the fetal risks of preterm delivery, the potential for associated anomalies, and the transient nature of neonatal MG should be discussed.

Prenatal

Treatment is frequently necessary before, during, and after pregnancy to ensure maternal and fetal well-being. Pregnancy-related changes in drug absorption, increased renal clearance, and expanded plasma volume may require alterations in medication in order to maintain adequate drug levels. The first line of therapy is quaternary ammonium compounds with anticholinesterase activity. Although neostigmine (Prostigmin) was the first such drug to be used, its short half-life was a major drawback. Pyridostigmine (Mestinon), which has a longer half-life, is the most popular long-acting medication currently used for maintenance therapy of MG. There is now a sustained-release form of the drug (Mestinon Timespan, 180 mg), but its popularity is limited by concerns about irregular absorption and drug preparation. Oral pyridostigmine is typically given in doses of 240 to 1500 mg/day in divided doses at 3- to 8-hour intervals. When used, the sustained-release preparation is typically given as a single bedtime dose of 180 to 540 mg. If the patient requires more drug, as is often the case with advancing pregnancy, it is best to first shorten the interval between doses. If this fails to control symptoms, the dose of pyridostigmine should be increased by increments of 15 to 30 mg. Such maneuvers usually lead to adequate control of MG during pregnancy. The most common side effects of these medications are due to the accumulation of acetylcholine (muscarinic effects). These include gastrointestinal symptoms (nausea, vomiting, cramping, diarrhea) and increased oral and bronchial secretions. Overdose of anticholinesterase drugs results in the rare so-called *cholinergic crisis*, which paradoxically includes muscle weakness and respiratory failure.

Glucocorticoids are effective in most patients with MG. Most authorities prefer high doses (prednisone 60 to 80 mg/day) to start; the dose is tapered over many months after improvement is noted. The disease may transiently worsen soon after the steroids are started; for this reason, patients should be hospitalized for steroid therapy. Unfortunately, remission appears to be maintained only if the patient continues on steroids, and withdrawal of steroids may cause myasthenic exacerbations. For these reasons, pregnant MG patients should maintain glucocorticoid therapy through pregnancy and the postpartum period. Some authors believe that glucocorticoid-induced remission is a particularly good time for pregnancy in patients with MG.

Plasmapheresis has been used with success in severe MG. Most patients were also taking glucocorticoids. There is one case report of using plasmapheresis to successfully treat MG in pregnancy.[262] It may be that maternal plasmapheresis might be the treatment of choice in MG pregnancies in which the fetus has markedly reduced or absent fetal movement predisposing it to AMC.

Thymectomy may result in improvement in many patients with MG by mechanisms that are unknown. However, resorting to thymectomy during pregnancy would seem imprudent because of frequent long delays before improvement and perioperative maternal and fetal concerns.

Patients with MG should be seen relatively frequently throughout pregnancy, every 2 weeks in the first and second trimester, and every week in the third trimester. Undue emotional and physical stress are to be avoided, since they may result in exacerbation of MG. The patient and physician should be alert to the possibility of preterm labor, and appropriate preventive steps instituted. Although care must be individualized, limiting exercise and work is probably in order for many patients. Infections may also result in exacerbation of MG. Respiratory and urinary tract infections must be identified and treated promptly.

Fetal involvement with MG is suspected by poor fetal movement and hydramnios. This is not treatable in utero. Differentiating poor fetal movement due to MG from that due to fetal hypoxemia may be difficult, but normal fetal heart rate tests, especially a negative contraction stress test, and a normal biophysical profile score, are reassuring.

Labor and Delivery

The management of labor and delivery in patients with MG requires limitation of emotional and physical stress and the appropriate use of parenteral anticholinesterase drugs. Neostigmine can be given subcutaneously, intramuscularly, or intravenously. As a rough guide, 60 mg oral pyridostigmine is equivalent to 0.5 mg IV neostigmine and 1.5 mg subcutaneous neostigmine. The usual dose of parenteral neostigmine is 0.5 to 2.5 mg. Maximal effects on skeletal muscle may occur 2 to 30 minutes after intramuscular injection; the effects last for about 2.5 hours. Pyridostigmine can be given intramuscularly or very slowly intravenously. The usual dose is 2 mg (approximately 1/30 of the usual oral dose) every 2 to 3 hours. The course of the first stage of labor in patients with MG is not altered because MG does not affect smooth muscle.[245] The second stage of labor could be affected by the weakened material expulsive efforts, although the average duration of labor in MG patients is normal.

It is important to recognize that certain medications that may be used in the management of obstetric concerns are contraindicated in patients with MG. These are listed in Table 44–11. Magnesium sulfate is absolutely contraindicated because it further interferes with the neuromuscular blockade of MG. Preterm labor can probably be treated with beta-sympathomimetics,[260] but the associated hypokalemia should be carefully avoided. A small number of patients with MG have an associated cardiomyopathy, which could increase the risks of beta-sympathomimetics.

Because the patient with MG is particularly sensitive to neuromuscular drugs, analgesic and anesthetic considerations are important before the onset of labor. All patients with MG should be seen in consultation with an anesthesiologist early in the course of pregnancy. Epidural anesthesia is probably best because it limits the need for analgesia, may help prevent anxiety and fatigue, and is excellent for forceps procedures. Amide-type local anesthesia agents are used.[263] Some authors recommend general endotracheal anesthesia for cesarean section in patients with respiratory involvement. Myasthenic crises requiring ventilatory support may be precipitated by the stress of labor and delivery, an inadvertent change in medication, or surgery. Rarely, cholinergic crises may result from overdosage with anticholinesterase drugs. These patients have prominent muscarinic symptoms in addition to respiratory weakness. In all patients with MG, labor and delivery management should include the immediate availability of personnel and equipment for ventilatory support and airway maintenance. Postoperative care may be best accomplished in an intensive care setting.

Postnatal

It would be difficult to find a patient, following delivery, who is not fatigued and weakened. Differentiating this normal state of affairs from exacerbation of MG may be difficult without objective testing. Drug dosages may need to be rapidly adjusted, in particular downward, as the effects of the volume expansion of pregnancy clear.

TABLE 44–11

Medications that May Exacerbate or Cause Muscle Weakness in Patients with Myasthenia Gravis

Magnesium salts	Cholistin
Aminoglycosides	Polymyxin B
Halothane	Quinine
Propranolol	Lincomycin
Tetracycline	Procainamide
Barbiturates	Ether
Lithium salts	Penicillamine
Trichlorethylene	

SUMMARY OF MANAGEMENT OPTIONS
Myasthenia Gravis

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Counsel regarding risk of exacerbation during pregnancy and risk of medication exposure.	III	B	240
Review therapy; establish good control of MG; adjust maintenance medications.	III	B	249–255
If possible, discontinue cytotoxic medications before conception. This should be done only under careful supervision.	III	B	—
Consider thymectomy in symptomatic women who are refractory to therapy.	III	B	—
Prenatal			
Institute joint obstetrician and physician surveillance.	III	B	252
Continue pre-existing drugs:			
• Anticholinesterase	III	B	240
• Steroids			
• Azathioprine			
Consider plasmapheresis and IVIG in refractory cases.	III	B	240
Maintain fetal surveillance, especially activity (?biophysical profile score).	—	GPP	—
Initiate antenatal surveillance at 30 to 32 weeks' gestation.	—	GPP	—
Avoid/minimize physical/emotional stress.	III	B	249–255
Labor and Delivery			
Minimize stress.	III	B	—
Continue anticholinesterase drugs (parenteral).	III	B	—
Prescribe intravenous glucocorticoids for delivery in patients who have received maintenance or steroid bursts during pregnancy.	—	GPP	—
Regional analgesia preferable to narcotics for pain relief and general anesthesia.	III	B	249–255
Consult with experienced anesthetists if general anesthesia (advisable to consult in prenatal period).	III	B	249–255
Assisted second stage more likely.	III	B	249–255
Avoid magnesium sulfate (and other contraindicated drugs) in patients with preeclampsia.	IV	C	254
Postnatal			
Provide special care and surveillance of newborn; may need short-term anticholinesterases.	III	B	240, 259
Review dosage of drugs.	III	B	240

CONCLUSIONS

- Autoimmune disorders in pregnancy carry risks to mother (especially miscarriage, preeclampsia, and thromboembolism) and fetus (especially IUGR and fetal death); the newborn can show residual effects of transplacental maternal antibody passage.
- Prepregnancy care should cover explaining the risks of the condition and optimizing medical control, ideally using drugs that are safe in pregnancy.

CONCLUSIONS (Continued)

- Prenatal care largely focuses on maintenance of disease control, anticoagulation where indicated, and surveillance for preeclampsia in the mother and uteroplacental disease in the fetus.
- Labor and delivery are usually determined by the development of complications; anticoagulation will need to be reduced in the short term.
- After delivery the priority is to maintain vigilance for maternal exacerbation.
- Maternal therapy should be adjusted as indicated.
- Neonatal surveillance and management is required if maternal antibodies persist.

Diabetes

INTRODUCTION

CLASSIFICATION AND TYPES OF DIABETES

Diabetes

Christine Ang / David Howe / Mary Lumsden

INTRODUCTION

Diabetes mellitus is a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both. Approximately 150 million are affected worldwide. The World Health Organization (WHO) has predicted that between 1995 and 2025 there will be a 35% increase in the worldwide prevalence of diabetes. In the United Kingdom, it was estimated in the year 2000 that 1.4 million people suffer from diabetes and another million remain undiagnosed. It is variously estimated that 3% to 5% of pregnancies are complicated by diabetes. Approximately 0.2% to 0.5% of all pregnancies occur in women with a preexisting diagnosis of type 1 diabetes mellitus,[1] and a similar number have preexisting type 2 diabetes mellitus.[2] An additional 1% to 6% of women will develop sufficient hyperglycemia during pregnancy to meet the criteria for a diagnosis of diabetes (termed *gestational diabetes*, or GDM).[3] Of those women with gestational diabetes, between 20% and 50% subsequently develop type 2 diabetes mellitus.[3]

Chronic hyperglycemia is associated with long-term damage, dysfunction, and failure of various organs, especially the eyes, kidneys, nerves, heart, and blood vessels.[4] Women entering pregnancy with a preexisting diagnosis of diabetes historically had a poor prognosis for successful pregnancy. Numerous studies have shown that with careful attention to control of blood sugar near-normal outcomes can be achieved and the risk of progression of diabetic complications during pregnancy is minimal. Sadly, many diabetic women are unable to achieve ideal glucose control for whatever reason, and diabetic pregnancy remains associated with increased rates of congenital abnormality, miscarriage, hypertension, late stillbirth, fetal macrosomia, and obstructed labor.[1,5,6] Additionally, the physiologic changes that occur in pregnancy can accelerate the progression of diabetic complications, such as retinopathy and nephropathy, particularly if the diabetes is poorly controlled. These issues are considered in more detail in the section on established diabetes.

More controversial is the diagnosis of gestational diabetes, in which hyperglycemia develops in pregnancy. Undoubtedly, many of the obstetric complications of diabetes occur to some degree across a continuum of glucose concentrations. The difficulty lies in deciding at which level of glucose to intervene. Setting the threshold too low will result in overinvestigation and treatment of many women who can be expected to have a good pregnancy outcome. Furthermore, it is not entirely clear that rigorous glucose control instituted in late pregnancy successfully reduces the risks of these complications.[3,7–9] The evidence for screening for gestational diabetes is considered in the Gestational Diabetes section.

Several bodies, including the Scottish Intercollegiate Guidelines Network (SIGN), Diabetes UK, The American Diabetes Association, and the American College of Obstetricians and Gynecologists, have produced guidelines and position statements on the management of pregnant women with diabetes and on screening for gestational diabetes and fetal macrosomia.[10–15]

CLASSIFICATION AND DIAGNOSIS OF DIABETES

Traditionally, diabetes mellitus has been divided into insulin dependent (type 1) and noninsulin dependent (type 2) forms. More recently, a classification into five groups (see Table 45–1) has been advanced, based on patterns of inheritance and clinical presentation. Pregnancy itself is a state of physiologic insulin resistance. In a number of women the physiologic increase in insulin resistance during pregnancy on a background of inherited insulin resistance or obesity is enough to make them overtly diabetic. GDM refers to women who are shown to be diabetic for the first time during pregnancy, regardless of whether the diabetes persists after pregnancy.[9]

Classification of Diabetes Mellitus

Type 1 diabetes mellitus	Immune-mediated DM (cell-mediated immune destruction of beta cells of pancreas)
	Idiopathic DM (forms of the disease with no known etiology)
Type 2 diabetes mellitus	Relative rather than absolute insulin deficiency
Impaired glucose homeostasis	Impaired fasting glucose (fasting glucose higher than normal, but less than diagnostic)
	Impaired glucose tolerance (plasma glucose following a 75 g challenge higher than normal, but less than diagnostic)
Gestational diabetes mellitus	Glucose intolerance in pregnancy
Other specific types	DM due to specific etiologies:

- Genetic defects of beta cell function (MODY 1, 2, 3)
- Genetic defects of insulin action
- Disease of exocrine pancreas (pancreatitis, cystic fibrosis)
- Endocrine (Cushing's)
- Drug or chemical induced
- Infection (rubella, coxsackie, cytomegalovirus)
- Uncommon forms of immune-related diabetes
- Other genetic syndromes

From Abbertini K, Zimmet P: Definition, diagnosis and classification of diabetes mellitus and its complications. Part 1: Diagnosis and classification of diabetes mellitus. Provisional report of a WHO consultation. Diabetes Med 1998;15:539–553.

The diagnosis of diabetes in nonpregnant subjects is made on the finding of elevated fasting blood glucose and/or elevated blood glucose following an oral glucose challenge. Multiple genetic and epigenetic factors modify fasting glucose concentrations and the response to an oral glucose challenge, so that there is not a clear bimodal separation of "normal" glucose tolerance and "diabetic" states. Instead there is a continuum of fasting blood glucose concentrations and of the response to an oral glucose challenge. The accepted criteria used to diagnose diabetes are shown in Table 45-2.[16,17] In addition, for glucose values falling between "normal" and "diabetic," the terms *impaired glucose tolerance* and *impaired fasting glycemia* have been coined. Impaired glucose homeostasis and impaired fasting glycemia are not recognized as diseases, but their presence does indicate an increased likelihood of developing diabetes.

World Health Organization Criteria for the Diagnosis of Diabetes

	FASTING PLASMA GLUCOSE		120 MIN GLUCOSE
Impaired fasting glucose	6.1–6.9 mmol/L		
Impaired glucose tolerance	≤7.0 mmol/L	and	7.8–11.0 mmol/L
Diabetes	≥7.0 mmol/L	or	≥11.1 mmol/L

Key:
Blood glucose levels are plasma levels in venous blood following a 75-g oral glucose challenge in fasted subjects. *Values in mg/dL: 6.1 mmol/L = 110 mg/dL, 7.0 mmol/L = 126 mg/dL, 7.8 mmol/L = 140 mg/dL, 11.1 mmol/L = 200 mg/dL.*
From Abbertini K, Zimmet P: Definition, diagnosis and classification of diabetes mellitus and its complications. Part 1: Diagnosis and classification of diabetes mellitus. Provisional report of a WHO consultation. Diabetes Med 1998;15:539–553.

MATERNAL AND FETAL GLUCOSE HOMEOSTASIS IN PREGNANCY

During pregnancy there is a physiologic increase in insulin resistance in maternal tissues, presumably to satisfy the nutritional demands of the fetus.[18] Placental glucose transport is noninsulin sensitive. Instead glucose is moved across the placenta by facilitated diffusion down a concentration gradient. High levels of maternal glucose result in high levels of fetal glucose. The fetal pancreas is stimulated by hyperglycemia, and there is an early increase in beta cell mass of the pancreatic islets, so that the pancreas of fetuses exposed to repeated hyperglycemia secretes relatively more insulin than that of normoglycemic fetuses.[19] Insulin appears to promote fetal growth, either directly through insulin receptors or by increasing the bioactivity of insulin-like growth factor-1 (IGF-1). The mechanism of fetal macrosomia in diabetes is likely due to accelerated pancreatic maturation and higher fetal insulin levels, and this has come to be known as the *Pedersen hypothesis*.[20] Other factors besides glucose stimulate fetal insulin release, and this may be one reason why maternal glucose levels explain only a limited amount of birth weight variation.

Impact of Maternal Diabetic Vascular Disease

Diabetes is associated with both microvascular and macrovascular disease. Microvascular disease leads to retinopathy, nephropathy, and neuropathy, whereas accelerated atherosclerosis of large vessels predisposes to myocardial infarction, stroke, and limb ischemia. Microvascular disease seems to be a result of sustained episodes of hyperglycemia with increased production of metabolites that lead to vascular damage.[21] The endothe-

lial lining of blood vessels plays a pivotal role in the regulation of tissue blood flow, and hyperglycemia-induced endothelial dysfunction of small-resistance arteries leads ultimately to tissue hypoperfusion. There are probably several phases to vascular damage mediated by hyperglycemia. In animal models endothelial-dependent vasodilation is sequentially increased, unaltered, and impaired by hyperglycemia.[22] Studies in pregnant humans have found either normal or impaired function.[23,24]

The fetal placental circulation by definition develops during pregnancy, and numerous researchers have sought evidence for abnormal development of the placental circulation in diabetic pregnancies. Any structural changes are relatively subtle.[25] The regulation of fetal placental blood flow is poorly understood, but in the absence of autonomic or cholinergic innervation is entirely dependent on circulating hormonal and autocrine factors. There is evidence for disturbances in the activity of endothelial-derived nitric oxide in the diabetic placenta.[26]

ESTABLISHED/PREEXISTING DIABETES

Maternal Risks

Prior to the discovery of insulin in 1921 by Frederic Banting and Charles Best, women with diabetes rarely became pregnant, and those who did experienced a high incidence of maternal and fetal morbidity. Nowadays, most women starting pregnancy with a preexisting diagnosis of diabetes have their diabetes relatively well controlled. Nonetheless pregnancy is associated with a physiologic worsening of tissue insulin resistance and with renal and cardiovascular adaptations that might be expected to accelerate the progression of diabetic complications such as retinopathy and nephropathy. Diabetic women are more prone to developing hypertension in pregnancy, and the increased susceptibility to infection means that diabetic women are more likely to suffer from pyelonephritis and perhaps from other infection-mediated adverse obstetric events. Several large studies in nonpregnant subjects have convincingly shown that intensive glucose control reduces the development and progression of diabetic complications.[27–30] The same is true during pregnancy; women can be encouraged that improvement in glycemic control during pregnancy has long-term health benefits. At the same time, intensive glycemic control increases the risk of hypoglycemia and may be one reason why some women choose not to comply with suggested treatment.

Hypoglycemia

For many women, the degree of glycemic control encouraged during pregnancy is much tighter than normal. Concerns about hypoglycemia may be a reason for poor compliance with diet and insulin regimens. Most hypoglycemic episodes occur in the first 20 weeks and in women who have experienced hypoglycemic episodes before pregnancy.[31] It has been estimated that for every 1% fall in glycosylated hemoglobin (HbA_{1c}) levels, there is approximately a 33% increase in hypoglycemic attacks. It is important that family members are educated about the use of glucagon injection for emergency treatment of profound hypoglycemia.

Diabetic Ketoacidosis

In established diabetics ketoacidosis is rare, affecting less than 1% of pregnancies, due to the increased level of supervision and tighter glycemic control generally seen during pregnancy.[1] Occasionally the first presentation of type 1 diabetes mellitus may be with ketoacidosis in pregnancy. The 1994–1996 Report on Confidential Enquiries into Maternal deaths in the United Kingdom reported two indirect maternal deaths from diabetes mellitus and two late deaths from diabetic ketoacidosis. The risk of ketoacidosis increases in the presence of obvious precipitants such as hyperemesis and infection. Obstetricians should be aware that tocolytic therapy with beta-sympathomimetics and corticosteroid therapy results in increased insulin requirements. The metabolic effects of antenatal corticosteroids, are prolonged, and it may be appropriate to use a sliding scale of intravenous insulin to maintain normoglycemia.

Retinopathy

Diabetic retinopathy complicates both type 1 and type 2 diabetes mellitus. In patients who developed diabetes before age 30 and who have had diabetes for more than 20 years, almost all will have retinopathy, and about half of these will have proliferative retinopathy.[32] In women with minimal or early retinopathy, there is a 10% chance of progression during pregnancy; in those with proliferative retinopathy, there is a 50% chance of progression.[33] Hypertension and preeclampsia further increase the risk of progressive retinopathy.[34] Instituting a regimen of intensive glycemic control in patients with moderate to severe nonproliferative retinopathy may result in progression of retinopathy; it is usual to increase the frequency of funduscopic examination.[32]

Nephropathy

End-stage renal disease is one of the major complications of diabetes and accounts for 40% of all patients on dialysis.[35] The incidence of diabetic nephropathy increases with duration of disease and is present in around 25% of diabetics after 15 years.[36] It is estimated that about 6% of pregnant type 1 diabetics will have clinically significant renal impairment.[37]

The impact of pregnancy on diabetic nephropathy depends on prepregnancy renal function. Most case series are small, but in general in women with good renal function (creatinine <150 micromol/L; <1.70mg/dL), there is little evidence of worsening of renal function.[38,39]

In women with markedly decreased glomerular filtration rates prior to pregnancy there is a significant risk of permanent decline in renal function.[39,40] Renal disease is a risk factor for the development of hypertension in pregnancy, and hypertension further accelerates the decline in renal function. Microalbuminuria in early pregnancy is a sensitive predictor of those women likely to develop hypertension.[41] Women with nephropathy are more likely to suffer from pregnancy complications. The incidences of low birth weight, preeclampsia, and preterm delivery are increased in women with nephropathy.[39,42,43]

Hypertension

In diabetic women with chronic hypertension, the normal physiologic changes in blood pressure occur during pregnancy but start from a higher baseline.[44] Chronic hypertension is a risk factor for the development of preeclampsia, and worsening proteinuria and hypertension in later pregnancy may indicate the development of superimposed preeclampsia.[44] Clinically, however, it can be difficult to distinguish between preeclampsia and worsening nephropathy. The development of proteinuric hypertension is reported to complicate 12% to 40% of diabetic pregnancies.[45–48] The presence of microvascular disease (as indicated by the presence of retinopathy) increases the risk of developing hypertension.[49,50]

Atherosclerosis

Macrovascular disease is also a feature of diabetes; the exaggerated lipid changes in pregnancy, along with rheologic and prothrombotic changes, might be expected to accelerate atherosclerosis. Myocardial infarction, however, remains a rare event in pregnant diabetics[51]; equally, there is little evidence of progression of peripheral arterial disease during pregnancy.[52]

Neuropathy

Peripheral neuropathy has usually developed to some degree in most diabetics after 10 to 15 years. Autonomic neuropathy may delay gastric emptying and blunt cardiovascular reflexes, but there are few case reports in the literature suggesting that these considerations are not common.[53] Autonomic neuropathy also results in lack of hypoglycemic awareness. Painful *insulin neuritis*, often described as an ache or burning sensation, sometimes complicates a rapid tightening of glycemic control.[54]

Infection

Maternal infections are more common in diabetics. It has been estimated that about 80% of pregnancies in women with type 1 diabetes mellitus will have at least one episode of infection, compared with 25% of pregnancies in nondiabetic women.[55] Infection is a risk factor for preterm labor and for ketoacidosis. Chronic urinary tract infection, besides being a risk factor for preterm labor, con-

tributes to nephropathy. Pyelonephritis complicates about 4% of diabetic pregnancies and only 1% of nondiabetic pregnancies.[56] Postpartum endometritis and wound infections are also more common in diabetics.

Other Associated Endocrine Diseases

Type 1 diabetes mellitus is an autoimmune condition, and women with type 1 diabetes are at risk of other autoimmune endocrine diseases, notably those affecting the thyroid. The incidence of thyroid dysfunction during pregnancy and the first year postpartum in type 1 diabetics is about 3 times higher than that of the normal population.[57]

Operative Delivery

Maternal diabetes is a risk factor for cesarean delivery. Reported rates of cesarean section in diabetic women range from 25% to 80% and reflect wide divergences in obstetric practice.[39,43,58–61] Many factors account for the high cesarean section rate, including prematurity, macrosomia, and the presence of diabetic complications such as nephropathy. The diagnosis of diabetes, or the knowledge that women are being treated with insulin, triggers an increase in intervention among obstetricians.[62]

Pelvic Floor Trauma

Macrosomia, nulliparity, episiotomy, and instrumental delivery are established risk factors for third- and fourth-degree tears. Approximately 20% of diabetic women who deliver vaginally suffer second-, third-, or fourth-degree tears.[59] Shoulder dystocia is also a risk factor for perineal trauma. Langer reported that when the birth weight was less than 4000 g, the incidence of shoulder dystocia was 0.3%, which rose to 4.9% when the birth weight was above 4000 g. Furthermore, as a group, nondiabetic women had shoulder dystocia rate of 0.5% compared to 3.2% in women who were diabetic.[63]

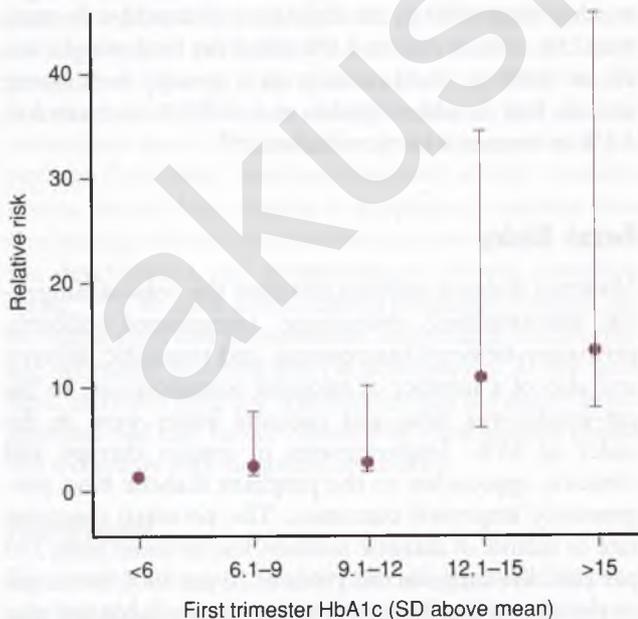
Fetal Risks

Maternal diabetes mellitus increases the risks of congenital abnormalities, miscarriage, unexplained stillbirth, premature delivery, macrosomia, and traumatic delivery, and also of a number of neonatal complications. In the pre-insulin era, fetal and neonatal losses were in the order of 65%. Improvements in insulin therapy and obstetric approaches to the pregnant diabetic have progressively improved outcomes. The perinatal mortality rate of infants of diabetic mothers has declined from 250 per 1000 live births in the 1960s to 20 per 1000 live births in the 1980s. Furthermore, it has been established that tight glycemic control before conception and during pregnancy can reduce the rate of congenital malformations, miscarriage, and fetal macrosomia. Fatal congenital abnormalities now appear to be the leading cause of

perinatal death, but unexplained late stillbirth remains a problem.

Congenital Anomalies

Many centers around the world continue to report that approximately 3% to 8% of infants of diabetic mothers suffer from major congenital abnormalities.[64–67] The reduction in the incidence of congenital anomalies remains a major goal, especially when it is considered that congenital anomalies account for between 20% and 50% of the perinatal deaths to diabetic women.[64,68] The increased risk of congenital anomaly is found in type 1 and type 2 diabetics who had hyperglycemia during early pregnancy. Women with gestational diabetes diagnosed later in pregnancy do not seem to be at risk.

The congenital abnormalities found in the infants of diabetic women do not form a clear syndrome. Neural tube defects and cardiac malformations are more common than in the nondiabetic population, and caudal regression (or sacral agenesis) is reported to be 200 to 400 times more common in infants of women with diabetes.[69–71] There is good evidence that the abnormalities arise as a consequence of poor glycemic control periconceptually and during embryogenesis.[70] When the HbA_{1c} is less than 6 standard deviations above the mean, the congenital anomaly rate is about 3%, but when the HbA_{1c} is more than 12 standard deviations above the mean, the anomaly rises to rate 35%. Figure 45–1 shows the relationship between first-trimester HbA_{1c} and congenital abnormalities. Small studies have reported low rates of congenital abnormality where preconceptual input has


optimized glycemic control.[72,73] In the larger Diabetes In Early Pregnancy Study, where women were enrolled within 21 days of conception, infants of diabetic mothers had higher rates of congenital abnormality than those of nondiabetic mothers, but the investigators were unable to relate the risk of abnormality to mean glucose or to glycosylated HbA_{1c}.[74] The randomized prospective Diabetes Control and Complications Trial showed that the timely institution of intensive therapy for blood glucose control is associated with rates of spontaneous abortion and congenital malformations that are similar to those in the nondiabetic population.[75]

Both hyperglycemia and hypoglycemia have been suggested as possible causes of congenital anomaly. Studies with nonhuman embryos in culture identified that hypoglycemia is teratogenic.[71] In clinical practice, however, increased frequency of hypoglycemic episodes does not increase the incidence of congenital anomaly, suggesting that human embryos in utero can tolerate short-lived periods of hypoglycemia.[73] More likely, hyperglycemia or some metabolic derangement consequent on hyperglycemia is responsible for damage to the developing embryo. Intensive control of glucose concentrations around the time of conception and embryogenesis can reduce the incidence of congenital abnormalities in infants of diabetic women to that seen in nondiabetic women.[72,73,75] The higher incidence of neural tube defects in diabetic pregnancies does not seem to be associated with deranged folate metabolism, though this is not to argue against the importance of folate supplementation.[76]

Early Pregnancy Losses

The incidence of miscarriage is increased in diabetic pregnancies and, as with all complications, is related to the degree of glycemic control since it increases with greater HbA_{1c} levels.[77,78] Figure 45–2 shows the relationship between first-trimester HbA_{1c} and miscarriage. The Diabetes Control and Complications Trial showed that intensive therapy for blood glucose control reduces the rate of spontaneous abortion to that in the nondiabetic population.[75]

Preterm Labor

The frequency of spontaneous preterm labor is reported to be higher in diabetics (in one series complicating about 20% of pregnancies).[79,80] The mechanism of preterm labor is not known. Polyhydramnios and increased susceptibility to infection in poorly controlled diabetics may both be contributory factors.

Fetal Growth

The birth weight of infants of diabetic mothers is greater than those of nondiabetic mothers, and the incidences of obstructed labor and shoulder dystocia are correspondingly increased. The distribution of standardized birth weight in infants of diabetic women is unimodal and

FIGURE 45–1

Am J Obstet Gynecol 1995;173:146–156.

shifted about 1.2 to 1.5 standard deviations to the right.[81,82] Between 20% and 40% of infants of diabetic mothers have a birth weight over the 90th percentile for gestation.[19] Fetal macrosomia develops from about 20 weeks' gestation on.[83] At birth, diabetic infants have significantly more adipose tissue, larger shoulders, and decreased head-to-shoulder ratio compared to nondiabetic infants of similar birth weight and length.[84] The widely accepted Pederson model suggests that maternal hyperglycemia leads to fetal hyperglycemia, and this in turn leads to hyperplasia of fetal pancreatic beta cells and increased fetal insulin concentrations. Insulin can be detected in increased amounts in the cord blood and amniotic fluid of diabetic women from 20 weeks' gestation onward.[85,86]

Much effort has been devoted to identifying which parameter of glycemic control best predicts the development of macrosomia. Mean daily glucose, preprandial glucose, and postprandial glucose concentrations have all been advocated. At the center of the debate is the concept that the peak excursions of hyperglycemia associated with meals may be relatively more important in determining macrosomia than the average background glucose. In both diabetic and nondiabetic women, postprandial glucose concentrations in the third trimester rather than fasting glucose levels are correlated with fetal size and birth weight.[87,88] Figure 45–3 shows the relationship between birth weight and the 2-hour plasma glucose following a 100-g oral glucose tolerance test (GTT) in women with a normal glucose tolerance. In diabetic women, mean postprandial whole blood glucose above

6.7 mmol/L (120 mg/dL) was associated with a 30% chance of macrosomia.[87]

Polyhydramnios is considered a complication of diabetes. The precise mechanism of polyhydramnios is not known, but it may relate to the higher incidence of congenital anomalies, to increased osmotic pressure in amniotic fluid (due to high glucose concentrations), or to fetal polyuria.[89,90] Polyhydramnios does not necessarily indicate that the pregnancy is at risk. A review of all cases of polydramnios, regardless of diabetic status from a database of over 40,000 women concluded that the overall incidence of polyhydramnios was about 1% and that the diagnosis of polyhydramnios was associated with an increase in perinatal mortality and congenital anomalies.[91]

Perinatal Mortality

The perinatal mortality rate in diabetic pregnancies remains consistently higher than the background perinatal mortality rate.[64,92–98] It is estimated that between 10% and 50% of perinatal mortality in women with diabetes is due to congenital abnormalities.[64,68,97] There is also a significantly higher rate of stillbirth unrelated to congenital anomaly in diabetic pregnancies in most case series.[64,92–94,97] It is likely that some of the stillbirths seen in diabetic pregnancies are due to intrauterine growth restriction (IUGR) produced by the usual mechanisms that affect nondiabetic pregnancies. The rightward shift in the birth weight distribution of diabetic infants can mask the diagnosis of significant IUGR.

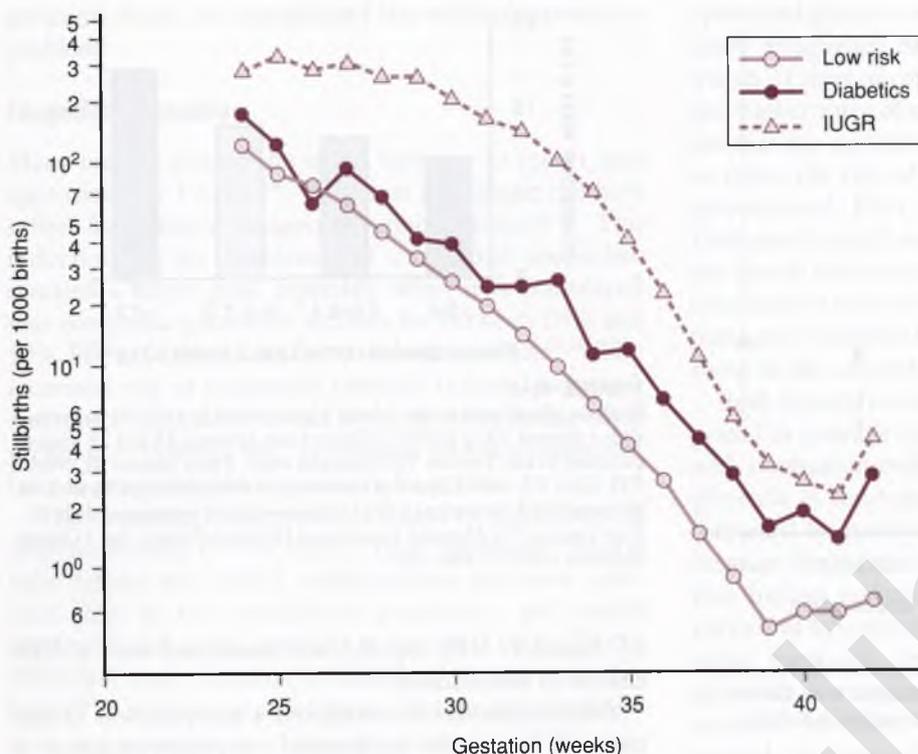
Stillbirths are more common in diabetic pregnancies across all infant birth weights, suggesting that factors other than placental insufficiency are involved (Figure 45–4).[99] It is generally stated that "poor glycemic control" is associated with stillbirth. In animal models, fetal hyperglycemia results in increased oxygen consumption and ultimately hypoxia and acidosis.[100,101] Fetal cord


FIGURE 45–4

Key: Note rates are displayed on a logarithmic scale. Adapted from Smulian JC, Ananth CV, Vintzileos AM, et al: Fetal deaths in the United States: Influence of high-risk conditions and implications for management. Obstet Gynecol 2002;100:1183–1189.

blood sampling in human diabetic pregnancies has confirmed that fetal acidemia is significantly associated with both the maternal and fetal blood glucose concentrations.[102] Furthermore, chronic fetal hypoxia may be exacerbated in poorly controlled patients in whom a shift to the left in the maternal oxyhemoglobin dissociation curve results in reduced red cell oxygen delivery at tissue level.[103] Although uncommon, maternal ketoacidosis is also associated with a high (20% to 50%) fetal mortality rate.[104] Interestingly, reversible fetal hydrops, presumably due to fetal tachyarrhythmia, has been reported in a case of maternal ketoacidotic coma.[105] It is suggested that tachycardia, particularly in the context of fetal hypertrophic obstructive cardiomyopathy, may further contribute to unexplained stillbirth in diabetic women. Whatever the mechanism, unexplained stillbirth remains difficult to predict or prevent: There are reports of stillbirth within 72 hours of seemingly normal fetal monitoring.[106]

Shoulder Dystocia and Birth Trauma

The macrosomic fetus is at an increased risk of traumatic delivery, particularly shoulder dystocia. Diabetic women were six times as likely as nondiabetic women to suffer shoulder dystocia (see also Figure 45–5).[63] A 13-year retrospective review of 231 infants weighing over 4500 g born vaginally found that around 8% had serious trauma (brachial plexus injuries or clavicular fracture).[107]

Neonatal Complications of Diabetic Infant

A number of neonatal complications have been well characterized in the infants of diabetic pregnancies.[108] These are summarized in Table 45–3. Hypoglycemia is relatively common but usually of little consequence and results from a rapid drop in plasma glucose concentrations following clamping of the umbilical cord. Even in well-controlled diabetic mothers, the incidence of early hypoglycemia in infants is still high, particularly in those mothers who had a longer duration of diabetes. Hypocalcemia and hypomagnesemia are also more common in infants of diabetic mothers. The etiology is unknown, but adult diabetics seem to have a lower set point for parathyroid hormone regulation of calcium.[109] More strict control of glucose during pregnancy is associated with a reduction in the incidence of hypocalcemia.

Infants of diabetic mothers typically have elevated cord blood erythropoeitin levels and are polycythemic.[102] The increased red cell mass contributes to a higher incidence of postnatal hyperbilirubinemia and the need for phototherapy.

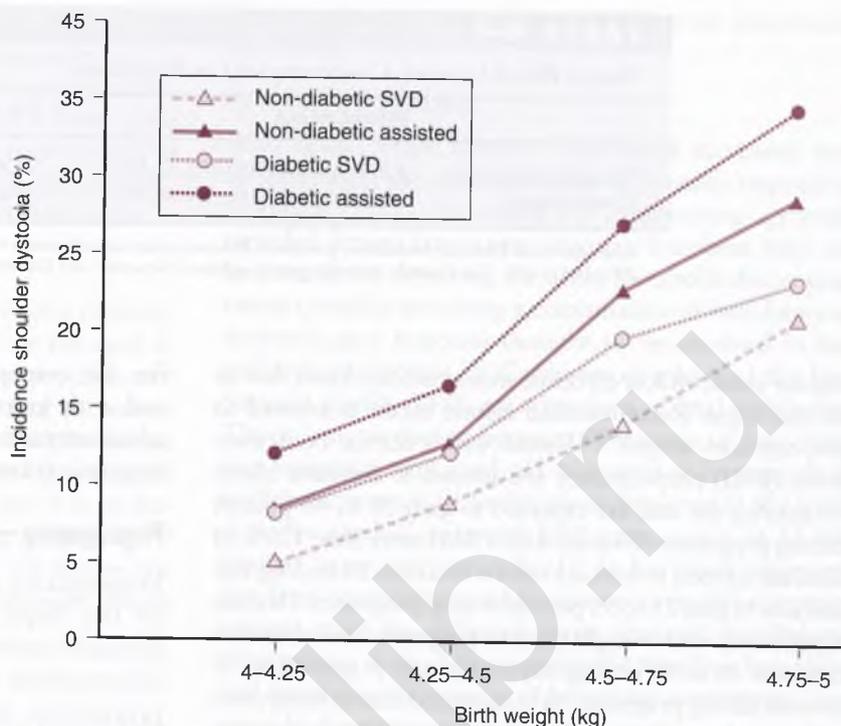
Classically, the incidence of respiratory distress syndrome in infants of diabetic mothers was reported to be higher than that of nondiabetics. More recent data (from women with better glycemic control) indicate that this statement is no longer true.[110] Routine fetal lung maturity testing in well-controlled diabetics at term is not required, because less than 1% of infants will develop respiratory distress.[111] Furthermore, not all cases of respiratory distress in term infants of diabetic mothers are due to pulmonary surfactant deficiency; transient tachypnea, polycythemia, and hypertrophic obstructive cardiomyopathy also contribute.[112] Nonetheless, hyperglycemia and hyperinsulinemia do seem to delay lung maturation and the production of surfactant in experimental models.[113]


FIGURE 45–5

Fetal hyperinsulinemia is also believed to cause hypertrophy of the myocardium and particularly of the ventricular septum.[114] The ventricular hypertrophy in infants of diabetic pregnancies may be asymptomatic and only picked up on echocardiographic screening.[108,115] It is estimated that as many as 30% of fetuses may have cardiac hypertrophy. Intensive glycemic control during pregnancy reduces the incidence of hypertrophic myopathy.[116] Importantly, the prognosis is good: hypertrophy seems reversible in the neonatal period.[115,116]

Management Options

Prepregnancy and Prenatal Care — Diabetes Management

TARGET PLASMA GLUCOSE CONCENTRATION

In nondiabetic subjects, glucose remains between about 4 mmol/L (70mg/dL) in the fasting state and 7 mmol/L

(126 mg/dL) in the immediate aftermath of a meal.[117] Diabetic subjects tend to have higher postprandial peaks and sustained minor elevations of glucose between meals. The goal of intensive treatment must be to try to reproduce near physiologic levels of glucose throughout the day. Diabetic women are routinely asked to measure their own blood glucose several times a day to aid adjustment of insulin doses. A thorough daily profile requires patients to check blood glucose early morning (fasting) and before meals, at 2 hours after meals, and during the night, but it is probably unrealistic to expect patients to comply with this sort of monitoring every day. Physicians should be aware that self-recorded log books may not always be accurate.[118] Table 45–4 shows typical target figures for blood glucose recommended in UK and North American guidelines.[13–15]

GLYCOSYLATED HEMOGLOBIN

Proteins react spontaneously with glucose to form glycosylated derivatives. HbA_{1c} serves as a retrospective indicator of the average glucose concentration over the previous 8 to 10 weeks.[119,120] The HbA_{1c} level is more strongly correlated to preprandial than postprandial glucose concentrations. In the third trimester, however, HbA_{1c} levels may only reflect mean glucose values over the previous 2 weeks, presumably because of increased rates of erythropoiesis.[121] HbA_{1c} is expressed as a percentage of the normal hemoglobin, and the normal range is approximately 4% to 6%.[122]

DIETARY REGULATION

For some women, alteration in diet alone is enough to ensure a more normal level of blood glucose. Dietary advice should include a redistribution of meals to ensure a

TABLE 45-4

Target Blood Glucose Concentrations in Pregnancy

	BEFORE MEALS	2 H POSTPRANDIAL
Whole blood glucose	3.9–5.6 mmol/L (70-100 mg/dL)	<7.8 mmol/L (140 mg/dL)
Plasma glucose	4.4–6.1 mmol/L (80-110 mg/dL)	<8.6 mmol/L (155 mg/dL)

regular intake of low glycemic index carbohydrates, low in fat and sugar. Recommended caloric intake is tailored to prepregnancy weight.[69] Women with a normal body mass index (BMI) prepregnancy are advised to consume about 30 kcal/kg/day and are expected to gain 28 to 40 pounds during pregnancy. Women with a BMI more than 120% of ideal are advised to cut back caloric intake to 24 kcal/kg/day and aim to gain 25 to 35 pounds during pregnancy. Women significantly underweight prior to pregnancy are advised to consume 36 to 40 kcal/kg/day and to aim to gain 15 to 25 pounds during pregnancy. It is suggested that carbohydrate make up about 40% to 50% of the diet, which is less than is usually advised for nonpregnant patients, in an attempt to limit postprandial peaks of glucose.

INSULIN REGIMENS

Women with type 1 diabetes mellitus require increasing doses of insulin as their pregnancies advance due to changes in carbohydrate metabolism. Those with type 2 diabetes mellitus controlled either by diet or with oral hypoglycemic drugs prepregnancy usually require treatment with insulin once pregnant. In women with established type 2 diabetes controlled by diet alone, persistent postprandial hyperglycemia (>7.5 to 8.0 mmol/L; 120 mg/dL) or fasting hyperglycemia (>6.0 mmol/L; 105 mg/dL) are indications for the introduction of insulin therapy.[15]

Women requiring insulin during pregnancy are managed on a regimen requiring multiple daily dosing. Once-daily or twice-daily subcutaneous doses of intermediate or long-acting insulin are combined with doses of regular insulin before meals. The pharmocodynamics of regular insulin absorption from subcutaneous injections dictates that injections need to be given at least 1/2 hour before meals and that the effects may last for several hours afterward.[123] The insulin analogue Lispro offers a better pharmacodynamic profile than insulin[123] and appears to be safe in pregnancy.[124]

ORAL HYPOGLYCEMIC AGENTS

Oral hypoglycemic drugs (both sulfonylureas and biguanides) are usually avoided in pregnancy because they cross the placenta, potentially resulting in fetal hypoglycemia. However, they have been used in all trimesters and are reportedly safe.[125] Hypoglycemic agents might therefore provide an alternative to insulin

for the management of women with type 2 diabetes and with gestational diabetes,[126] especially where self-administration of insulin is difficult for educational or linguistic reasons.

Prepregnancy—Other Issues

Prepregnancy clinics were first introduced in the 1970s in the hope that preconceptual improvements in glycemic control would reduce the number of congenital abnormalities and spontaneous miscarriages in diabetic pregnancies. Several studies have demonstrated the value of this approach.[73,127] A significant number of diabetic women, however, do not plan their pregnancies or choose not to attend such clinics.[128]

Points to be considered during counseling might include the risks of progression of diabetic retinopathy and nephropathy, risks of obstetric outcomes, and risks of diabetes in the offspring. The risk of diabetes in the child is 2% to 3% if the mother has type 1 diabetes mellitus and 4% to 5% if the father is affected. The need for folate supplementation should also be stressed. Women with established diabetes are at an increased risk of having babies with neural tube defects and are therefore recommended to take up to 5 mg of folic acid daily.

A small number of women with complications of diabetes may be on medical treatment that is contraindicated in pregnancy, such as angiotensin-converting enzyme inhibitors to reduce the progression of diabetic nephropathy, and these should be changed to a more appropriate antihypertensive. Lipid-lowering agents that inhibit HMG CoA reductase are also contraindicated in pregnancy because they have been shown to be teratogenic at higher doses in animal studies.

Prenatal—Other Issues

Prenatal care of the diabetic woman is directed at detecting and, if possible, reducing the complications of diabetes.

GLUCOSE CONTROL

Ideally, this will have been optimized before conception, but if not, the prompt confirmation of a viable pregnancy by early scan allows for adjustment of insulin regimens to achieve good glucose control. This requires close liaison between the supervising physician or diabetes nurse and the patient.

BASELINE INVESTIGATIONS

Routine baseline investigations in early pregnancy might be supplemented by an electrocardiogram and by measurement of urea and electrolytes and/or 24-hour urine protein excretion to detect undiagnosed nephropathy if diabetes has been of long duration. A thyroid autoantibody screen and thyroid function test should be done.

CLINICAL REVIEW

If a funduscopic examination has not been done recently, this should be arranged; it should usually be repeated at a later date in pregnancy to exclude proliferative retinopathy. Hypertension should be treated to reduce the risks of progression of retinopathy and nephropathy. A target diastolic blood pressure of 80 mm Hg is advised for nonpregnant hypertensive diabetics, and it is probably wise to aim for similar levels during pregnancy.[129] Meta-analysis suggests that women with risk factors for hypertension and preeclampsia, such as diabetes, might benefit from low-dose aspirin.[130]

SCREENING FOR ABNORMALITY

Early studies of biochemical screening for neural tube defects, trisomy 21, and Edwards syndrome suggested that different reference ranges might be required for diabetics. However, this work has not been supported by later studies.[131] Nuchal translucency measurements in diabetics without congenital anomalies lie in the normal range for the background population.[132] Given the higher incidence of congenital anomalies in diabetic pregnancies, most centers plan to offer a detailed fetal survey around 18 to 20 weeks' gestation. Reported antenatal detection rates for cardiac, CNS, and skeletal abnormalities in insulin-dependent diabetics are around 70%.[133] Approximately 60% to 80% of non-cardiac lesions and 33% to 50% of cardiac lesions are identified antenatally. These rates are not different from routine detailed ultrasonography of low risk populations. Fetal echocardiography can help to identify fetuses with obstructive cardiomyopathy.

FETAL GROWTH

Serial ultrasound estimation of fetal weight is routinely used to identify fetuses showing accelerated growth. Although currently the best tool available, sonographic estimation of fetal weight is often inaccurate, with errors of around 7% of birth weight.[134] It is also worth pointing out that the charts used to calculate fetal weight are not specifically validated for diabetic fetuses, where there are disturbances of body proportions. The positive predictive value of ultrasound measurements for birth weight over 4500 g is only 35%.[135] Magnetic resonance imaging may ultimately offer a more accurate estimate of fetal volume or weight.[136] There has been little published work on the role of more intense insulin therapy in reducing fetal growth in established diabetics once macrosomia has been identified, although most obstetri-

cians use the presence of macrosomia as an indicator of poor control.

FETAL HEALTH SURVEILLANCE

Most obstetricians support a policy of increased fetal assessment in the third trimester to identify impending stillbirth. Paradigms used for monitoring growth-retarded fetuses have been adopted, but these may not be suitable for detecting the acute metabolic decompensation (possibly involving a combination of fetal hypoxia, acidemia, and hypoxia) thought to be involved in late stillbirth in diabetes.[137] Cardiotocography and the biophysical profile (BPP) are acute tests of fetal well-being. There is a correlation between BPP score or fetal heart rate variability and cord pH measured at cordocentesis in diabetic women.[137] In this study, however, 9 of 12 acidotic fetuses had a normal BPP score, and 6 of 12 had normal heart rate variability.[137] It has been suggested that fetal neurobehavioral development in diabetic pregnancies may be different from that of nondiabetic pregnancies, with differences in the baseline breathing and heart rate, frequency of breathing movements, and gross body movements.[138]

Assessment of umbilical blood flow velocity waveform by Doppler is useful in identifying those pregnancies with significant placental vascular resistance. One of the most quoted studies of Doppler ultrasonography in diabetic pregnancy measured the flow velocity waveform every 2 weeks from 28 weeks' gestation in 128 diabetic women and 170 controls.[139] There were 9 abnormal umbilical flow velocity waveforms in the diabetic group, and most of these infants were growth retarded. It was also apparent that significant fetal compromise can occur in the presence of a normal flow waveform. As with nondiabetic pregnancies, abnormal results on Doppler ultrasonography indicate the need for more intense surveillance with cardiotocography or BPP scoring. In women with significant complications of diabetes, where there is an increased risk of IUGR and/or preeclampsia, there is merit in starting fetal surveillance early (from 26 weeks' gestation on), but in those without complications, monitoring could be delayed to after 32 weeks' gestation.[140] There is little evidence to guide the decision about frequency of monitoring, except that twice-weekly nonstress testing in the third trimester is associated with a low perinatal mortality rate.[141] Falling insulin requirements in the third trimester reflect the fact that the fetus is hyperinsulinemic and functioning as a "glucose-sink," draining maternal glucose. It is not clear if such a change indicates the need for increased surveillance.

Labor and Delivery

TIMING AND MODE OF DELIVERY

Decisions regarding the timing and mode of delivery must balance the risks of prematurity with the risks of late intrauterine death and macrosomia. Gestation-

specific risks of stillbirth in diabetics continue to fall up to around 38 weeks' gestation and then increase slightly in postdate pregnancies.[142] Most obstetricians and their patients are comfortable with delivery around 38 to 39 weeks. Invasive testing of the lecithin-to-sphingomyelin (L/S) ratio in amniotic fluid to predict fetal lung maturity is difficult to justify in well-controlled term diabetics.[111] The mode of delivery is probably also largely a matter of personal choice, given the increasing cesarean section rate in general. Cost-benefit analysis suggests that in diabetic women, 489 cesarean sections are needed to prevent 1 case of permanent brachial plexus injury where the estimated fetal weight is >4000 g, and 443 cesareans are needed where the estimated fetal weight is >4500 g.[143] Current guidelines issued by the American College of Obstetricians and Gynecologists are to strongly consider elective cesarean where the estimated fetal weight is above 4500 g.[12] Shoulder dystocia remains difficult to predict; in fact the incidence of shoulder dystocia with infants weighing less than 4000 g ranges from 26% to 58% in various reports. There are no conclusive data that early induction of labor prevents dystocia.[12]

GLUCOSE CONTROL

Labor is a time of unpredictable glucose and insulin demands.[69] Unless a rapid labor and delivery is predicted, blood glucose is probably best controlled by a sliding scale of insulin and glucose infusion, adjusted according to regular capillary blood glucose monitoring. Maternal plasma glucose levels during labor and delivery should be maintained at approximately 4 to 8 mmol/L (72 to 144 mg/dL) to avoid maternal hypoglycemia and the associated adverse fetal response.[69]

Postnatal

Following the third stage of labor, the insulin infusion rate is halved; once the woman is eating normally, subcutaneous insulin can be recommended at the prepregnancy dose.[69] The abrupt decline in pregnancy hormones postpartum results in improved insulin sensitivity, which is further improved by breastfeeding. Insulin doses may need frequent adjustment in the early postpartum period. For breastfeeding women with preexisting type 2 diabetes mellitus, oral hypoglycemic agents should be restarted cautiously because of a risk of hypoglycemia in the infant.

GESTATIONAL DIABETES MELLITUS

Gestational diabetes mellitus (GDM) is defined as "carbohydrate intolerance resulting in hyperglycemia of variable severity with onset or first recognition during pregnancy, whether or not insulin is used and regardless of whether diabetes persists after pregnancy."[17] The original work by O'Sullivan studied women who had been given a 100 g oral glucose challenge test in pregnancy.[144] Diagnostic criteria were developed based on the number

of women who subsequently became diabetic. This is not an obstetrically useful outcome, and attention has since focused on defining the relationship between glucose intolerance in pregnancy and outcomes such as macrosomia, operative delivery, and perinatal mortality. Coustan succinctly summarized the issues surrounding the diagnosis of gestational diabetes by posing four key questions[145]:

- What level of maternal hyperglycemia measurably worsens pregnancy outcome?
- Does intervention improve outcome?
- Is such intervention cost effective?
- What is the optimum screening and/or diagnostic test?

Screening for Diabetes in Pregnancy

RATIONALE FOR SCREENING

Successful screening tests require that the condition should be prevalent in the target population, that treatment improves the prognosis, and that treatment is cost effective. Debate continues about the advantages of screening for GDM because not all studies have confirmed a higher incidence of pregnancy complications in women with GDM. A major flaw has been a failure to stratify the degree of hyperglycemia. Some women diagnosed with GDM have severe hyperglycemia and in fact probably have undiagnosed existing diabetes. Others have mild hyperglycemia just above the upper end of the normal range. It is estimated that 70% of women diagnosed with GDM have modest hyperglycemia and require only dietary intervention.[3]

MATERNAL AND FETAL RISKS

The risk of complications is related to the degree of hyperglycemia. In the Toronto Tri-Hospitals study, a cohort of 3637 women who tested negative for GDM at 28 weeks' gestation were followed through pregnancy. Even in these women without GDM, increasing carbohydrate intolerance was associated with a significantly increased incidence of cesarean section, preeclampsia, macrosomia, and need for neonatal phototherapy.[146] In women who have been diagnosed with GDM the incidence of fetal macrosomia is increased. Recent studies suggest 20% to 30% of women with untreated GDM give birth to infants heavier than 4000 g.[62,147] It has been estimated that about 4% of women with GDM will give birth to an infant weighing over 4500 g; the figure for the general obstetric population is about 2% of women.[148] Not surprisingly, most studies of GDM report a cesarean section rate of up to 30%.[62,149–151] It is important, however, to ask if diagnosing and treating GDM significantly changes outcomes. Certainly birth weight can be reduced by insulin treatment in GDM,[151–153] but in the randomized controlled trials reported so far, this does not appear to translate into a reduction in the cesarean section rate or in brachial plexus injury.[3] It should be noted that the trials are small, often the difference in glycemic control

between the treated and control groups is minimal, and reductions in birth weight are similarly small.

The evidence for a significant increase in the incidence of preeclampsia and nonproteinuric hypertension in GDM is conflicting. In one case-control study comparing 197 women with GDM to nondiabetic pregnancies, there was a statistically significant but clinically insignificant rise in blood pressure in the third trimester in the diabetic group.[154] Others report an increased incidence of preeclampsia and nonproteinuric hypertension affecting 6% to 20% of pregnancies complicated by GDM, as opposed to 6% to 11% of control pregnancies.[149,153,155,156] Insulin treatment may not reduce the incidence of hypertension, since, even in women with mild glucose intolerance not diagnostic of GDM, preeclampsia and nonproteinuric hypertension were diagnosed in about 20% of cases.[62]

The diagnosis of GDM does not in general indicate increased risk to the fetus and neonate. The perinatal mortality rate for women with GDM or impaired glucose tolerance who are not requiring insulin is low.[157,158]

It has been argued that the principal benefit of screening for GDM is the ability to identify a group of women at risk of subsequently developing diabetes. The cumulative incidence of type 2 diabetes mellitus increases markedly in the first 5 years after delivery and appears to plateau after 10 years.[159] For this to be a justification for screening, however, it would need to be established that such women could successfully be targeted in programs to modify lifestyle (to decrease obesity) and comply with regular follow-up to aid the early identification of diabetes.

SCREENING OPTIONS

The diagnostic test for GDM is the oral GTT. Unfortunately, several bodies have advocated different tests and diagnostic criteria, as shown in Table 45–5.[3] The World Health Association (WHO) definition is based on a 75-g oral test, whereas in North America, a 100-g oral test is used, and two different professional

bodies in the United States have even recommended different criteria. Most centers in the United Kingdom use the 75-g oral GTT recommended by the WHO as a single-step screening and diagnostic test. The diagnosis of GDM is made when the fasting and 2-hour glucose values are sufficient for a diagnosis of either impaired glucose tolerance or diabetes. In North America, the American Diabetes Association[160] and National Diabetes Data Group[161] recommend a 100-g oral glucose challenge as the diagnostic test, and a randomly administered 50-g oral glucose challenge as the screening test.[3] The WHO criteria label twice as many women with GDM as do the National Diabetes Data Group criteria.[3] Screening is carried out between 24 and 28 weeks' gestation when insulin resistance tends to be at its maximum.

Several strategies are used for selecting women to undergo diagnostic testing. An inclusive strategy, in which every woman is tested, is expensive and may over-diagnose GDM. A more targeted approach selects women on the basis of risk factors (such as previous GDM, family history, and obesity). It has been estimated that, applying a strategy of universal screening to a population with an average risk of GDM, 8900 women need to be screened to prevent one case of brachial plexus injury using North American criteria.[3] As the prevalence of diabetes increases, the number needed to screen reduces (and this is the advantage of using risk factors to select women for screening). In the Toronto Tri-Hospital study, maternal BMI, age, and race were risk factors for a positive 100-g oral glucose challenge; and using such risk factors meant that about 35% of the general population could be excluded from screening.[162] The American College of Obstetricians and Gynecologists has suggested that women fulfilling the criteria listed in Table 45–6 could be exempted from universal screening.[11]

Another strategy is to take a simple, cheap screening test such as random or fasting blood glucose from all women in pregnancy and to perform formal diagnostic testing on a subgroup identified on the basis of values

from the screening test. Measurements of random blood glucose or glycated proteins such as fructosamine or HbA_{1c}, however, perform poorly as screening tools.[8,163–165] Assessment of fasting blood glucose provides better sensitivity, but even so fasting levels that identify women with GDM on formal testing with either the 75-g or 100-g GTT result in 30% to 50% of women with normal glucose tolerance also requiring testing.[166] In North America, the American Diabetes Association and the National Diabetes Data Group recommend a randomly administered 50-g oral glucose challenge as the screening test.[160,161] Plasma glucose greater than 130 mg/dL or 140 mg/dL 1 hour after a 50-g load indicates the need for a full diagnostic glucose challenge. Screening with a 50-g challenge compared with simple measurement of fasting glucose reduces the number of women requiring a diagnostic GTT from around 30% to 15%.[167]

Management Options

The diagnosis of GDM encompasses a wide range of glucose intolerance; many women can be managed without the need for insulin. A reasonable goal of medical therapy might be to reduce the incidence of macrosomia, because this should impact on the cesarean section rate, shoulder dystocia, and brachial plexus injury. Women with GDM can be taught to monitor blood glucose at home, although the optimum frequency of glucose assessment has not been established. Similarly, women with GDM should be given the same advice about diet as women with established diabetes. About 45% of women with GDM diagnosed by 100-g oral challenge can be managed by diet alone.[150] As the number of abnormal glucose values on the GTT increases, so do the chances of the woman requiring insulin therapy

Several different strategies have been employed when deciding when to start insulin treatment. Fasting plasma glucose above 6.0 mmol/L (108 mg/dL) or a 2-hour postprandial value of 7.0 mmol/L (126 mg/dL) have been incorporated into guidelines as an indication to commence insulin therapy.[10,13] Others have suggested using the presence of fetal macrosomia as the trigger for starting insulin.[168,169] A more invasive, physiologically driven approach involves amniocentesis to measure amniotic fluid insulin and starting insulin treatment where there is evidence of fetal hyperinsulinemia. None of these approaches has been subjected to a sufficiently powered randomized study.[3,19]

The perinatal mortality rate in GDM is generally lower than that in established diabetes, and it is likely to be difficult to establish whether antenatal monitoring reduces the perinatal mortality rate. Pragmatically, however, it may be best to use an approach similar to that used in established diabetes, especially in women with GDM requiring insulin.[170]

Delivery can be planned at 40 weeks' gestation if the GDM is well-controlled, because the incidence of intrauterine death near term is lower than in preexisting diabetes, at least for women not requiring insulin.[157,158] In a randomized controlled trial comparing routine induction of labor between 38 and 39 weeks' gestation to expectant management, there did not appear to be any difference in the incidence of cesarean delivery; however, there were proportionally more babies that were large for gestational age in the group of women that were managed expectantly, compared to those that were induced.[171] Lurie and colleagues showed that there were more cases of shoulder dystocia in women who were managed expectantly compared to those who were induced at 38 to 39 weeks' gestation (10% versus 1.4%), with no difference in the cesarean section rate.[172]

A diagnosis of GDM carries the implication that diabetes may subsequently develop with pregnancy. A formal oral GTT should be carried out some 2 to 3 months after pregnancy, when approximately 3% of women will be found to have diabetes.[159] It would seem prudent to offer advice about lifestyle modifications that might reduce the likelihood of developing diabetes. Follow-up studies of women with GDM indicate that up to 70% will develop diabetes within 28 years.[159] The American Diabetes Association has recommended a 3-yearly oral GTT to screen for the development of diabetes in these women.

CONCLUSIONS

- In most centers the pregnancy outcome goals in women with diabetes is still approximate to that of the nondiabetic woman.
- Some women with long-standing diabetes enter pregnancy with impaired renal function, retinopathy, or chronic hypertension and are predictably at increased risk of a poor outcome.

CONCLUSIONS (Continued)

- All of the recognized pregnancy complications of diabetes (congenital abnormalities, miscarriage, preterm delivery, late stillbirth, macrosomia, and preeclampsia) are exacerbated by hyperglycemia and can be largely negated by strict attention to glycemic control periconceptually and throughout pregnancy.
- Current regimens of insulin do not restore the blood glucose profile throughout the day to normal.
- Women diagnosed with GDM or impaired glucose tolerance are a heterogeneous group:
  - Some have glucose tolerance just above the normal range and are at low risk for pregnancy complications.
  - Others almost certainly have undiagnosed diabetes and require insulin treatment and pregnancy surveillance in the same way as established diabetics.
  - Because of the heterogeneous nature of the group and pregnancy outcomes, the cost-effectiveness of screening for GDM is low; such screening may not be justified.

SUMMARY OF MANAGEMENT OPTIONS
Diabetes in Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Explain general risks and management of diabetes in pregnancy.	IV	C	175
Evaluate any additional risks with appropriate specialist referral (e.g., renal, ophthalmologic).	III Ib	B A	176 177
Optimize blood glucose control with the same target range as for pregnancy (see Table 45–4) (main aim is to reduce congenital abnormalities).	Ib III	A B	73 127
Discuss effective contraception until good glucose control (avoid estrogen-containing preparations with vascular disease).	–	GPP	–
Provide folate supplementation (4–5 mg daily) for at least 2 months before and during first trimester.	Ib	A	178
Prenatal			
Screen for gestational diabetes ideally in all pregnancies at ~28 weeks; WHO recommends 75-g oral GTT for diagnosis (see Table 45–2).	IV	C	16,179
Perform regular capillary glucose series; start/adjust insulin regimen to keep capillary glucose values within Table 45–4 target range.	IV	C	13,14,15
Insulin pump does not confer advantage over conventional insulin treatment.	Ib	A	180
Data limited but probably best to avoid oral hypoglycemic agents.	III	B	125,126
Suggest appropriate diet in accordance with prepregnancy weight.	IV	C	69
Instruct partners/relatives in glucagon use for hypoglycemic attacks.	–	GPP	–
Monitor baseline renal and possibly cardiac function.	–	GPP	–
Ensure regular ophthalmologic review.	Ib	A	177
Monitor for hypertensive disease; aim to keep diastolic at ~80 mm Hg.	III IV	B C	176 129
Avoid/change from ACE inhibitors.	III	B	181
Low-dose aspirin is safe and may be beneficial; possibly reserve use only to those with vascular disease.	Ia	A	130
Initiate fetal surveillance (limited evidence to determine the value of these tests in diabetic pregnancies):			
• Normality (serum screening, NT, 20-week ultrasound)	III	B	131,132,133
• Growth (Note: limitations and overestimation of fetal weight)	III	B	134,135
• Well-being (Note: NST, BPS, and AFV may not be as predictive of fetal risk as in IUGR)	III	B	137,138,173

Diabetes in Pregnancy *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal—(Continued)			
• Umbilical artery blood flow (Note: predictive of fetal risk in pregnancies complicated by placental vascular disease; uncertain value in other diabetic pregnancies)	III	B	139,173
• Timing and frequency of testing uncertain; possibly from 26 weeks' with vascular disease and 32 weeks' otherwise	III	B	140
Gestational Diabetes			
Initially try to control with diet before insulin.	IV	C	10,13
	III	B	150
• Criteria for starting insulin vary (high glucose values vs macrosomia).	Ib	A	168
	III	B	169
• Otherwise manage as for established diabetics. (Evidence supporting this approach is limited.)	—	GPP	—
• Timing of delivery: conflicting evidence for the value of 38 vs 40 weeks.	Ib	A	171
	III	B	172
• GTT after pregnancy:	Ia	A	159
• at 2-3 months (to confirm resolution)			
• every 3 years (to identify development of type 2 diabetes).			
Labor and Delivery			
Can be delayed until term (38-39 weeks) if diabetes is well controlled and pregnancy uncomplicated.	Ib	A	142,171
Use of tests of lung maturity not considered necessary at that gestation.	IIb	B	111
Method of delivery will depend on complications in mother and/or fetus.	—	GPP	—
No evidence that induction of labor reduces risk of shoulder dystocia.	IV	C	12
ACOG recommends consider elective cesarean section if estimated fetal weight >4.5 kg.	IV	C	12
Maintain good perinatal glucose control.	IV	C	69
Postnatal			
Insulin requirements usually reduced to prepregnancy requirements (often lower if breastfeeding).	IV	C	69
Continue capillary glucose monitoring.	IV	C	69
Encourage breastfeeding.	—	GPP	—
Give contraceptive advice.	—	GPP	—

Thyroid Disease

Anna P. Kenyon / Catherine Nelson-Piercy

INTRODUCTION

Thyroid disease is the second most common cause of endocrine dysfunction in women of childbearing age (diabetes is the first). Thyroid disease can be challenging to diagnose and manage because many of its symptoms are common in pregnancy. Physiologic changes in serum levels of pituitary and thyroid hormones may hamper diagnosis, and a clear understanding of these changes is needed when managing patients with suspected or known thyroid disease.

The thyroid gland is a bilobed gland composed of spherical follicles. Each follicle has a colloid center surrounded by a single layer of follicle cells. Intimately involved with the follicle cells are parafollicular C cells, lymphatic drainage channels, and capillary networks.

Iodide ions are actively transported from the blood onto the apical surface of the follicle cells and are oxidized to iodine through the action of thyroid peroxidase. The thyroid gland regulates the amount of iodide it actively traps and can withstand fluctuations in dietary supply. In the lumen, colloid iodide is incorporated into the tyrosine residues of thyroglobulin (also made in the follicle cells) to produce inactive mono-iodotyrosine and di-iodotyrosine. This process is known as organification of iodide. Combinations of these products lead to the formation of the active thyroid compounds thyroxine (T_4) and tri-iodothyronine (T_3), which are released into the capillary network at the apical surface of follicle cells having re-entered from the colloid at their basal surface (endocytosis).

Production is controlled by the hypothalamus-pituitary-thyroid axis. Thyroid-releasing hormone is released from the hypothalamus, and thyroid-stimulating hormone (TSH) is released from the anterior pituitary. TSH is a glycoprotein with alpha and beta subunits. Many anterior pituitary hormones share the alpha subunits, but the beta subunit is unique. TSH has many actions, including increasing the release of T_4 and T_3 through increased iodide transport into follicular cells, organification and release of thyroglobulin into the follicular lumen, and endocytosis of colloid.

More T_4 than T_3 is produced by the thyroid gland, but T_4 is converted in some peripheral tissues (liver, kidney, and muscle) to the more potent T_3.

In plasma, more than 99% of T_3 and T_4 is bound by carrier proteins to thyroid-binding globulin, albumin, and transthyretin (previously known as thyroid-binding prealbumin). Thyroid-binding globulin has the highest affinity for T_3 and T_4, so although it is present in the lowest concentration, 75% of all thyroid hormones are bound to it. Only the free hormones (free T_4 and free T_3) are biologically active (0.04% of total T_4 and 0.5% of total T_3).

Pregnancy is a state of relative iodine deficiency because of increased renal loss (increased glomerular filtration rate in the early first trimester) and transfer of iodine to the developing fetus. To compensate, the thyroid gland increases its uptake of iodine from the blood. If the supply is insufficient, cellular hyperplasia and goiter result. Although a physiologic goiter may be seen on ultrasound examination by a change in gland size of 10% to 20%, this change is not clinically detectable. A clinically apparent goiter suggests iodine deficiency or pathology.[1]

The fetal thyroid gland begins to form at 5 weeks' gestation and has some function at 10 weeks, but it is only autonomous at 12 weeks, when T_4, T_3, and TSH levels can be measured in fetal serum.[2] Levels continue to increase until 35 to 37 weeks' gestation, when they reach adult levels. The gland is relatively immature, however, with high TSH levels relative to the amount of T_4 produced. The fetal thyroid concentrates iodine at a significantly higher rate than the maternal thyroid. Diagnostic scanning or uptake with radioactive tracers, such as iodine-131 or technetium-99, or radioactive iodine therapy should be avoided because of the risks of exposure to the developing fetus.[3]

TSH and hCG and share a common alpha subunit, and their beta subunits share some similarities, as do their

receptors. The increase in hCG that occurs in early pregnancy "spills over" and stimulates the TSH receptor, suppressing TSH and increasing T_4. The reason for this increase may be to provide the fetus with T_4 before it becomes autonomous. These changes must be considered when a diagnosis of hyperthyroidism is contemplated in early pregnancy, especially in the context of hyperemesis gravidarum, where hCG secretion may be exaggerated, or in trophoblastic disease, where it is grossly elevated. Two thirds of women with hyperemesis have abnormal thyroid function test results in the absence of thyroid disease, with 30% having undetectable TSH, 60% having suppressed TSH, and 59% having an elevated free T_4 level.[4]

Little T_4 crosses the placenta after the first trimester, and the placenta is relatively impermeable to TSH and T_3.

Thyroid-releasing hormone, antithyroid medications (propylthiouracil, carbimazole, and methimazole), and iodine cross the placenta and may alter the fetal physiology.

Pregnancy causes an increase in thyroid-binding globulin (and transthyretin) through the effects of estrogen, which increases synthesis and decreases clearance. The elevation is present at 2 weeks' gestation and peaks at 20 weeks' gestation.[1] This elevation necessitates a small increase in the production of T_4 (1%–3%) and T_3 until this plateau is reached. Thus, total T_4 and T_3 are elevated.[5] Because only the free hormone is biologically active, only free hormone measurements are used in pregnancy.

Further physiologic changes in thyroid function occur with advancing gestation, but there is controversy about the precise nature of these changes. As described earlier, TSH decreases in early pregnancy, but may increase in the third trimester,[6,7] although some authors have not shown this finding.[8] Concentrations of free T_4 decrease in the second half of pregnancy (below the range seen outside pregnancy). Peripheral conversion of free T_4 to free T_3 is enhanced, and this increased efficiency may be in preparation for the exertions of labor and delivery.[9]

Table 46–1 shows normal values for thyroid function test results throughout pregnancy.

Serum autoantibodies to the thyroid are common and may be destructive or stimulating. Occasionally, both coexist in the same patient. TSH receptor-stimulating antibodies (immunoglobulin G) are found in Graves' disease (hyperthyroid), and antimicrosomal (thyroid peroxidase) antibodies are seen in Hashimoto's thyroiditis (hypothyroid). Antithyroglobulin antibodies can cause destruction of thyroid tissue. All of these antibodies freely cross the placenta, with varying possible fetal effects.

HYPERTHYROIDISM

General

Hyperthyroidism affects 0.2% of pregnant women[10,11]; 95% of these have a diagnosis of Graves' disease, an autoimmune disorder associated with circulating immunoglobulin G antibodies to the thyroid TSH receptor that stimulate thyroid hormone production.

Possible causes of hyperthyroidism include the following:

- Graves' disease
- Toxic multinodular goiter
- Toxic nodule or adenoma
- Subacute thyroiditis
- Acute thyroiditis (de Quervain's [viral] or postpartum)
- Iodine treatment
- Amiodarone therapy
- Lithium therapy
- Hyperfunctioning ovarian teratoma (struma ovarii)
- TSH-producing adenoma
- hCG-producing tumor
- Thyroid carcinoma

Diagnosis

Thyrotoxicosis usually occurs in the late first or early second trimester. Symptoms are the same as in thyrotoxicosis outside pregnancy, but they may be unhelpful in establishing a diagnosis and are commonly reported by many euthyroid pregnant women (e.g., palmar erythema, emotional lability, vomiting, goiter, heat intolerance). Discriminatory symptoms include weight loss, tremor, lid lag, lid retraction, and persistent tachycardia greater than 100 beats/minute.

Diagnosing hyperthyroidism in early pregnancy may be difficult. When interpreting the results of thyroid function tests suggesting biochemical thyrotoxicosis in early pregnancy, hyperemesis gravidarum and trophoblastic disease must be excluded.

Symptoms that persist beyond 10 to 20 weeks' gestation, symptoms that antedate the pregnancy, and the presence of thyroid-stimulating antibodies suggest true hyperthyroidism. The diagnosis of hyperthyroidism is confirmed by an elevated free T_4 or free T_3 level with suppressed TSH levels.

TABLE 46–1

Normal Values for Thyroid Function Tests during Pregnancy

TEST	NON PREGNANT	FIRST TRIMESTER	SECOND TRIMESTER	THIRD TRIMESTER
Free T_4 (pmol/L)	11–23	10–24	9–19	7–17
Free T_3 (pmol/L)	4–9	4–8	4–7	3–5
TSH (mu/L)	<4	0–1.6	1–1.8	7–7.3

Adapted from Chan BY, Swaminathan R: Serum thyrotropin concentration measured by sensitive assays in normal pregnancy. BJOG 1988;95:1332–1334; Parker JH: Amerlex free triiodothyronine and free-thyroxine levels in normal pregnancy. BJOG 1985;92:1234–1238; Girling JC: Thyroid disorders in pregnancy. Curr Obstet Gynaecol 2003;13:45–51.

Carbimazole (methimazole is similar and available in the United States) and propylthiouracil are used to treat hyperthyroidism in and throughout pregnancy. Both agents are thionamides and act by competitively inhibiting the peroxidase-catalyzed reactions that are necessary for iodine organification. They also block the coupling of iodotyrosine, especially the formation of di-iodothyronine. Their onset of action is delayed until the preformed hormones are depleted, a process that can take 3 to 4 weeks. Thionamides may suppress the immune system, but this effect is controversial (discussed later).[12]

Maternal and Fetal Risks

Important maternal side effects of thionamides are agranulocytosis and hepatitis that is idiosyncratic with propylthiouracil, but dose-related with carbimazole. Monitoring of liver function may be necessary. In women with sore throat or fever, a white blood cell count must be obtained to exclude agranulocytosis. If neutropenia occurs, therapy is discontinued, and thionamides should not be given again. Drug rash or urticaria is reported in 1% to 5% of cases and necessitates a switch to an alternative preparation. Additional symptoms may include nausea, vomiting, and diarrhea.

The two most serious maternal complications of untreated hyperthyroidism are heart failure and thyroid storm. Thyroid storm is a medical emergency with a maternal mortality rate of 25%, even with appropriate management (discussed later).[13] Heart failure, the more common of the two serious maternal complications, is caused by the long-term myocardial effects of T_4 and is intensified by other pregnancy-related conditions, such as preeclampsia, infection, or anemia.[14]

When diagnosed in pregnancy, thyrotoxicosis is associated with adverse outcomes, including miscarriage, growth restriction, premature labor, placental abruption, pregnancy-induced hypertension, preeclampsia, infection, and increased perinatal mortality. One study suggested an increased risk of chromosomal abnormalities.[15] The relative risk of low birth weight was 0.74 in one euthyroid (controlled hyperthyroidism) population, 2.36 in the same population with uncontrolled hyperthyroidism in the first half of pregnancy, and 9.24 in patients with hyperthyroidism throughout pregnancy. The same study showed an odds ratio for preeclampsia of 4.74 in patients with uncontrolled hyperthyroidism at term.[16] This study suggests that treatment improves outcome and is supported by another study showing stillbirth in 24% of women with untreated hyperthyroidism and in 5% to 7% of women receiving treatment. The incidence of prematurity was 53%, decreasing to 9% to 11% with treatment.[17]

There is a risk of fetal or neonatal thyrotoxicosis because of the passive transplacental passage of immunoglobulins that is associated with Graves' disease. These antibodies exert an effect on the fetal thyroid at 20 weeks' gestation.[18] Infants born to mothers with high titers of antibodies or poorly controlled disease[10,18] are particularly at risk. Studies report prevalences of 1% to 17%.[18,19] Fewer cases are diagnosed in utero than in the neonatal period. Fetal thyrotoxicosis may be suspected in a fetus with persistent tachycardia (>160 beats/min), goiter, or growth restriction.[18] The diagnosis may be made on the basis of antenatal ultrasound.[20,21]

Fetal thyrotoxicosis may lead to premature delivery (90%),[18] fetal craniosynostosis, exophthalmos, heart failure (hydrops fetalis), hepatosplenomegaly, thrombocytopenia, goiter (with neck obstruction and polyhydramnios), and growth restriction. Additional neonatal features include jaundice, poor feeding, poor weight gain, and irritability.[18] The mortality rate may be as high as 25%.[11]

Thyrotoxicosis in the neonatal period is usually transient, lasting only 2 to 3 months after delivery. Symptoms may be delayed up to 2 weeks postnatally if the mother was taking medication at the time of delivery. The effects of maternal antithyroid medication are eventually cleared from the neonatal circulation, but thyroid-stimulating antibodies are cleared more slowly.

To predict fetal thyrotoxicosis, maternal TSH receptor autoantibodies are tested in early pregnancy. To predict neonatal disease, they are tested again in late pregnancy.[22] One suggested protocol is to test in the first trimester and again at 6 months' gestation.[23] If high titers of antibodies are detected in early pregnancy or if levels have not decreased with advancing gestation, fetal thyrotoxicosis should be anticipated. Obstetric ultrasound may be recommended to assess fetal growth, heart rate, and goiter. If antibodies are detected in late pregnancy, then cord blood and neonatal (days 3–4 and 7–10)[11,24] thyroid function tests (TSH and free T_4) should be performed.[22]

Fetal thyrotoxicosis can be treated in utero by giving the mother increased doses of antithyroid medication. Subsequent maternal hypothyroidism can be treated with thyroxine, which does not cross the placenta in significant amounts. Percutaneous fetal blood sampling to measure thyroid function (for which normal ranges are available) is technically possible and may play a role in management.[2,25]

Fetal effects of maternal antithyroid medication have been reported, particularly the association of carbimazole or methimazole with aplasia cutis.[26] This condition results in patches of absent skin at birth, 70% to 85% of which occur on the scalp. However, the condition is rare. The natural incidence is 0.03%.[27] However, in one study, in a population of 49,000 infants, none of the mothers who took antithyroid medication had an affected infant and no cases occurred in 643 women with Graves' disease.[28]

High doses of antithyroid medication may cause fetal hypothyroidism, but rarely cause goiter. In one study, 43 women treated with thionamides until delivery were compared with 27 women in whom treatment was discontinued in pregnancy. Free T_4 levels were slightly lower in fetuses compared with mothers in the first group. Levels in fetuses were higher in the second group,

and some maternal and cord T_4 levels were in the thyrotoxic range at delivery.[29] If maternal disease is controlled too tightly, some infants may become hypothyroid. Neonatal hypothyroidism usually resolves spontaneously by day 5 of life[30] and occurs in 10% to 20% of patients treated with thionamides.[31]

Management Options

Prepregnancy

Menstrual abnormalities are less common now than reported in previous series. The most common manifestations are hypomenorrhea and oligomenorrhea. However, most thyrotoxic women are believed to remain ovulatory.[32]

Therapy for hyperthyroidism is best begun before pregnancy to allow for the use of radioactive iodine studies for diagnosis, higher initial doses of pharmacologic agents without concern about fetal effects, and surgery, when needed, for patients who do not respond to therapy. Patients who have had radioactive iodine are advised not to conceive until 4 months after the last treatment.[33] Some argue for establishing a euthyroid state 3 months before conception. Counseling should be supportive and reassuring. Treated thyrotoxicosis has a low risk of adverse obstetric outcome. Women should be counseled against discontinuing medication either prepregnancy or antenatally.

Prenatal

The goal of treatment is to maintain a euthyroid clinical state and a free T_4 level at the upper limit of normal for pregnancy-specific ranges. This approach allows use of the lowest possible dose and minimizes the risk of fetal hypothyroidism. Women with newly diagnosed hyperthyroidism should undergo examination and thyroid function tests monthly. Less frequent testing is needed in those with stable disease.

Patients with Graves' disease often have temporary worsening of control in early pregnancy as a result of increasing hCG levels and perhaps reduced absorption of medication as a result of vomiting. Improvement may then occur, with women often requiring less medication as the relative immune suppression of pregnancy results in a decrease in antibody levels. In 30% of patients, all medication can be discontinued in the last weeks of pregnancy.[34]

Block-and-replace regimens that are sometimes used outside pregnancy are not suitable for pregnant women. Antithyroid medications cross the placenta freely, whereas thyroxine does not. Therefore, this regimen places the fetus at risk for hypothyroidism. Fetal abnormalities are more common in the offspring of women receiving thyroxine and carbimazole (9.5%) than in those receiving carbimazole alone (4.1%).[20,28] These regimens may be of use in the treatment of fetal thyrotoxicosis (discussed earlier).

Therapeutic modalities for hyperthyroidism are divided into the following five categories:

- Thionamides (propylthiouracil and carbimazole)
- β-blockers
- Iodides
- Radioactive iodine
- Surgery

Propylthiouracil and carbimazole are the mainstays of treatment for hyperthyroidism in pregnancy. Propylthiouracil crosses the placenta less readily than carbimazole and is usually the first choice; however, women whose disease is well controlled with carbimazole need not change.[35] The disadvantage of propylthiouracil is that more frequent dosing is often necessary compared with carbimazole. Newly diagnosed cases should be treated aggressively initially, with high doses (e.g., carbimazole 40 mg, propylthiouracil 400 mg daily) for 4 to 6 weeks. The doses can be reduced gradually by up to 25%.

In patients with troublesome autonomic (sympathetic) symptoms of palpitations, tachycardia, and tremor, propranolol 20 to 40 mg three times daily may be used for up to 1 month until longer-term treatment with thionamides becomes effective. Longer treatment courses should be avoided because of the risk of growth restriction.[36] β-blockers have the additional benefit of reducing peripheral conversion of T_4 to T_3.

Iodide treatment is an older mode of therapy and is now limited to preoperative use. Long-term use of this therapy results in a high incidence of fetal goiter and hypothyroidism and does not result in adequate control of thyrotoxicosis.[37]

Radioactive iodine (iodine-131) is used widely outside pregnancy to treat Graves' disease and is used in high doses to treat carcinoma. However, it is absolutely contraindicated in pregnancy because it ablates the fetal thyroid, causing fetal and neonatal hypothyroidism. There is additional concern about possible effects on the parental gonads, and pregnancy should be delayed until after treatment. Radioactive iodine also frequently results in maternal hypothyroidism.[17,28]

Surgery is reserved for patients who do not respond to medication or who cannot tolerate the medication. Thyroid surgery is associated with a high incidence of hypothyroidism postoperatively. Other postoperative complications include hypoparathyroidism (1%–2%) and recurrent laryngeal nerve palsy (1%–2%). Surgical and anesthetic morbidity and mortality rates are also increased in pregnancy. The reported pregnancy loss rate associated with general anesthesia and surgery of all types in the first trimester is approximately 8%. The rate decreases to 6.5% in the second trimester. Before surgery, patients should be prepared medically with 7 to 10 days of iodide treatment to decrease gland vascularity and prevent thyroid storm. Overall, surgery is reserved for patients in whom standard medical therapy is unsuccessful

and women with a significant goiter that causes stridor, respiratory distress, dysphagia, or carcinoma.

Labor and Delivery

In women with adequately treated thyrotoxicosis, labor and delivery are not associated with increased risks. However, labor and delivery may precipitate thyroid storm in pregnant women with poorly treated or untreated thyrotoxicosis. The patient may have extreme symptoms of hyperthyroidism, particularly cardiovascular symptoms (palpitations, tachycardia, and atrial fibrillation with rapid ventricular response). If the symptoms are severe, high-output cardiac failure may occur. Blood pressure is usually normal, although pulse pressure may be increased. With prolonged duration of symptoms, shock may ensue.[38]

Fever is invariably present, is progressive, begins a few hours after a stressful event, and may exceed 40°C. Mental status is commonly altered, ranging from restlessness and confusion to psychosis, seizures, and coma. Severe diarrhea, nausea, vomiting, and nonspecific abdominal pain may also be present.[39] If the patient has a large goiter, exophthalmos, or a history of hyperthyroidism, the diagnosis of thyroid storm usually is not difficult to establish. However, without the obvious findings or history, the diagnosis may be difficult to establish because the results of biochemical tests may not differ from those in patients who have thyrotoxicosis without thyroid storm. Treatment should not be delayed if the condition is suspected.

The goals of treatment in thyroid storm are to decrease the production of thyroid hormones, to decrease the effect of circulating hormones, to provide supportive therapy, and to treat the underlying cause.

Methimazole and carbimazole may be used, although propylthiouracil (300–400 mg every 8 hours orally, by nasogastric tube, or rectally) is preferred because it decreases peripheral conversion of T_4 to T_3 and decreases thyroid hormone production. Potassium iodide (2–5 drops orally) or sodium iodide (0.5–1.0 g IV) every 8 hours should be initiated approximately 1 to 2 hours after the initiation of therapy with thionamides. This treatment is provided in an attempt to block the release of preformed thyroid hormones from the colloid space.[40]

Supportive therapy involves maintaining blood volume, glycemic control, and temperature control, and restoring the electrolyte balance.[40]

Propranolol (40–80 mg orally or 1 mg/min intravenously) is given to reduce adrenergic overactivity.[40]

Postnatal

To exclude hyperthyroidism as a result of passive antibody transfer and hypothyroidism as a result of transfer of antithyroid medications (discussed earlier), thyroid function tests should be performed on umbilical cord blood and in the neonate in women who are breastfeeding. For propylthiouracil, only 0.07% of the maternal dose is excreted in breast milk, with a slightly higher dose excreted for carbimazole (0.5%) and methimazole (10%).[20] Breastfeeding is generally considered safe in patients who take propylthiouracil (<150 mg daily) and carbimazole (<15 mg daily).[20,41]

Graves' disease can flare postnatally as maternal antibody levels increase. In patients who stopped taking medication, it is often necessary to reintroduce it 2 to 3 months postpartum. These changes must be distinguished from true postpartum thyroiditis (discussed later).

SUMMARY OF MANAGEMENT OPTIONS
Hyperthyroidism

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Establish the diagnosis of hyperthyroidism (elevated free T_4 or free T_3 level with suppressed thyroid-stimulating hormone [TSH] levels) before pregnancy so that a complete diagnostic workup (including radioactive iodine studies) can be performed and therapy instituted.	–	GPP	–
Avoid conception until 4 months after the completion of radioiodine therapy. The patient should be euthyroid for 3 months before conception.	IV	C	32
Prenatal			
Use pregnancy-specific reference ranges when interpreting the results of thyroid function tests.	III	B	6,7

HYPOTHYROIDISM

General

Hypothyroidism affects 1% of pregnant women, and as with hyperthyroidism, many of the symptoms occur in normal pregnancy. Discriminatory symptoms are cold intolerance, slow heart rate, and delayed relaxation of deep tendon reflexes, particularly those of the ankle.

The most common cause of hypothyroidism is autoimmune associated with thyroid peroxidase autoantibodies, leading to destruction of the gland, lymphoid infiltration, and eventual atrophy and fibrosis. This type is known as atrophic (autoimmune) hypothyroidism. In some cases, antibodies blocking the TSH receptor have been implicated. Hashimoto's thyroiditis is a different form of autoimmune thyroiditis, also with thyroid peroxidase (microsomal) autoantibodies, often at high titers. However, atrophic changes occur with regeneration and result in goiter formation. When the origin is autoimmune, other autoimmune diseases (e.g., pernicious anemia, insulin-dependent [type I] diabetes mellitus, and vitiligo) may be present.

Hypothyroidism may be iatrogenic after treatment with lithium, amiodarone, or antithyroid drugs. Alternatively, it may be transient, occurring as part of the disease course in subacute de Quervain's thyroiditis or postpartum thyroiditis.

Any woman who is taking thyroxine for iatrogenic hypothyroidism should have a careful history taken to determine the original cause of disease. Particular care should be taken in women who are using thyroxine after

thyroidectomy or after radioactive iodine treatment when the original diagnosis was hyperthyroidism. Thyrotoxic symptoms in these women should not be attributed to treatment excess until a flare of residual disease has been excluded.[42]

Diagnosis

Hypothyroidism may be diagnosed in patients with a reduced free T_4 concentration in association with an elevated TSH level. Outside pregnancy, an elevated TSH level is a sensitive indicator of the degree of thyroid hormone deficiency. Results must be interpreted with pregnancy-specific reference ranges. Identifying thyroid peroxidase autoantibodies can confirm the diagnosis, but these are nonspecific and are present in 20% to 30% of the normal population.[43]

Maternal and Fetal Risks

The most serious consequence of hypothyroidism is myxoedema coma. This event is extremely rare in pregnancy, but is a true medical emergency, with a 20% mortality rate. The clinical picture includes hypothermia, bradycardia, decreased deep tendon reflexes, and altered consciousness. Hyponatremia, hypoglycemia, hypoxia, and hypercapnia may be present as well. Once the diagnosis is made, therapy should begin immediately with supportive care and thyroid hormone replacement. Symptoms usually improve after 12 to 24 hours of therapy.[44]

Recent studies of subclinical hypothyroidism showed no association with miscarriage. Therefore, screening of thyroid function in asymptomatic women with miscarriage is not recommended.[45]

One study of outcome in hypothyroidism showed that gestational hypertension, (eclampsia, preeclampsia, and pregnancy-induced hypertension) occurred more commonly in patients with overt and subclinical hypothyroidism than in the general population, with rates of 22%, 15%, and 7.6%, respectively. In addition, 36% of patients with overt hypothyroidism and 25% of those with subclinical hypothyroidism who remained hypothyroid at delivery had gestational hypertension. Low birth weight in both groups of patients was secondary to premature delivery for gestational hypertension. Older studies suggested a link with congenital malformations, but more recent studies showed no association.[46]

T_4 is important in the early development of the fetal brain, and some studies[47–49] suggest that neuropsychiatric development is impaired in the offspring of mothers with hypothyroidism. As discussed earlier, the fetus is reliant on maternal T_4 before 12 weeks' gestation. Correction of maternal hypothyroxinemia in the first 12 weeks of pregnancy might be expected to improve neurodevelopmental outcome.[49] A study of intelligence quotient scores in offspring born to mothers with hypothyroidism in early

pregnancy who were subsequently treated showed no adverse effect compared with siblings born when the same mothers were euthyroid.[50]

Cretinism (deaf mutism, spastic motor disorder, and hypothyroidism) is a distinct and severe form of brain damage caused by severe maternal iodine deficiency.

Neonatal or fetal hypothyroidism as a result of transplacental transfer of maternal autoantibodies is extremely rare (1 in 180,000 neonates, or approximately 2% of infants with congenital hypothyroidism),[51] if it occurs at all.[52]

Congenital absence of the thyroid gland is exceptionally rare. In these cases, the fetus is reliant on transfer of maternal T_3 and T_4 across the placenta[53] throughout gestation.

All infants are screened for hypothyroidism with the blood spot Guthrie card. Blood is collected with a heel prick on day 6 of life. Those with an abnormality are recalled for further testing (0.2%–0.3% of the general population).

The fetus is not believed to be at risk for hyperthyroidism as a result of maternal T_4 therapy because placental transfer is poor.

Management Options

Prepregnancy

In hypothyroidism, the frequency of menstrual irregularities has been reported at 56% to 80%. Oligomennorhea, amennorhea, polymenorrhea, and menorrhagia have been reported. Most cases are likely to be attributed to anovulatory cycles. However, a recent study reported far fewer menstrual irregularities, only 23.4% in 171 hypothyroid patients studied (three times more frequent than in 124 control subjects). The most common manifestation was oligomenorrhea (42.5%), followed by menorrhagia (30%). Reduced libido may be an associated feature.

Ovulation and conception can occur in patients with mild hypothyroidism.[32] Severe hypothyroidism is likely associated with failure of ovulation; therefore, tests of thyroid function are appropriate in the evaluation of an infertile couple. The Royal College of Obstetricians and Gynaecologists guidelines suggest that testing should be done only when the woman reports menstrual irregularities or other symptoms.[54]

Given the association of hypothyroidism and other autoimmune disease, performing thyroid function tests in women with insulin-dependent (type I) diabetes mellitus before pregnancy may be a useful screening tool.

Patients with hypothyroidism should be counseled to delay pregnancy until maintenance levels of T_4 have been achieved. Reassurance should be given about the safety of T_4 use during pregnancy. It is useful to perform baseline TSH and free T_4 measurements in those contemplating pregnancy in the near future, or testing may be performed as early as possible after conception.

Prenatal

Antithyroid peroxidase and antithyroglobulin antibodies may be found more commonly in women with recurrent miscarriage (three or more),[55] the risk of which may be associated with antibody titer and avidity.[23,55,56] It is not clear whether this increased risk is a manifestation of an altered humoral response to pregnancy or whether the thyroid autoantibodies are implicated in the pathophysiology. These studies tested women because of their history of recurrent miscarriage (they were therefore at risk for subsequent miscarriage) rather than clinical or biochemical features of hypothyroidism. This selection may explain the observation (discussed earlier) that there does not seem to be an increased frequency of miscarriage in patients with mild hypothyroidism.

A new diagnosis of hypothyroidism in pregnancy is uncommon, given the association with infertility. A more common problem is pregnancy in a woman with inadequately treated hypothyroidism or the diagnosis of hypothyroidism after an episode of postpartum thyroiditis that resolved.

Those who enter pregnancy euthyroid can expect a good outcome. Hypothyroidism requires treatment with thyroxine. If there is no coexisting heart disease, an initial dose of thyroxine 100 μg is usually required. In women who are stable while receiving treatment, checking thyroid function in each trimester is sufficient. However, if dosage changes are implemented, thyroid function (TSH and free T_4) should be measured after 4 to 6 weeks. More frequent testing (every 2 weeks) may be needed in patients with very poor control in early pregnancy. When dosage adjustments are made, free T_4 should be used rather than TSH, which may decrease slowly. However, poor compliance may also result in an increased TSH level with a normal free T_4 level. Kaplan

(1992),[57] Glinoer (1998),[23] and Mandel and colleagues (1990)[58] variously advocated increasing the dose of thyroxine with advancing gestation. They suggested a dose of 200 μg and an 80% increase in dosage in all patients. They also suggested that patients with a TSH level less than 10 should have a dose increase of 41 plus or minus 24 μg daily. If the TSH level is 10 to 20, a dose increase of 65 plus or minus 19 μg daily is recommended, and if the TSH level is greater than 20, a dose increase of 105 plus or minus 32 μg daily is required. Suggested mechanisms for this increased requirement include an elevated extrathyroidal pool of T_4; the need to saturate large quantities of thyroid-binding globulin; increased degradation of T_4; reduced absorption of T_4, especially if taken with iron supplements; and increased transfer of T_4 from mother to fetus.[59] However, Girling and DeSwiet (1992)[5] and, more recently, Chopra and Baber (2003)[60] suggested that there is no need to adjust the dose of T_4 replacement if replacement was adequate before pregnancy. However, in the Girling and DeSwiet[5] study, in 20% of women, hypothyroidism was not adequately treated on entering the pregnancy.[5] The Chopra and Baber[60] study emphasized that taking T_4 at the same time as iron supplements may reduce its absorption and therefore its effectiveness.[5]

Labor and Delivery

When adequate control is achieved, no specific measures are needed for labor or delivery. However, when a large goiter causes respiratory compromise, anesthetic or surgical advice may be required.

Postnatal

Thyroid peroxidase autoantibodies are significantly associated with postpartum thyroiditis (discussed later) and postpartum depression.[61]

SUMMARY OF MANAGEMENT OPTIONS

Hypothyroidism (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Perform thyroid function tests every 3 months, more frequently if dosage adjustments are made.	–	GPP	–
Routine increases in thyroxine dosage are not required. Make dosage adjustments based on the results of thyroid function tests.	III	B	5,59
Patients should avoid taking iron supplements at the same time as oral thyroxine therapy. Check compliance in patients with vomiting.	III	B	58,59
Labor and Delivery			
A larger maternal goiter may cause anesthetic complications (difficulties with intubation).	–	GPP	–
Postnatal			
Observe the patient for signs of postpartum thyroiditis.	–	GPP	–
Screen for postpartum depression.	III	B	60

THYROID NODULES AND THYROID CANCER

General

Thyroid nodules, solitary toxic nodules, or adenomas are found in 2% of pregnant women,[62] and they usually cause hyperthyroidism. Although they are rare overall,[14] 90% of thyroid cancers are thyroid nodules. Carcinomas derived from the thyroid epithelium may be papillary, follicular (differentiated), or undifferentiated. They are rarely active hormonally, but 90% secrete thyroglobulin, which is used outside pregnancy as a tumor marker. There may be an increased incidence of malignancy in pregnancy (40%).[20] Enlargement of the thyroid gland in pregnancy[63] and recent pregnancy (within 5 years) have been associated with thyroid cancer.[64,65] However, because these malignancies are most common in women of childbearing age, additional risk in pregnancy may be difficult to determine. Only nodules that are believed to be malignant need further evaluation or treatment, usually with surgery, with or without radioactive iodine. After treatment, T_4 may be used to suppress the production of TSH and prevent stimulation of residual thyroid tissue or tumor.

Diagnosis

Outside pregnancy, radioactive iodine is used to distinguish "cold" (more likely to be malignant) from "hot" (functioning) nodules. However, these studies cannot be performed in pregnancy. Therefore, ultrasound is the main investigative tool. Fine-needle aspiration is reserved for rapidly enlarging nodules, cystic nodules larger than 4 cm, and solid nodules larger than 2 cm.[20] Cystic nodules are usually benign (multinodular goiter or solitary toxic adenoma). Those with retrosternal extension or tracheal deviation and respiratory compromise may require further imaging. Biopsy results are usually of four types: First, the sample may be insufficient (<5%); biopsy should be repeated. Second, the nodule may be definitely benign (75%); these patients should be reassured. Third, the nodule may be definitely malignant (5%); these patients should undergo surgery. Finally, the finding may be indeterminate (20%). This finding usually occurs when follicular cells are seen; patients often require surgery. The prognosis is similar for patients diagnosed during or outside of pregnancy.[62]

Management Options

Prepregnancy

Thyroid nodules should be evaluated and treated before the patient becomes pregnant. Pregnancy should be delayed for 1 year after thyroid cancer has been treated with high-dose radioactive iodine because congenital abnormalities have been reported.[33]

Prenatal

Because of the risk of malignancy, testing should proceed as outlined earlier and should not be delayed

because of pregnancy. Antithyroid drugs should be used as described earlier to treat hyperthyroidism, but nodules do not usually remit after this treatment. Only if a nodule is found beyond 20 weeks' gestation should aspiration wait until the postnatal period. If biopsy confirms malignancy, the pregnant patient should undergo surgery unless she is only a few weeks from term. Those with indeterminate pathology may delay surgery until after delivery. Surgery is safest when carried out in the second trimester, and with these exceptions, should not be delayed because of pregnancy.[66,67] Radioactive iodine should not be used in pregnancy. Suppressive doses of T_4 should be safe in pregnancy, but care should be taken to avoid maternal thyrotoxicosis.

Labor and Delivery

In patients with a large goiter with retrosternal extension, careful consideration must be given to possible respiratory compromise and complications of intubation if a general anesthetic agent is used. Retrosternal extension should be suspected in patients with respiratory symptoms or dysphagia and in the rare patient with vocal cord paralysis, Horner's syndrome, and vascular or lymphatic compromise.

Postnatal

Radioactive iodine may be administered after delivery, but not while the patient is breastfeeding. Contact with the infant may need to be limited temporarily to reduce exposure.[68]

POSTPARTUM THYROIDITIS

General

Postpartum thyroiditis is believed to occur in 5% to 10% of pregnancies.[69] The frequency of diagnosis depends largely on the extent to which it is sought. Women may not report symptoms and may attribute them to normal postpartum physiology. The condition occurs 3 to 4 months postpartum, but has been reported up to 6 months after delivery.[70] It is an autoimmune disorder, and women with thyroid antibodies in the first trimester have a 33% to 50% chance of having postpartum thyroiditis.[69] The disease is more common (threefold higher) in those with insulin-dependent (type I) diabetes mellitus,[71] a family history of the disease, or thyroid peroxidase antibodies (75% of affected individuals).

The differential diagnosis of postpartum hyperthyroidism includes the following:

- Postpartum painless thyroiditis
- Postpartum Graves' disease
- Postpartum Hashimoto's thyroiditis
- Postpartum toxic multinodular goiter

The most common diagnosis is postpartum painless thyroiditis, which is characterized by an initial destructive phase in the first 2 months, with release of preformed thyroid hormone that causes hyperthyroidism. Three months later, hypothyroidism occurs as stores of preformed thyroid hormone are depleted and the gland is destroyed. However, any combination of clinical states is possible at any time. Most cases resolve spontaneously.

Diagnosis

Radioactive iodine uptake studies can be used in women who choose not to breast-feed. Low uptake is seen in postpartum painless thyroiditis, where only preformed T_4 is released. In contrast, in Graves' disease, new T_4 is generated. In women who are breast-feeding, repeat thyroid function tests 1 month later may show a transition from hyperthyroidism to hypothyroidism, confirming the diagnosis.

Management Options

Most cases resolve spontaneously. However, in a recent study of 86 women, only 51% of those who were not treated were biochemically euthyroid at 9 months. Early institution of permanent T_4 replacement is recommended in women with postpartum thyroid dysfunction, elevated TSH levels, and thyroid antibodies.[72] Later, hypothyroidism (23%–39%) may occur in those who recover, particularly when antibodies are found. For this reason, some advocate yearly thyroid function tests. Thyroxine may be discontinued in some patients. Close observation in the puerperium of any future pregnancies should be undertaken in view of the risk of recurrence.

CONCLUSIONS

HYPOTHYROIDISM

- Thyroxine is important in the early development of the fetal brain, and ensuring adequate replacement in the first trimester is important.
- Little T4 crosses the placenta after the first trimester.
- Adequately treated women with hypothyroidism can expect a good pregnancy outcome.

HYPERTHYROIDISM

- Hyperthyroidism can be difficult to diagnose before 20 weeks' gestation. At earlier gestations consider the differential diagnosis carefully.
- Untreated or poorly controlled hyperthyroidism in pregnancy is associated with adverse outcome.
- Antithyroid medications cross the placenta. Using the lowest possible dose will minimize the risk of fetal hypothyroidism: Thyroid function tests in cord blood and from breastfed neonates may be necessary.
- Passive transfer of antibody may cause fetal or neonatal hyperthyroidism: Thyroid function tests in cord blood and from breastfed neonates may be necessary.
- Thionamides can cause maternal agranulocytosis and hepatitis.
- Adequately treated women with hyperthyroidism can expect a good pregnancy outcome.

Pituitary and Adrenal Disease

Mark B. Landon

PITUITARY DISEASE

Normal Changes in Pregnancy

The anterior lobe of the pituitary gland may enlarge significantly during pregnancy as a result of lactotroph proliferation. Magnetic resonance imaging (MRI) scans confirm that the gland more than doubles in size by the end of gestation.[1] Accordingly, prolactin levels increase approximately 10-fold in preparation for lactation.[2]

Pregnancy also affects the levels of other pituitary hormones. Gonadotropin concentrations decrease and show a diminished response to gonadotropin-releasing hormone. The response of growth hormone (GH) to insulin or arginine stimulation is similarly blunted. Plasma levels of adrenocorticotropic hormone (ACTH) increase throughout pregnancy, but absolute levels remain lower in the pregnant than in the nonpregnant state.[3] Curiously, the increase in ACTH levels occurs despite an increase in free and bound cortisol, suggesting an alternate mechanism to the normal negative feedback loop between cortisol and ACTH. The diurnal variation of cortisol, although blunted, is maintained during pregnancy. Thyrotropin levels are unaffected by pregnancy. Free levels of thyroxine and triiodothyronine are unchanged, whereas total levels increase as a result of estrogen-induced synthesis of thyroxine-binding globulin.

Posterior pituitary function is also altered during normal pregnancy. A significant preterm increase in oxytocin is observed, whereas plasma levels of vasopressin remain similar to those obtained in the nonpregnant state. However, plasma osmolality decreases 5 to 10 mOsm/kg in pregnant women, indicating a decreased threshold for vasopressin secretion in pregnancy. During gestation, patients also experience thirst at a lower plasma osmolality.[4]

Prolactin-Producing Adenomas

Maternal and Fetal Risks

Widely available radioimmunoassays for serum prolactin and improved techniques for radiologic diagnosis have led to the detection of an increasing number of prolactin-secreting pituitary adenomas in women. Spontaneous ovulation is uncommon in patients with a pituitary tumor. Therefore, most patients with this disorder have amenorrhea-galactorrhea or anovulatory cycles and infertility. With ovulation induction and suppression of prolactin synthesis by dopaminergic agents, such as bromocriptine, pregnancy can often be achieved in patients with prolactinomas.

Much of the normal pituitary gland enlargement that occurs in pregnancy is secondary to hyperplasia of the anterior pituitary lactotrophic cells, which are stimulated by estrogen. Although this stimulus may cause enlargement of adenomas during pregnancy,[5] most patients with a microadenoma, a pituitary tumor of less than 1 cm, have an uneventful pregnancy.[6–8] In the few patients who have symptoms, regression usually occurs after delivery.

Management Options

PREPREGNANCY

Most women with prolactin-secreting adenomas require ovulation induction to conceive. Nonpregnant patients who have amenorrhea-galactorrhea and hyperprolactinemia (prolactin level >20 ng/mL) should be evaluated for pituitary adenoma. Although serum prolactin levels are correlated with pituitary adenomas, when a patient with hyperprolactinemia is considering pregnancy, a thorough radiologic examination is warranted. MRI has replaced both computed axial tomography and coned down sella turcica radiographs as the procedure of choice to evaluate the size of the pituitary gland.

Once a pituitary tumor is diagnosed, it may be prudent to re-evaluate the gland for growth after several months before attempting ovulation induction. Bromocriptine therapy is often all that is required for patients with microadenomas. Macroadenomas, which are tumors that measure 1 cm or more, should be treated definitively with surgery. These patients are more likely to have symptoms during pregnancy when treated with medical therapy alone.[5,8] Continued bromocriptine therapy after surgery is indicated if symptomatic residual tumor enlargement occurs.

PRENATAL

Evaluation for possible prolactin-secreting tumors is difficult during pregnancy because of the physiologic increase in serum prolactin that occurs in normal gestation. At term, serum prolactin levels may reach values that are 20 times normal. Further, prolactin levels do not always increase during pregnancy in women with prolactinomas, nor do they always increase with pregnancy-induced tumor enlargement (Fig. 47–1).[9] Enlargement usually produces a headache as the first clinical feature, before visual disturbance. Therefore, radiologic diagnosis is necessary for the pregnant patient who has severe headaches or a visual field defect.

Management of the pregnant patient with a previously diagnosed prolactinoma requires careful attention by a team of physicians, including an obstetrician, an endocrinologist, and an ophthalmologist. Women with symptomatic macroadenomas should be seen monthly. Prompt self-referral in patients with headache or visual symptoms should be encouraged. Visual field testing should be performed monthly in women with macroadenomas.

Headaches may reflect tumor enlargement and impingement on the diaphragmatic sella or adjacent dura. Visual disturbances are caused by compression of the optic nerve. If the optic chiasm is compressed by superior extension, bitemporal hemianopsia may develop. Although the limitations of serum prolactin levels have been discussed, marked elevations outside the normal range for pregnancy at a given gestational age may signal rapid tumor enlargement.

Gemzell and Wang[5] reviewed the course of 85 women during 91 pregnancies affected by previously untreated microadenomas. Only 5% had complications. Four of the five patients with headache and visual disturbances showed resolution after delivery. One patient who had a visual field defect noted early in pregnancy subsequently underwent transsphenoidal hypophysectomy after cesarean delivery for a triplet gestation at 36 weeks. Similarly, Albrecht and Betz[10] reported a low rate of complications in women with untreated microadenomas during gestation. Of 352 patients, 8 (2.3%) had visual disturbances and 17 (4.8%) had headaches.

Maygar and Marshall[6] reported that symptoms are more common in the first trimester than in the second or third, with a median time at onset of 10 weeks' gestation. However, the likelihood of visual symptoms did not differ among trimesters (Fig. 47–2). In this series, symptoms requiring therapy occurred in more than 20% of the 91 patients with untreated tumors, but in only 1% of women with previously treated adenomas.

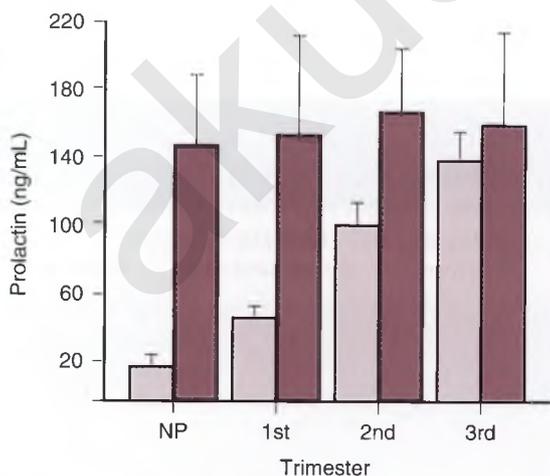
Molitch[8] reviewed 16 series that included 246 cases of prolactin-secreting pituitary microadenomas in pregnancy. Only 4 of the 246 women (1.6%) had symptoms of tumor enlargement, and 11 (4.5%) had asymptomatic enlargement on radiologic examination (Table 47–1). In


FIGURE 47–1

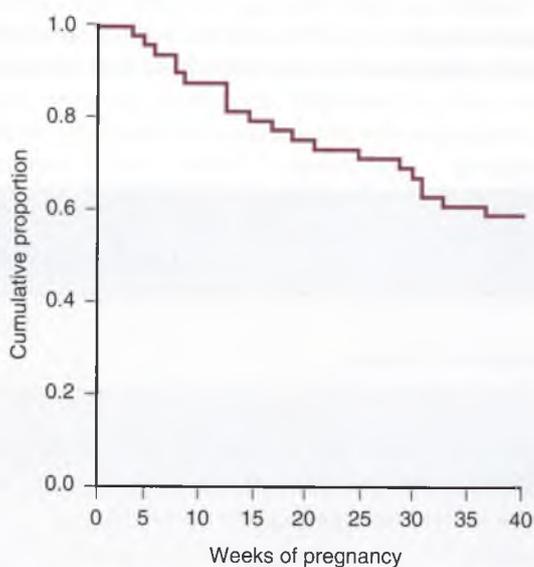

FIGURE 47–2

Time from the beginning of pregnancy to the onset of symptoms (headache or visual disturbances) in 91 pregnancies in women with previously untreated pituitary tumors. (From Maygar DM, Marshall JR: Pituitary tumors and pregnancy. Am J Obstet Gynecol 1978;132:739.)

no case was surgical intervention necessary. Molitch[8] also reviewed 45 patients with macroadenomas, 7 of whom (15.5%) had symptomatic tumor enlargement. Four of these women required surgery during pregnancy. Cabergoline, a dopamine agonist, has been used to treat refractory cases of tumor enlargement during pregnancy.[11] Although data on cabergoline are less extensive, preliminary evidence does not suggest an increase in adverse perinatal outcomes.[12] The risk of symptoms is probably related to the size of the tumor at the onset of pregnancy. Further data are needed to define which group of patients with a microadenoma should be treated with bromocriptine for a prolonged period before conception.

Treatment of complications during pregnancy is influenced by both gestational age and the severity of symptoms. If the fetus is mature, induction of labor or cesarean delivery should be accomplished. Cesarean section is generally performed for obstetric indications. Earlier in gestation, therapy should not be delayed if radiologic evidence suggests tumor enlargement. Medical treatment with bromocriptine or cabergoline is successful in most symptomatic patients and has become the preferred primary approach during pregnancy.[9] Bromocriptine has an established safety profile in early pregnancy, as evidenced by its use to induce ovulation in large groups of women with hyperprolactinemia without an increased incidence of congenital malformations.[13,14] Other treatment modalities used during pregnancy include transsphenoidal surgery,[6–8] and in one case, hydrocortisone therapy.[14] Complications of transsphenoidal surgery include infection, hypopituitarism, hemorrhage, and transient diabetes insipidus. The risk of these complications is probably not increased during pregnancy.

LABOR AND DELIVERY

Intrapartum care of the patient with a prolactin-producing adenoma does not differ from that of the gen-

eral obstetric population. Some undiagnosed patients may have sudden visual impairment, and prolactinoma must be differentiated from more common conditions, such as preeclampsia and migraine, which may cause the same symptoms.

POSTNATAL

After delivery, radiologic assessment of tumor size and a serum prolactin assay should be performed at the first postpartum visit. Breast-feeding is not contraindicated in patients with a prolactin-secreting microadenoma.[7] Because serum prolactin levels may remain elevated during breast-feeding, caution must be used in interpreting these results. However, serum prolactin levels do not appear to be significantly higher than prepregnancy levels in women with microadenomas who choose to breastfeed.[15] Counseling patients about future pregnancies requires establishing that progression of tumor growth has not occurred. Some suggest continuing bromocriptine therapy for 12 months before conception to reduce the risk of tumor enlargement during gestation.[12] Gemzell and Wang[5] concluded that in 16 patients with untreated pituitary adenomas, symptoms did not seem to occur with increasing frequency in subsequent pregnancies.

TABLE 47–1

Effect of Pregnancy on Prolactinomas

SUMMARY OF MANAGEMENT OPTIONS
Prolactin-Producing Adenomas

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Treatment (bromocriptine, cabergoline, surgery, or radiation therapy, depending on tumor size)	III	B	15, 52
Advise against pregnancy until cure is achieved.	III	B	7
Prenatal			
Bromocriptine is safe for the fetus.	III	B	7,13,15
Cabergoline is probably also safe, but there is less experience in pregnancy.	III	B	11,12

SUMMARY OF MANAGEMENT OPTIONS
Prolactin-Producing Adenomas *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal—Continued			
Screening or monitoring for recurrence or exacerbation is best undertaken by vigilance for clinical features (headaches, visual disturbance) and prompt testing. Some recommend visual field testing every month.	III	B	7,9,15,50
Interdisciplinary management	III	B	7,9,15,50
If enlargement or recurrence is seen:			
• Bromocriptine if the fetus is not mature; delivery and definitive management if the fetus is mature	III	B	13–15
• Cabergoline for resistant cases (less experience)	III	B	11,12
• Limited experience with hydrocortisone	IV	C	14
• Surgery in extreme cases that do not respond to medical measures	III	B	7,8
Postnatal			
Can breastfeed	III	B	7,15
Monitor symptoms, the prolactin level (may be difficult to interpret in breastfeeding mothers), and tumor size by imaging.	III	B	15

Acromegaly

Maternal and Fetal Risks

Acromegaly is caused by excessive secretion of GH, most often because of an acidophilic or chromophobic pituitary adenoma. Although amenorrhea is common in women with acromegaly, pregnancy occasionally occurs.[16] Pregnancy may be accompanied by tumor expansion that necessitates medical treatment and surgical resection.[17] Patients with acromegaly are at increased risk for diabetes, hypertension, and cardiomyopathy.

Management Options

Documenting elevation of GH levels during pregnancy may be difficult because of placental expression of a GH variant.[18] Few laboratories offer specific radioimmunoassays to differentiate GH from the placental variant. Lack of suppression of GH levels below 5 mg/mL during a glucose tolerance test can help to establish the diagnosis. Measurement of the level of somatomedin C, which mediates the effects of GH, is more useful in establishing the diagnosis of acromegaly in nonpregnant women. Levels of this insulin-like growth factor may increase in normal pregnancy. Definitive surgical treatment or radiation therapy is often undertaken before conception. Dopaminergic agents may paradoxically decrease GH levels in patients with acromegaly. Case reports confirm the lack of tumor expansion during pregnancy in women receiving bromocriptine therapy.[19] More recently, octreotide (Sandostatin) was used to reduce GH levels in women with acromegaly who were pregnant or were attempting pregnancy.[20] Maternal–fetal transfer of octreotide has been shown to occur without side effects. However, few cases have been reported, and the potential benefits of octreotide treatment should be weighed carefully against the potential risks.[21]

SUMMARY OF MANAGEMENT OPTIONS

Normal elevation of growth hormone levels in pregnancy makes the diagnosis difficult. Lack of suppression of growth hormone levels during a glucose tolerance test is suggestive of the diagnosis. Elevation of somatomedin C levels is a more precise indicator of the diagnosis.	III	B	18
Screen for diabetes, hypertension, and cardiomyopathy.	—	GPP	—
Vigilance for tumor expansion (headaches, visual disturbance)	—	GPP	—
Bromocriptine is an effective and safe treatment in pregnancy.	IV	C	19
Octreotide has been used in pregnancy, but only in a small number of cases, so probably is best avoided.	IV	C	20,21

Diabetes Insipidus

Maternal and Fetal Risks

Diabetes insipidus is rare, with fewer than 100 cases complicating pregnancy reported in the literature. The disease results from inadequate or absent antidiuretic hormone (vasopressin) production by the posterior pituitary gland. The etiology of diabetes insipidus is often unknown, although in most cases, it follows pituitary surgery or destruction of the normal pituitary architecture by tumor. It is a primary idiopathic disorder in up to 50% of cases. Many cases are likely autoimmune, with lymphocytic infiltration of the posterior pituitary gland. Massive polyuria, caused by failure of the renal tubular concentrating mechanism, and dilute urine, with a specific gravity less than 1.005, are characteristic of diabetes insipidus. To combat dehydration and the intense thirst produced by this syndrome, patients consume large quantities of fluid. The diagnosis of diabetes insipidus relies on the finding of continued polyuria and relative urinary hyposmolarity when water is restricted. Administration of intramuscular vasopressin causes water retention and an appropriate increase in urine osmolality. This response is not seen in patients with nephrogenic diabetes insipidus, in which free water clearance is increased because of insensitivity of the renal tubules to antidiuretic hormone. In patients with primary polydipsia or psychogenic diabetes insipidus, urine osmolality increases in response to vasopressin or desmopressin (DDAVP). However, the increase is not as marked as in individuals with central diabetes insipidus. Other conditions that cause polyuria, such as diabetes mellitus, hyperparathyroidism with hypercalcemia, and chronic renal tubular disease, must be considered in the differential diagnosis. However, these conditions usually can be distinguished from central diabetes insipidus by appropriate laboratory testing.

Hime and Richardson[22] reviewed 67 cases of diabetes insipidus complicating pregnancy and noted that 58% of patients showed deterioration during gestation, whereas 20% of patients showed improvement. To explain this phenomenon, it has been suggested that the increased glomerular filtration rate seen in pregnancy may increase the requirement for antidiuretic hormone.[23] Mild disease may worsen during pregnancy because antidiuretic hormone clearance is increased by increased placental vasopressinase activity.[24] Impaired liver function, including fatty liver of pregnancy, is seen with diabetes insipidus during pregnancy, suggesting that several factors may explain the observed worsening of this condition.

Transient diabetes insipidus of pregnancy has been reported during the last trimester.[25] It is associated with acute fatty liver and HELLP syndrome as well as twin gestation. Increased placental vasopressinase activity, along with insufficient liver degradation in HELLP syndrome and acute fatty liver, may unmask this condition.

Management Options

Synthetic vasopressin, in the form of l-deamino-8-D-arginine vasopressin (DDAVP), is the treatment of choice. This drug is given intranasally in doses of approximately 0.1 to 0.25 mg twice daily. Plasma electrolytes and fluid status should be monitored carefully with initiation of therapy. A stable dose is usually easy to achieve. Oxytocic activity is rarely observed. The successful use of DDAVP in pregnancy and the puerperium suggests that this drug is safe for both mother and fetus as well as during lactation.[26]

Spontaneous labor and lactation seem to occur in most patients with diabetes insipidus. Although older reports suggest an increased incidence of dysfunctional labor in affected patients, oxytocin release appears to be independent of vasopressin secretion.[27]

SUMMARY OF MANAGEMENT OPTIONS
Diabetes Insipidus

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Vigilance for tumor expansion (headaches, visual disturbance)	–	GPP	–
Prenatal			
Continue supplementation with synthetic vasopressin (DDAVP), which is effective and safe in pregnancy. The dose may need to be increased during pregnancy.	IV	C	25,26
Monitor disease control with clinical features and the specific gravity or osmolarity of urine.	IV	C	26
Labor and Delivery			
Vigilance for dysfunctional labor (seen in only a few cases)	IV	C	26,27
Postnatal			
Vigilance for poor lactation (seen in only a few cases)	IV	C	26

Pituitary Insufficiency

Maternal and Fetal Risks

Approximately 65 years ago, Sheehan described postpartum ischemic necrosis of the anterior pituitary.[28] This form of hypopituitarism is usually observed in patients with severe postpartum hemorrhage and hypotensive shock. Because pituitary necrosis is uncommon in patients with other conditions associated with hypovolemic shock, the hyperplastic pituitary gland of pregnancy may be more susceptible to hypoperfusion. Lymphocytic hypophysitis, an autoimmune form of hypopituitarism, is also more common in pregnant women and during the puerperium. It should be considered when hypopituitarism is suspected in patients without preceding postpartum hemorrhage. Slow clinical progression suggests that factors other than ischemia may be involved in the pathogenesis of pituitary insufficiency after pregnancy. Tissue necrosis may release sequestered antigens, triggering autoimmunity of the pituitary and delayed hypopituitarism in Sheehan's syndrome.[29] Destruction of the gland as a result of tumor invasion, surgery, or radiation therapy may accompany pregnancy, although fertility is often compromised. Antepartum pituitary infarction is a rare complication of insulin-dependent diabetes mellitus.[30] In these cases, insulin requirements may decrease dramatically.

Patients with Sheehan's syndrome may have varying degrees of hypopituitarism, and specific assays of tropic hormones as well as stimulation and suppression tests may be necessary to establish the diagnosis. During pregnancy, because of normal physiologic changes, adjustments must be made in interpreting both hormone levels and responses to various stimuli. An average delay of 7 years is observed between onset and diagnosis. Hypovolemic shock from postpartum hemorrhage is a precipitating event in up to 79% of cases.[31] There is no apparent correlation between the degree of hemorrhage and the occurrence of Sheehan's syndrome. The characteristic clinical picture begins with failure to lactate. However, this does not occur in all cases. Some patients have late-onset disease and progress to loss of axillary and pubic hair, oligomenorrhea, or amenorrhea with senile vaginal atrophic changes as well as signs and symptoms of hypothyroidism. Patients with these findings are usually infertile, although the frequency of pregnancy is difficult to ascertain. In a review of 19 patients with Sheehan's syndrome documented by endocrinology studies or postmortem examination, 39 pregnancies occurred after the onset of hypopituitarism.[31] Eleven of these women required hormonal therapy to establish a pregnancy, and replacement therapy was used during 15 (38%) of the 39 pregnancies. The treated group had a live birth rate of 87%, compared with 54% in untreated patients, suggesting that early diagnosis and proper therapy improve outcome.

Because pregnancy may occur in women with Sheehan's syndrome, this diagnosis should be considered in all patients with a history of postpartum hemorrhage. Measuring gonadotropin levels is of little value because levels decrease with normal pregnancy. However, the finding of a low or low-normal level of thyroid-stimulating hormone in conjunction with a low serum thyroxine level is consistent with secondary hypothyroidism. Similarly, low cortisol levels that do not increase with stress and decreased ACTH levels support the diagnosis.

Management Options

The treatment of pituitary insufficiency involves replacement of hormones that are necessary to maintain normal metabolism and respond to stress. Thyroid hormone may be provided as L-thyroxine in doses of 0.1 to 0.2 mg daily. Corticosteroids are essential for patients who have adrenal insufficiency. Maintenance dosage is cortisone acetate 25 mg every morning and 12.5 mg every evening or prednisone 5 mg every morning and 2.5 mg every evening. Mineralocorticoid replacement is rarely necessary because adrenal production of aldosterone is not solely dependent on ACTH stimulation. The dose of glucocorticoids should be increased during the stress of labor and delivery.

SUMMARY OF MANAGEMENT OPTIONS

Readjust glucocorticoid and thyroxine dosage if necessary.	–	GPP	–

ADRENAL DISEASE

Normal Changes in Pregnancy

A twofold to threefold increase in cortisol levels is observed by the end of normal pregnancy.[32] Most of this increase is caused by an estrogen-induced increase in cortisol-binding globulin levels; however, biologically active free cortisol levels are also elevated.[33] An increase in free, or unbound, cortisol is apparent by the end of the first trimester. The urinary free cortisol concentration is also elevated during gestation.

Increased cortisol-binding globulin levels prolong the half-life of cortisol in plasma, and cortisol production is also increased. Urinary 17-hydroxycorticosteroid levels are actually lower in pregnancy because excretion of cortisol tetrahedron metabolites is decreased.[34] ACTH levels increase throughout pregnancy, but absolute levels remain lower in the pregnant than in the nonpregnant state.[35] Both ACTH and cortisol surge during labor. Unlike cortisol, ACTH does not cross the placenta. ACTH is manufactured by the placenta, as is corticotropin-releasing hormone. The relationship between these placental hormones and maternal adrenal function is unknown. Aldosterone secretion, which is controlled by the renin-angiotensin system, increases in early pregnancy. Finally, the production of dehydroepiandrosterone in the adrenal cortex is elevated in normal pregnancy. This hormone is aromatized to estradiol and estrone by the placenta.

Cushing's Syndrome

Maternal and Fetal Risks

Cushing's syndrome, which is characterized by excess glucocorticoid production, arises from ACTH-dependent or independent inappropriate hypersecretion of ACTH by a pituitary adenoma or from ectopic production of ACTH. Cushing's syndrome as a result of primary adrenal disease, usually an adrenal adenoma, is more common during pregnancy than in the nonpregnant state. It accounts for approximately 50% of Cushing's syndrome cases during pregnancy.[36] Patients with pituitary disease and secondary adrenal hyperplasia are more likely to have excess androgen secretion, which can inhibit pituitary gonadotropin release. Amenorrhea is common in this setting. In contrast, adrenal adenomas are more likely to be pure cortisol producers and less likely to impair fertility.[32] Other causes of Cushing's syndrome include neoplastic ectopic ACTH production, nodular adrenal hyperplasia, and excessive doses of exogenous corticosteroids.

Because women with Cushing's syndrome are usually infertile, de novo cases are rare in pregnancy. Most cases occur in patients who were previously or partially treated. The clinical features may be difficult to distinguish from many signs and symptoms that accompany normal pregnancy. Weakness, weight gain, edema, striae, hypertension, and impaired glucose tolerance may be observed, both during gestation and in Cushing's syndrome. Early onset of hypertension, with easy bruising and proximal myopathy, strongly suggests the diagnosis and requires further evaluation.

Laboratory diagnosis includes elevated serum cortisol levels without diurnal variation and failure to suppress cortisol secretion with the administration of dexamethasone. Assays for ACTH are of variable accuracy and may confuse the diagnosis. However, an elevated early-morning ACTH value in the presence of high urinary levels of cortisol suggests ACTH-dependent Cushing's syndrome. During gestation, total and free cortisol levels normally increase. Therefore, laboratory results must be compared with established norms for pregnancy. Diurnal variation in cortisol production is maintained in normal pregnancy, although free plasma cortisol levels at term may be two to three times higher than those in nonpregnant women. Further, even in normal pregnant patients, cortisol secretion may not be suppressed with low doses of dexamethasone (1 mg).[35] The preferred screening test for Cushing's syndrome is a 24-hour urine free cortisol measurement. If two collections show elevated levels, then Cushing's syndrome is diagnosed and the cause of excess cortisol production must be determined. A high-dose dexamethasone test may be helpful. Most patients with adrenocortical hyperplasia show a reduction in plasma and urinary corticosteroid levels with an 8-mg dose (2 mg every 6 hours for 2 days). If suppression is unsuccessful, an adrenal tumor, an autonomous adrenal nodule, or ectopic ACTH production must be considered. After testing, pituitary or adrenal gland imaging should be undertaken. MRI is the optimal imaging modality during pregnancy because no radiation is used.

Several reports suggest that Cushing's syndrome may be exacerbated by pregnancy, with improvement of symptoms after delivery.[32,36] In most cases, Cushing's syndrome is associated with an adrenal adenoma.[32] Keegan and colleagues[37] speculated that placental ACTH may stimulate a latent adrenal tumor, with adrenal cortisol secretion decreasing after parturition. The idea that pregnancy may stimulate the development of Cushing's syndrome is supported by the fact that in virtually all reports of Cushing's syndrome in pregnancy, the diagnosis was not established until pregnancy occurred.[32] Several cases of recurrent Cushing's syndrome during pregnancy have been described. These may represent hyperresponsiveness of adrenocortical cells to a non-ACTH or non-corticotropin-releasing hormone substance that is produced during pregnancy.[38]

Pregnancy outcome in Cushing's syndrome is marked by a high rate of preterm delivery (67%) and stillbirth (7%) when elective termination is not performed.[32,33,35,37] Maternal hyperglycemia may be a contributing factor to the intrauterine deaths observed (Table 47–2). Hypertension has been reported in 65% of cases, and preeclampsia in 9%.[32]

Koerten and colleagues[39] reviewed 33 cases of Cushing's syndrome in pregnancy and concluded that maternal complications are more common with adrenal adenomas than with hyperplasia. In this review, every patient with an adenoma had hypertension if the pregnancy progressed beyond the first trimester. Seven of 16 (47%) patients had pulmonary edema, and 1 died. In contrast, only 1 of the 12 patients with adrenal hyperplasia had hypertensive disease. The overall prematurity rate (delivery after 20 weeks' gestation) was 20 of 33 cases (61%); stillbirth occurred in 4 cases.

Management Options

Management of the pregnant patient with cortisol excess includes identifying the source of hormone production and instituting proper therapy. Patients with pituitary disease are most often treated surgically if a tumor can be well defined. Surgical removal of adrenal adenomas can be accomplished through a posterior incision. Bevan and associates[40] examined maternal and fetal outcomes based on the timing of surgery. Fetal loss occurred in 1 of 11 (9%) patients treated during gestation versus 8 of 26 (31%) in whom definitive therapy was delayed. In Buescher's review of 105 cases in which 32 women underwent therapy to relieve hypercortisolism, treatment reduced the perinatal mortality rate from 15% to 6.3%.[32] Again, because the incidence of adrenal adenoma and carcinoma appears to be increased in pregnant patients with Cushing's syndrome, prompt evaluation with MRI is warranted, particularly if high levels of dexamethasone do not suppress excess cortisol production. Surgery is indicated if an adrenal tumor is discovered. Treatment may be delayed in the third trimester if an expedited delivery is planned.

TABLE 47–2

Cushing's Syndrome and Perinatal Complications in 65 Pregnancies

COMPLICATION	N	(%)
Miscarriage	2	(3.1)
Perinatal death		
Neonatal death	5	(7.7)
Stillbirth	5	(7.7)
Premature birth	42	(64.6)
Intrauterine growth retardation	17	(26.2)

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Complete testing and treatment (usually surgical) before conception.	—	GPP	—
Prenatal			
If the diagnosis is made during pregnancy, identify and treat the cause or source of hormone production (usually by surgery). The only exception is diagnosis in the third trimester. In this case, delivery and subsequent definitive management may be an option.	III	B	32,36,40
Testing includes magnetic resonance imaging, especially because of the risk of carcinoma.	—	GPP	—

Primary Aldosteronism

Maternal and Fetal Risks

Few cases of primary aldosteronism during pregnancy have been reported. The diagnosis is suggested in a patient with hypertension, hypokalemia, and metabolic alkalosis. Adrenal adenoma is the most common etiology, present in nearly 75% of cases. Glucocorticoid-remediable aldosteronism is a hereditary form of primary aldosterone excess that causes hypokalemia and hypertension in childhood. This diagnosis is established before pregnancy and is amenable to medical treatment. The clinical course of these pregnancies has been described, including a high rate of preeclampsia in patients with underlying chronic hypertension.[41] Because aldosterone secretion is increased during pregnancy, the diagnosis of new-onset hyperaldosteronism can be difficult to establish. However, elevated aldosterone levels accompanied by suppressed renin levels support the diagnosis of primary hyperaldosteronism. High levels of urinary potassium with serum hypokalemia also help to establish the diagnosis. Failure to replace serum potassium may also suppress aldosterone secretion, obscuring the diagnosis.[42] Inappropriately high aldosterone levels are present after suppression testing. The potassium level should be normalized before the administration of suppression tests, such as 9-α-fludrocortisone. Amelioration of hypertension and hypokalemia during gestation is attributed to high levels of progesterone, which may block the action of aldosterone. Even so, patients often have severe hypertension and superimposed preeclampsia.

Management Options

The management of patients without toxemia complicating primary aldosteronism is controversial. Although early case reports suggested prompt surgical excision of underlying adrenal adenomas, Lotgerring and associates[43] described successful medical therapy from midgestation with spironolactone, an aldosterone antagonist, and other antihypertensive medications. This therapy should be used cautiously because spironolactone is an antiandrogen that may cause feminization of a male fetus. Laparoscopic adrenalectomy has been used to treat primary hyperaldosteronism during pregnancy.[44]

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal			
If the diagnosis is made during pregnancy, options are:			
• Medical treatment (antihypertensives and spironolactone), although spironolactone is an antiandrogen, with an associated risk of feminization	IV	C	43
• Laparoscopic adrenalectomy	IV	C	44
• Open surgery	IV	C	42

Adrenal Insufficiency

Maternal and Fetal Risks

Adrenal insufficiency is usually primary (Addison's disease) and caused by autoimmune destruction. Granulomatous diseases, such as tuberculosis, bilateral adrenalectomy, fungal infection, and AIDS, are other rare etiologies. Pituitary failure or adrenal suppression as a result of steroid replacement may also lead to adrenal insufficiency. In these cases, mineralocorticoid production is preserved. Adrenal crisis, an acute, life-threatening condition, may accompany stressful conditions, such as labor, the puerperium, or surgery. Unfortunately, the diagnosis of hypoadrenalism is often difficult, particularly in patients who have enough adrenal reserve to sustain normal daily activity. Postpartum adrenal crisis may lead to the diagnosis of adrenal insufficiency for the first time.[45]

The clinical presentation of Addison's disease during gestation is similar to that in the nonpregnant state. Fatigue, weakness, anorexia, nausea, hypotension, non-specific abdominal pain, hypoglycemia, and increased skin pigmentation are hallmarks of this endocrinopathy. Mineralocorticoid deficiency leads to renal sodium loss, with resultant depletion of intravascular volume. A small cardiac silhouette on chest radiography is often associated with reduced cardiac output and eventual circulatory collapse. Hypoglycemia, which is common in early pregnancy, may be exacerbated by glucocorticoid deficiency.

Management Options

The diagnosis of adrenal insufficiency is based on specific laboratory findings. Plasma cortisol levels are decreased. However, because the level of cortisol-binding globulin is elevated in pregnancy, even low-normal cortisol values may reflect adrenal insufficiency.[45]

Stimulation of the adrenal gland by synthetic ACTH may help to establish a diagnosis.[46] After intravenous administration of 0.25 mg cosyntropin (Cortrosyn), the plasma cortisol level should be increased at least twofold over baseline values. Failure to respond to this stimulus suggests primary adrenal insufficiency. This test may be used in pregnancy because little ACTH crosses the placenta. A longer ACTH stimulation test is used if the short test does not confirm the diagnosis. Measurement of serum ACTH may also help to distinguish primary adrenal insufficiency from hypopituitarism. Low baseline serum cortisol levels, coupled with ACTH levels greater than 250 pg/mL, confirm the diagnosis of primary adrenal insufficiency.

Pregnancy usually proceeds normally in treated patients. Maintenance replacement of adrenocortical hormones is provided by cortisone acetate 25 mg orally each morning and 12.5 mg in the evening. As an alternative, prednisone may be substituted at doses of 5 mg and 2.5 mg, respectively. Mineralocorticoid deficiency is treated with fludrocortisone acetate (Florinef) 0.05 to 0.1 mg daily. Stress doses of glucocorticoids should be administered during labor and delivery. With doses of glucocorticoids exceeding 300 mg in 24 hours, supplemental mineralocorticoid therapy is unnecessary. The use of a mineralocorticoid requires careful observation for symptoms of fluid overload. Patients with edema, excess weight gain, and electrolyte imbalance require dose adjustment.

Adrenal crisis is a rare, life-threatening condition that requires immediate medical attention. Treatment in an intensive care setting is recommended. Women with undiagnosed Addison's disease may have a crisis during the puerperium. Symptoms include nausea, vomiting, and profound epigastric pain accompanied by hypothermia and hypotension. Treatment initially consists of glucocorticoid and fluid replacement. Intravenous hydrocortisone is given at a dose of 100 mg, followed by repeat doses every 6 hours for up to several days. Mineralocorticoid replacement is indicated in cases of refractory hypotension or hyperkalemia.

Patients with adrenal insufficiency should wear an identifying bracelet. Emergency medical kits are available to help these patients when they travel. Women with Addison's disease require an increase in steroid replacement during periods of infection or stress and during labor and delivery. Cortisol is administered at a dose of 100 mg intravenously every 8 hours for the first 24 hours. The dose of steroids is reduced by 50% the next day.

SUMMARY OF MANAGEMENT OPTIONS
Adrenal Insufficiency

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal			
Continue glucocorticoid and mineralocorticoid supplementation.	IV	C	45,46
Vigilance for fluid overload and electrolyte disturbance	IV	C	45,46

Continued

Adrenal Insufficiency *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal—Continued			
Vigilance for adrenal crisis: • IV hydrocortisone • IV fluids • Supportive medical therapy • Critical care setting	IV	C	45,46
Labor and Delivery			
Increase glucocorticoid supplementation.	IV	C	45,46

Pheochromocytoma

Maternal and Fetal Risks

Pheochromocytoma is a rare, catecholamine-producing tumor that is uncommon in pregnancy. The tumors arise from the chromaffin cells of the adrenal medulla or sympathetic nervous tissue, including remnants of the organs of Zuckerkandl, neural crest tissue that lies along the abdominal aorta. In pregnancy, as in the nonpregnant state, the tumor is located in the adrenal gland in 90% of cases.[47] The incidence of malignancy, which can be diagnosed only when metastases are present, is approximately 10%. In patients with a family history of pheochromocytoma, multiple endocrine neoplasia syndrome (MEN types IIa and IIb) should be suspected. Pheochromocytoma is more common in patients with neurofibromatosis. Schenker and colleagues[47,48] reported mortality rates of 55% with postpartum diagnosis versus 11% with diagnosis during pregnancy. Fetal loss rates can exceed 50%.

In pregnancy, pheochromocytoma may cause a hypertensive crisis, with cerebral hemorrhage or severe congestive heart failure. Pheochromocytoma is easily confused with other medical diseases. The signs and symptoms may mimic those of severe pregnancy-induced hypertension (Table 47–3). Hypertension, headache, abdominal pain, and blurring of vision are common to both entities. Although not uniformly present, paroxysmal hypertension (particularly before 20 weeks' gestation), orthostasis, and absence of significant proteinuria and edema may be helpful in the differential diagnosis. Severe thyrotoxicosis may also resemble this disease. However, significant diastolic hypertension is rarely seen with hyperthyroidism. Aggravation of hypertension with administration of β-blockers suggests pheochromocytoma. An unexplained hypertensive response to anesthesia or circulatory collapse after delivery should prompt consideration of this diagnosis.

Management Options

PREPREGNANCY

If this condition is suspected, a complete diagnostic evaluation is indicated before pregnancy is attempted. Definitive therapy should be undertaken (discussed later).

PRENATAL

The definitive diagnosis depends on laboratory measurement of catecholamines and their metabolites in a 24-hour urine collection. Elevated metanephrine excretion appears to be the most sensitive and specific finding, although isolated elevated vanillylmandelic acid excretion may be present.[47] Because episodic secretion of catecholamines occurs with some tumors, plasma assay of epinephrine or norepinephrine may be helpful during symptomatic episodes.[48] Levels of catecholamines are unaffected by normal pregnancy. Levels may be elevated after eclamptic seizures. Extra-adrenal tumors have characteristic elevations of norepinephrine, but not epinephrine.

Pharmacologic testing may establish the diagnosis in the nonpregnant patient. The phentolamine (Regitine) test is based on the observation that marked α-adrenergic

TABLE 47–3	
Symptoms and Signs in 89 Cases of Pheochromocytoma in Pregnancy	
SYMPTOM OR SIGN	**%**
Paroxysmal or sustained hypertension	82
Headaches	66
Palpitation	36
Sweating	30
Blurred vision	17
Anxiety	15
Convulsion and dyspnea	10

blockade causes a decrease in blood pressure in many patients with pheochromocytoma. This test is not advised during pregnancy because it is associated with maternal and fetal deaths.[49] Nonetheless, it is of extreme importance that the diagnosis be established. Approximately 90% of maternal deaths as a result of pheochromocytoma occur in patients who are undiagnosed before delivery.[50] When symptoms suggest pheochromocytoma and laboratory findings support the diagnosis, the tumor should be localized with radiologic techniques. MRI is the procedure of choice in pregnancy. In the nonpregnant state, selective venous catheterization of the adrenals may be performed. The tumor is bilateral in approximately 10% of cases, including those that occur during gestation.

Before surgery, the patient's condition should be stabilized with oral doses of phenoxybenzamine and α-adrenergic receptor blockers. Careful evaluation of fluid status with central monitoring is essential when using these preparations. β-Blockade with propranolol or similar selective agents is reserved for the treatment of tachyarrhythmias and should not be instituted before α-blockade because hypertensive crisis may ensue. Labetalol is not recommended because it is a combined adrenergic blocking agent. Hypertensive crisis requires intravenous phentolamine administration in an intensive care setting.

Schenker and Granat[48] recommend prompt surgical removal of pheochromocytomas detected before 24 weeks' gestation. Laparoscopic removal has been achieved during pregnancy.[51] When the diagnosis is made during the early third trimester, maternal stabilization with medical therapy has been successful, allowing further fetal maturation.

LABOR, DELIVERY, AND POSTNATAL

Cesarean delivery is preferred because it minimizes the potential catecholamine surges associated with labor and vaginal delivery. Adrenal exploration is performed at the time of cesarean delivery. Careful follow-up is needed because tumors may recur and are potentially malignant.

SUMMARY OF MANAGEMENT OPTIONS
Pheochromocytoma

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Avoid pregnancy until definitive treatment is implemented and cure is achieved.	–	GPP	–
Prenatal			
If the diagnosis is suspected clinically, establish the diagnosis with 24-hour catecholamine testing. Establish the location of the tumor (10% are bilateral) with magnetic resonance imaging.	III	B	47–49
Establish medical stabilization and control of blood pressure before and during surgery.	III	B	47–49
Some give medical treatment and defer surgery until after delivery.	IV	C	50
Laparoscopic surgery has been undertaken.	IV	C	51
Labor and Delivery			
Cesarean delivery is preferable once medical stablization is established.	III	B	47–49
Concomitant surgery at the time of cesarean delivery is debatable.	III	B	47–49
Postnatal			
Monitor for recurrence.	III	B	47–49

CONCLUSIONS

- Pituitary and adrenal problems are very rare in pregnancy.
- The evidence underlying management is limited.
- An interdisciplinary approach is needed.
- Ideally, patients should be evaluated and treated before pregnancy.
- Insufficiency requires continuation with supplements in pregnancy.
- Patients taking glucocorticoids need increased doses to cover labor and delivery.
- Although surgery has been performed during pregnancy, most cases can be managed medically and surgery deferred until the pregnancy is complete.

Hepatic and Gastrointestinal Disease

Catherine Williamson / Joanna Girling

INTRODUCTION

Anatomy and Physiology of the Liver

An understanding of the physiologic changes of normal pregnancy is vital if pathologic conditions are to be correctly defined. False-positive and false-negative interpretations can result if the normal changes due to pregnancy are not fully appreciated.

The liver moves superiorly and posteriorly in pregnancy, such that a palpable liver edge is likely to be pathologic. Absolute blood flow to the liver is unchanged, although the proportion of cardiac output perfusing the liver falls from 35% to 25%. Venous pressure increases in the esophagus due to increased circulating volume, increased portal pressure, and increased pressure from the gravid uterus, thereby diverting a greater proportion of venous return from the inferior vena cava via the azygos system. This results in transient esophageal varices in up to 60% of healthy pregnant women.[1,2] Spider nevi, palmar erythema, and edema are common findings in normal pregnancy, reflecting, in part, peripheral vasodilatation; they should not be assumed to be due to chronic liver disease unless they clearly antedate the pregnancy.

The liver has several important functions, including protein synthesis, metabolism, excretion, and inactivation of a number of substances. Changes in each of these should be considered both in relation to the effect of normal pregnancy and potential overlap with the changes of liver disease outside pregnancy:

- Protein synthesis increases in pregnancy, with rises in coagulation factors VII, VIII, X, and fibrinogen: The last of which has usually doubled by the end of pregnancy, so an apparently normal result may reflect a significant abnormality in, for example, disseminated intravascular coagulopathy (DIC).[3] This increase is probably the main cause of the increase in erythrocyte sedimentation rate that occurs in pregnancy; the 95th percentile for the second trimester in a nonanemic woman being 70 mm/hour.[4] In acute liver failure, prolongation of the prothrombin time may be the first sign of coagulopathy, because prothrombin has the shortest half-life of those coagulation factors manufactured in the liver. Production of albumin is not changed during uncomplicated pregnancy, and hemodilution results in a fall in concentration, so that levels of 28 g/L are commonly seen: these do not reflect failure of hepatic synthesis as might be the case outside pregnancy. The concentration of many hormone-binding proteins is increased, largely due to reduced metabolism rather than increased hepatic synthesis. For example, the higher concentration of estrogen stimulates greater sialylation of the carbohydrate moieties of thyroxine-binding globulin, which extends its half-life from 15 minutes to 3 days[5] and so greatly increases the total T_4.

- Amino acids undergo oxidative deamination in the liver to produce ammonia, which is converted to urea in the Krebs cycle. Failure of this process in severe liver disease can contribute to hepatic encephalopathy. It may also be associated with low urea concentrations, which must not be confused with the fall in urea that occurs as a consequence of the increased glomerular filtration rate of normal pregnancy.[6]

- Hypercholesterolemia occurs in some forms of chronic liver disease due to impaired excretion. Hypertriglyceridemia can occur in chronic alcohol abuse. In normal pregnancy their concentrations increase by 50% and 300%, respectively,[7] and take several months to return to normal after delivery.

- The liver is responsible for postprandial glucose storage and subsequent release during fasting. Hypoglycemia

may occur, despite these large glucose reserves, in patients with massive liver necrosis, for example, in acute fatty liver of pregnancy and is an important cause of liver coma. Serial measurements of blood glucose and subsequently intravenous infusion of 50% dextrose are important in preventing hypoglycemic coma in patients with severe liver failure.

Anatomy and Physiology of the Gastrointestinal Tract

The gastrointestinal tract also undergoes extensive physiological changes in pregnancy. These changes contribute to the common findings of nausea and vomiting, gastroesophageal reflux, constipation, and hemorrhoids, although the exact basis for these changes is not clearly understood. Nausea and vomiting seem to be due to the combined actions of estrogen and progesterone, although this is not certain; human chorionic gonadotrophin may also make a contribution (see hyperemesis gravidarum). Gastroesophageal reflux occurs in up to 80% of pregnancies,[8] and is thought to be due to a combination of reduced lower esophageal sphincter pressure, raised intragastric pressure, reduced pyloric sphincter competence with backwash of alkaline bile and failure of clearance of acid gastric contents. Constipation is traditionally attributed to progesterone-driven smooth muscle relaxation, and increasing transit times allowing more fluid to be absorbed. However, in pregnancy only small bowel transit times have been reported,[9] colonic times have not been studied directly. Iron supplements, dietary changes and altered exercise levels may also contribute, as may mechanical problems in the lower gastrointestinal tract especially the anal sphincter.[10]

Liver Function Tests

So-called "liver function tests" (LFT) are really nonspecific tests of liver cell damage: In essence they reflect the extent of hepatocyte damage, although if damage is exten-

sive and sustained, values may plummet. In pregnancy, significant changes occur in the commonly measured tests of liver function, which must be borne in mind when interpreting blood results. Aspartate transaminase, alanine transaminase, γ-glutamyl transferase, and total bilirubin each fall during pregnancy, the upper limit of normal being about 25% lower than outside pregnancy. This is mainly as a result of haemodilution[11] (Table 48–1). Alkaline phosphatase rises steadily through pregnancy, reaching a peak in the third trimester up to 300% above the nonpregnant range, due to the production of a heat-stable placental isoenzyme: If there is a clinical indication to differentiate the hepatic from the placental form, then the sample can be heat-treated to 60°C for 10 minutes and then reanalyzed, the fall representing the liver isoenzyme.

In the postnatal period, alkaline phosphatase falls steadily, reaching nonpregnant values by day 13 in most women. The transaminases may rise considerably, especially during the first 5 days of the puerperium and can exceed both the pregnant and nonpregnant reference ranges[12] (Table 48–2). This is because they are not specific to liver, occurring also in breast, smooth and striated muscle, and red blood cells. The exercise of labor, the trauma of delivery, and breast-feeding may all contribute to this phenomenon. It is essential to bear this in mind when managing liver disease in the puerperium.

The Fetus and Maternal Liver Disease

In many cases, the fetus is only affected by the maternal liver condition if the pregnant woman is systemically unwell, for example, febrile, dehydrated, hypoglycemic, or profoundly malnourished. Specific issues relating to transmission of infection, the genetic input of the fetus to the maternal condition (e.g., acute fatty liver of pregnancy), the role of the placenta (e.g., preeclampsia and HELLP syndrome), and fetal "poisoning" (e.g., obstetric cholestasis) are covered in the relevant sections. It does not seem that fetal exposure to raised bilirubin, even if prolonged, or toxic metabolites of maternal liver failure

TABLE 48–1

Liver Function Tests in Normal Pregnancy[11]

	NONPREGNANT	FIRST TRIMESTER	SECOND TRIMESTER	THIRD TRIMESTER

influence development.[13] Unconjugated bilirubin crosses the placenta bidirectionally, and this is the main route of fetal clearance. There is not a simple link between maternal and fetal levels of bilirubin.

JAUNDICE IN PREGNANCY

Jaundice may be coincidental to the pregnancy or due to a condition that is specific to the pregnancy. Worldwide the most common cause of jaundice in pregnancy is viral hepatitis, usually hepatitis A. In some parts of the world hepatitis B, C, or E are most prevalent. Hepatitis secondary to infection with cytomegalovirus, Epstein-Barr virus, toxoplasmosis, or herpes simplex should also be considered as causes of jaundice in pregnancy, not least because of the other important implications that these infections have for the fetus. Other common causes of jaundice not related to the pregnancy are the complications of gallstones, drug reactions (in the United Kingdom co-amoxiclav is the commonest cause of cholestatic jaundice) and drug abuse, including alcohol.

The pregnancy-specific causes of jaundice are acute fatty liver of pregnancy, HELLP (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets) syndrome, obstetric cholestasis, and hyperemesis gravidarum. Only in the first of these, which is also the rarest, is jaundice a common feature.

Physiology

When faced with the challenge of a jaundiced pregnant patient, it is easier to reach a diagnosis if a simple logical pathway is followed. Initially the jaundice should be classified according to its type. Then its cause can usually be determined. An understanding of the physiology of bilirubin handling makes this much easier.

Following the destruction of a red blood cell, the released hemoglobin is broken down into globin and heme; other heme-containing proteins, such as myoglobin, cytochromes, and catalase, contribute up to 15% of the total heme. The heme is broken down to biliverdin, which is reduced to form bilirubin, usually amounting to 250 to 300 mg daily: This is not changed by pregnancy. This bilirubin is unconjugated and water-insoluble, and usually carried to the liver bound to albumin. In this state it is unable to pass through the kidney or the blood-brain barrier. However, unbound unconjugated bilirubin is lipid-soluble and can cross the blood-brain barrier. This is most likely in neonates with immature conjugating mechanisms or in the presence of either profound hypoalbuminemia or displacement of bilirubin from albumin by, for example, fatty acids, salicylates, or sulfonamides.

At the hepatocyte membrane, unconjugated bilirubin is actively taken up and conjugated to two molecules of glucuronide, by the action of uridine diphosphoglucurosyl (UDP) transferase. This conjugated bilirubin is water-soluble and usually remains in the liver. Hepatocyte (or canalicular) damage allows it to enter the blood, and the part that remains unbound passes into urine and causes the dark urine of cholestatic jaundice; it is always abnormal to find bilirubinuria. The protein-bound conjugated bilirubin contributes to the yellow discoloration of skin and mucus membranes and the hyperbilirubinemia of liver disease.

From the hepatocyte, bilirubin is actively taken up by the bile canaliculus. It is these energy-dependent steps that are most likely to be impaired by either liver damage or by increased pressure in the biliary tract. From the canaliculus, conjugated bilirubin drains into the extrahepatic bile ducts, the common bile duct, and finally the small intestine. The conjugated bilirubin is too large to be absorbed from this location. It passes to the terminal ileum where bacterial action hydrolyses it to free bilirubin, which is then reduced to urobilinogen. Some of this undergoes further bacterial action in the stool, changing it to stercobilinogen, which contributes to the dark color of feces—reduced entry of bilirubin into the gut accounts for the pale stool of cholestatic jaundice. The rest of the urobilinogen is absorbed and returns to the liver via the enterohepatic circulation; from there it is re-excreted into the bile. This urobilinogen is water-soluble, and in normal circumstances a small amount passes into the urine. Urinary urobilinogen is increased either if there is an increased load of bilirubin, in which case the hepatic capacity to re-excrete the urobilinogen may be overwhelmed, or if hepatic damage impairs re-excretion.

Classification

In Figure 48–1, the potential points for pathological processes resulting in jaundice are highlighted. Three pathologic processes lead to jaundice:

- Hemolysis
- Congenital hyperbilirubinemia
  - unconjugated
  - conjugated

FIGURE 48–1

  - extrahepatic

Hemolytic Jaundice

Hemolytic jaundice occurs when there is excess breakdown of red blood cells and is characterized by increased unconjugated bilirubinemia. There are no abnormalities in transaminases unless liver disease is present as well. Investigations are centered on causes of hemolytic anemia, including hereditary spherocytosis or elliptocytosis, thalassemia, sickle cell disease, glucose-6-phosphate dehydrogenase, blood group incompatibility, or drug reaction. In HELLP syndrome, the main cause of jaundice may be hemolysis.

Congenital Hyperbilirubinemia

In this group of disorders raised bilirubin is the only biochemical abnormality. It occurs when there is either defective conjugation or abnormal handling of bilirubin. The most common condition in this category is Gilbert's syndrome. This benign, familial cause of unconjugated hyperbilirubinemia affects up to 7% of the general population. Most patients have a reduced level of UDP transferase, to around 30% of normal. A number of gene mutations have been described, although phenotypic expression of carriers varies widely, with some individuals being asymptomatic and others experiencing intermittent jaundice. Fasting, intercurrent illness, and pregnancy have been reported to increase the level of unconjugated bilirubinemia, with up to half of pregnant women developing worsening of jaundice.[14] Apart from the raised bilirubin, the other LFTs are normal, and there are no stigmata of chronic liver disease. The reticulocyte count is not raised, thus excluding hemolysis.

Crigler-Najjar syndrome is a very rare and much more serious cause of unconjugated hyperbilirubinemia, which is due to either absence of (autosomal recessive) or marked reduction of (autosomal dominant) UDP transferase. This usually presents at birth, with jaundice and sometimes kernicterus.

Conjugated hyperbilirubinemia is due to defective handling of bilirubin within the liver. Dubin-Johnson syndrome is autosomal recessive and results from a mutation in the *MRP2* (multidrug-resistance protein 2) gene, which is responsible for transporting a wide range of compounds out of the hepatocyte across the canalicular border, including bilirubin and bile salts. It is benign, with a good prognosis, most affected individuals experiencing only mild and fluctuating jaundice. Rotor syndrome is a similar condition, which is often autosomal dominant. In both conditions bilirubinuria is present.

Benign recurrent intrahepatic cholestasis (BRIC) and progressive familial intrahepatic cholestasis (PFIC) are rare causes of conjugated congenital hyperbilirubinemia, which in pregnancy may account for a small proportion of cases of obstetric cholestasis (see following sections).

Cholestatic Jaundice

The broad term *cholestasis* refers to failure to excrete bile from the hepatocyte, the canaliculus (intrahepatic), or the common bile duct (extrahepatic) due to acquired damage or obstruction. Consequently, some or all of the substances usually excreted by this route, including bilirubin, bile salts, cholesterol, and phospholipids, accumulate in the blood. Alkaline phosphatase levels may rise, due to either increased synthesis at the sinusoidal surface of the hepatocyte or to re-entry from the sinusoids into the systemic circulation in response to raised intraductal pressure. Cholestasis may occur without jaundice if excretion of bilirubin is maintained or only part of the liver is affected. Jaundice occurs when the failure of excretion of bilirubin results in its accumulation in the circulation.

Intrahepatic cholestatic jaundice is due to any of a wide range of abnormalities at a cellular level and has a diverse number of clinical causes. Within this category fall viral hepatitis, drug reactions, alcohol abuse, cirrhosis of any cause, obstetric cholestasis, acute fatty liver of pregnancy, and hyperemesis gravidarum. Extrahepatic cholestasis is due to obstruction to the flow of bile at any point beyond the canaliculus; causes include gallstones, biliary stricture, pancreatitis, and malignancy.

In both forms of cholestatic jaundice there may be pale stool, dark urine, and conjugated bilirubinemia. They must be clearly differentiated from each other by careful history, examination, and investigation because they require different management strategies.

In practical terms, an important step in assessing a patient with jaundice is to establish the type of jaundice (see section on Classification and Table 48–3). This is very simply and quickly done by asking the laboratory to report the bilirubin both as the total amount and divided into conjugated and unconjugated forms (also referred to as direct and indirect bilirubin). Commercial urine dipsticks

TABLE 48–3

should be used to test for bilirubinuria (which is always abnormal) and urinary urobilinogen. Table 48–3 can then be used to establish the most likely type of jaundice.

Management Options

Prepregnancy

Some causes of jaundice have long-term implications for maternal health and should be discussed prior to pregnancy.

Prenatal

It is important to determine the type of jaundice and its cause. Management depends on the cause and involves interdisciplinary approaches with health professionals from other specialties according to differential diagnosis.

Labor and Delivery

Planned early delivery may be required as "treatment" for some pregnancy-specific causes of jaundice, but is not inevitable. An epidural should not be sited if a coagulopathy or profound thrombocytopenia is present.

Postnatal

Resolution of jaundice should be confirmed. Care should be taken with the use of the oral contraceptive pill. Implications for future pregnancy depend on the cause and should be discussed with the patient.

OBSTETRIC CHOLESTASIS

General

Obstetric cholestasis (OC) affects 0.7% of pregnancies in Caucasians in the United Kingdom and approximately double this proportion of women of South Asian origin.[15,16] It is associated with maternal hepatic impairment and with fetal morbidity and mortality. OC has a complex etiology, with genetic, environmental, and endocrinologic factors playing a role. Evidence for a genetic cause includes the high prevalence in specific ethnic groups; for example, it affects 5.5% of pregnancies in Chilean Araucanians,[17] and the fact that sisters have a relative risk of 17%.[18] Recent genetic studies of cholestasis in nonpregnant cases have also added to our understanding of the etiology of OC. Mutations in genes that influence hepatic bile acid transport (i.e., *MDR3*, *FIC1*, and *BSEP*) have been demonstrated in two conditions: PFIC and BRIC.[19–21] A small proportion of the heterozygous mothers of children with PFIC have been shown to have mutations in at least one of these genes and to have a higher incidence of OC than expected.[21–23]

Women who develop OC are thought to have an increased sensitivity to the cholestatic effect of raised serum estrogens in pregnancy; the condition occurs most commonly in the third trimester when estrogen levels are highest and some women with a previous history of OC develop similar symptoms when taking the oral contraceptive pill[24] or when challenged with exogenous estrogens.[25] It has also been suggested that progesterone may play a role in the etiology of the condition as 34 (68%) of 50 women in a French prospective series of OC cases had been treated with oral micronized natural progesterone for risk of premature delivery.[26]

Diagnosis

The classical maternal symptom of OC is generalized pruritus without a rash. Dark urine, pale stool, or jaundice may also be present, but these are uncommon. If pruritus is associated with abnormal liver transaminases or raised bile acids, a diagnosis of OC should be considered. A recent UK study demonstrated that pruritus without hepatic impairment occurs in approximately 50% of pregnancies, but this is most commonly transient, localized to the abdomen and limited to the first trimester.[27] Amongst women with pruritus, 3% had OC (using a diagnosis of pruritus plus raised serum transaminases or bile acids), and in this group the itch was more commonly described as "all over," "on the legs," or "on the palms and soles." However, OC did also occur in women who only complained of pruritus on the abdomen, so we recommend that the LFTs and serum bile acids should be checked in all pregnant women who complain of pruritus without rash.

Measurement of bile acids is the most useful test for the diagnosis of OC. In unaffected pregnancies the levels of serum bile acids change little.[28] The extent of the rise in OC pregnancies is variable and can be marked. However, more moderate rises in serum bile acids may still be associated with an adverse fetal outcome, so it is important to consider the diagnosis in all women with levels above the normal range. Serum transaminases [alanine aminotransferase (ALT) and aspartate aminotransferase (AST)] also rise in the majority of cases, but the extent of the rise may not be marked (i.e., two- to threefold). The relative value of serum bile acids, ALT and AST for the diagnosis of OC is a matter of debate as it is not yet certain which is the best prognostic indicator: The diagnosis can be entertained if one or more of these are abnormal. Studies have shown that serum bile acids and transaminases are both raised in more than 90%,[29] or all cases,[30,31] although the timing of the changes may be different. In a subgroup of women the rise in serum bile acids and transaminases can occur up to 15 weeks after the onset of pruritus, so it is advisable to repeat the tests in women with persistent symptoms of OC even if the initial results are normal.[32]

Raised bilirubin can occur in OC, but it is not commonly seen and should not be used alone to make the diagnosis. Alkaline phosphatase rises in the third trimester of normal pregnancies, mainly as a consequence of the placental isoenzyme, and is therefore not of value in the diagnosis of OC. Gamma-glutamyltransferase is elevated in approximately 33% of cases.[28]

A new marker of hepatocellular damage, glutathione-S-transferase alpha (GSTα), seems to be a better early discriminator between pruritus gravidarum and OC, because in the latter condition it becomes raised 9 weeks before transaminases or bile salts.[33]

Women with pruritus and abnormal LFTs should have viral hepatitis (hepatitis A, B, C, CMV, and EBV) and autoimmune hepatitis excluded: Blood needs to be taken for the appropriate serologic tests, antimitochondrial antibodies to exclude primary biliary cirrhosis and anti-smooth muscle antibodies to exclude autoimmune chronic active hepatitis. An ultrasound scan of the liver and biliary tree should be performed to exclude other causes of biliary obstruction. In a study of 227 UK cases of OC, gallstones were present in 13%, and of these cases 70% had a history of symptoms of cholelithiasis prior to pregnancy.[34] Asymptomatic gallstones are unlikely to cause OC and are more likely to be present because mutations in at least one gene predispose affected women to both OC and gallstones.[35]

The diagnosis of OC should be one of exclusion and be finally confirmed by resolution of symptoms and biochemical abnormalities postpartum. Antenatally, once the diagnosis of OC has been made, the LFTs, including a prothrombin time, should be checked once per week: The purpose of this is not to assess disease severity,

because the risk to the fetus is not clearly linked at present to levels of any biochemical markers, but to ensure continued cholestasis.

It is particularly important to establish whether a woman with OC has hepatitis C, because pregnancies in seropositive women are more likely to be complicated by spontaneous prematurity.[36] Also women with hepatitis C infection have a higher prevalence of OC.[36] If a woman is found to be seropositive, it is important to discuss the risk of vertical transmission, although this is currently thought to be low and not markedly influenced by the mode of delivery or breast-feeding. An additional argument for screening for hepatitis C in women with OC is that treatment with interferon and ribavirin postnatally can be curative.

Maternal and Fetal Risks

Maternal Risks

Pruritus can be a very distressing symptom, and some women may have such marked dermatitis artefacta that they develop permanent scars (Fig. 48–1). We are aware of one woman who was so disturbed by pruritus that she put her feet in ice water and developed frostbite.

The main maternal risk in pregnancy is postpartum hemorrhage as a consequence of the prolonged prothrombin time that can occur in association with hepatic impairment.[37]

The pruritus and hepatic impairment resolve rapidly after delivery in the majority of cases, although epidural opiates seem to be associated with a transient deterioration of itch in a few women. If symptoms or biochemical abnormalities persist more than 3 months postpartum, women should be referred to a hepatologist.

There was a 90% risk of recurrence of OC in UK cases. Twenty-seven percent of women complained of either cyclical or oral contraceptive-induced pruritus when they were not pregnant,[34] but the condition did not influence their health in the long term. Therefore, women with OC should be advised to avoid estrogen-containing contraceptives. If no alternatives are suitable, the oral contraceptive pill should only be introduced with serial monitoring of LFTs, surveillance for pruritus, and discontinuation if changes develop.

Fetal Risks

OC has been reported to be associated with increased rates of spontaneous prematurity, fetal distress (defined as meconium-stained amniotic fluid or CTG abnormalities), and intrauterine death (IUD). In the 1995 CESDI report[38] 5% of all full-term stillbirths were attributed to OC. Table 48–4 summarizes the frequency of these complications in each of the studies that has been performed in all successive cases within specific hospitals. Although the rates of IUD have decreased following a policy of delivery by 38 weeks' gestation (see Table 48–4), women are still referred to the obstetric medicine clinic at Queen Charlotte's Hospital having had OC pregnancies complicated by IUD. We suspect that this complication still occurs in approximately 0.5% of affected pregnancies, even with early delivery. The data in Table 48–4 and the results of a study of OC pregnancies complicated by IUD in the UK[34] suggest that delivery by 37 weeks' gestation reduces the risks of IUD. Some data from *in vitro* animal studies suggest that ursodeoxycholic acid (UDCA) and dexamethasone treatment may also be protective.[39] It may be of relevance that these therapeutic agents were given to 40% of women in a recent series of 70 cases in which no IUDs were reported.[16]

Iatrogenic prematurity is also commoner in OC pregnancies,[34] and it is important not to underestimate the fetal risks of elective delivery at 37 weeks' gestation. A study of neonatal respiratory morbidity following elective cesarean section for all indications reported a higher incidence of respiratory distress syndrome and transient tachypnea of the newborn in those that were delivered during the week 37 + 0 to 37 + 6 compared with 38 + 0 to 38 + 6, and a similar difference was seen when this was compared with deliveries the following week of gestation.[40] Another study demonstrated that a markedly

* That is, in the majority of cases in the study.

higher proportion of babies required ventilation for respiratory distress syndrome when delivered at an earlier gestation; that is, 1:73 (1.4%) at 35 weeks, compared with 1:557 (0.2%) at 37 weeks (and 1:1692 at 38 weeks).[41] In our study of 70 women with OC, 58 were delivered at or beyond 37 weeks' gestation, and of these, nine babies were admitted to the special care baby unit and two needed ventilation.[16] However, most women consider these risks to be more acceptable than the risk of IUD in OC pregnancies not delivered by 38 weeks.[42,43]

Management Options

Once the diagnosis of OC has been made, we recommend that affected women are delivered between 37 to 38 weeks' gestation to reduce the risk of IUD. Fetal surveillance can be performed with regular cardiotocography, although there is no evidence that this predicts which pregnancies are at risk of fetal distress or IUD. It is, however, often reassuring for affected women and for the team caring for them. We recommend that vitamin K 10 mg orally should be taken daily to reduce the risk of hemorrhage. Two drugs, UDCA and dexamethasone, have been shown to improve maternal symptoms and biochemical abnormalities in OC. We recommend UDCA treatment for women with distressing symptoms of pruritus. Dexamethasone, and other therapeutic agents discussed in the following sections, can be considered in women who do not respond to UDCA treatment.

Vitamin K

The active vitamin-K-dependent clotting factors (II, VII, IX, and X) are formed from precursors in the liver, and patients with liver disease are at risk of hemorrhage due to deficiency of these clotting factors. In OC, impaired intestinal absorption secondary to steatorrhea is the most likely cause of vitamin K deficiency, although hepatic impairment may also contribute in some cases. It is thought that the increased prevalence of postpartum hemorrhage in OC is related to vitamin K deficiency, although it is feasible that prematurity, induction of labor, instrumental delivery, or other factors are also relevant. There been one report of reduction in the prothrombin level in a woman with OC[37] and a case report of severe fetal intracranial hemorrhage in a woman treated with cholestyramine that was thought to be due to vitamin K deficiency.[44] Once OC is diagnosed, we recommend that all women are treated with water-soluble oral vitamin K 10 mg daily.

Ursodeoxycholic Acid

There have been more studies of UDCA than any other drug for the treatment of OC. In the Cochrane Database of Systematic reviews, three trials totaling 56 women are identified in which UDCA is compared with placebo: In

two there is no difference in relief of symptoms; in one trial, greater reduction in bile salts and liver enzymes was noted with UDCA.[45] When the results of ten studies with a total of 85 affected women who have been treated with UDCA are combined, 74 (87%) showed clinical or biochemical improvement or both.[46] In addition, UDCA has been shown to reduce the levels of bile acids in the cord blood and amniotic fluid at the time of delivery.[47] UDCA is commonly started at a dose of 500 mg twice a day, but doses of up to 2000 mg/day were given in several studies, and some women will only respond to higher doses. All babies born to mothers given UDCA were delivered safely, and no problems attributable to treatment have been reported, although there has been no follow-up of these babies.

Dexamethasone

One Finnish study demonstrated improvement in clinical symptoms and biochemical abnormalities in ten women with OC who were treated with oral dexamethasone 12 mg daily for 7 days, with a gradual reduction in dose over the subsequent 3 days.[48] The results of this study are encouraging, but this is the only series of cases treated with dexamethasone in the literature to date. There has been one case report of worsening of maternal pruritus and ALT following dexamethasone treatment.[49] Our experience of 12 women suggests that approximately 40% of those whose symptoms and biochemical abnormalities do not respond to initial treatment with UDCA will respond to dexamethasone treatment.

There have been no long-term studies of the subsequent effects on the child of antenatal exposure to high doses of dexamethasone in the 7- to 10-day regimen used in obstetric cholestasis, but there is some uncertainty about the fetal risks of such high doses of corticosteroids. It is thought that treatment with two doses of dexamethasone (12 mg IM) for fetal lung maturity is safe, but some animal and human data suggest a possible association between repeated courses of steroids and decreased birth weight[50] and abnormal neuronal development.[51] Widespread use of dexamethasone cannot yet be recommended. Its use should be carefully considered in women with severe resistant symptoms who are remote from delivery.

Other Drugs that Can Be Used to Treat Obstetric Cholestasis

Several other drugs have been used to treat OC, including cholestyramine, S-adenosylmethionine, and guar gum (reviewed in reference[46]). Although all resulted in clinical improvement in some studies, none of these agents consistently resulted in a biochemical improvement and no studies were powered to show improvement in fetal outcome.

Aqueous cream with menthol often relieves the pruritus for a short time, and some women find this helps them to fall to sleep.

Amniocentesis and Amnioscopy

Meconium staining of the amniotic fluid is reported in almost all cases of IUD that complicate OC in the current literature. Amniocentesis for the presence of meconium has been proposed as the best way to predict the at-risk fetus.[52] No IUDs were reported in a series of 206 women in whom amnioscopy and amniocentesis were used to test for meconium before 37 weeks' gestation as part of a man-agement protocol for OC.[53] However, such an approach may be considered too intrusive to be used routinely by most obstetricians. Also, amnioscopy or amniocentesis may give misleading results because the passage of mater-nal bile acids to the fetus may stimulate passage of meco-nium into the amniotic fluid regardless of whether there is fetal distress. Also the absence of meconium does not guarantee either its ongoing absence or fetal well-being.

SUMMARY OF MANAGEMENT OPTIONS
Obstetric Cholestasis

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
If previous history of OC, advise of recurrence risk of 90%.	III	B	53
Biliary tract ultrasonography to exclude other pathology	III	B	34
Prenatal			
Confirm the diagnosis with serum bile acid, ALT, or AST measurement.	IIa	B	28–32
Exclude viral infection, including hepatitis C, autoimmune hepatitis, and other causes of biliary obstruction.	III	B	34–36
Treatment of maternal symptoms initially is with oral vitamin K and simple topical measures (e.g., aqueous cream with menthol).	IV	C	37, 44
Consider UDCA 500 mg bid for women with severe symptoms.	IIa	B	47
Dexamethasone (problem of possible fetal adverse neurological effects of repeated doses)	IIb	B	48, 49
Cholestyramine, guar gum	IV	C	46
Monitor fetal well-being, though does not predict at-risk fetus.	III	B	16,161,162
Labor and Delivery			
Consider elective delivery at 37–38 weeks.	III	B	16,161,162
Vigilance for postpartum hemorrhage	IV	C	37
Postnatal			
Monitor biochemical resolution; generally long-term maternal and baby health are good.	–	GPP	–
Vitamin K supplement for baby	–	GPP	–
Use oral contraceptives only with close clinical and biochemical monitoring; 27% of cases have cyclical or oral contraceptive-induced pruritus.	III	B	34
Consider referral to hepatologist if symptoms and biochemical abnormalities persist.	–	GPP	–

ALT, alanine aminotransaminase; AST, aspartate aminotransaminase; OC, obstetric cholestasis; UDCA, ursodeoxycholic acid.

ACUTE FATTY LIVER OF PREGNANCY

Acute fatty liver of pregnancy (AFLP) is a rare but dan-gerous disorder. The clinical symptoms and signs are not specific, the definition is one of exclusion (rather than inclusion), and so the diagnosis can be difficult to reach. However, failure to do so may jeopardize the life of the pregnant woman or her fetus.

General

Definition

AFLP may be defined as acute liver failure with reduced hepatic metabolic capacity in the absence of other causes. Histologically there is panlobular microvesicular steato-sis, with sparing of periportal areas and intrahepatic cholestasis: These appearances are not unique to AFLP,

and can be difficult to detect with conventional fixing and staining techniques. The very nature of the illness means that a liver biopsy is often not appropriate. In reviewing the literature it is clear that subjective diagnoses are often used, and this, in conjunction with the rarity of the condition, makes evidence-based care of women with AFLP challenging.

Incidence

AFLP has been reported to occur in between 1 in 7000 (clinical diagnosis alone in 27 of 28 cases)[54] and 1 in 13,000 pregnancies (10 cases, all biopsy-proven).[55] Most cases are reported in the third trimester, although it is described as early as 20 weeks and in the puerperium. Age, parity, and race do not seem to influence the risk; multiple pregnancies and male fetuses are reported more commonly than expected, although there is not a clear explanation for the pathophysiology behind this.

Diagnosis

The symptoms and signs of AFLP are vague and non-specific. It is likely that many women experience a prodromal phase in which there is only a gradual deterioration in their condition and when jaundice may not be apparent: in one study this lasted on average for 9 days, although the range was 1 to 21 days[54] prior to the rapid and sometimes catastrophic decline that can occur with AFLP. There should be a low threshold for performing LFTs on pregnant women who present in the third trimester with prodromal symptoms including new-onset nausea, vomiting, epigastric or right upper quadrant pain, and malaise.

Other features in the condition include pruritus, headache, fever, preeclampsia (hypertension and proteinuria), and, in severe cases, impaired conscious level or coma. Abnormalities in laboratory investigations may include:

- raised transaminases: typically three to ten times the upper limit of normal; transaminase levels above 1000 iμ/L may occur with hepatic ischemia or hypoglycemia
- hyperbilirubinemia
- hypoglycemia
- neutrophil leukocytosis often reaching 20,000-30,000
- hyperuricemia
- prolonged prothrombin time

One of the keys to the diagnosis of AFLP is the rapidity with which LFT can deteriorate in the aggressive phase of the disease. This typically is combined with features of hepatic synthetic failure, including hypoglycemia, deranged clotting, and confusion secondary to hepatic encephalopathy. Other pregnancy-specific liver conditions do not impair liver function in this way. Other causes of fulminating liver failure must be excluded: Paracetamol (acetaminophen) overdose and acute viral

hepatitis are the commonest causes, and rarer causes include Wilson's disease, poisoning with carbon tetrachloride, and drug reactions (e.g., to halothane or isoniazid).

Imaging of the liver has not been successful in accurately detecting fatty infiltration nor, if it is present, determining its cause. Techniques that have been used include ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI). Apart from ultrasound, it is unlikely that imaging will be either portable or easily accessible to the delivery suite; abdominal CT is better avoided when possible prior to delivery because of radiation exposure to the fetus, and many pregnant women will be too large to fit inside a standard MRI even if they are well enough to be moved there. False-positive and false-negative diagnoses are equally common with all modalities.[56] If the diagnosis remains in doubt and, in particular, if there is not a rapid improvement after delivery, the place for imaging the liver should be reconsidered.

Liver biopsy is another possibly helpful diagnostic tool. Bearing in mind the histopathologic caveats outlined earlier and the potential complexities of performing a biopsy in the presence of deranged clotting, the need for a tissue diagnosis should be carefully assessed on an individual basis.

Maternal and Fetal Risks

Significant risks, including maternal and fetal mortality, are undoubtedly associated with AFLP. Several case series seem to demonstrate improved outcome for mother and baby in recent years. In the 1960s, 16 cases of AFLP associated with the use of tetracycline were reported, with a 70% maternal mortality.[57] Among 33 pregnancies with biopsy-proven AFLP reported in the 1980s, maternal mortality was 21% and fetal mortality was 27%.[58] More recently, Castro and associates reported 28 clinically diagnosed cases with no maternal mortality and a 7% neonatal mortality.[54]

The Report on Confidential Enquiries into Maternal Deaths in the United Kingdom continues to report maternal death from AFLP, with three women dying in the triennium 2000 to 2002.[59] There is an ongoing need for all obstetricians to be aware of AFLP, not just those in large tertiary referral centers. In 2005 the UK Obstetrics Surveillance System (UKOSS) was launched. AFLP is the subject of their initial surveillance and the results are eagerly awaited.

Etiology

The cause of AFLP is uncertain, but is likely to be multifactorial, with a genetic component in a number of cases. In some women, AFLP may occur because of an autosomal recessive abnormality in fetal long-chain fatty acid beta oxidation. This is an interesting concept, as it demonstrates that the fetus may determine maternal

complications of pregnancy. In addition, for these families, the risk of recurrence is significant.

Long-chain hydroxyacyl coenzyme A dehydrogenase (LCHAD) deficiency is a recently described disorder of mitochondrial fatty acid oxidation that is usually asymptomatic in heterozygous carriers. Affected individuals often die in early childhood or sooner from complications of hypoglycemia, cardiomyopathy, or fatty liver failure; those who live longer develop chorioretinopathy, rhabdomyolysis, and peripheral neuropathy, although these can be ameliorated by a high-carbohydrate, low-fat diet, in which the fat component is medium-chain triglycerides. Several mutations of the alpha subunit of the mitochondrial trifunctional protein cause deficiency of LCHAD. In Finland a guanine cytosine transposition, G1528C, and in America a glutamic acid to glutamine change, E474Q, have been identified.[60,61] The latter group estimates that 1 in 175 of their population is heterozygous for E474Q, and therefore that 1 in 62,000 pregnancies results in LCHAD deficiency. Affected fetuses do not metabolize long-chain fatty acids completely, resulting in accumulation of abnormal and highly toxic intermediates in the mother's liver, and the acute clinical picture we recognize as AFLP. It is also hypothesized that fat accumulation may occur in the placenta, and that this may induce the clinical picture of preeclampsia. Preeclampsia has been described in pregnancies with fetuses affected by homozygous LCHAD deficiency more commonly than would be expected, and more than in pregnancies in the same women with unaffected fetuses.[62]

It is not certain what proportion of cases of AFLP may be due to LCHAD deficiency. It is likely that this will vary between countries, depending in part on the prevalence of the known (and unknown) genetic mutations in the local populations. Mansouri and colleagues[63] reported no carriers of the G1528C mutation in 14 histologically proven cases of AFLP, but Treem and associates found that 75% of 12 women with AFLP had LCHAD levels compatible with carrier status.[64] A recent larger study identified LCHAD mutations in 5 of 27 women with AFLP, all of whom had a fetus with LCHAD deficiency.[65] All five affected fetuses had at least one copy of the E474Q mutation, and the authors therefore recommended screening for this mutation in the children of women who have had pregnancies complicated by AFLP. In contrast, the same study demonstrated that only 1 of 81 women with HELLP had an LCHAD mutation and this was not inherited by the fetus, indicating that it is not justified to screen the offspring from all pregnancies affected by HELLP.

Conversely, not all pregnancies where the baby has LCHAD deficiency will result in AFLP or other serious maternal liver disease. Ibdah and colleagues[66] found that in 15 of 24 pregnancies in which the baby had LCHAD deficiency either AFLP (n = 12) or HELLP (n = 3) syndrome developed, and in the other 9 pregnancies there were no complications. These women had 11 other pregnancies with unaffected babies in which maternal liver disease did not occur. Similarly, Tyni and associates[62] found some form of liver disease of pregnancy and or preeclampsia in 15 of 29 pregnancies in which the fetus was homozygous for LCHAD deficiency and described 7 of the remaining 14 pregnancies as completely normal; none of the other 34 pregnancies from these women (when the fetus did not have homozygous LCHAD deficiency) were complicated by significant liver disease.

Management Options

The ultimate management option is to deliver the baby, because this seems to be the optimal way to improve the maternal condition and to protect the fetus. The decision to deliver brings with it a not uncommon conundrum for obstetricians: A vaginal delivery minimizes the risk of maternal hemorrhage in the face of a coagulopathy, but may take several hours or longer to achieve, and this could be significantly detrimental to the mother or fetus; a cesarean section allows delivery to be achieved more quickly but may be complicated by bleeding. An individual decision regarding the severity of the maternal and fetal conditions needs to be made. Often, induction of labor can be started while the maternal condition is stabilized and blood products made available, and then the ongoing management can be reviewed according to the current balance of concerns.

From the maternal perspective, she should have one to one nursing on the delivery suite, preferably in a high-dependency area. All vital signs should be measured and recorded clearly on a 24-hour spread sheet; it is usually advisable to insert a central line early in the course of the disease before coagulopathy ensues. Glucose assessments should be made at least every two hours, and hypoglycemia treated with large doses of high-concentration intravenous glucose via a long line. Prothrombin time should also be measured every six hours along with LFTs, renal function tests and electrolytes, and full blood count. Formal assessment of level of consciousness must be made hourly, as hepatic coma is a potential complication of AFLP.

One of the keys to successful management is a multidisciplinary approach. Senior obstetric, anesthesiology, hematology, and hepatology colleagues should be involved at an early stage. If no hepatologists are inhouse, the obstetrician should liaise directly with the nearest liver transplant unit. This serves several purposes: firstly it provides expert advise on both the investigations and the management; secondly it alerts the transplant team who are usually able to accept transfer after delivery if recovery does not commence. Most women will be transferred from the delivery suite to the intensive care unit after delivery.

Follow-up and Recurrence

Once they have recovered, all women affected by AFLP should have the opportunity with their partners to be debriefed about the complications of their pregnancy. In those women who survive, complete recovery of the liver is expected.

Pediatricians should consider screening all babies of women with AFLP for LCHAD deficiency, either by measuring LCHAD activity in cultured skin fibroblasts or liver, or by doing DNA studies looking for the common mutations. Affected babies should be placed on the appropriate dietary restrictions. Not only does this

screening minimize the complications for the index baby, but also it allows the couple to make an informed choice about the risks to the mother and fetus in a future pregnancy.

The risk of recurrence of AFLP depends largely on whether the baby has LCHAD deficiency. If he or she does, the rate is between 15% and 25% for future pregnancies from the same partnership; if the baby does not, then the recurrence risk is very much lower, although it is difficult to give a precise figure since so many women decide against a further pregnancy.

When a woman has had an affected baby previously, prenatal diagnosis (of LCHAD) is possible in subsequent

pregnancies, by enzyme assay in amniocytes[67] or DNA analysis from chorionic villus sampling (CVS).[66]

LIVER HEMATOMA AND NONTRAUMATIC LIVER RUPTURE

General

Liver hematoma is an uncommon and potentially dangerous problem in pregnancy, its most hazardous complication being hepatic rupture. Rupture of the liver capsule occurs in between 1 in 45,000 and 1 in 225,000 deliveries.[68,69]

The vast majority of cases are reported in association with preeclampsia, and a very high proportion are in multiparous women older than 30 years of age. Only two cases have been described in the puerperium following a normal pregnancy.[70] In over 85% of cases, the right lobe of the liver is affected. Rinehart and associates[71] reviewed the literature and presented figures for the common symptoms and signs of hepatic rupture. Not surprisingly, they found that almost 70% of patients had epigastric pain, 65% had hypertension, and over 50% were shocked. However, there was a wide range of other presentations, including some women with mild symptoms prior to massive circulatory collapse. HELLP syndrome seems to be particularly associated with intrahepatic hemorrhage, subcapsular hematoma, and capsular rupture.

The pathogenesis is debated. One attractive theory suggests that preeclampsia causes hepatic ischemia via intravascular volume depletion, which results in local necrosis and hemorrhage. Subsequently, neovascularization occurs, and these vessels are especially susceptible to rupture and further hemorrhage, particularly during hypertensive episodes. Subcapsular hematoma may then expand sufficiently to result in hepatic rupture.[71]

Maternal and Fetal Risks

Hepatic rupture is dangerous for mother and baby. Maternal mortality is between 16% and 60%, and peri-natal mortality is between 40% and 60%.[72,73] Current management options have contributed greatly to lowering the mortality rates.

Management Options

The management will obviously be determined by the seriousness of the situation. There should be a low threshold for imaging the liver in older, multiparous women with preeclampsia and epigastric pain. Ultrasound will usually be readily available and is helpful in diagnosing subcapsular hematomas. CT (Fig. 48–2) and MRI hepatic digital subtraction angiography may have greater sensitivity for identifying small amounts of intraperitoneal blood and small hematomas but have the disadvantage of being less readily available and less portable if the patient is unwell.

Treatment of hepatic rupture is based on resuscitating the patient and stopping the hemorrhage. If the diagnosis is suspected, a midline laparotomy with the involvement of an experienced surgeon should be considered: This allows the diagnosis to be confirmed, the baby to be delivered (which will improve the maternal circulation and remove the baby to a place of safety), and treatment to be instituted. If unexplained hemoperitoneum is found at a Pfannenstiel laparotomy for presumed abruption or

FIGURE 48–2
Liver hematoma.

uterine rupture, careful exploration of the upper abdomen, preferably by an experienced general or hepatic surgeon and possibly with an upper midline incision to improve access, must be strongly considered.

A wide variety of therapeutic maneuvers for liver rupture have been described. Currently the most successful seem to involve digital compression of the hepatic artery and portal vein to temporarily arrest the hemorrhage (Pringle maneuver),[72] evacuation of the residual hematoma, and temporary packing with large dry gauze swabs.[74] Packs are removed at a further laparotomy 24 to 36 hours later, once correction of hypovolemia, coagulopathy, acidosis, and hypothermia is complete. Liver resection and transplantation have

also been described, but not surprisingly their mortality rate is very high.

Unruptured small hematomas have been managed conservatively, following delivery of the baby, with serial imaging of their size to exclude expansion[72]: Delayed rupture 6 weeks after initial diagnosis has been reported,[75] so care must be taken if this option is adopted. Tense, large, or expanding hematomas should probably be evacuated surgically to obviate the impending rupture. Hepatic embolization has been described in these circumstances (and in others) but seems to carry a high risk of ischemic necrosis of the liver, liver failure, and sepsis,[76] and may not be accessible to many units; others have described this technique as a "gold standard."[70]

HELLP, hemolysis, elevated liver enzymes, low platelets; PET, preeclampsia toxemia.

HYPEREMESIS GRAVIDARUM

General

Nausea and vomiting affect up to 50% of pregnant women. Most women are able to maintain fluid and nutrient intake by dietary modification, and the symptoms will resolve by the end of the first trimester. Hyperemesis gravidarum affects 0.5% to 1% of pregnancies and causes

severe and protracted vomiting that results in ketosis, dehydration, and weight loss. The cause of hyperemesis gravidarum remains unidentified, but it is thought to result from a combination of endocrine, biochemical, and psychological factors. Seropositivity for *Helicobacter pylori* is commoner in women with hyperemesis than in controls,[77,78] and one study of endoscopic biopsy findings demonstrated that the severity of gastric symptoms may be associated with the density of infection.[79]

Diagnosis

The onset of hyperemesis gravidarum is always in the first trimester. In addition to nausea, vomiting, and weight loss, women often report ptyalism (excessive salivation), and there may be signs of dehydration, including postural hypotension and tachycardia. Hyperemesis gravidarum is a diagnosis of exclusion (Table 48–5), and it is important to make a thorough clinical assessment and to ensure that investigations are performed for common and serious causes of vomiting.

An ultrasound of the uterus should be performed to confirm that a woman is pregnant, to establish the number of fetuses, and to exclude hydatidiform mole.

Laboratory investigations commonly reveal hyponatremia, hypokalemia, and raised hematocrit. A biochemical hyperthyroidism and abnormal LFTs may also be present. These are both markers of the severity of the disease and resolve with successful treatment. Women with biochemical hyperthyroidism should be examined for signs of hyperthyroidism, but these are rarely present.

Maternal and Fetal Risks

Maternal Risks

Serious maternal morbidity and mortality may result if hyperemesis gravidarum is not managed correctly. Wernicke's encephalopathy can develop as a result of thiamine (vitamin B_1) deficiency. This is associated with diplopia, sixth nerve palsy, nystagmus, ataxia, and confusion. If untreated, Wernicke's encephalopathy may lead to Korsakoff's psychosis (amnesia, impaired ability to learn) or death. Other vitamin deficiencies may occur, for example, peripheral neuropathy and anemia may result from deficiency of vitamins B_{12} and B_6.

Hyponatremia (plasma sodium <120 mmol/L) can cause confusion, seizures, and respiratory arrest. If hyponatremia is severe, or if it is treated too rapidly, women may develop central pontine myelinolysis. This is caused by symmetrical destruction of myelin at the centre of the basal pons and can result in pyramidal tract signs, spastic quadraparesis, pseudobulbar palsy, and impaired consciousness.

Other risks include deep venous thrombosis that may result from dehydration and reduced mobility, Mallory-Weiss tear due to prolonged vomiting, and muscle wasting with weakness.

Fetal Risks

Infants of mothers with severe hyperemesis, abnormal biochemistry, and weight loss have been reported to have lower birth weights in some studies[80,81] but not others.[82,83]

There are few known fetal risks from the therapeutic agents used to treat hyperemesis.

Management Options

Rehydration and Vitamin Supplementation

Fluid replacement therapy should be with either normal saline (NaCl 0.9%; 150 mmol/L Na$^+$) or Hartmann's solution (NaCl 0.6%; 131 mmol/L Na$^+$). Dextrose-containing fluids should not be used because they do not contain sufficient sodium to correct hyponatremia, and Wernicke's encephalopathy can be precipitated by intravenous dextrose and carbohydrate-rich foods. Double-strength saline should not be used to correct hyponatremia in hyperemesis gravidarum, because central pontine myelinolysis can occur if the serum sodium level is corrected too rapidly. Potassium supplements should be added to the intravenous fluid replacement therapy as required. Thiamine supplements should be given, as a daily dose of either 50 to 150 mg orally, or 100 mg diluted in 100 mL normal saline as an intravenous infusion.

TABLE 48–5		
Differential Diagnosis of Hyperemesis Gravidarum		
SYSTEM	**DIAGNOSIS**	**INVESTIGATION/INITIAL ASSESSMENT**
Genitourinary	Urinary tract infection	Mid-stream urine specimen
	Uremia	Urea and electrolytes
	Molar pregnancy	Ultrasound of the uterus
Gastrointestinal	Gastritis/peptic ulceration	*Helicobacter pylori* antibodies
	Pancreatitis	Amylase, blood glucose, calcium
	Bowel obstruction	Plain supine abdominal radiograph
Endocrine	Addison's disease	Urea and electrolytes, early morning cortisol, short synacthen test with ACTH
	Hyperthyroidism	Surveillance for symptoms and signs of hyperthyroidism, TFTs, thyroid autoantibodies
	Diabetic ketoacidosis	Blood glucose, urinary dipstick for ketones, glucose tolerance test
CNS	Intracranial tumor	CNS examination, brain imaging
	Vestibular disease	CNS examination
Drug-induced	–	Discontinue agent

ACTH, adrenocorticotrophic hormone; CNS, central nervous system; TFT, thyroid function test.

Urine output should be monitored and dipsticks used to assess ketonuria. Women should be weighed on admission and regularly thereafter if their symptoms do not resolve. Serial assessments of electrolytes should be carried out.

Antiemetics

There is no evidence for teratogenicity following treatment with dopamine antagonists (metoclopramide, domperidone),[84,85] phenothiazines (chlorpromazine, prochlorperazine),[86,87] anticholinergics (dicyclomine),[88] or antihistamine H_1-receptor antagonists (promethazine, cyclizine), and one of these should be tried in the first instance. Women with hyperemesis often find nonoral preparations, such as rectal domperidone or subcutaneous metoclopramide, preferable.

In women with severe hyperemesis who have not responded to these antiemetic therapies, promising results have been reported with both corticosteroids and 5-hydroxytryptamine$_3$ (5-HT$_3$) receptor antagonists (ondansetron, cisapride).

Corticosteroids

Corticosteroids have been reported to be an effective treatment for hyperemesis gravidarum in several case reports.[89–91] In an American double-blind study of 40 women with hyperemesis who were randomized to receive either oral methylprednisolone 16 mg or oral promethazine 25 mg (three times daily for both) the response to both drugs was similar after 2 days, but no women who received methylprednisolone were readmitted within 1 week of discharge. In contrast, five (25%) women who received promethazine were readmitted with hyperemesis.[92] A British double-blind study of 25 women who were randomized to receive either 40 mg prednisolone or placebo daily demonstrated a trend toward improved nausea and vomiting and reduced dependence on intravenous fluids, but this did not reach statistical significance. However, steroid therapy did result in an improved sense of well-being, improved appetite, and weight gain compared with placebo.[93] Overall, the studies of corticosteroid treatment for hyperemesis suggest that the treatment is effective for some patients. We recommend starting intravenous hydrocortisone 100 mg three times a day in women with severe and resistant symptoms who are unable to tolerate fluids, followed by prednisolone 40 mg once daily. This should be reduced by approximately 5 mg every 5 days, provided symptoms are controlled.

5-Hydroxytryptamine Receptor Antagonists

Ondansetron is a 5-HT$_3$ receptor antagonist and is a potent antiemetic drug for the treatment of chemotherapy-associated and postoperative nausea. It has been used to treat hyperemesis successfully in several case reports, in which it was given for between 2 and 19 weeks and was commenced at 11, 14, or 30 weeks' gestation.[94–96] In all cases there were no known adverse fetal events. One double-blind controlled trial in which 30 patients were randomized to receive either 10 mg intravenous ondansetron or 50 mg intravenous promethazine failed to demonstrate any significant difference in the degree of nausea, weight gain, or days of hospitalization between the two groups.[97] However, the entry criteria for this study were less stringent than for the randomized, double-blind studies of corticosteroid treatment for hyperemesis gravidarum.[92,93] Therefore it remains likely that ondansetron may be an effective treatment for women with more severe disease. Experience of its use in the first trimester is limited, and we would recommend reserving ondansetron treatment for the second trimester except in very severe cases.

Other Treatment Options

There has been one double-blind randomized cross-over trial of the efficacy of powdered root ginger and placebo in which women reported a reduced severity and greater relief of symptoms in the period in which ginger was given and no side effects were observed.[98] Several authors have reported success in managing severe hyperemesis gravidarum using enteral and parenteral nutrition.[99–101] However, as the complications can be serious, such treatment is usually reserved for women whose symptoms are sufficiently severe as to be life threatening to the mother. In one series of 16 cases with good pregnancy outcomes, there were 3 cases of line sepsis, and pneumothorax, thrombosis, and dislodgement of the line.[101]

It is advisable to give thromboembolic deterrent stockings and thromboprophylaxis such as enoxaparine 40 mg daily to women with hyperemesis while they are inpatients.

PEPTIC ULCERATION IN PREGNANCY

General

Dyspepsia is common, affecting up to 50% of pregnant women.[102] It usually worsens as pregnancy progresses, and it is more prevalent in women who are older, multiparous, or have a prepregnancy history of heartburn.[103]

Peptic ulceration, however, is uncommon in pregnancy.[104] In addition, women with established peptic ulcer disease can report symptomatic improvement. This is thought to be secondary to reduced gastric acid output and increased protective mucus production associated with raised progesterone levels, in addition to a healthier diet and increased medical supervision.

Diagnosis

It is important to have a high index of suspicion for peptic ulcer disease because the classical symptoms (e.g., severe regular dyspepsia) may be absent. Also, symptoms may not correlate with severity of disease. Patients who are smokers and have a previous history of peptic ulcer disease or previous nonsteroidal anti-inflammatory drug use are at highest risk for peptic ulceration in pregnancy.

Investigations should include blood tests for hemoglobin, electrolytes, and serum amylase, as well as LFTs. An abdominal ultrasound is useful to exclude cholelithiasis and pancreatitis secondary to gallstones. However, if peptic ulcer disease is suspected from the history and examination, *Helicobacter pylori* antibodies should be checked

for, and if a woman has positive serology, treatment should be considered (Table 48–6). Although endoscopy is the investigation of choice outside pregnancy and is safe in pregnancy,[105] too few cases have been reported for the frequency of complications to be assessed. However, endoscopy does allow direct visualization of upper gastrointestinal tract pathology, permits biopsies to be taken for histopathology, and provides a therapeutic option (e.g., injection of adrenaline for acute bleeding ulcers).

Zollinger-Ellison Syndrome

This syndrome is caused by pancreatic gastrin-secreting tumors that result in a marked increase in gastric acid secretion. If untreated the condition causes severe gastroesophageal reflux, peptic ulceration, and malabsorption, and therefore the acid secretion usually requires treatment. There have been recent reports of the successful management of Zollinger-Ellison syndrome in pregnancy.

Maternal and Fetal Risks

Maternal Risks

Complications of peptic ulcer disease in the general, nonpregnant population include bleeding and perforation. These are rarely reported in pregnancy.

Acute gastrointestinal bleeding presents with hematemesis, melena, or the passage of fresh blood from the rectum. It can be associated with hypotension and tachycardia and may result in anemia. It is important to insert a nasogastric tube if gastrointestinal bleeding is suspected. This will allow upper and lower gastrointestinal bleeding to be distinguished and will help to ensure a clear view for endoscopy. When endoscopy is performed, pregnant women should be placed in the left lateral position to reduce inferior vena caval obstruction and reduced venous return. A large-bore cannula should be sited, the woman should be fasting, and a transfusion should be commenced if acute bleeding is confirmed.

Ulcer perforation is rare in pregnancy. Clinical features include abdominal pain with abdominal guarding and rebound tenderness, nausea, vomiting, pyrexia, dehydration, hypotension, and a leukocytosis. If suspected, an abdominal radiograph should be performed to investigate for the presence of pneumoperitoneum or free gas in the abdomen.

Fetal Risks

The fetus may be compromised if there is major maternal hemorrhage or perforation of a peptic ulcer. Otherwise few fetal risks arise from the drugs that can be used to treat peptic ulcer disease, with the exception of sodium bicarbonate-containing preparations and misoprostol (see subsequent section on Misoprostol).

Management Options

Antacids, H_2-antagonists, or proton pump inhibitors can be used to treat established peptic ulcer disease in pregnancy, including Zollinger-Ellison syndrome. If gastrointestinal bleeding is present, therapeutic endoscopy or surgery is indicated, and perforation requires surgical management.

Antacids

Aluminum and magnesium-containing antacids are generally considered to be safe in pregnancy and breastfeeding,[108,109] as are the nonabsorbed alginate-containing drugs such as Gaviscon[110] and the mucosal protective agent sucralfate.[111] Magnesium-based antacids may be preferred to aluminum-based ones, because the latter can be associated with constipation. Sodium bicarbonate-containing antacids should be avoided because they may cause respiratory alkalosis and fluid overload in the mother and fetus.[112]

Acid-Suppressing Drugs

Several recent studies have indicated that H_2-receptor antagonists[113–116] and proton pump inhibitors[114–117] are safe in pregnancy. Three studies have compared the rate of congenital malformations in pregnancies in which there was first-trimester exposure to either H_2-receptor antagonists or omeprazole. A Swedish cohort study in which H_2-receptor antagonists had been taken in 255 pregnancies, proton pump inhibitors in 275, and both in

TABLE 48–6

Therapeutic Options for *Helicobacter Pylori* in Pregnancy.*

| | ANTIBIOTIC | | |
ACID SUPPRESSANT	AMOXYCILLIN	CLARITHROMYCIN	METRONIDAZOLE
Omeprazole 20 mg bid	1 g bid	500 mg bid	–
Omeprazole 20 mg bid	500 mg tid	–	400 mg tid
Omeprazole 20 mg bid	–	500 mg bid	400 mg bid

bid, twice a day; tid, three time a day.
*Modified from the British National Formulary.

20 pregnancies did not demonstrate an increased rate of congenital malformation compared with all births at that time.[114] Similar results were found in a study of 447 British and 108 Italian pregnancies with first-trimester exposure to ranitidine, cimetidine, or omeprazole.[116] Similarly, there was no evidence of increased risk of major malformations in a prospective, multicenter, controlled study in which two groups of 113 women were treated with either omeprazole or with H_2-receptor antagonists and compared with the same number of controls.[115]

Less is known about lansoprazole than omeprazole, but there has recently been a reassuring report of good fetal outcomes with lansoprazole treatment in six cases where there was first-trimester exposure.[118]

One prospective, controlled, multicenter study of the use of cisapride, a 5-HT$_3$ receptor antagonist for the treatment of gastroesophageal reflux, gastrointestinal pain, and duodenal ulcer in pregnancy, showed no increase in the rate of major or minor malformations nor fetal distress.[119]

Triple Therapy for Helicobacter Pylori

If peptic ulcer disease is suspected, serology should be sent for *Helicobacter pylori* antibodies. If a woman has distressing symptoms, appropriate therapy will eradicate the infection and may improve the symptoms. Of the recommended therapeutic regimens at the time of writing, only three include the use of omeprazole (see Table 48–6). The others advise the use of alternative acid-suppressant drugs, about which there is little experience in pregnancy. We therefore recommend that one of the three regimens outlined in Table 48–6 should be used, for 7 days. The regimens containing amoxicillin are recommended for community-based use. Studies of the incidence of congenital abnormalities and adverse pregnancy outcomes in women who have taken these antibiotics indicate that there is no increased risk for amoxicillin,[120] clarithromycin,[121] or metronidazole.[122,123]

Misoprostol

Misoprostol is a synthetic prostaglandin E_1 analogue that has antisecretory and protective properties believed to promote healing of peptic ulcers. However its use is contraindicated in pregnancy because it is a potent stimulant of uterine contractions and can induce spontaneous abortion or uterine bleeding. It is also teratogenic.[124–126]

Therapeutic Endoscopy and Surgery

There is very little experience of therapeutic endoscopy in pregnancy. Of four cases in the literature, thermocoagulation was performed in one for bleeding duodenal ulcer,[105] sclerotherapy for bleeding duodenal ulcer was performed in two,[105,127] and sclerotherapy for a bleeding Mallory-Weiss tear in the fourth.[128] The fetal outcome in three cases was good and was not specifically reported in the fourth.[128]

The indications for surgery are the same as in the nonpregnant patient. A perforated ulcer requires emergency surgery, and the patient should receive broad-spectrum antibiotics. Surgery should also be performed in patients with hemorrhage from peptic ulcers if they have not responded to a transfusion of six units of blood.

SUMMARY OF MANAGEMENT OPTIONS

Peptic Ulceration in Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Advise against agents that may exacerbate peptic ulcer disease (e.g., alcohol, smoking).	–	GPP	–
If taking bicarbonate-containing antacids or misoprostol, advise cessation of treatment.	III	B	112,124–126
Perform investigations to establish the cause of peptic ulceration.	–	GPP	–
Anticipate improvement in clinical symptoms with pregnancy.	–	GPP	–
Aluminum- and magnesium-containing antacids, mucosal protective agents, and histamine receptor blockers are safe in pregnancy.	IIb	B	108–111
Avoid bicarbonate-containing antacids (danger of respiratory alkalosis and fluid overload).	IV	C	112
Consider anti-*Helicobacter* treatment with positive immunological diagnosis and if other therapy has been ineffective.	–	GPP	–

Prepregnancy(Continued)			
Endoscopy is also safe with an experienced operator if no response to medical management; surgery rarely required and mainly needed for those with severe bleeding/perforation.	–	GPP	–
Postnatal			
Symptoms of dyspepsia are likely to improve postnatally.	–	GPP	–
Repeat endoscopy if indicated by initial findings.	–	GPP	–

CELIAC DISEASE

General

Definition and Incidence

Celiac disease, or gluten-sensitive enteropathy, is a common disorder in which gluten-containing foods trigger inflammation of the jejunal mucosa, which improves when a gluten-free diet is taken. In England it occurs in 1 in 1000, and in Ireland 1 in 300 individuals,[129] although more may have silent or undiagnosed celiac disease; it seems to be rare in black Africans, although this may reflect reporting bias. The cause is multifactorial. There is a genetic component, with 10% to 15% of first-degree relatives being affected.[130] However, 30% of identical twins are discordant,[131] suggesting additional factors are involved, such as viral infection.

Etiology

Gluten is present in the cereals wheat, barley, and rye, but not oats. There are four main gluten fractions, but α-gliadin is the most damaging to small intestine mucosa. The enzyme tissue transglutaminase, the main antigen of the endomysial antibody, modifies gliadin and enhances gliadin-specific T-cell responses in genetically predisposed individuals. This is one of several immunologic abnormalities that revert to normal when a gluten-free diet is assumed. Histologically the small bowel shows partial villus atrophy, with crypt hypertrophy and chronic inflammatory changes, the extent of the damage decreasing toward the ileum as gluten is progressively digested into smaller and less damaging moieties.

Diagnosis

Clinically celiac disease presents at any age and is more common in females than males. The symptoms are variable and may include tiredness and malaise (often in conjunction with anemia), diarrhea, steatorrhea, abdominal pain or bloating, weight loss, mouth ulcers, osteoporosis, and neurological symptoms from folate, B_6, or B_{12} deficiency. In pregnancy the most common presentation is with nonspecific symptoms without overt malabsorption, or with anemia.

A new diagnosis of celiac disease should be considered in pregnant women with iron-deficiency anemia or in the presence of otherwise unexplained folate or B_{12}-deficiency anemia. There should be a low threshold for investigating unexplained iron-deficiency anemia, diarrhea, or weight loss in pregnancy, especially if the anemia responds poorly to iron supplementation or folate or B_{12} deficiency is also present. In a study of premenopausal nonpregnant women, 1 in 16 asymptomatic but anemic volunteer blood donors were found to have celiac disease.[132] Among anemic pregnant women, 1 in 43 were found to have antiendomysial antibodies, although apparently none were investigated further for celiac disease.[133] The diagnosis of celiac disease is confirmed by finding endomysial, gliadin, or tissue transglutaminase antibodies, which have high specificity and sensitivity. Outside pregnancy, a jejunal biopsy is usually obtained; within pregnancy most experts feel that this is best avoided, although duodenoscopy can be performed if clinically indicated.

It is important not to miss the diagnosis of celiac disease, because left untreated the condition causes significant morbidity for both the pregnant woman and her fetus and carries with it an increased lifetime increase in mortality mostly from small bowel carcinomas and lymphomas. All of these risks can be ameliorated by assuming a gluten-free diet.

Maternal and Fetal Risks

Maternal Risks

Untreated celiac disease is associated with later menarche, earlier menopause, and a greater risk of secondary amenorrhea compared with control groups of either unaffected women or women with treated celiac

disease.[134] Women with treated celiac disease who adhere to a gluten-free diet have no more gynecologic problems than a group of women without celiac disease. Infertility itself is more common in women with celiac disease than in the general population and has been reported to affect 4% to 8% of cases.[135,136] The pathophysiology of these problems remains uncertain.

Male subfertility is also reported in celiac disease. Abnormal sperm forms, which resolve once dietary gluten is withdrawn, have been observed in nearly half of men with untreated disease. Another group found that male fertility improved after treatment.[137–139]

Anemia is common in women with celiac disease. They should take iron and folate supplements throughout pregnancy; they may also need B^{12} supplementation, and so should be monitored appropriately. Women with celiac disease who are not anemic before pregnancy should be tested for anemia and iron, folate and B^{12} deficiency regularly throughout the pregnancy. Hypocalcemia is less common but must be considered.

Ideally women with celiac disease should take 5 mg, not 400 µg of folate preconceptually, in order to optimize their levels of folic acid. There is insufficient evidence to support, or refute, the claim that celiac disease increases the risk of neural tube defect. This may be because most series of women are too small to make meaningful conclusions.

Fetal Risks

Several reports show first-trimester pregnancy loss to be up to nine times more common in women with untreated celiac disease than in those who have received treatment and to be much more common in pregnancies in the same woman before compared with after treatment with a gluten-free diet.[140] Low-birth-weight babies are nearly six times more common in women with untreated compared with treated celiac disease, and in a cohort of 12 women, once they assumed a gluten-free diet, the number of low-birth-weight babies born fell from nearly 30% to 0%.[140] Similarly, a gluten-free diet increased the duration of breast-feeding more than twofold.

Gasbarrini and colleagues investigated a group of 83 women with either two or more consecutive miscarriages or an unexplained growth-restricted baby (<tenth percentile) and 50 controls. In the poor-outcome groups, 8% and 15%, respectively, had immunologic and histologic features of celiac disease, compared with none of 50 controls.[141] They hypothesize that treatment with a gluten-free diet might improve pregnancy outcome. Martinelli and associates found similar results in an Italian population: among 845 pregnant women screened for celiac disease, 12 cases were discovered and these women had more small-for-gestational-age infants than the other women.[142]

More recently an intriguing hypothesis suggests that men with celiac disease may father more pregnancies complicated by low birth weight than other men do. In a prospective, population-based cohort of 10,000 pregnancies in Sweden, babies of the 27 fathers with celiac disease were delivered at the same gestational age as the rest of the population, but weighed on average 266 g less and were five times more likely to weigh less than 2.5 kg; babies of fathers with a wide range of autoimmune conditions were not similarly affected. The babies of the 53 mothers with celiac disease had similar outcomes to those of the babies born to fathers with celiac disease. No difference was noted for babies with siblings or other relatives with celiac disease ($n = 512$). The exact mechanism for this is uncertain but indicates the importance of nonnutritional factors for neonatal outcome in parents with celiac disease. Genetic factors must be implicated.[143]

Management Options

Women with celiac disease should have a strict gluten-free diet prior to conception to minimize the risk of miscarriage. They should persist with this throughout pregnancy to minimize the risks of growth restriction, prematurity, and anemia. In order to achieve this they should ideally have prepregnancy advice. Once they are pregnant, a management plan should include growth scans, testing for anemia, and iron and possibly folate and B_{12} supplementation. Some women with celiac disease malabsorb calcium: A baseline measurement should be taken, and a calcium-rich diet recommended; supplementation may be necessary for some women.

INFLAMMATORY BOWEL DISEASE IN PREGNANCY

General

The term *inflammatory bowel disease* describes Crohn's disease and ulcerative colitis, as well as other less common forms of colitis. Crohn's disease is a chronic, granulomatous inflammatory disease of the intestine in which affected segments of bowel are often separated by normal bowel (skip lesions). It most commonly involves the terminal ileum. Common symptoms are abdominal pain and diarrhea, and there may also be anemia and weight loss, fresh blood or melena per rectum, fistulae, or perianal sepsis. Nonintestinal tract manifestations of the disease include aphthous ulcers, sacroiliitis, sclerosing cholangitis, and uveitis.

Ulcerative colitis is a chronic inflammatory disease of the colon and rectum. It commonly presents with diarrhea and rectal passage of mucus and blood. Typically the disease starts in the rectum and spreads proximally, without skip lesions. Severe attacks are characterized by passage of a large number of bowel movements a day and can be complicated by fever and abdominal distension (toxic megacolon), which can be fatal. Other complications include anemia, weight loss, hypoalbuminemia, electrolyte imbalances, and carcinoma of the colon (with long-standing disease). Nonintestinal features are similar to those seen in Crohn's.

Although Crohn's disease and ulcerative colitis are both chronic inflammatory disorders of the gastrointestinal tract, the cause of the inflammation does not appear to be the same in each condition. Both are thought to be caused by immune dysregulation in response to constituents of normal gut flora in genetically predisposed individuals. The inflammatory response in Crohn's disease is driven by interleukin-12 (IL-12) and interferon-γ (IF-γ),[144] whereas in ulcerative colitis it is caused by IL-13 release by natural killer T (NKT) cells in a murine model.[145]

There is evidence for a genetic origin in both Crohn's disease and ulcerative colitis. A recent study reported that in siblings with similar genetic susceptibility for inflammatory bowel disease, smoking was associated with an increased risk of Crohn's disease and nonsmoking was associated with the development of ulcerative colitis.[146] Laboratory studies have also demonstrated mutations in *NOD2*, a gene that encodes an intracellular receptor for bacterial lipopolysaccharide, in a subgroup of patients with Crohn's ileitis, but not in patients with colitis or anorectal disease.[147]

Diagnosis

If a woman has known inflammatory bowel disease and is complaining of symptoms consistent with an exacerbation, stool culture should be performed to exclude infection. Blood specimens should be taken to establish whether she has anemia, electrolyte imbalance, or hepatic impairment, and inflammatory markers should be checked. The erythrocyte sedimentation rate is raised in normal pregnancy, but the C-reactive protein is not and is of value in the assessment of patients with Crohn's disease and ulcerative colitis. If a flare-up of inflammatory bowel disease is confirmed, care should be shared between obstetricians and gastroenterologists. If there is

severe disease or if toxic megacolon is suspected, an abdominal radiograph should be performed, and the woman should be referred for a surgical opinion.

In a woman who does not have a history of inflammatory bowel disease, the diagnosis is based on imaging of the upper and lower gastrointestinal tract, colonoscopy, and biopsy. Most women will have had the diagnosis made before they conceive, but if a new presentation of inflammatory bowel disease occurs in pregnancy, endoscopy and biopsy are preferable to barium studies.

Maternal and Fetal Risks

Maternal Risks

Fertility is reduced in women with active Crohn's disease and possibly in those with ulcerative colitis, but there is no evidence of reduced fertility with quiescent inflammatory bowel disease. The frequency of exacerbations of both Crohn's disease and ulcerative colitis is the same as outside pregnancy (30%–40% women per annum).[148] Flares may occur at any stage of pregnancy although they occur most commonly in the first trimester.

Women who have had an ileostomy or colostomy usually tolerate pregnancy well, providing at least 50% of the small intestine remains. Complications that can occur in patients who have had gut resection include malabsorption of fat, fat-soluble vitamins, vitamin B_{12}, water, and electrolyte imbalance. Also, women can have obstruction of ileostomy as pregnancy progresses.

The mode of delivery is not usually influenced by inflammatory bowel disease, even in those with an ileal pouch-anal anastomosis. There are few reports of the management of labor in such cases, but two studies have reported normal vaginal deliveries in the majority of women.[149,150] However, cesarean section should be considered in women with impaired anal continence, in those who have had extensive perineal surgery due to scarring causing skin inelasticity, or in women with active perianal disease, as episiotomy may result in fistula formation. These cesarean procedures may be complicated, and an experienced obstetrician should be present.

Postpartum flare is not a feature of ulcerative colitis but can occur in Crohn's disease.

Fetal Risks

For the majority of cases, if the maternal inflammatory bowel disease is quiescent at the time of conception, the fetal outcome is no different to that in unaffected pregnancies. However, active disease at the time of conception is associated with an increased rate of miscarriage, and flares during pregnancy result in low birth weight and prematurity.[151–153]

Because the etiology of inflammatory bowel disease has both hereditary and immune components, breastfeeding should be encouraged in an effort to reduce the risks to the children of affected women.

Management Options

Acute exacerbations of inflammatory bowel disease can be treated with 5-aminosalicylic acid (5-ASA)-containing compounds and corticosteroids taken rectally, and then orally if local therapy is not sufficient to control symptoms. In severe attacks intravenous corticosteroids may be required. Loperamide can be used for the treatment of diarrhea. Metronidazole is used to treat anal disease and fistulae, particularly in active Crohn's disease. 5-ASA-containing compounds, corticosteroids, and the immunosuppressives azathioprine and 6-mercaptopurine can be used during remission to prevent relapse rates. Long-term management for recurrent Crohn's disease also includes attention to diet and vitamin supplementation. Pregnant women with inflammatory bowel disease should be advised to take high-dose folate (5 mg daily).

5-Aminosalicylic Acid Derivatives

Many women are now treated with 5-ASA derivatives. Salazopyrin, or Azulfidine (sulfasalazine), is a prodrug that is converted by colonic bacteria into sulphapyridine and 5-ASA. The efficacy of Salazopyrin in the treatment of inflammatory bowel disease resides in the 5-ASA component. Many of the side effects of the drug have been attributed to sulphapyridine, and therefore newer preparations that do not have this component are now used more commonly than Salazopyrin. These include mesalazine (5-ASA), balsalazine (a prodrug of 5-ASA), and olsalazine (a dimer of 5-ASA that is cleaved in the lower bowel). Both oral and topical preparations of 5-ASA and Salazopyrin are safe in pregnancy. In a U.S. study that included 186 cases in which the mother was treated with Salazopyrin, the fetal complication rate was lower than the reported rates in the general population.[154] A prospective Canadian study of 165 women who were exposed to oral mesalazine in pregnancy, 146 of whom had first-trimester exposure, demonstrated no increase in major congenital malformations when compared with matched controls who had not been exposed to teratogenic drugs.[155] In a French study designed to address whether treatment with high doses of mesalazine in pregnancy were associated with an adverse fetal outcome, 86 women who received less than 3 g mesalazine daily were compared with 37 who received more than 3 g daily. The results revealed no difference in the rates of congenital malformations, prematurity, nor fetal death between the groups, and the prevalence of these complications was not different from the quoted rates from the general population.[156] Only very small amounts of 5-ASA pass into breast milk, and the drug is therefore also thought to be safe in lactating women.[157]

Corticosteroids

Corticosteroids taken orally in low doses may reduce recurrence rates, and in higher doses are used for acute

intestinal symptoms, orally or intravenously. Distal disease can respond to steroid enemas.

Azathioprine

Azathioprine is an immunosuppressant that is metabolized to 6-mercaptopurine. There are many reports of renal transplant recipients who have conceived while taking azathioprine and who have had normal children. Thus the drug is thought to not be teratogenic in humans. Azathioprine crosses the placenta, but the fetal liver lacks the enzyme that converts it to its active metabolite, and this is thought to explain the fetal protection from teratogenic effects. There is no reason to suspect that the risks in women with inflammatory bowel disease should be different from those who have had renal transplants. One case series reported the outcome of 16 pregnancies in 14 women with inflammatory bowel disease who were treated with azathioprine. There were no congenital abnormalities, and the children's growth and development were normal.[158]

6-Mercaptopurine

There have been very few reports of 6-mercaptopurine use in pregnancy. In one large case series of patients with inflammatory bowel disease treated with the drug, two women had ongoing pregnancies after having stopped the drug at 3 and 4 weeks' gestation, respectively, and no congenital abnormalities were found in their children.[159]

Metronidazole

Because metronidazole is used to treat *Trichomonas vaginalis*, there have been several studies of its use in the first trimester. A Canadian meta-analysis of all studies that contained at least ten women exposed to metronidazole in the first trimester and untreated controls did not find evidence that the drug is teratogenic.[122] A Spanish meta-analysis that included five cohort and case-control studies reported similar results.[123] This study included three series that were also included in the Canadian study.

Antidiarrheal agents

Loperamide is a synthetic piperidine derivative that is used for the treatment of diarrhea. In a prospective, controlled, multicenter study of loperamide in pregnancy in which 105 women were studied and 89 were exposed to loperamide in the first trimester, there were no significant differences in the rate of major or minor congenital malformations when compared with matched controls.[160]

SUMMARY OF MANAGEMENT OPTIONS
Inflammatory Bowel Disease in Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Preconception counseling and control and encourage conception when disease is quiescent	IIa	B	151–153
Consider modification of drug therapy to those with a good safety record in pregnancy (see below); steroids do not reduce the risk of relapse.	–	GPP	–
Ensure folate supplementation (5 mg/day).	–	GPP	–
Prenatal			
Continue appropriate drug therapy prenatally:			
Salicylates	IIa	B	154–157
Corticosteroids (oral or rectal)	III	B	154
Azathioprine	III	B	158
6-Mercaptopurine – limited experience in pregnancy	III	B	159
Metronidazole	III	B	122,123
Loperamide	IIa	B	160
Flares should be treated in the same way as outside pregnancy.	–	GPP	–
Attention to nutrition, iron, and folate supplementation	–	GPP	–
Monitor fetal growth.	IIa	B	151–153

SUMMARY OF MANAGEMENT OPTIONS
Inflammatory Bowel Disease in Pregnancy (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Labor and Delivery			
Cesarean section is rarely indicated.	–	GPP	–
Exceptions are women with severe perianal disease, postoperative perineal scarring, or impaired anal continence with an ileal pouch-anal anastamosis.	–	GPP	–
Scrupulous attention to wound repair (abdominal and perineal) with Crohn's disease	–	GPP	–
Postnatal			
If severe diarrhea and malabsorption is present, consider alternatives to oral contraceptives.	–	GPP	–
Breast-feeding is safe for women taking sulphasalazine, mesalazine, corticosteroids, and metronidazole.	IIa	B	154–157, 122,123
There are currently insufficient data about azathioprine and breastfeeding to give evidence-based guidance, although most experts in the field feel that the benefits of maintaining remission and achieving lactation outweigh the risks of discontinuing therapy.	III	B	158
An increased frequency of flares in the postpartum period is reported in Crohn's disease but not in ulcerative colitis.	–	GPP	–

CONCLUSIONS

- Jaundice is uncommon in pregnancy and should prompt extensive investigation to find the cause.
- Obstetric cholestasis is common in pregnancy with significant fetal risks; predicting that risk is not reliable; ursodeoxycholic acid is effective against maternal symptoms but its value in improving fetal outcome is not known.
- Acute fatty liver is a rare but dangerous disorder; intensive/high-dependency supportive multidisciplinary care is needed, followed by urgent delivery.
- Liver hematoma and rupture are very rare events; delay in diagnosis is a risk; multidisciplinary care with hepatic surgeon is required.
- Hyperemesis gravidarum affects about 1% of women; if untreated it can lead to dehydration, ketosis, and weight loss; parenteral fluid and vitamin support are often needed together with pharmacologic control of the vomiting; parenteral nutrition is only rarely necessary.
- Peptic ulceration often improves in pregnancy; it can be managed medically in most cases.
- Celiac disease should not result in any serious problems provided the woman religiously adheres to a gluten-free diet prior to and during pregnancy.
- Inflammatory bowel disease often improves in pregnancy; medical management should be used as in the nonpregnant patient, with the only caveat being that the drugs used should be those with a proven safety record in pregnancy.

Neurologic Disorders

J. Ricardo Carhuapoma / Mark W. Tomlinson / Steven R. Levine

INTRODUCTION

Neurologic conditions seen in reproductive-age women will be encountered during pregnancy. Table 49–1 shows the incidence of several such neurologic diseases. The relative rarity of many of these conditions limits the actual clinical experience of both the managing obstetrician and neurologist. In addition, the individual practitioner is further hampered by the limited amount of pregnancy-specific information available. The frequent overlap of symptoms associated with common pregnancy complaints, the sometimes disabling and lethal consequences of the disease, and fetal effects of maternal treatment make the diagnosis and management of neurologic disease during pregnancy an often daunting task.

Optimal and effective management commonly requires the expertise of several disciplines. This obviously includes the obstetrician or maternal-fetal medicine specialist and the neurologist. Involvement of an anesthesiologist is essential at the time of labor and delivery to provide appropriate analgesia or anesthesia. Early involvement of the pediatrician or neonatologist is important to anticipating neonatal needs and adequately caring for the newborn. Drugs discussed are listed with a risk factor category used by the Food and Drug Administration (FDA). The categories and definitions are shown in Table 49–2.[1] There are very few randomized clinical trials to guide evidence-based medicine in the field of neurologic complications of pregnancy.

SEIZURES

Neurologic Complications of Preeclampsia and Eclampsia

Maternal and Fetal Risks

Preeclampsia and eclampsia are also discussed in Chapters 37 and 74. The reported incidence of eclampsia in both the United Kingdom and the United States is approximately 0.05% of births.[2] As with preeclampsia, the specific cause and pathophysiology leading to eclampsia is unknown. Postulated contributing factors include cerebral edema, vasospasm, ischemia, hemorrhage, or hypertensive encephalopathy.[3]

Hypertension is an important factor associated with convulsions. Increasing systolic and diastolic blood pressures in a previously normotensive patient challenge the autoregulatory properties of cerebral blood vessels. In normotensive patients, autoregulation is preserved between mean arterial pressure (MAP) values from 50 mm Hg to 150 mm Hg. Beyond this range, cerebral blood vessels lose their tone and an angiographic pattern of vasodilation with segments of vasoconstriction develops. The blood-brain barrier and its "tight junctions" are

TABLE 49–1	
Incidence of Neurologic Disease in Childbearing Population	
Migraine	1:5
Epilepsy	1:150
Multiple sclerosis	1:1000
Cerebral venous thrombosis	1:2500–10,000 deliveries
Ruptured cerebral aneurysm	1:10,000 pregnancies
Bleed from cerebral AVM	1:10,000 pregnancies
Myasthenia gravis	1:25,000
Malignant brain tumor	1:50,000
Guillain–Barré syndrome	1.5:100,000

AVM, arteriovenous malformation.

Classification System for Fetal Risk Associated with Medications Used during Pregnancy

Category A	Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester (and there is no evidence of a risk in later trimesters), and the possibility of fetal harm appears remote.
Category B	Either animal-reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women, or animal-reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).
Category C	Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal, or other) and there are no controlled studies in women, or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.
Category D	There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (e.g., if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).
Category X	Studies in animals or human beings have demonstrated fetal abnormalities, or there is evidence of fetal risk based on human experience, or both, and the risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

disrupted, and vasogenic edema ensues.[4-9] This process occurs preferentially in the occipital lobes and in "watershed" areas of the brain.[10] The neuropathologic changes are widespread throughout the neuraxis.[11] Cerebral edema is evident, and the presence of petechial hemorrhages surrounding arterioles is conspicuous, conceivably rendering certain neuronal populations hyperexcitable. Although hypertension through this cascade of events can initiate the pathogenic process of convulsions in many instances, it does not explain all cases. Eclampsia can be seen in patients without significant blood pressure elevations.[3] As many as 38% of all eclamptics have been reported to have no hypertension or proteinuria identified before the initial seizure.[12]

In addition to convulsions, a variety of visual symptoms may be seen. These may be nonspecific but can include retinal detachments and cortical blindness secondary to hypertension-induced retinal arteriolar dilatation, papilledema,[13] central retinal artery occlusion,[14] and vasospasm.[15] Visual changes generally improve with

delivery and hypertension control. Headache is also common and may involve increased intracranial pressure (ICP) resulting from vasogenic edema.[16] More severe findings such as lethargy, stupor, and coma in a preeclamptic patient should always raise the suspicion of an intracerebral hemorrhage or of worsening brain edema with the subsequent risk of brain herniation.[17]

Although maternal mortality rates have decreased over the past several decades, eclampsia continues to be a significant contributor, particularly in underdeveloped countries. During the early 1980s in the Unites States pregnancy-induced hypertension (PIH) was the third leading cause of maternal deaths, accounting for 22.5%. Eclampsia and other central nervous system (CNS) complications were a factor in more than 60% of the PIH deaths.[18] In a more recent series, approximately 1% of pregnancies complicated by eclampsia still resulted in maternal death.[12,19] In developing countries, maternal mortality is reported in 8% to 14% of patients with eclampsia.[20] Fetal and neonatal complication rates also tend to be high and are attributed to prematurity, placental insufficiency, and placental abruption.[21]

Management Options (See also Chapters 36 and 80)

PRENATAL, LABOR, DELIVERY, AND POSTNATAL

Eclampsia most frequently occurs during the antepartum and intrapartum periods, but approximately one third of cases are seen postpartum. Between 28% and 56% of postpartum convulsions occur more than 48 hours after delivery.[22,23] The diagnosis is clinical, and additional diagnostic evaluation is not always necessary when typical preeclampsia precedes the seizure. When the presentation is not classic, however, imaging studies such as brain computed tomography (CT) and magnetic resonance imaging (MRI), including diffusion-weighted imaging (DWI), can be helpful in identifying complications or other causes of seizure, such as hemorrhage, cerebral infarction, or cerebral venous thrombosis (Fig. 49–1).

Magnesium sulfate has been the mainstay of both seizure prophylaxis and abortive therapy in the United States.[24] The precise mechanism of action remains poorly understood. Current hypotheses include reduction in cerebral vasospasm through calcium antagonism, and N-methyl-D-aspartate (NMDA) receptor channel blockade providing "neuroprotection" from ischemic injury resulting from vasospasm.[25-28]

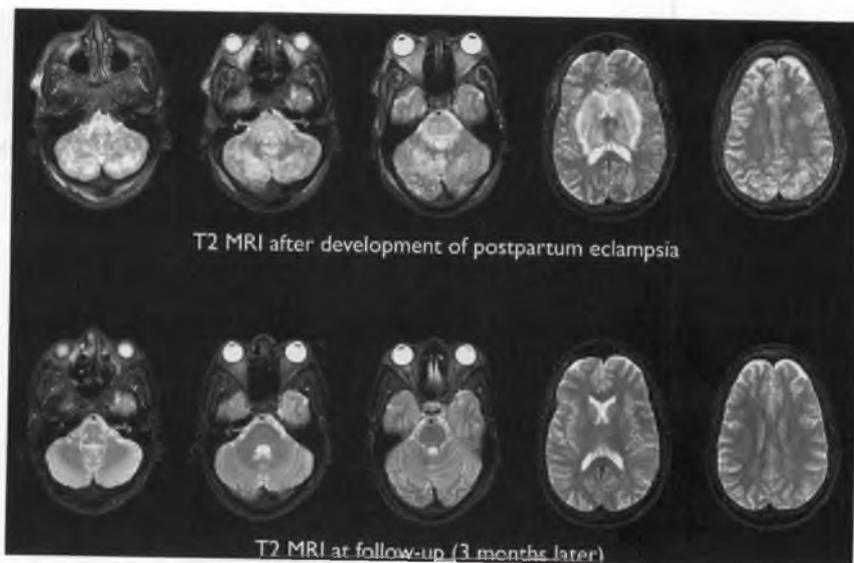
The efficacy of magnesium has been established.[29] Recent larger trials provide compelling evidence that magnesium sulfate is superior to phenytoin and diazepam in both treatment and prophylaxis of eclamptic seizures.[30] A multicenter worldwide trial including more than 1600 eclamptic patients reported that magne-


FIGURE 49–1

Axial head T_2-weighted MRI of a woman with headaches, proteinuria, and postpartum seizures. There are multiple regions of T_2 hyperintensity in the cerebellum, pons, basal ganglia, and the hemispheric white matter consistent with changes seen in eclampsia. These radiologic abnormalities reversed on subsequent MR evaluation that followed the complete clinical resolution of this patient's initial neurologic presentation.

sium sulfate was associated with a 52% lower risk of recurrent seizures than diazepam, and a 67% lower risk than phenytoin. Furthermore, maternal and neonatal morbidity rates were lower in the magnesium group than for those receiving phenytoin. Magnesium sulfate has also been shown to be superior to placebo and phenytoin when used prophylacticly to prevent seizures. A large North American study comparing the efficacy of magnesium and phenytoin for seizure prophylaxis was stopped early when interim analysis showed that phenytoin provided ineffective seizure prophylaxis.[30] Management differences between eclampsia and epilepsy should not be surprising because the pathophysiology of the two conditions is likely to be different. A recent Cochrane Review shows that magnesium sulfate more than halves the risk of eclampsia and probably reduces the risk of maternal death (RR 0.41: 95% CI, 0.29–0.58). Magnesium sulfate does not improve outcome of the newborn. The risk of placental abruption was also reduced.[29]

Specific dosing recommendations have varied, but generally consist of a 4 to 6 g intravenous load given over 5 to 30 min. This is followed by a maintenance dose of 1 to 3 g/hr intravenously. Therapeutic serum levels are in the range of 4 to 8 mEq/L. The magnesium infusion is usually continued for approximately 24 hours into the postpartum period. The duration of therapy is empiric and based on the distribution of postpartum seizure risk. Complications associated with the use of magnesium cen-

ter on its calcium antagonism at the neuromuscular junction, which can result in neuromuscular blockade. At levels above 10 mEq/L deep tendon reflexes are lost. Lethargy and respiratory depression are also seen. Levels of 12 to 15 mEq/L result in respiratory paralysis. Higher levels can result in cardiac standstill. Management of overdose includes respiratory support, calcium gluconate (1 g), and cardiac monitoring. A recent randomized controlled trial failed to prevent preeclampsia with low-dose aspirin in women with abnormal uterine artery Doppler.[31]

Blood pressure control is also important in both preventing and managing neurologic complications associated with preeclampsia/eclampsia. Some investigators have suggested that a greater emphasis should be placed on blood pressure control with the potential elimination of seizure prophylaxis.[32,33] Hydralazine and labetalol are frequently used as first-line agents, with continuous IV infusions of nicardipine, sodium nitroprusside, and nitroglycerin being used in refractory cases. The NHLBI recently convened a working group on research of hypertension in pregnancy.[34]

Simple first-aid measures (avoiding injury, nursing semiprone, maintaining airway, and giving oxygen) should not be forgotten. Maternal renal, liver, and coagulation status should be monitored, together with the fetal condition if the eclampsia is prenatal. Fluid overload should be avoided. Most obstetricians deliver the fetus once the mother is stable if the eclampsia occurs during pregnancy (see Chapters 36 and 80).

Epilepsy

Maternal and Fetal Risks

Epilepsy is probably the most common serious neurologic problem faced by obstetricians. Approximately 1 million American women of childbearing age have epilepsy, delivering roughly 20,000 babies annually. Seizures during pregnancy have an incidence of 0.15% to 10%.[35,36] The interrelationship of maternal epilepsy, antiepileptic drug metabolism and pharmacodynamics, genetics, drug-induced embryopathies, and maternal behavior is complex and has led to considerable controversy concerning epilepsy in pregnancy.

One area of unresolved controversy involves the effect of pregnancy on seizure frequency.[37–39] Approximately one third of patient's will have an increase in frequency, whereas the remainder will experience no change or a decrease.[38] Some of the change can be attributed to physiologic changes and psychological stress associated with pregnancy.[40] These factors include increased steroid hormone levels, sleep deprivation, and metabolic changes. More commonly when seizure frequency increases, deliberate patient noncompliance secondary to fear of fetal drug effects is likely to blame.[41] The effect of pregnancy on epilepsy may be inferred from the women's seizure frequency before pregnancy. As a rule, the fewer the number of seizures occurring in the 9 months before conception, the less the risk of worsening epilepsy during pregnancy.[38,41] If the seizure frequency is at least one seizure monthly before pregnancy, then the probability of increased seizure frequency during pregnancy is high. This is in contrast to women having only one seizure

during the 9 months before pregnancy. These patients have only a 25% risk of seizing during pregnancy.

Decreases in most antiepileptic drug (AED) levels occur during pregnancy and can affect seizure frequency.[42] Gastrointestinal absorption decreases, whereas hepatic and renal clearance increase for most AEDs. Albumin levels decrease, leading to lower total drug levels.[43] Pregnancy-associated changes in specific agents are described in Table 49–3. Postpartum these changes reverse, with a resultant increase in drug levels. In reality, the availability of serum drug level testing allows women to maintain prepregnancy therapeutic levels. When this is accomplished only 10% of patients will experience increased seizure frequency during pregnancy.[38]

The effects of AEDs on the fetus are complex and controversial.[44,45] The four most commonly used agents (carbamazepine, phenobarbital, phenytoin, and valproic acid) are known to cross the placenta and all are believed to

have teratogenic effects. The rate of congenital malformations in patients using these drugs is approximately two to three times that of infants of nonepileptic mothers (i.e., 6%–8% in epileptic pregnancies).[41] Thus, more than 90% of mothers taking AEDs during pregnancy will deliver normal children.

Additional factors have been linked to the increased rate of anomalies seen in patients using AEDs. Multiagent therapy appears to enhance malformation rates.[46] In addition, phenytoin,[47] primidone,[48] and carbamazepine[49] have been associated with patterns of malformation that are quite similar. Common anomalies include a mildly dysmorphic face and fingers with stubby distal phalanges and hypoplastic fingernails, suggesting a "fetal AED syndrome."[41] A genetic predisposition may play a role in development of these malformations. Such a link has been reported for the enzyme epoxide hydrolase. A reduction in the enzyme's activity was seen in amniocytes of fetuses who had findings of fetal hydantoin syndrome, but not in those lacking findings.[50] Further confusing the issue is evidence that some anomalies associated with AEDs are found in mothers with epilepsy who have not been exposed to these medications.[51]

Despite the etiologic uncertainty, individual drugs have been associated with specific anomalies. Cleft lip and palate, as well as cardiac and urogenital defects are reported with phenytoin. Spina bifida is found in 1% to 2% of patients taking valproic acid.[52] The malformation pattern associated with phenobarbital is similar to that seen with phenytoin. Carbamazepine was felt to be the safest of the AEDs, but recently it was associated with spina bifida at a rate of approximately 1%.[46] Developmentally, most children have normal motor function but may have some degree of cognitive dysfunction. The latter-observed abnormalities appear more likely to relate to seizures during pregnancy and lower levels of paternal education rather than AEDs.[53]

Coagulopathies have been reported in approximately half of all babies born to mothers taking phenobarbital, primidone, or phenytoin. A deficiency of vitamin K-dependent clotting factors is responsible. Few infants have clinical symptoms.[54]

Management Options

PREPREGNANCY

Ideally patients are seen prior to conception to optimize antiepileptic therapy. The patient should be evaluated for withdrawal of antiepileptic medications in conjunction with a neurologist. Some patients who have been seizure-free for longer than 2 years are potential candidates. However, other factors must also be considered before a decision is made. Age of onset, seizure type, electroencephalographic findings, and number of seizures occurring before control was achieved all affect the risk of recurrence.[55,56] If complete withdrawal is not possible or practical, monotherapy should be attempted to reduce

the risk of fetal malformations. The drug chosen should be that which is most effective for a given seizure type.[41]

Those who will be continuing on AEDs should be counseled about the importance of seizure control and the current understanding of fetal risks for malformations. Such counseling may decrease the number of patients who inappropriately discontinue their medication. Initiation of folic acid supplementation should also be considered preconceptionally. Although there is no direct evidence of benefit in epileptic patients, the recommendation is based on findings demonstrating a decrease in recurrence of neural tube defects in women with a previously affected child. The goal of therapy is to maintain normal serum and red cell folate levels.[41]

PRENATAL

Patients on AEDs should have drug levels monitored. They should be maintained on the lowest effective dose. With valproic acid, multiple doses at intervals during the day are preferred. A fall in drug level is common and does not necessarily require an increase in dose. Decisions to change the drug dose should be based on the clinical status, with drug levels used to guide such changes. Free drug levels change to a lesser degree than the total levels and may be used to serially monitor the patient.[41] A targeted ultrasound examination should be performed in the second trimester to search for fetal anomalies. In addition, maternal serum alpha-fetoprotein screening or amniocentesis for alpha fetoprotein and acetylcholinesterase should be considered to screen for neural tube defects in patients taking valproate or carbamazepine. Vitamin K can be given to the mother during the final 4 weeks of gestation to decrease the risk of fetal coagulopathy.[41] Should seizures recur, short-acting benzodiazepines may be used acutely. Free serum levels should be rechecked and drug dosage optimized.

In recent years, the use of new AEDs has become widespread in patients with epilepsy. However, the alterations in the pharmacokinetics of these agents during pregnancy have not been adequately studied. Data are lacking for drugs such as gabapentin (GBP), topiramate (TPM), tiagabine (TGB), oxcarbazepine (OXC), levetiracetam (LEV), and zonisamide (ZNS), but no definitive adverse effects have been demonstrated in humans. All these drugs are classified as category C. Their use during pregnancy should be based on an evaluation of the benefits of the drug in a given patient versus the unknown potential for adverse outcome.

The majority of AEDs are characterized by significant increases in clearance during pregnancy.[57] Limited studies of the newer AEDs indicate similar extensive transplacental transfer (lamotrigine, OXC, TPM, and ZNS). Current recommendations are that ideal AED concentration should be established for each patient before conception and that monitoring of AED levels should be performed during each trimester and the last month of pregnancy.[57]

LABOR AND DELIVERY

Most patients with epilepsy are able to labor normally and achieve a vaginal delivery. Elective cesarean section may be considered in patients refractory to treatment during the third trimester or in those who exhibit status epilepticus with significant stress. During labor, repeated seizures that cannot be controlled or status epilepticus may require an operative delivery. Fetal asphyxia can occur with prolonged or repeated seizures. Cesarean delivery may also be considered when repeated absence or psychomotor seizures limit maternal awareness and ability to cooperate. Tonic-clonic seizures are seen in approximately 1% to 2% of women during labor. Lorazepam, a short-acting benzodiazepine, is the drug of choice for treating seizures acutely.[41] The drug is administered in 2 mg boluses every 5 minutes as necessary. Some use 5 to 10 mg boluses of diazepam as an alternative.

POSTNATAL

Antiepileptic drug levels must be monitored after delivery because reversal of the physiologic alterations causing a decline in levels during gestation leads to a rise postpartum. If the medication dose was increased during pregnancy, the regimen should be returned to that used prior to pregnancy to avoid toxicity. During the first postpartum day an additional 1% to 2% of women will have tonic-clonic convulsions. Again lorazepam is the agent of choice for acute control. New-onset seizures in the postpartum period require complete evaluation to rule out intracerebral hemorrhage, cortical vein thrombosis, infection, or eclampsia.

Neonates should be given vitamin K 1 mg IM after birth to prevent a coagulopathy. All AEDs can cross into the breast milk but breastfeeding is not contraindicated for most agents. The effects of diazepam on nursing infants are unknown, and it should be used with caution. Phenobarbital should only be used when no alternatives exist because neonatal sedation can occur along with neonatal withdrawal on weaning.[58]

Status Epilepticus

Maternal and Fetal Risks

Status epilepticus (SE) is defined as ongoing seizure activity lasting longer than 30 minutes or recurrent seizures without full recovery of consciousness between episodes. The actual incidence during pregnancy is unknown. The important causes are listed in Table 49–4. Predisposing factors include poor compliance with AEDs, CNS infections, trauma, and illicit drug use.[38] Status epilepticus represents a medical emergency. Most seizures are generalized tonic-clonic. During the tonic phase, contractions of the respiratory muscles impair

adequate maternal oxygenation, leading to fetal hypoxia and asphyxia. During the convulsive phase, metabolic acidosis ensues. Rhabdomyolysis occurs and can lead to acute renal failure. After 30 minutes of continuous brain electrical activity, even in the absence of the metabolic derangements, irreversible neuronal injury can occur. The hippocampus and amygdala of the temporal lobe are particularly sensitive to permanent damage.[59] Trauma from recurrent seizure activity can result in preterm labor, rupture of membranes, abruptio placenta, and fetal death.[38]

Management Options

PRENATAL, LABOR AND DELIVERY, AND POSTNATAL

Diagnostic and therapeutic interventions should be performed simultaneously. A patent airway must be secured and supplemental oxygenation given. Hypotension should be avoided to prevent decreased cerebral perfusion pressure. Complete blood count with differential, electrolyte profile, blood urea nitrogen, creatinine, urine toxicology screen, and AED levels should be obtained. Cerebrospinal fluid (CSF) analysis is performed if meningoencephalitis is suspected.

Intravenous benzodiazepines are used acutely. Again lorazepam is the drug of choice. It is given in 2-mg boluses every 5 minutes. Simultaneously, the patient is loaded with phenytoin 18 mg/kg administered at a rate not exceeding 50 mg/min. The administration of intravenous valproic acid (20 mg/kg loading dose) is an alternative if phenytoin is otherwise contraindicated. The combination of phenytoin and benzodiazepines is effective in controlling 75% to 85% cases of status epilepticus. In those patients with persistent seizures, higher levels of phenytoin can be achieved with an additional 5 mg/kg. In refractory cases where barbiturates or a continuous infusion of benzodiazepines are needed, elective intubation is required to protect the airway. Continuous electroencephalographic monitoring should also be initiated. Once identified, the underlying cause should be treated.

CEREBROVASCULAR DISEASE

Ischemic Stroke and Transient Ischemic Attacks

Maternal and Fetal Risks

For many years it was believed that the incidence of cerebral ischemia is significantly higher during pregnancy. Currently, controversy exists because the evidence is inconclusive.[60] What seems clear from a recent epidemiologic study is that the relative risk of stroke rises to 8.7 during the postpartum period. In that same population-based report the relative risk of stroke during gestation was found to be 0.7.[61] The incidence of pregnancy-associated ischemic stroke is approximately 3 to 4 cases/100,000/yr.[62] For reasons that are unclear, middle cerebral artery occlusions may be overrepresented during pregnancy and internal carotid artery occlusions during the postpartum period.

Most of the conditions associated with "stroke in the young" are shared by pregnant women suffering cerebral ischemia and therefore demand an extensive diagnostic evaluation to identify the cause and provide optimal treatment. The causes can be divided into processes that involve the "ABCs" of stroke: arteries, blood components, and cardiac sources of emboli. A detailed list of specific causes is given in Table 49–5.

Premature or accelerated atherosclerosis accounts for almost 25% of ischemic strokes in pregnant women.

Nonbacterial thrombotic endocarditis
Peripartum cardiomyopathy

Women with hypertension, diabetes mellitus, tobacco use, hyperlipidemia, and family history of premature atherosclerotic disease are especially at risk for this stroke mechanism. Identification and treatment of these factors may have contributed to the decline in cerebrovascular events noted in pregnant women.

Less common vascular causes include arterial dissection during labor and delivery,[63] inflammatory arteritis such as Takayasu's arteritis,[64] and fibromuscular dysplasia. The last of these has been associated with cerebral ischemia as well as intracranial aneurysms, carotid artery dissection, and carotid-cavernous fistula.[62,63] Fibromuscular dysplasia appears to occur more commonly in young women and may also affect the renal arteries.[65]

Physiologic alterations seen in pregnancy may theoretically predispose the pregnant woman to develop cerebral ischemia. Increases in clotting factors, including fibrinogen, increased platelet aggregability, decreased antithrombin III concentration,[66,67] and impaired fibrinolytic activity, all occur during normal pregnancy.[68,69] These changes persist through the first several postpartum weeks and may be the only identifiable predisposing risk factors during pregnancy. The risk of thrombosis due to congenital deficiencies in antithrombin III, protein C, or protein S is compounded by pregnancy (see also Chapter 42). Activated protein C resistance is a recently identified cause of thrombosis resulting from a point mutation in factor V, rendering it resistant to inactivation

by activated protein C. The abnormal factor V is called factor V Leiden and is the most common hereditary cause of thrombosis.[70] The Leiden mutation may be a risk factor for stroke during pregnancy.[71] It has also been identified in neonates with cerebral ischemic or hemorrhagic infarct and placental infarcts.[72] Thrombotic thrombocytopenic purpura may initially present during pregnancy and is often mistaken for eclampsia.[73]

Substance abuse is an under-recognized cause of stroke, especially in poor, urban woman (see also Chapter 35). Cocaine (Fig. 49–2), amphetamines, heroin, and other sympathomimetics are associated with both ischemic and hemorrhagic stroke.[74–76] Mechanisms of injury include vasospasm (Fig. 49–3), vasculitis, endocarditis, drug-induced cardiomyopathy with cerebral embolism, foreign material embolism, rupture of preexisting arteriovenous malformations (AVMs) and aneurysms, and acute hypertensive hemorrhage.

Antiphospholipid antibody syndrome is also associated with cerebral arterial occlusive disease (Fig. 49–4) (See also Chapter 44).[77] The syndrome consists of venous or arterial thrombosis, recurrent pregnancy loss, or thrombocytopenia in the presence of antiphospholipid antibodies (lupus anticoagulant or anticardiolipin).[78–82] Some of these patients have coexistent systemic lupus erythematosus. Patients with higher titers of IgG anticardiolipin antibodies may be at higher risk for recurrent thrombo-occlusive events.[83,84]

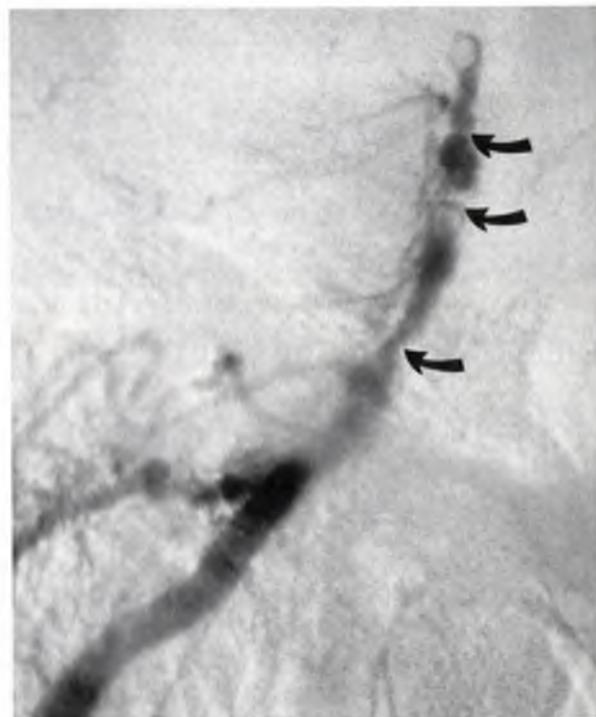
Sickle cell disease and sickle cell trait are associated with an increased risk of stroke. Vessel wall injury may


FIGURE 49–2

occur during periods of crises. The recurrent vascular damage can lead to endothelial proliferation and subsequent vessel occlusion.[85] Frequent blood transfusions can dramatically reduce the vessel damage.

Congestive heart failure during pregnancy or the postpartum period is associated with significant maternal

FIGURE 49–4

morbidity and mortality (see also Chapter 39). Pulmonary or systemic emboli occur in as many as 50% of these patients. Peripartum cardiomyopathy and rheumatic heart disease are causes of congestive heart failure in pregnancy. Emboli result from ventricular wall thrombosis secondary to a low cardiac output or atrial thrombosis from atrial fibrillation.[86] Watershed infarction in the brain has also been reported secondary to low cardiac output.[87]

Cerebral embolism has been associated with mitral valve prolapse (MVP) in case reports.[88] MVP is a common condition with a prevalence of 2% to 4% in the general population and as high as 20% in reproductive age women.[89] The rarity of stroke in pregnancy makes it unlikely to be a significant complication for pregnant women with MVP. Complications associated with atrial septal defects (ASD) are uncommon in reproductive-age women. However, ASD been found in up to 50% of young patients with unexplained ischemic stroke.[90] Paradoxic emboli from the venous to systemic circulation are responsible. Mechanical heart valves may also cause stroke in pregnant women, secondary to emboli from valve thrombosis.[91,92] Bacterial endocarditis can also result in ischemic or hemorrhagic stroke.[93] Cardiac disease associated with systemic lupus erythematosus and antiphospholipid syndrome represents another potential cause.[94]

Management Options

PRENATAL, LABOR, DELIVERY, AND POSTNATAL

Any focal neurologic deficit in the pregnant woman, transient (<24 hr) or persistent, should raise the suspicion of cerebral ischemia. A careful history and physical examination often give enough information to narrow the diagnostic evaluation. An early imaging study of the brain is essential to exclude hemorrhage or a mass lesion. CT is not contraindicated in pregnancy under these circumstances. Abdominal shielding limits the minimal fetal radiation exposure. MRI can also be used during pregnancy. Although it is more sensitive than a CT scan, it is tolerated less well by critically ill patients and is often less available.

Initial blood work should include a complete blood count with differential and platelet counts, electrolytes, serum glucose, blood urea nitrogen, creatinine, prothrombin time/activated partial thromboplastin time (aPTT). Antinuclear antibody, lupus anticoagulant and anticardiolipin antibody, rheumatoid factor, VDRL, and HIV testing should be obtained. Other blood studies include protein C and S and antithrombin III assays, activated protein C resistance and polymerase chain reaction for factor V Leiden, along with serum protein and hemoglobin electrophoresis. Blood and urine toxicology evaluation should be obtained. Carotid and transcranial Doppler should be considered. If cardiac origin is suspected, an electrocardiograph, echocardiogram, Holter monitor, and possibly evaluation for deep venous thrombosis can be performed. A lumbar puncture may also be indicated. In the absence

of identified cause, cerebral angiography is recommended. Despite a thorough evaluation, the cause of ischemic stroke is elusive in 20% to 40% of nonpregnant patients. Although no specific data are currently available, this probably holds true for pregnant patients as well.

Many of the thrombotic and embolic conditions leading to stroke require either prophylactic or therapeutic anticoagulation. When anticoagulation is deemed necessary, heparin is the agent of choice in most instances. Warfarin is an option, but first-trimester embryopathy and the potential for fetal hemorrhage limit its usefulness. Heparin does not cross the placenta and is shorter acting than warfarin. This decreases fetal risk while making peripartum management easier and more predictable. Complications associated with heparin include thrombocytopenia and osteopenia, in addition to bleeding.[95,96]

Prophylactic doses of heparin tend to need to be higher in pregnancy and increase with increasing gestational age.[97] Typical doses are 7500 to 10,000 IU/mL, given subcutaneously every 12 hours. As in the nonpregnant patient, full anticoagulation aims to maintain the aPTT 1.5 times control. Therapy is individualized with subcutaneous heparin two to three times daily.

Low-molecular-weight heparin is now commonly used in pregnancy. Advantages over unfractionated heparin include longer duration of action, more reliable antithrombotic effect, and a suggestion of decreased risk of thrombocytopenia and osteopenia.[98,99] Increasing data on use during pregnancy suggest it is safe and effective in preventing noncerebral thrombotic complications.[100,101] Treatment of acute ischemic stroke with low-molecular-weight heparin is of uncertain benefit. Patients with inherited thrombophilias requiring full anticoagulation before pregnancy should be placed on therapeutic doses of heparin preconceptually or once pregnancy is discovered. The optimal therapy for activated protein C resistance during pregnancy is unknown, but likely should at least utilize prophylactic doses of heparin. Optimal treatment for the antiphospholipid antibody syndrome is a matter of current investigation. Some authors recommend the use of low-dose aspirin (60–80 mg/day) and heparin during the pregnancy.[78,79] The role of corticosteroids, immunosuppression or plasma exchange, and intravenous gamma globulin is not well defined.[102] In patients with cardiomyopathy or atrial fibrillation, heparin has been used in both prophylactic and therapeutic doses.[103]

Thrombolytic therapy for acute ischemic stroke is indicated in carefully selected patients within 180 minutes of symptom onset using a defined protocol.[104] Its use in pregnancy is uncertain, however, because pregnant or lactating women were excluded from the trial that demonstrated efficacy. Recent case reports have documented the relative safety of intravenous and intra-arterial thrombolysis used for neurologic and medical indications during early pregnancy.[105] Nevertheless, the widespread use of thrombolytics during pregnancy cannot be recommended, and they should only be used after a careful discussion of the risks and benefits of this form

of treatment with the patient or surrogates. Plasmapheresis has been used successfully in some patients with thrombotic thrombocytopenic purpura.[106]

Cerebrovenous Thrombosis

Maternal and Fetal Risks

Cerebrovenous thrombosis has been traditionally associated with pregnancy, especially the puerperium. The condition is seen throughout gestation[107–109] but most commonly is identified during the second to third week postpartum.[107] The incidence is highest in developing countries where it is the most common cause of stroke associated with pregnancy. The original description of severe headache, papilledema, and seizures has evolved through the years. Additional findings at presentation include focal neurologic deficits, bilateral long tract signs, aphasia, visual disturbances, headache, focal seizures and the syndrome of idiopathic intracranial hypertension. When the deep cerebral venous system is involved, lethargy and coma are common. The superficial venous sinuses, particularly the superior sagittal sinus, are commonly involved.

Cerebrovenous thrombosis has classically been associated with infection and dehydration. Other underlying conditions such as hemoglobinopathies, hyperviscosity syndromes, anemia, leukemia, collagen vascular diseases, malignancy, AVM, and paroxysmal nocturnal hemoglobinuria should be sought.[110] In addition, hypercoagulable states such as protein C and S deficiencies have been implicated.[69,111] More recently, activated protein C resistance,[112,113] lupus anticoagulants, and anticardiolipin antibodies have been identified in patients with cerebrovenous thrombosis.[114–116]

Management Options

PRENATAL, LABOR, DELIVERY, AND POSTNATAL

Timely diagnosis of cerebrovenous thrombosis requires a high index of suspicion. During pregnancy the initial evaluation begins with a brain CT without contrast. A partially filled posterior segment of the superior sagittal sinus is seen (empty delta sign) (Fig. 49–5). MRI with MR venography can identify the thrombus. It provides greater sensitivity and is currently the test of choice within the limitations previously described.

The only prospective, randomized, case-controlled study evaluating acute treatment found systemic anticoagulation to be the treatment of choice, even in the presence of intracerebral hemorrhage.[117] Thrombolytic therapy is an emergent therapeutic approach; however, due to the lack of experience in pregnant patients, caution should be exercised.[118] The overall prognosis is generally good in the absence of coma, recurrent seizures, or rapid decline in neurologic function. Long-term outcome is generally better than for arterial stroke. Prolonged anticoagulation with warfarin is required postpartum.

Subarachnoid Hemorrhage in Pregnancy

Maternal and Fetal Risks

Subarachnoid hemorrhage (SAH) is a rare but often catastrophic event that can occur during pregnancy. The incidence of SAH is 1 to 5/10 000 pregnancies. Maternal mortality is 30% to 40%, but rates as high as 80% have been reported.[119] Fetal outcome parallels that of the mother and reflects the maternal condition and gestational age at delivery.[119] The primary cause during gestation is ruptured cerebral aneurysms or AVMs. Less common causes include moyamoya disease,[120] dural venous sinus thrombosis, mycotic aneurysm, choriocarcinoma, vasculitides, brain tumors,[121] and coagulopathies. Drugs such as cocaine and phenylpropanolamine have been linked with SAH in pregnant patients.[122–124]

Aneurysms and AVMs are believed to develop secondary to congenital defects in cerebral vasculature formation. Aneurysms are generally located at an angle of vessel bifurcation in or near the circle of Willis. AVMs, on the other hand, can be located anywhere between the frontal region and the brainstem, but occur with a higher frequency in the frontoparietal and temporal regions (Fig. 49–6). The anatomic distribution of both lesions is similar to that in the nongravid population.[119]

Information describing the natural history of intracranial aneurysms during pregnancy is scarce. In the nonpregnant patient asymptomatic lesions account for 95% of intracranial aneurysms and are typically identified incidentally. They rupture at a rate of 1% to 2% per year.[125] Activities reported to precede aneurysmal rupture include emotional strain, heavy lifting, coughing, coitus, urination, and defecation. Outcomes of patients with AVMs are influenced by the presenting symptoms and subsequent treatment. Most present with spontaneous bleeding, and these patients have the worst prognosis. Other presenting symptoms in order of frequency include seizures, headache, and neurologic deficit. If left untreated there is an annual hemorrhage rate of 4%.[125]

Rarely, unruptured aneurysms are first identified during pregnancy. Because SAH is uncommon during gestation, the effect of pregnancy on cerebral aneurysms or AVMs is controversial. More than 85% of SAH cases occur during the second or third trimester.[126] Several physiologic changes occur during pregnancy, which may theoretically predispose these cerebrovascular abnormalities to bleed. These factors include increases in blood volume, stroke volume, and cardiac output. Estrogen levels are also increased and may result in vasodilation of already abnormal vessels.[127] The many dynamic events occurring during labor and delivery would seem to make this a time of particularly high risk.

Despite the associated physiologic changes, pregnancy does not appear to increase the incidence of SAH, and,

surprisingly, bleeding during the time of labor and delivery is infrequent.[119,128] Most pregnancies complicated by SAH are preceded by unaffected gestations. In a review of 154 patients prepared by Dias and Sekhar only 25% were nulliparous, and the mean parity of patients with aneurysmal and AVM ruptures were 2.0 and 1.4, respectively.[119] Barno and Freeman reviewed 24 years of maternal mortality in Minnesota resulting from SAH. The mean parity among the 37 deaths was 2.9.[129] Forster and colleagues reported their experience with AVMs in reproductive-age women. Although the annual hemorrhage rate was higher when these women were pregnant than when not (9.3% vs. 4.5%), it was no different from the 9.6% annual rate in reproductive age women who never became pregnant.[128] Although Horton and associates identified a lower annual rate of hemorrhage in both pregnant and nonpregnant patients with AVMs (3.5% vs. 3.1%), they too concluded that pregnancy was not a risk factor for bleeding.[130]

Once bleeding has occurred, the patient's course is significantly modified by her neurologic condition at presentation. The Hunt and Hess classification system has prognostic implications and is shown in Table 49–6. Left untreated, half of all nonpregnant patients will die as a result of the initial event, with another 25% to 35% succumbing to a subsequent bleed. Other factors affecting the patient's ultimate outcome are neurologic status, presence of vasospasm, and blood pressure. Maternal mortality rates associated with aneurysmal bleeding do not increase due to pregnancy.[119] Conversely, AVM-associated mortality appears to be increased in gravid compared with nongravid patients. This is likely related to the poor neurologic condition of these patients at presentation.[119]

Pregnancy does not significantly alter the clinical presentation of SAH. Signs and symptoms of aneurysmal or AVM bleeding are indistinguishable. A sudden-onset, "bursting" headache is generally the initial symptom. Frequently other signs and symptoms accompany the headache, which may include nausea and vomiting, meningeal signs, decreased level of consciousness, hypertension, focal neurologic signs, and seizures. Specific findings depend on the size, location, and rapidity of the bleed. When the hemorrhage is massive, the patient may be moribund at presentation.

Major complications associated with SAH include vasospasm and recurrent hemorrhage. Vasospasm is a serious problem seen in 30% to 40% of aneurysm patients, but much less commonly in those with AVMs. The resultant ischemia is a major cause of permanent disability and death. Recurrent hemorrhage is a particularly morbid complication. In the untreated nonpregnant patient the risk of rebleeding is 6% during the first 48 hours. Rebleeding continues to occur at a rate of 1.5% per day for the remainder of the first 2 weeks.[125] Mortality increases with each successive bleed with a rate of 64% and 80% after the first and second rebleed, respectively. Although considerably fewer data are available for the pregnant patient, the risk of recurrent bleeding appears to be similar in this population.[126]

Management Options

PRENATAL

Due to the rare and life-threatening nature of the condition, it is important to maintain a high index of suspicion. Occasionally SAH is confused with eclampsia, resulting in diagnostic delays and often a worse outcome. All abnormal neurologic signs and symptoms in the gravid patient should be thoroughly evaluated. CT scan of the brain, lumbar puncture (if necessary), and cerebral angiography is the common sequence of testing. The CT scan can predict, with a high degree of accuracy, the type of hemorrhage and its site of origin. If the CT scan is normal, the CSF should be examined for blood or xanthochromia. Nonclearing bloody CSF found at lumbar puncture supports the diagnosis of SAH, but it may also be seen with other conditions such as preeclampsia. Cerebral angiography remains the best diagnostic tool for identifying any vascular abnormality. Angiography may fail to visualize the cause of SAH in 20% of patients, however. In these cases, a repeat angiogram may be necessary to rule out false-negative results secondary to vasospasm or clot filling of the aneurysm. MRI scan may also be helpful when the initial angiogram fails to identify the lesion. Abdominal shielding should be considered during any radiologic examination of the gravid patient.

Management of SAH is based on standard neurosurgical principles with only slight alterations during pregnancy. The clinical goals remain prevention and treatment of neurologic complications. Early aneurysm clipping (<4 d) is now commonly recommended in the post-SAH period for conscious patients. Early operation also allows for therapies such as induced hypertension and volume expansion to be instituted to combat vasospasm without increasing the risk of rebleeding. Improved outcomes for both the mother and the fetus have been realized with early surgical intervention in pregnant patients.[119] Patients with significant neurologic deficits are less likely to undergo early aneurysm clipping due to an extremely high likelihood of operative mortal-

---

TABLE 49–6

Hunt and Hess Scale for Grading the Clinical Severity of Subarachnoid Hemorrhage

GRADE	EXAMINATION FINDINGS
I	Normal neurologic examination, mild headache, and slightly stiff neck
II	Moderate-to-severe headache and stiff neck; no confusion or neurologic deficit except for cranial nerve palsy
III	Persistent confusion and/or focal deficit
IV	Persistent stupor; moderate to severe neurologic deficit
V	Coma with moribund appearance

ity. Recent advances with endovascular procedures in the treatment of cerebral aneurysms (e.g., Guglielmi coiling) allow the early securing of these vascular lesions in high risk patients.[131] Medical therapy alone and careful monitoring of these high risk patients remain an alternative to any intervention if the patient is too unstable to leave the ICU.

The proper timing for resection of AVMs is more controversial due to the smaller number of cases. No clear benefit to surgery in these patients has been found,[119] with some surgeons advocating operative intervention in AVMs only to remove clinically significant hematomas.[132] One alternative is embolization of the AVM under angiographic control prior to surgical excision.[133]

A complete discussion of the neurosurgical and anesthetic principles of craniotomy for aneurysm clipping is beyond the scope of this chapter. However, two intraoperative therapies—hypotension and hypothermia—are commonly instituted to reduce complications, which raise special concerns in the pregnant patient. Hypotension is sometimes instituted to reduce the risk of rupture of the aneurysm during surgical dissection. Although maternal hypotension may pose a threat to fetal well-being, it has been successfully induced with sodium nitroprusside or isoflurane in a number of cases.[134,135] Based on experimental evidence, administration of sodium nitroprusside in pregnant patients has raised concerns regarding potential fetal cyanide toxicity. Thus, if surgery is to be performed during pregnancy it is recommended that infusion rates not exceed 10 mg/kg/min.[135] The fetal effects of maternal hypotension should be evaluated throughout the perianesthetic period with electronic fetal heart rate monitoring. Adverse changes in fetal cardiac activity suggest the need for elevation in maternal blood pressure if safe and feasible from the maternal standpoint. Many of the drugs used in anesthesia may decrease fetal heart rate variability, thereby complicating interpretation of the fetal heart rate monitor data. Excessive hyperventilation further decreases uterine blood flow during sodium nitroprusside administration and should be avoided.[136] Because of the potential fetal risks of maternal hypotension, some authors recommend cesarean delivery immediately prior to intracranial surgery if the fetus is mature enough.[137]

Hypothermia is instituted during cerebral aneurysm clipping as a means of cerebral protection from potential ischemia due to aneurysm rupture, retraction injury, or hypotension. Stange and Halldin suggested that hypothermia is well tolerated by the mother and fetus, provided that other confounding variables (e.g., respiratory exchange, acidosis, and electrolyte balance) are controlled.[138] However, most experience with hypothermia and hypotension in pregnancy is anecdotal. Regardless of the neurosurgical technique used, maternal outcome is the most important predictor of eventual fetal outcome.

Adjunctive medical therapy for SAH is directed toward reducing the risks of rebleeding and cerebral ischemia due

to vasospasm. Patients are generally confined to bed rest in a dark, quiet room. They are administered stool softeners and analgesics. Because of the presumed benefits of volume expansion, colloid solutions are frequently administered. Nimodipine, a dihydropyridine calcium channel blocker, is often given because it has been shown to improve neurologic outcome following SAH. Caution is advised in using this drug in pregnancy because the fetal effects have not been completely defined. In a small number of preeclamptic patients taking nimodipine for seizure prophylaxis no apparent adverse fetal outcomes were reported.[139] However, in an animal model, nicardipine (another dihydropyridine calcium channel blocker) led to the development of fetal acidosis and hypoxemia.[140]

ε-Aminocaproic acid (EACA) and tranexamic acid have been used to block the activation of plasminogen, a precursor of plasmin, a major fibrinolytic protein, and decrease the incidence of rebleeding. Initial clinical trials did find a reduction in the incidence of rebleeding with these agents; however, later work failed to demonstrate significant improvement in outcome.[141] EACA, because of the lack of proven benefit and potential interference with fetal fibrinolysis, which may be linked to the development of hyaline membrane disease, is not used in current clinical practice.[142]

Cerebral edema can result in elevated ICP. Intracranial invasive monitoring may be necessary. If the ICP elevation is secondary to cerebral edema, mannitol, an osmotic diuretic, may be used. Typically, 1 g/kg of mannitol is administered intravenously, as frequently as needed to keep the ICP below 20 mm Hg. The development of hyperosmolality due to dehydration is a potential hazard of mannitol therapy and can be monitored by frequent determinations of the patient's intravascular volume status. Normal values are 280 to 300 mOsm/L; the drug should be withheld when a level of 315 to 320 mOsm/L is reached. Care must be taken to prevent hypovolemia resulting from the accompanying diuresis, which could aggravate both cerebral and placental hypoperfusion. The use of hypertonic saline solutions (2% and 3% sodium chloride/acetate) is becoming a popular alternative to mannitol due to their efficacy and hemodynamic profile. Nevertheless, their safety during pregnancy is not defined, and the use of these solutions should be limited to only extreme cases of refractory ICP elevation.

LABOR AND DELIVERY

After a successful repair of an aneurysm or AVM, the most frequent obstetric concern relates to mode of delivery. Earlier authors routinely recommended elective cesarean section for these patients. This was particularly true along with consideration of sterilization if an AVM was responsible for the SAH.[143] More recent data and reanalysis of some older studies suggest that labor and vaginal delivery pose no additional risk to mother or fetus.[119,128,130,144] These recommendations probably also

hold true for the patient who begins labor before surgical correction is attempted or when the intracranial lesion is inaccessible to surgical intervention, but the data are limited. Young and colleagues have suggested that the rise in physiologic blood pressure known to occur in labor are counterbalanced by a parallel increase in CSF pressure, offering a potential explanation for the foregoing clinical observations.[145] Most authorities still advocate minimizing the hemodynamic stresses of labor, however, by using epidural anesthesia and shortening the second stage of labor with outlet forceps.[146,147] Ultimate management decisions should be individualized based primarily on the maternal condition with modifications for fetal intervention based on gestational age.

SUMMARY OF MANAGEMENT OPTIONS

CBC, complete blood count; CT computed tomography; MRI, magnetic resonance imaging.

HEADACHE

Maternal Risks

Headaches during pregnancy are extremely common. The most common categories are migraine and tension-type. Although a new-onset headache during pregnancy is most likely either a migraine or tension-type, it may be the first manifestation of an intracranial process that needs immediate attention.[148–150] Such conditions include aneurysm rupture, AVM, intracranial hypertension, cerebral ischemia, cerebrovenous thrombosis, meningitis, sinusitis, and intracranial masses. In addition, benign intracranial hypertension or pseudotumor cerebri may be seen with pregnancy, but it is uncommon. Patients receiving spinal or epidural analgesia or anesthesia may experience a spinal headache during the postpartum period.

Evaluation of the pregnant patient with headache represents a clinical challenge. The ailment's prevalence and typically benign nature make it desirable to minimize costs by limiting diagnostic testing while being certain to promptly diagnose uncommon but more serious conditions. The medical history is usually very helpful. Migraines are often associated with a history of similar previous episodes. With a history suggestive of migraine headaches, a normal neurologic examination, and resolution with simple measures, the patient may be followed clinically. If a new-onset headache severe enough to justify an emergency room visit or a preexisting condition becomes progressively worse, an "aura" is present, or a neurologic deficit is identified, diagnostic evaluation is indicated.

Migraine

Maternal and Fetal Risk

Migraines can be subdivided into those with or without an aura. The aura is described as the presence of transient neurologic signs or symptoms before, during, or even after the headache. The pain is often associated with nausea, vomiting, and photophobia. Sleep often provides relief. As with headaches in general during gestation, the course of migraines is variable. A decrease in frequency is seen in 50% to 80% of women, particularly in the third trimester.[151] Those patients experiencing migraines associated with menstruation are especially likely to show improvement. The headaches tend to worsen postpartum, with as many as 40% of patients complaining of pain during this time. Migraine recurred during the first week after childbirth in about one third of women.[152] Migraines may present for the first time during the puerperium in 4.5% of patients, however, and an aura may initially appear during this time period.[153] No demonstrated adverse fetal outcome is associated with migraines.[154]

Management Options

PRENATAL, LABOR, DELIVERY, AND POSTNATAL

A carefully obtained history and physical exam are essential. With a prior personal or family history of migraine and a typical presentation, no further investigation is needed. New-onset migraines represent a diagnosis of exclusion. In the absence of a past history or with focal neurologic findings, neuroimaging studies such as brain CT or MRI are indicated.[151] It is desirable to minimize abdominal and pelvic exposure to x-rays and avoid

contrast agents if possible. Radiologic studies should not be avoided on the basis of pregnancy alone, however. Prothrombin time, aPTT, fibrinogen, and complete blood count with platelets should be obtained. Additional investigations should include anticardiolipin antibodies, antithrombin III, protein C, protein S, and activated protein C resistance to exclude thrombophilias. Lumbar puncture is indicated once the absence of an intracranial mass effect has been ruled out by imaging studies. A normal opening pressure (range 5–15 mm Hg) excludes pseudotumor cerebri.

Migraine treatment during pregnancy is complicated by the fact that most drugs cross the placenta and many have potentially adverse fetal effects. As a result, physicians often avoid indicated drug therapy, despite relatively safe and effective options.[151] Therapy can be divided into abortive and prophylactic measures. The latter approach is reserved for patients with debilitating headaches or those with a frequency, for example, exceeding three migraine episodes per month. Beta-blockers (category B and C) are often helpful in this situation. Tricyclic antidepressants (most category D) are a useful second-line approach.

A variety of interventions are available once a headache has begun. When normal daily function is not significantly compromised, nonpharmacologic measures are advised. Such strategies include coping mechanisms such as ice, massage, sleep, and biofeedback. Reassurance is also of value, as many migraine sufferers experience improvement during gestation. When drug therapy is needed, acetaminophen and low-dose caffeine (both category B) can be used as first-line agents. During the first two trimesters, a short course of nonsteroidal anti-inflammatory drugs (NSAIDs) can be tried (many are category B in early pregnancy). Extended use of NSAIDs should be avoided, however, because of potential constriction of the fetal ductus arteriosus and oligohydramnios, particularly late in gestation (category D in the third trimester). Narcotics such as meperidine, morphine, and hydromorphone (category B) can be used if severity warrants.[155] Glucocorticoids (category B) are safe when used for short periods and may help in migraines refractory to standard treatment.[156] Magnesium sulfate can be used for prophylactic or abortive therapy. Benzodiazepines (category D), ergot derivatives (category D), and sumatriptan as well as the newer triptans (category C) should be avoided.[157] Although the association of benzodiazepines with birth defects is not clear, neonatal depression and withdrawal may occur with use during the latter part of pregnancy. Vasoconstriction caused by ergot derivatives may lead to fetal vascular disruption. In addition, these agents may increase uterine activity by an oxytocin-like action. In the most extreme cases, intravenous hydration, prochlorperazine 10 mg IV, and intravenous narcotics or corticosteroids may be necessary.[151]

Nausea is a common accompanying complaint. Mild symptoms can usually be successfully treated with phosphorylated carbohydrate solution (Emetrol) or doxylamine succinate (category B) and pyridoxine (vitamin B_6). In more severe cases, trimethobenzamide (category C) and some phenothiazine compounds including chlorpromazine, prochlorperazine, and promethazine (all category C) can be used parenterally or as suppositories. Most of the medications described above enter the breast milk. Those that can be used in pregnancy can continue to be utilized during breastfeeding. Chlorpromazine is an exception, because it can cause neonatal lethargy.

Tension-Type Headaches

Maternal and Fetal Risks

Tension-type headaches are characterized by daily headaches of mild to moderate severity with a global distribution. They typically worsen throughout the day, and nausea and vomiting are seldom reported. Patients may exhibit symptoms such as depressed mood, anorexia, and insomnia. In contrast with migraine, tension-type headache symptoms do not improve during pregnancy and may actually worsen. The pathogenesis is unclear. Contracture of the neck muscles and stretching of aponeurotic connections may be the result rather than the cause of the headache. Characteristically, the neurologic exam is normal and no neuroimaging studies are required.

Treatment is aimed at behavioral aspects of the condition. Mild analgesics are indicated only when there is considerable pain. Acetaminophen is preferable to aspirin. If depression is a cardinal component, antidepressant agents can be used. Despite their classification, tricyclic antidepressants (most category D) appear to be relatively safe during pregnancy and can be used when clinically indicated. There is considerably less experience with the serotonin reuptake inhibitors (most category B). Available information suggests that these agents may also be used relatively safely when indicated.[158,159]

Spinal Headache

Maternal Risks and Management Options

Spinal headaches are commonly seen after accidental dural puncture during epidural placement. The typical history is that of a severe headache, which is exacerbated with sitting or standing and palliated with lying flat. The frequency of symptoms is related to the large-bore needle used. Such headaches less commonly follow the use of spinal anesthesia. The symptoms are believed to be due to leakage of CSF and subsequent CSF hypotension. Initial management consists of intravenous hydration and bed rest lying flat. If the patient fails to show improvement within 24 hours of conservative management, then a blood patch is indicated. About 2 to 3 mL of autologous blood are injected near the area of the dural puncture. Dramatic resolution of symptoms is typically observed.[160]

Benign Intracranial Hypertension (Pseudotumor Cerebri)

Maternal Risks

Benign intracranial hypertension is characterized by diffuse global headache, nausea, vomiting, papilledema, and, at times, horizontal diplopia. It is typically worse during early morning hours. The cause of increased ICP is either increased production or decreased reabsorption of CSF.[161] This condition is more common in young, obese, reproductive-age women. There is no evidence that the incidence is higher during pregnancy. Although benign intracranial hypertension can develop throughout pregnancy, it is most often seen during the first half of gestation. Other causes of increased ICP are listed in Table 49–7.

Management Options

PRENATAL, LABOR, AND DELIVERY

The diagnosis is one of exclusion. It is confirmed by demonstrating a high opening pressure at the time of lumbar puncture in the presence of a normal CT scan. Although weight reduction is a part of treatment in nonpregnant individuals, it is not encouraged during pregnancy. However, excess weight gain should be avoided. Treatment is aimed at avoiding visual complications. Acetazolamide, a carbonic anhydrase inhibitor (category C), is used along with repeated lumbar puncture and CSF drainage. Refractory cases may be treated with a lumbar subarachnoid-peritoneal shunt. When vision is threatened, optic nerve sheath fenestration can be performed to relieve pressure on the optic nerve.

Cesarean section is reserved for obstetric indications. As lumbar puncture is a mainstay of treatment, regional anesthesia with either spinal or epidural is not contraindicated.

VENTRICULOPERITONEAL SHUNTS

Maternal Risks

Advances in extracranial shunt technology during the 1960s improved the prognosis for patients with hydrocephalus. As a result, an increasing number of women with ventriculoperitoneal shunts in place are reaching reproductive age and becoming pregnant.[162] Pregnancy is associated with signs and symptoms of elevated ICP in as many as 58% of patients with previously well-functioning shunts.[163] Several case reports suggest that shunt malfunction is more common in the third trimester. The causes of the malfunctions have been postulated to be functional rather than mechanical, due to increased intraperitoneal pressure associated with advancing gestational age.[164]

Management Options

Prepregnancy

A baseline CT scan or MRI preconceptually may be of value. Further investigation is indicated if there is any suggestion of shunt malfunction.[163] The baseline study can also be of benefit for comparison purposes in the diagnostic evaluation of symptoms suggestive of increased ICP. Patients using AEDs should have their therapy reevaluated. Genetic counseling and preconceptual folic acid should be provided when a maternal neural tube defect is present.[165]

Prenatal

Patients should be monitored for evidence of increased ICP, including headaches, nausea, vomiting, visual changes, and altered sensorium. In the presence of these symptoms a CT scan or MRI should be obtained. With radiologic evidence of elevated ICP, conservative management with bed rest and fluid restriction may be tried. More rapid relief and direct measurement of the ICP can be obtained during aspiration of the shunt reservoir.[166] Pumping of the shunt may also provide symptomatic relief.[167] This method is less invasive and theoretically can decrease the risk of shunt infection. Shunt replacement is reserved for those patients who fail conservative treatment.

Labor and Delivery

Intrapartum treatment of women with ventriculoperitoneal shunts centers on the optimal mode of delivery and the need for prophylactic antibiotics. Most reported cases were allowed to labor and deliver vaginally. No complications were noted.[162] Concern with the potential for intra-abdominal scarring associated with surgery and the favorable outcomes seen with vaginal delivery would suggest that cesarean section should be reserved for routine obstetric indications. Shortening of the second stage with forceps or vacuum can be considered, but it does not appear to be universally necessary.[162] Analgesia and anesthesia choices during labor and delivery are limited. Narcotic use should be minimized because of the potential further increase in ICP and alteration of sensorium. Epidural anesthesia can be used with caution. In patients with elevated ICP or a neural tube defect regional anesthesia should be avoided and general anesthesia used.

The use of prophylactic antibiotics during the intrapartum period is controversial, but the presence of a foreign body with a direct connection to the brain makes prophylaxis theoretically sensible.[163] No adverse outcomes were reported in several patients treated without the routine use of prophylaxis.[162] However, the number of involved patients was small, and increased experience will be required before a true lack of benefit is determined.

SPINAL CORD INJURY

Maternal Risks

Modern rehabilitation practices allow many patients with spinal cord injuries to lead increasingly independent lives. Often included is the desire to develop a family. Many of the medical problems common to patients with spinal cord problems may be exacerbated during pregnancy. Urinary tract infections (UTI) often with resistant organisms are common in all patients with spinal cord injury due to incomplete bladder emptying and indwelling or intermittent catheterization. During gestation, 75% or more women will develop a UTI. This increases the risk of pyelonephritis.[168] Anemia is present in 60% to 100% of patients.[168] Chronic constipation, another problem seen in nearly all patients with spinal cord injury, is compounded both by pregnancy itself and iron supplementation used in anemia treatment.[169] Immobility associated with many spinal lesions places patients at risk for pressure ulceration. One quarter to half of gravid patients have pressure sores, which with gestational weight gain is a potential aggravating factor. Patients with lesions above T10 may not feel contractions, resulting in failure to appreciate the onset of term or preterm labor, increasing the risk of precipitous or preterm delivery.

Autonomic dysreflexia is a potential life-threatening complication, which can occur in patients with spinal cord lesions at or above T5. The condition results from stimulation of pelvic or abdominal organs, with resultant sympathetic activation uncontrolled by higher centers. Clinical manifestations can include headache, flushing, sweating, cardiac arrhythmias, and hypertension. Several activities common to pregnancy, including bowel or bladder distension, bladder catheterization, labor, and even vaginal examination, may precipitate autonomic dysreflexia, making this a time of particular concern.

Management Options

Prenatal

Management is aimed at minimizing the risk of the common complications. Urine should be screened for bacteria, with appropriate treatment when significant bacteriuria is identified.[168] Prophylactic antibiotics for suppression may be considered. If bladder catheterization is necessary, intermittent is preferred over an indwelling catheter. Dietary changes, stool softeners, or enemas may be necessary to control constipation, with manual disimpaction used in extreme cases. Attention to padding and position changes is important to avoid skin breakdown. Patients should be monitored for preterm labor. Uterine palpation and serial cervical exams can be applied.

Labor and Delivery

Unnecessary stimuli that may lead to autonomic dysreflexia should be avoided. Since uterine contractions are often associated with the condition, epidural anesthesia may be placed early in labor to eliminate sympathetic tone. This should be done even if the patient does not feel the pain of contractions.

NEUROMUSCULAR DISEASE

Mononeuropathies

Facial Nerve Palsy (Bell's Palsy)

MATERNAL RISKS

Peripheral facial nerve palsy is characterized by acute-onset facial weakness, occasionally preceded by ipsilateral retroauricular pain. The sense of taste may be diminished over the anterior two thirds of the tongue in lesions proximal to the origin of the corda tympani. Viral infection may play an etiologic role. Bell's palsy appears to be more prevalent during pregnancy, with an increased frequency during the third trimester and postpartum. More than three quarters of the pregnancy-related cases occur during this period. The reported incidence is approximately 50 per 100,000 pregnancies, but only 17 per 100,000 in nonpregnant women of childbearing age.[170]

MANAGEMENT OPTIONS

Although the benefit of prednisone (category B) is uncertain, it is frequently used at a dose of 1 mg/kg/d for 5 to 7 days. Success rates are higher if therapy is started within 7 days of the onset of symptoms. The eye should be protected with drops and glasses or a patch. The outcome is quite favorable, with most women recovering completely within 3 to 6 weeks.

Carpal Tunnel Syndrome

MATERNAL RISKS

Carpal tunnel syndrome results from entrapment of the median nerve in the carpal tunnel of the wrist. It is one of the most common mononeuropathies encountered during pregnancy, with a prevalence of approximately 20%.[171] The syndrome is manifested by wrist pain and numbness in the first three digits (and occasionally part of the fourth) of the affected hand. The symptoms may often be severe enough to interfere with sleep; however, significant weakness and muscle wasting is uncommon. Excessive weight gain and fluid retention are predisposing factors. Symptoms typically begin in the second half of pregnancy; however, carpal tunnel syndrome may initially present in the puerperium.[172,173]

MANAGEMENT OPTIONS

The diagnosis is typically made clinically. Electrophysiologic studies may be used if necessary, which show a decreased conduction velocity in the median nerve across the wrist. Initial therapy is conservative and consists of rest and wrist splinting. Resolution of symptoms usually occurs within a few weeks after delivery. In those cases that first present postpartum, resolution is seen 2 to 3 weeks after breastfeeding is stopped. Very few patients will require surgical nerve decompression.

Lateral Femoral Cutaneous Neuropathy (Meralgia Paresthetica)

MATERNAL RISKS

Meralgia paresthetica is a minor but bothersome sensory disturbance caused by stretching or compression of the lateral femoral cutaneous nerve under the inguinal ligament.[174] Numbness, tingling, burning, or pain in the lateral aspect of the thigh and no other neurologic deficits characterizes it. Standing or walking aggravates the symptoms. Symptoms usually begin during the third trimester and are often associated with obesity and exaggerated lumbar lordosis. Prolonged labor may cause or precipitate this neuropathy due to straining with hips flexed.

MANAGEMENT OPTIONS

During pregnancy pain relief can usually be achieved with sitting. Resolution occurs postpartum without treatment in most instances. Occasionally antiepileptic or antidepressant drugs such as carbamazepine or amitriptyline,

respectively, may be required. Local steroid or lidocaine injections may be useful.

Lumbar Disc Disease

MATERNAL RISKS AND MANAGEMENT OPTIONS

Lower back pain is one of the most common complaints during pregnancy affecting more than 50% of pregnancies from the mid-second trimester onward.[175] Significant lumbar disc disease is relatively uncommon, however. Clear clinicoradiologic evidence of herniated disc was found in only 5 of nearly 49,000 consecutive deliveries.[176]

Fifty-six of 6048 (0.92%) interviewed women had a confirmed new nerve injury of the lower extremities.[177] Factors associated with nerve injury were nulliparity and prolonged second stage of labor. Median duration of symptoms was 2 months. Diagnostic studies include nerve conduction velocities and electromyography. MRI studies should be used cautiously because there is a significant prevalence of disc bulges and frank disc herniations in asymptomatic individuals.[178] Patients who are refractory to medical therapy after delivery may benefit from lumbar laminectomy. Intraoperative positioning during cesarean section may cause sciatica neuropathy.[179]

Polyneuropathies

Acute Inflammatory Demyelinating Polyneuropathy (Guillain-Barré Syndrome)

MATERNAL RISKS

Acute inflammatory demyelinating polyneuropathy is an acquired condition characterized by demyelination of the motor roots and the proximal segments of the peripheral nerves.[180] Pregnancy appears to have no effect on the incidence or course of the disease, although cases have been reported in the first trimester and 28th week of gestation. Guillain-Barré syndrome also does not adversely affect pregnancy.[181,182] Presentation usually consists of ascending paralysis associated with lower back pain and radicular symptoms. Deep tendon reflexes are typically very depressed or lost. In the most severe cases respiratory muscle paralysis is seen and mechanical ventilation is required. Viral infections such as cytomegalovirus (CMV), Epstein-Barr virus (EBV), HIV-1, and hepatitis virus may play a causative role. Flu-like symptoms often precede the

onset of weakness by 2 to 3 weeks. In addition, *Campylobacter jejuni* has been implicated as a causal agent.

MANAGEMENT OPTIONS

The diagnosis is made based on the history and physical examination. Confirmation is obtained with electrophysiologic studies. Abnormal findings become evident more than 7 days after the onset of symptoms. Plasmapheresis has been used in the treatment during pregnancy since 1980.[183] Volume status and fetal well-being should be monitored during therapy because significant hypovolemia can result from fluid shifts occurring during therapy. Intravenous immunoglobulins have been used as an alternative to plasmapheresis.[184] Intubation and mechanical ventilation along with appropriate supportive care should be utilized as indicated. Spontaneous labor and vaginal delivery can be allowed. There is no contraindication to epidural anesthesia.

Chronic Inflammatory Demyelinating Polyneuropathy

MATERNAL RISKS AND MANAGEMENT OPTIONS

Chronic inflammatory demyelinating polyneuropathy is a condition with clinical features similar to Guillain-Barré syndrome. A protracted course extending beyond 6 months and a tendency to relapse differentiates the two conditions. During pregnancy, recurrence is seen more often in the last half of gestation.[185] There are no known adverse fetal effects.

Corticosteroids, plasmapheresis, and immunoglobulins have been used therapeutically, individually or in combination. Treatment response is variable, and sometimes poor outcomes result. Data during pregnancy are limited, but labor and delivery are usually uneventful.

Multifocal motor neuropathy has been reported to worsen during pregnancy and to improve with intravenous immunoglobulin.[186]

Noninflammatory Myopathies (Myasthenia Gravis Is Discussed in Chapter 44)

Myotonic Dystrophy

MATERNAL AND FETAL RISKS

Myotonic dystrophy is an autosomal dominant genetic condition characterized by a progressive distal muscle weakness and wasting. There is an associated delay in relaxation in affected muscles. The effect of pregnancy on myotonic dystrophy is variable. Symptoms may first present during pregnancy,[187] exacerbations may occur particularly in the third trimester,[188] or the patient may remain asymptomatic.[189] Cardiac disease can occur in association with myotonic dystrophy, presenting as conduction defects, arrhythmias, or congestive heart failure.[190,191]

An elevated risk of poor fetal outcome is associated with myotonic dystrophy. There is an increased incidence

of spontaneous abortion, preterm labor and delivery, and neonatal death.[187] Polyhydramnios is frequently present and may be associated with an affected fetus.[192] Preterm labor is likely a result of the increased amniotic fluid volume and myotonic involvement of the uterus.[193] Congenital myotonic dystrophy presents as generalized hypotonia and weakness. The respiratory muscles may be involved, resulting in inadequate ventilation at birth. Neonatal death is frequent, but if the affected infant is able to survive the first few weeks, some improvement may be seen.[194] The overall long-term prognosis remains generally poor, however. Developmental milestones are delayed and the incidence of mental retardation is increased.[195] Congenital myotonic dystrophy is usually only found in neonates born to mothers with the disease and differs from the adult form.[196]

MANAGEMENT OPTIONS

Prepregnancy and Prenatal. Any maternal cardiac or pulmonary compromise should be determined. A baseline electrocardiograph and pulmonary function tests should be obtained and the patient informed of the signs and symptoms of arrhythmias. Physical activity should be encouraged to slow clinical progression. Genetic counseling and prenatal diagnosis using DNA linkage analysis should be offered. Serial ultrasonography should be used to assess the amniotic fluid volume. In the presence of polyhydramnios, patients need to be followed for evidence of preterm labor. In the third trimester, fetal surveillance may be indicated.

Labor, Delivery, and Postnatal. Despite the risk of preterm labor, myotonic involvement of the uterine smooth muscle can result in dysfunctional labor. Augmentation with oxytocin is often effective.[197] Shortening of the second stage of labor may be helpful in women with significant weakness. Postpartum hemorrhage is a common complication and should be anticipated.

Respiratory muscle weakness may be present and must be considered when offering analgesia and anesthesia. Local or regional anesthesia is preferred. The risk of apnea with narcotics may be increased, and these agents should be used with caution. Nondepolarizing neuromuscular blocking agents should be avoided because of generalized muscle contracture resulting in difficulty with airway management.[198] Prenatal consultation with an anesthesiologist may be prudent.

A pediatrician should be present in the delivery room to aid in neonatal resuscitation and ventilation. There are no newborn tests for myotonic dystrophy. When the mother is asymptomatic and neonatal myotonia is suspected, electromyographic studies on the mother can confirm the neonatal diagnosis.

Demyelinating Diseases

Multiple Sclerosis

MATERNAL AND FETAL RISKS

Multiple sclerosis (MS) is a demyelinating disease that affects the central nervous system at different levels and at varying times.[199] It is a relatively common neurologic disease among young adults, peaking at age 30. The prevalence in the United States is 1/1000. Women are affected twice as often as men.

Common symptoms include acute onset of diplopia, vertigo, gait instability, bladder incontinence, loss of vision, and fatigue. Any CNS symptom can be a manifestation of MS, however. The disease course in an individual patient is unpredictable. Different general disease patterns are recognized. One type is characterized as relapsing and remitting with an identified onset and resolution of symptoms. The chronic progressive pattern follows a protracted course, with worsening of symptoms over a prolonged period. Finally a relapsing progressing course displays identifiable exacerbations with no clear return to baseline neurologic function. Poor prognostic factors include prominent weakness, poor response to steroids, and older age at onset. The common pathologic lesion called a plaque demonstrates myelin loss and gliosis associated with inflammatory infiltrates.

Previous research on the effects of pregnancy on MS has generally been flawed, and well-controlled studies are needed.[200] Pregnancy itself may exert a short-term beneficial effect on the course of MS, including fewer, less severe relapses especially in the third trimester. However, this protection is lost in the postpartum period. The incidence of new cases of MS is decreased during pregnancy, as is the risk of exacerbation and progression of existing disease. Postpartum, the incidence of new-onset disease is not different from that in the nonpregnant population.[201] Exacerbation is reported to increase 20% to 40% during the first 6 months after delivery.[202,203] Despite the increase in disease activity postpartum, there does not appear to be any increase in long-term disability related to pregnancy.[204–206] Objective evidence of decreased MS activity during the latter half of gestation with a return to baseline postpartum has been seen using serial MRI scans in two patients.[207] The relative immunosuppression associated with pregnancy may play a role in pregnancy-related changes seen in MS. Children of MS mothers have a 3% risk of developing MS compared with a 0.1% risk seen in the general population.[208]

MANAGEMENT OPTIONS

Prepregnancy. The diagnosis of MS is made clinically. Brain imaging and CSF studies are used to support the clinical impression. High-intensity signal lesions are found in the CNS white matter on MRI scanning, and oligoclonal banding is seen in the CSF. Few data are available during pregnancy on the three FDA-approved treatments for MS patients with relapsing-remitting disease. The therapies include: copolymer 1 or glatiramer acetate (category B), interferon b1b, and interferon b1a (both category C). Corticosteroid therapy is also used.

Preconceptual evaluation and counseling is desirable. Disease activity should be assessed. In times of remission, with the lack of information regarding MS therapies during gestation and the fact that most patients show improvement during pregnancy, consideration should be given to stopping the drugs or minimizing the dose. Patients should also be informed of the increased risk of their offspring developing the disease.

Prenatal. Patients should be monitored for evidence of increased disease activity and the risks of therapy weighed against the potential concerns associated with lack of information. In those patients with urinary tract involvement, regular screening for asymptomatic bacteriuria should take place. Physical therapy and stretching exercises required prior to conception should be continued.

Labor and Delivery and Postnatal. Labor and delivery should not be significantly affected in patients with MS. Prolonged antepartum corticosteroid use requires stress dose steroids during labor. Hydrocortisone 25 mg parenterally every 8 hours in addition to the usual daily dose is an acceptable regimen.[209] Maternal exhaustion seen in the second stage can be managed with operative vaginal delivery. The use of spinal anesthesia has traditionally been avoided due to fear of increasing the risk of exacerbation. There are no data to support this concern, however, and spinal, epidural, and general anesthesia can all be used safely.[210] Breastfeeding may be encouraged, because there does not appear to be an increase in the frequency or severity of postpartum relapse.[211]

CEREBRAL TUMORS

Primary Brain Tumors

Maternal and Fetal Risks

All types of brain tumors have been described in pregnant women, but the overall incidence of primary brain tumors in pregnancy is small and not different from that seen in nonpregnant women of childbearing age. Nevertheless, normal physiologic changes such as increased fluid volumes and increased sex hormone levels occurring during gestation may have a profound effect on tumor growth and neurologic symptoms. Growth of some tumors with estrogen and progesterone receptors can be altered.[212,213] Although tumor growth may lead to initial diagnosis during pregnancy, signs and symptoms at presentation are the same as those in nongravid individuals.

Presenting symptoms relate to increased ICP or local mass effect. Common complaints or neurologic findings include headache, nausea, vomiting, visual changes, hemiparesis, cranial nerve deficits, and seizures. Most of these findings are nonspecific and commonly associated with normal pregnancy, potentially leading to a delay in diagnosis.

Management Options

PREPREGNANCY AND PRENATAL

Management of primary brain tumors in pregnancy depends on the type of tumor and whether it is benign or malignant. Maternal outcome will depend on these factors as well as histologic grade of malignant lesions.[214] Gestational age will also be an important consideration in determining timing and mode of therapy as well as maternal and fetal risks and benefits.

The diagnosis is made with neuroimaging studies. MRI is preferred because low-grade tumors may present as nonenhancing lesions on brain CT, making their classification difficult. Surgical therapy is the treatment of choice for most lesions. Resection is best performed prior to conception when a diagnosis is made before pregnancy. In benign tumors, such as most meningiomas or in low-grade malignant gliomas diagnosed during pregnancy, resection can often be delayed until after delivery providing the patient is neurologically stable. Malignant tumors should be resected promptly. Adjuvant chemotherapy can be given after the first trimester when maternal benefit outweighs fetal risk.

In tumors where radiation therapy is indicated as a primary treatment modality or an adjuvant, this should

be delayed until after delivery if possible. Preterm delivery may be undertaken in the presence of fetal pulmonary maturity to expedite therapy. If gestational age prohibits timely delivery, localized brain radiation may be used with careful abdominal shielding to minimize fetal exposure.

Vasogenic cerebral edema is seen with some tumor types and may require glucocorticoid therapy. Dexamethasone is the drug of choice. This agent readily crosses the placenta, so if prolonged high-dose treatment is required, prednisone may be considered as a substitute to decrease fetal exposure. Seizure prophylaxis with appropriate AEDs is indicated when there is a significant risk of convulsions.

LABOR AND DELIVERY

Little information exists to guide labor and delivery management. Vaginal delivery may be allowed with cesarean section reserved for obstetric indications. The second stage may be shortened with forceps or vacuum to avoid increased ICP with pushing.

Metastatic Brain Tumors (See also Chapter 53)

Maternal Risks and Management Options

The brain is a common site of metastatic cancer. Lung, breast, and gastrointestinal cancers are the most frequent site of the primary tumors. Rarely do maternal cancers spread to the fetoplacental unit.

Choriocarcinoma is a trophoblastic tumor that is rarely found associated with a normal pregnancy. The tumor spreads rapidly by the hematogenous route, with brain metastasis discovered at the time of diagnosis in as many as 20% of patients.[215-217] Brain involvement presenting as an ischemic stroke,[218] intracerebral hemorrhage,[219] or subdural hematoma resulting from metastatic infiltration and proliferation in vascular spaces may actually lead to the diagnosis. Chemotherapy is considered the treatment of choice in choriocarcinoma. Alternatives in special circumstances include surgical resection of single brain metastasis and cranial irradiation. The presence of brain lesions is associated with an overall worse prognosis.

Prolactinoma (See also Chapter 47)

Maternal Risks

Prolactinomas are the most common type of pituitary tumor. Most are microadenomas found during an evaluation for amenorrhea, galactorrhea, or infertility. In addition, macroadenomas (>10 mm diameter) may present with headache or bitemporal hemianopia. The use of bromocriptine to treat infertility has allowed women with prolactinomas to become pregnant. Pregnancy can stimulate tumor growth. Although this is rarely a problem with microadenomas, symptoms may develop or worsen in the presence of a macroadenoma.[220]

Management Options

If adenoma size has not previously been determined, neuroimaging studies are indicated to define the extent of the tumor. MRI is able to identify small adenomas and their relation to the optic nerve, whereas CT scan provides better definition of any bony erosion resulting from the tumor expansion.[221] With microadenomas, bromocriptine can be stopped once pregnancy is diagnosed with less than a 5% chance of the lesion becoming symptomatic.[222] Visual fields are periodically tested to detect evidence of tumor growth. Headaches are a useful early symptom of tumor enlargement. Bromocriptine may be started during pregnancy if symptoms develop. Macroadenomas have a 15% to 35% chance of enlargement. Bromocriptine may be continued throughout gestation, or patients must be followed closely for symptoms. Hypophysectomy or radiotherapy are reserved for cases that fail medical management. Adenomas generally decrease in size after delivery.

MOVEMENT DISORDERS

Maternal and Fetal Risks

Life-threatening, new-onset movement disorders are extremely rare during pregnancy.[223,224] Movement disorders are classified based on either excessive (hyperkinetic or dyskinetic) or slowed (hypokinetic) motor activity. The findings can be persistent or intermittent. In reproductive-age women, the hyperkinetic or dyskinetic disorders predominate. Several of the movement disorders are associated with abnormalities of tone, but most are not associated with actual weakness.

Most movement disorders are the result of disease involving the basal ganglion (caudate nucleus, globus pallidus, putamen, substantia nigra) and its connections. However, abnormalities of the thalamus, cerebellum, spinal cord, and peripheral nerves can cause abnormal movements. A wide spectrum of pathologic processes, including degenerative conditions, toxins, metabolic aberrations, cerebrovascular disease, neoplasms, autoimmune conditions, infections, and trauma, can lead to movement disorders.[224] In addition, dopamine receptor antagonists commonly used to treat nausea and vomiting in early pregnancy may rarely induce new-onset dystonia, chorea, tremors, and parkinsonism.

Chorea Gravidarum

Maternal and Fetal Risks

Chorea gravidarum, a hyperkinetic disorder, is an uncommon condition that encompasses any cause of chorea occurring during pregnancy.[225-227] In the preantibiotic era, it was commonly due to group A streptococcal infection and rheumatic fever. Clinical manifestations of chorea include abrupt, rapid, unsus-

tained, involuntary, purposeless, irregular, and non-rhythmic movement of a limb or axial structure. The movements may be isolated and of brief duration or they may be more flowing and sustained. Patients are often unable to persist with voluntary motor activity. This is illustrated by difficulty in maintaining protrusion of their tongue or closure of their eyes. There are multiple causes of chorea gravidarum. Most cases are due to medications, toxins, infections (e.g., HIV or cerebral toxoplasmosis), autoimmune disorders, cerebrovascular disease, or an endocrinopathy. Specific causes are shown in Table 49–8.

Management Options

Management of chorea depends on the underlying origin and its severity. The diagnostic evaluation is complex and aimed at excluding the conditions listed in Table 49–8. Therapeutic intervention is aimed primarily at the underlying cause. The actual chorea is usually benign and of secondary concern. Treatments typically offer only symptomatic relief and have the potential for adverse effects. Expectant management is preferred except when movements may lead to dehydration, malnutrition, or insomnia or when they are exceedingly violent and pose a risk of maternal injury. Short-term use of low-dose haloperidol (category C) can reduce chorea movements.

Wilson's Disease

Maternal and Fetal Risks

Wilson's disease is an autosomal recessive disorder of copper metabolism associated with a deficiency of the copper-binding and carrier protein, ceruloplasmin. Disease manifestations include chorea, tremors, hyper-

salivation, dystonia, myoclonus, or slurred speech. Copper deposition in the brain is responsible for the clinical findings. Kayser-Fleischer rings describe copper deposition in the cornea and are one of the classic physical findings. Other organ systems are also affected. The defective gene is located on chromosome 13 (p14).[223,224] The carrier frequency in the population is between 1/90 and 1/200.

Management Options

Typically the diagnosis is made when serum ceruloplasmin levels are less than 20 mg/dL. Half of patients with Wilson's disease will have levels less than 5 mg/dL. The diagnosis may be complicated in pregnancy because increased estrogen levels increase ceruloplasmin levels, leading to false-negative assays. Prior to penicillamine therapy pregnancy was uncommon because of the development of infertility, and when conception did occur the rate of spontaneous abortions was increased.[228,229]

Penicillamine (category D) therapy is the first-line treatment of Wilson's disease.[230] Five consecutive successful pregnancies in the same woman with Wilson's disease have been reported.[231] Therapy has been associated with adverse fetal effects. Fetal connective tissue anomalies secondary to an inhibition of collagen synthesis can result.[230,232] Also neonatal inguinal hernia, reversible cutis laxa,[223,224] hyperflexible joints, vascular fragility, and poor wound healing have all been reported.[233,234] Many infants born to mothers taking penicillamine during pregnancy are free of defects, however.

With proper therapy the course of Wilson's disease does not appear to be affected by pregnancy. Penicillamine therapy should be continued during pregnancy. Halting therapy could lead to irreversible damage to the maternal brain, liver, and other organs. To minimize the risk of poor wound healing following delivery, the daily penicillamine dose should be decreased from 1 g to 250 mg during the third trimester. An alternative therapy uses zinc and trientine. Collagen synthesis is not adversely affected, but experience with this regimen in pregnancy is limited.[228]

Restless Leg Syndrome

Maternal Risks

Restless leg syndrome is a common condition with 11% to 19% of pregnant women affected.[235] It consists of an unpleasant sensation of the legs often associated with periodic movements during or just before sleep, or in the late evening when fatigue is present. Clinically there is flexion of the hip and knee with dorsiflexion of the ankle and extension of the great toe. The cause is unclear; however, in nonpregnant patients there has been an association with iron deficiency. Treatment aimed at

iron replacement has been associated with an improvement in symptoms.[236] Symptoms often disappear with walking.

Management Options

Treatment is supportive and includes reassurance, massage, flexion and extension leg exercises, and walking. With the high incidence of iron deficiency in pregnancy, iron supplementation may be a prudent early intervention. Severe cases can be managed with opiates.

Parkinson's Disease

Maternal and Fetal Risks

Parkinson's disease is an idiopathic hypokinetic disorder typically seen after the age of 40, but approximately 5% of cases may present earlier.[223] Thus Parkinson's disease may be seen in women of childbearing age. The condition is a degenerative disorder of unknown origin related to a deficiency of dopamine-secreting neurons in the substantia nigra of the brainstem mesencephalon (midbrain). Manifestations include slowed movements (bradykinesia), increased tone (rigidity), resting tremor, loss of postural reflexes, masked facies, and transient akinesia. Patients often have difficulty initiating movements, and automatic movements are reduced. This constellation of findings is termed parkinsonism and represents a common clinical presentation for a variety of conditions in addition to Parkinson's disease. The differential diagnosis includes intracranial processes such as hydrocephalus, head trauma, subdural hematomas, cerebrovascular disease, and encephalitis. Carbon monoxide poisoning, metabolic abnormalities, and cyanide and manganese toxicity have also been implicated. Also several medications, including alpha methyldopa, disulfiram, dopamine receptor antagonists, lithium, methanol, reserpine, and tetrabenazine, may lead to parkinsonism. Discon-

tinuation of the offending drug if clinically feasible may lead to varying degrees of symptomatic improvement.

Information describing the course of Parkinson's disease in pregnancy is limited. There are reports of worsening during pregnancy with improvement postpartum.[223,224] Symptoms may be exacerbated by several factors, including hormonal changes, medications, weight gain, increased fatigue, and dehydration.

Management Options

Initial evaluation of a patient suspected of having Parkinson's disease should exclude other conditions associated with parkinsonism. As with the condition itself, information regarding the safety of antiparkinsonism medications during pregnancy is limited. Use of the combination of levodopa/carbidopa (not categorized), a mainstay in the treatment of Parkinson's disease, has been associated with malformations in animals, but adequate human data are not available. These medications should be used with caution. Amantidine (category C) has also been associated with malformations in animals. In humans, the overall malformation rate is reported to be higher, but there is no specific pattern. Again, data are limited, and caution should precede its use.[1]

Bromocriptine (category C) is a second-line agent for the treatment of Parkinson's disease. Although it is not as efficacious as the levodopa/carbidopa combination, there is considerably more experience during pregnancy. The information is based on lower doses used to treat prolactinomas.[237] It is considered safe without excess risk of complications based on 1335 women receiving it during pregnancy for a prolactinoma. Bromocriptine may be added to the levodopa/carbidopa combination when disabling symptomatology appears such as dopa-induced dyskinesias. Selegiline (Category C) and pergolide (category B) are newer treatments that lack adequate pregnancy data.[238]

Management Options	Quality of Evidence	Strength of Recommendation	References
SUMMARY OF MANAGEMENT OPTIONS — **Movement Disorders**			
Chorea Gravidarum			
Management depends on cause	IV	C	224
Treatment only given if:	IV	C	224
Dehydration			
Malnutrition			
Insomnia			
Violence			
Risk of maternal injury			
Short-term low-dose haloperidol commonly used.	IV	C	224

SUMMARY OF MANAGEMENT OPTIONS
Movement Disorders *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Wilson's Disease			
Penicillamine is the treatment of choice, but lowest dose that gives disease control should be used (risk of fetal defects).	III IV	B C	228–230,232
Restless Leg Syndrome			

Supportive treatment:
  Reassurance
  Massage, exercises, and physiotherapy
  Walking
	III	B	235

Iron supplementation if deficient	IV	C	236
Opiates for severe cases	III	B	235
Parkinson's Disease			
Levodopa/cardidopa is probably safe for the fetus (limited human data).	—	GPP	—
Bromocriptine is often added to this with severe cases.	III	B	237
Amantadine, selegiline, and pergolide have limited published data.	—	GPP	—

CEREBRAL ABSCESS

Maternal Risks

Pregnancy and puerperium-associated cerebral abscesses are exceedingly rare, with fewer than 15 cases reported.[239] Although most abscesses are supratentorial and solitary (Fig. 49–7), focal neurologic deficits are not always present despite headache, fever, seizures, or depressed level of consciousness. Sources of infection include otitis media, venous sinus thrombosis, and hemorrhage into the basal ganglia. In most cases a source is not found. Cerebral abscesses have been reported in immunocompetent hosts. Approximately half the cases have been associated with eclampsia. Overall mortality is 35%, and when the abscess is associated with eclampsia, mortality reaches 50%.

Management Options

Although rare, a cerebral abscess should be a part of the differential diagnosis when a mass lesion is seen on brain imaging. As a rule, aggressive medical management of the abscess is often adequate, and surgical evacuation may not be necessary. Medical therapy includes the appropriate use of intravenous antibiotic(s) to cover a broad spectrum of potential organisms. A source for the infection should be promptly and thoroughly sought and treated and when found may give information about the responsible organism(s). Surgical drainage may be indicated if there is an initial poor response to the antibiotics.

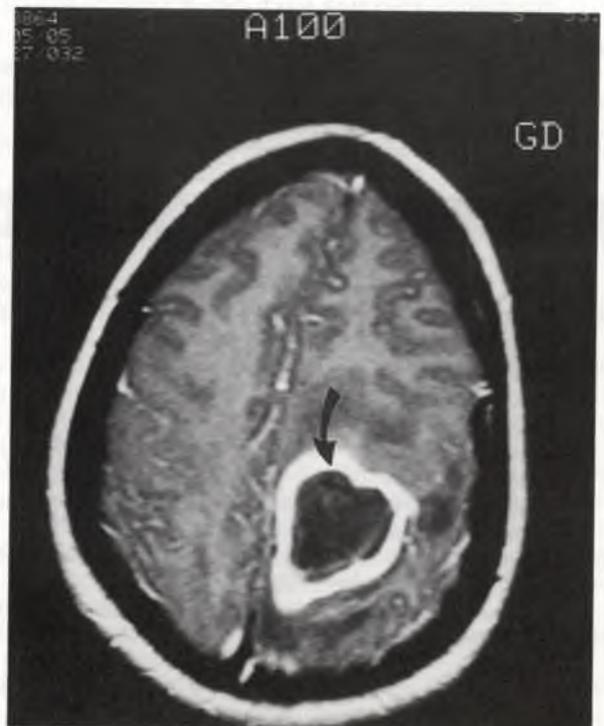
ACKNOWLEDGEMENTS


FIGURE 49–7
Axial head MRI revealing a ring-enhancing lesion, proven to be a puerperal cerebral abscess (*curved arrow*) at surgery.

CONCLUSIONS

- The optimal and effective management of neurologic complications of pregnancy include the early involvement of the obstetrician, anesthesiologist, and neurologist. The early participation of the pediatrician/neonatologist is also important to anticipating and treating neonatal needs.
- Eclampsia most frequently occurs during the antepartum and intrapartum periods, but approximately one-third of cases are seen postpartum.
- Magnesium sulfate and blood pressure control have been mainstay of both seizure prophylaxis and abortive therapy in patients with preeclampsia and eclampsia.
- Although it was believed that the incidence of stroke is higher during pregnancy, the most recent evidence is less conclusive. Nevertheless, the relative risk of stroke rises to 8.7 during the postpartum period.
- Despite the associated physiologic changes associated with pregnancy and delivery, the risk of subarachnoid hemorrhage does not appear to increase during these physiologic states and bleeding during the time of labor and delivery is infrequent.
- Although previous research on the effects of pregnancy on multiple sclerosis (MS) has been flawed, it is now thought that pregnancy itself may exert a short-term beneficial effect on the course of MS.
- Carpal tunnel syndrome is one of the most common mononeuropathies encountered during pregnancy, with a prevalence of about 20%. Resolution of symptoms usually occurs within the first few weeks after delivery.
- In cases of benign tumors, such as most meningiomas or in low-grade malignant gliomas diagnosed during pregnancy, resection often can be delayed until after delivery, providing the patient is neurologically stable. Malignant tumors should be resected promptly.
- Aggressive medical management of brain abscesses during pregnancy is often adequate, and surgical evacuation is not necessary unless there is poor response to appropriate antibiotic therapy.

Renal Disorders

David Williams

INTRODUCTION

The kidneys undergo marked hemodynamic, renal tubular, and endocrine changes during pregnancy. A failure of these adaptations in women with renal disease creates a suboptimal environment for fetal development and increases the risk of obstetric complications such as preeclampsia, preterm labor, and intrauterine growth restriction (IUGR). In turn, during pregnancy the diseased maternal kidneys are exposed to the damaging consequences of a prothrombotic state, ascending urinary infections, gestational hypertension, and altered hemodynamics that exacerbate proteinuria. Women with a preconception glomerular filtration rate (GFR) of less than 25 mL/min, (serum creatinine >177 μmol/L; 2.0 mg/dL) have a 1:3 chance of a pregnancy-related decline to end-stage renal failure (ESRF) and are likely to have preterm, growth-restricted babies. Preexisting hypertension, proteinuria, recurrent urinary tract infections (UTIs), and in women with diabetic nephropathy— poor glycemic control, are all independently, but cumulatively detrimental to maternal and fetal outcome. Women with ESRF are far more likely to have a successful pregnancy following a kidney transplant compared with those on dialysis. Pregnancy itself can cause acute renal disease or uncover a previously subclinical renal condition. This chapter describes gestational changes to the kidney during healthy pregnancy, the influence of pregnancy on chronic renal disease, and, conversely, the effect of chronic renal disease on pregnancy outcome. The management of specific acute and chronic renal diseases during pregnancy is also discussed.

RENAL CHANGES DURING NORMAL PREGNANCY

Renal Glomerular Function during Pregnancy

Renal adaptation to pregnancy is anticipated prior to conception, during the luteal phase of each menstrual cycle. Renal blood flow and GFR increase by 10% to 20% before menstruation.[1,2] If pregnancy is established, the corpus luteum persists and these hemodynamic changes continue.[2,3] By 16 weeks' gestation GFR is 55% above nonpregnant levels.[3,4] This increment is mediated through an increase in renal blood flow that reaches a maximum of 70% to 80% above nonpregnant levels by the second trimester, before falling to around 45% above nonpregnant levels at term.[5] Elegant human studies have confirmed that unlike the hyperfiltration that precedes diabetic nephropathy, gestational hyperfiltration is not associated with a damaging rise in glomerular capillary blood pressure (BP).[4]

The changes to renal physiology in healthy pregnancy can both hide and mimic renal disease (Table 50–1). The increased GFR of pregnancy leads to a fall in serum creatinine concentration (SCr), so that values considered normal in the nonpregnant state may be abnormal during pregnancy. SCr levels fall from a nonpregnant mean value of 73 μmol/L (0.82 mg/dL) to 60 μmol/L (0.68 mg/dL), 54 μmol/L (0.61 mg/dL) and 64 μmol/L (0.72 mg/dL) in successive trimesters.[6] SCr is not, however, linearly correlated with creatinine clearance and is influenced by muscle mass, physical exercise, racial differences, and dietary intake of meat. As SCr roughly doubles for every 50% reduction in GFR, a more useful parameter by which to monitor serial changes in renal function is the reciprocal of SCr (1/SCr). Estimates of GFR can be further refined using the Cockcroft-Gault equation, which calculates GFR using SCr, maternal age, and prepregnancy weight.[7] For women, the Cockcroft-Gault equation is

$$\text{GFR (mL/min)} = 0.8 \times [140 - \text{age (years)} \times \text{weight (kg)}] / \text{SCr (μmol/L)}$$

(1 mg/dL creatinine = 88.4 μmol/L creatinine)

The gestational rise in renal blood flow also causes the kidneys to swell so that bipolar renal length increases by approximately 1 cm. During the third trimester renal blood flow falls, leading to a fall in creatinine clearance

Physiologic Changes of Pregnancy Can Both Mask and Mimic Renal Disease in Pregnancy

Pregnancy Mimics Renal Disease

Increased proteinuria (should not exceed 200 mg/24h)
Decreased serum albumin (reduced by 5–10 g/L)
Increased cholesterol by 50% in third trimester[16]
Salt and water retention (dependent edema)
Dilatation of the renal tracts (mimics renal obstruction, especially on right side)
Glycosuria (present in 10% of nondiabetic mothers)
Hypercalciuria
Physiologic reduction in hemoglobin concentration
Symptoms mimicking cystitis
Metabolic acidosis (bicarbonaturia to compensate for respiratory alkalosis)

Pregnancy Masks Renal Disease

Physiologic vasodilatation reducing systemic BP
Increased GFR reducing SCr and serum urea

BP, blood pressure; GFR, glomerular filtration rate; SCr, serum creatinine.

and a rise in reciprocal SCr. Serum urea levels, however, continue to fall in the third trimester due to reduced maternal hepatic urea synthesis.[8] This metabolic adaptation ensures that more nitrogen is available for fetal protein synthesis.[8]

The renal pelvicaliceal system and ureters, particularly on the right side, dilate and can appear obstructed to those unaware of these changes.[9] The right pelvicaliceal system dilates by a maximum of 0.5 mm each week from 6 to 32 weeks, reaching a maximum diameter of approximately 20 mm (90th percentile), which is maintained until term.[10] The left pelvicaliceal system reaches a maximum diameter of 8 mm (90th percentile) at 20 weeks' gestation.[10]

Proteinuria increases as pregnancy progresses, but levels over 200 mg/24 hours during the third trimester are above the 95% confidence limit for the normal population.[11] A random urine protein:creatinine ratio is a useful guide to 24-hour urinary protein excretion, but is not a substitute for either a 12-hour[12] or 24-hour urine collection, due to the high incidence of both false-positive and false-negative results.[13,14] A random urine sample that gives a protein (mg): creatinine (mmol) ratio of more than 0.19 is a good predictor of significant proteinuria[13] and is an indication for more accurate assessment of proteinuria with a 12- or 24-hour urine collection.

Serum albumin levels fall by 5 to 10 g/L,[15] serum cholesterol and triglyceride concentrations increase significantly,[16] and dependent edema affects most pregnancies at term. Normal pregnancy therefore simulates the classic features of nephrotic syndrome (see Table 50–1).

Renal Tubular Function During Pregnancy

Increased alveolar ventilation causes a respiratory alkalosis to which the kidney responds by increased bicarbonaturia and a compensatory metabolic acidosis.[17] Other renal tubular changes include reduced tubular glucose reabsorption, which leads to glycosuria in approximately 10% of healthy pregnant women,[18] a 250% to 300% increase in urinary calcium excretion,[19] and a first-trimester increase in urate excretion that decreases toward term, at which time plasma urate levels rise again to nonpregnancy levels.[20]

During healthy pregnancy a mother gains 6 to 8 kg of fluid, of which approximately 1.2 L is due to an increase in plasma volume.[3] Plasma osmolality falls by 10 mOsm/kg by 5 to 8 weeks' gestation due to a fall in both the threshold for thirst and for the release of antidiuretic hormone (vasopressin).[21] During pregnancy, vasopressin is metabolized by placental vasopressinase, and at term the maternal posterior pituitary produces four times as much vasopressin to maintain physiologic concentrations.[22] Failure of the maternal pituitary to keep up with the increased metabolic clearance of vasopressin leads to a transient polyuric state in the third trimester, which is known as transient diabetes insipidus of pregnancy.[23]

Renal Endocrine Function During Pregnancy

The kidney also acts as an endocrine organ that produces erythropoietin,[24] active vitamin D,[25] and renin.[3] The production of all three hormones increases during healthy pregnancy, but their effects are masked by other changes.[3,24,25] In early pregnancy, peripheral vasodilatation exceeds renin/aldosterone-mediated plasma volume expansion, so diastolic BP falls by 12 weeks.[26] Conversely, plasma volume expansion exceeds the erythropoietin-mediated increase in red cell mass, causing a "physiologic anemia," which should not normally lead to a hemoglobin (Hb) concentration of less than 9.5 g/dL.[27] Similarly, extra active vitamin D produced by the placenta circulates at twice nongravid levels, but concomitant halving of parathyroid hormone levels, hypercalciuria, and increased fetal requirements keep maternal plasma ionized calcium levels unchanged.[19,28]

LOWER URINARY TRACT INFECTION

General

The incidence of asymptomatic bacteriuria (significant growth of a uropathogen in the absence of symptoms) is 2% to 10%, which is the same during pregnancy as it is in sexually active nonpregnant women.[29] However, the structural and immune changes to the urothelium of the renal tracts during pregnancy[30] make it more likely that a lower UTI will ascend to cause acute pyelonephritis.[29,31] During pregnancy, 12.5% to 30% of women with untreated asymptomatic bacteriuria will develop acute pyelonephritis,[29–33] a serious infection with significant morbidity to mother and fetus.

Diagnosis of a Urinary Tract Infection

During pregnancy symptoms suggestive of a UTI are dysuria and offensive-smelling urine. Other symptoms, usually associated with a UTI are urinary frequency, nocturia, urge-incontinence, and strangury (the urge to pass urine having just done so), but these symptoms are also found in healthy pregnant women.

Microscopy and culture of a freshly voided midstream urine sample will allow quantification of pyuria (leukocytes in the urine) and growth of a urinary pathogen. Bacterial UTI is the most common cause of pyuria and is considered significant if microscopy of a sample of unspun midstream urine reveals more than 10 leukocytes per microliter. Urine culture is conventionally recognized as significant if there is growth of more than 10^5 colony forming units per milliliter (CFU/mL) of a single recognized uropathogen in association with pyuria.[34] Low counts of bacteriuria (10^2–10^4 CFU/mL) may still be significant if symptomatic women have a high fluid intake or are infected with a slow-growing organism. If left untreated, most symptomatic women with "low-count bacteriuria" will have 10^5 CFU/mL 2 days later.[34] During pregnancy, the most common uropathogens are bowel commensals, *Escherichia coli* (70%–80%), *Klebsiella*, *Proteus*, *Enterobacter*, and *Staphylococcus saprophyticus*.

If urine from a symptomatic pregnant woman is cloudy and positive on dipstick testing for nitrite (produced by most uropathogens) and leukocyte esterase (produced by white blood cells), then a UTI is likely, and empirical treatment can be started.[34] These urine sticks are not sensitive enough to be used for screening for asymptomatic bacteriuria in early pregnancy;[35] therefore, microscopy and culture of a clean catch midstream urine sample is necessary. Hematuria and proteinuria are unreliable indicators of a UTI, but are important signs of renal disease (see later discussion).

Asymptomatic Bacteriuria

Maternal and Fetal Risks

During pregnancy, untreated asymptomatic bacteriuria will develop into acute pyelonephritis in 12.5% to 30% of women, but if treated less than 1% of pregnant women develop pyelonephritis.[29–33] A systematic review of 14 studies confirmed that antibiotic treatment of asymptomatic bacteriuria, compared with placebo or no treatment, significantly reduced the incidence of pyelonephritis (odds ratio 0.24; 95% CI 0.19–0.32).[36] Following successful treatment of asymptomatic bacteriuria, monthly screening of midstream urine is necessary, because approximately 30% of women will have a relapse of bacteriuria, making them vulnerable to acute pyelonephritis again.[29]

Asymptomatic bacteriuria has also been associated with an increased risk of preterm delivery and low birth weight.[37] Treatment of asymptomatic bacteriuria has

been shown to reduce the incidence of preterm delivery and low-birth-weight babies (odds ratio 0.60; 95% CI 0.45–0.80).[36] Others have not, however, found the same association between preterm labor and bacteriuria.[31] It has been suggested that the underlying renal pathology, which is commonly associated with bacteriuria, is responsible for poor pregnancy outcomes.[31] Further good quality studies are needed to settle this issue.

Management Options

Contrary to much published advice, not all pregnant women need to be screened for asymptomatic bacteriuria. There are two main reasons. Firstly, the prevalence of asymptomatic bacteriuria varies among populations, and where it is low (<2.5%) it is hard to justify the cost-effectiveness of screening. In populations where the prevalence of asymptomatic bacteriuria is greater than 5%, the case for screening is much stronger.[32] Secondly, approximately 1% to 2% of the 90% to 98% of asymptomatic women who test negative for bacteriuria in the first trimester will develop a symptomatic UTI.[33,38] Therefore a third of all women who develop a UTI in late pregnancy would have been missed on first-trimester screening.[33,38] Women at increased risk of pyelonephritis or renal impairment should be screened for asymptomatic bacteriuria every 4 to 6 weeks throughout pregnancy (Table 50–2).

Treatment of Urinary Tract Infections

There is no consensus about the optimal treatment of asymptomatic bacteriuria[47] nor the empirical treatment of symptomatic UTIs in pregnancy.[48] Most UTIs during pregnancy (approximately 75%) are caused by *E. coli*, which is usually sensitive to nitrofurantoin (89%), trimethoprim (with or without sulfamethoxazole) (87%), ampicillin (72%), or cephalosporins.[49,50] Therefore until well-structured trials are done, the most cost-effective treatment regimen for treating asymptomatic bacteriuria or a first episode of cystitis is either nitrofurantoin monohydrate macrocrystals (100 mg bid for 3 days) or

---

TABLE 50–2

Screening for Asymptomatic Bacteriuria (every 4–6 weeks) Is Recommended for the Following Groups of Pregnant Women

History of asymptomatic bacteriuria[39]
Previous recurrent UTIs[39]
Preexisting renal disease, especially scarred kidneys due to reflux nephropathy[36,40–42]
Structural and neuropathic abnormalities of the renal tracts[31,43]
Renal calculi[44]
Preexisting diabetes mellitus[45] but not gestational diabetes[46]
Sickle cell disease and trait[39]
Low socioeconomic group and less than 12 years higher education[33,39]

UTI, urinary tract infection.

trimethoprim (200 mg bid for 3 days).[50] Nitrofurantoin should be avoided after the onset of labor in patients with glucose-6-phosphate dehydrogenase deficiency, although no well-documented cases of hemolysis in neonates have ever been recorded,[51] and trimethoprim should be avoided in the first trimester because it is a folic acid antagonist associated with an increased risk of neural tube defect.[52]

Screening for recurrent infections should begin one week after completion of initial treatment and then every 4 to 6 weeks for the rest of pregnancy. Recurrent infections or a first infection in a pregnant woman at high risk of pyelonephritis (see Table 50–2) should be treated with

a 7- to 10-day course of an antibiotic that reflects antibacterial sensitivities.[50] Women who have had two episodes of asymptomatic bacteriuria or cystitis should be considered for low-dose antibiotic prophylaxis—guided by the sensitivities of the most recent infective organism, for the remainder of pregnancy and until 4 to 6 weeks postpartum.[53] Suitable regimes for long-term antibiotic prophylaxis include nitrofurantoin 50 to 100 mg at night, amoxicillin 250 mg at night, cephalexin 125 to 250 mg at night, or trimethoprim 100 to 150 mg at night.[53] These women should also be investigated for structural abnormalities of the renal tracts or renal calculus, using ultrasonography.

SUMMARY OF MANAGEMENT OPTIONS			
Lower Urinary Tract Infections			
Management Options	**Quality of Evidence**	**Strength of Recommendation**	**References**
Prepregnancy			
Identify women at high risk of UTI to screen for asymptomatic bacteriuria (see Table 50–2).	III	B	39,40,43, 44,45
Prenatal Screening			
All women at high risk for pyelonephritis or renal impairment should be screened (see Table 50–2).	III	B	39,40,43,44, 45
Screening in a low risk population is more controversial; possibly base the screening policy on the prevalence of asymptomatic bacteriuria.	Ib	A	32
Prenatal Treatment			
If asymptomatic or symptomatic UTI, treat with nitrofurantoin or trimethoprim or according to antibiotic sensitivities.	III	B	49,50

ACUTE PYELONEPHRITIS

General

The same uropathogens that cause asymptomatic bacteriuria and cystitis are responsible for acute pyelonephritis.[54] Therefore the prevalence of asympto-

matic bacteriuria in a pregnant population (see previous section), dictates the incidence of acute pyelonephritis. Screening and treating a high risk population for asymptomatic bacteriuria (see Table 50–2) reduces the incidence of acute pyelonephritis to less than 1%.[33,36] Unless acute pyelonephritis is treated promptly there is considerable maternal and fetal morbidity.[54]

Maternal Symptoms and Signs

Most women with acute pyelonephritis present in the second and third trimester.[54] Over 80% of women present with backache, fever, rigors, and costovertebral angle tenderness, and about half have lower urinary tract symptoms, nausea, and vomiting.[54] Bacteremia is present in 15% to 20% of pregnant women with acute pyelonephritis,[54] and a small proportion of these women will develop septic shock and increased capillary leak, leading to pulmonary edema.[55] It is important, therefore, to differentiate the hypotension due to reduced intravascular volume (fever, nausea and vomiting) from that due to septic shock. Women with pyelonephritis at risk of serious complications are those who present with the highest fever (>39.4°C), tachycardia (>110 bpm), at more than 20 weeks' gestation and who have received tocolytic agents and injudicious fluid replacement.[56]

Fetal Risks

Acute pyelonephritis can trigger uterine contractions and preterm labour.[57] Antibiotic treatment of pyelonephritis will reduce uterine activity, but those with recurrent infection or marked uterine activity are at increased risk of preterm labour.[57] Because uterine activity often occurs in the absence of cervical change and because tocolysis using β-adrenergics aggravates the cardiovascular response to endotoxaemia,[56] tocolytic therapy should be used with care and only in those with cervical changes.[58]

Management Options

Women suspected of having acute pyelonephritis from their history, symptoms, and signs should be admitted to the hospital. Laboratory tests should include full blood count, SCr, urea, electrolytes, and urine culture. If systemic symptoms or septic shock are present, a blood culture may be useful. Pregnant women with pyelonephritis and septic shock need intensive care. In these women, assessment of the state of hydration is critical and often requires invasive hemodynamic monitoring with a central venous pressure line. This will optimize fluid balance, aiming for a urine output greater than 30 mL/hour to minimize renal impairment and reduce the risk of pulmonary edema. Intravenous antibiotics should be started empirically (see following section) until sensitivities of blood and urine cultures are known. These women often have transient renal impairment, thrombocytopenia, and hemolysis, suggesting that the alveolar capillary endothelium is damaged by endotoxin.[55] A blood film and lactate dehydrogenase concentration will diagnose hemolysis.

Trials investigating the outpatient management of pyelonephritis in pregnancy have identified a group of women who can be treated at home.[58] These women should be at less than 24 weeks' gestation, be relatively healthy, and understand the importance of compliance. They should have an initial period of observation in the hospital to demonstrate their ability to take oral fluids and receive intramuscular cefuroxime/ceftriaxone, and following satisfactory laboratory tests can go home to be seen again within 24 hours for a second intramuscular dose of a cephalosporin. They then start a 10-day course of oral cephalexin 500 mg four times daily or appropriate antibiotic with regular outpatient follow-up.[57] Following this regimen 90% of women will improve as outpatients and 10% will require hospital admission due to sepsis or recurrent pyelonephritis. Women with acute pyelonephritis who are over 24 weeks' gestation should be admitted for at least 24 hours to observe the maternal condition as described earlier and to monitor uterine activity and fetal condition including heart rate.[58]

Choice of Antibiotic

Gram-negative bacteria causing pyelonephritis in pregnancy are often resistant to ampicillin,[59] therefore, intravenous cefuroxime 750 mg to 1.5 g (depending on severity of condition) every 8 hours is an effective first choice until sensitivities are known.[48] Women allergic to β-lactam antibiotics can be given IV gentamicin (1.5 mg/kg /8h) for the initial treatment of acute pyelonephritis. A single-dose regimen (7 mg/kg/24h) should be avoided during pregnancy to reduce the very small risk of eighth nerve damage to the fetus.[50] Serum concentrations of gentamicin should be measured and dose adjustments made according to levels. Intravenous antibiotics should be continued until the patient has been afebrile for 24 hours. Oral antibiotics should then be given for 7 to 10 days, according to bacterial sensitivities, or, if not available, as if for symptomatic lower UTI (see previous section).[50]

Failure of these measures to improve the maternal clinical condition within 48 to 72 hours suggests an underlying structural abnormality. Ultrasonography is an easy but inconclusive way of excluding stones. If clinical suspicion is high, a plain abdominal radiograph will identify 90% of renal stones, and a one-shot intravenous urogram (IVU) at 20 to 30 minutes will identify the rest.[58] The risk to the fetus from radiation of one or two radiographs is minimal, especially when compared with the clinical benefit of identifying an obstructed, nonfunctioning kidney. Urinary tract obstruction can also be detected using magnetic resonance urography, especially during the second and third trimesters.[60]

Following one episode of pyelonephritis, pregnant women should have monthly urine cultures to screen for a recurrence.[58] The risk of recurrent pyelonephritis can be reduced with antimicrobial prophylaxis, according to the sensitivities of initial bacterial infection[53,61] or with nitrofurantoin 100 mg at night continued until 4 to 6 weeks postpartum.[58]

SUMMARY OF MANAGEMENT OPTIONS
Acute Pyelonephritis

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Identify women at high risk of UTI to screen for asymptomatic bacteriuria (see Table 50–2).	III	B	39,40,43, 44,45
Prenatal Screening			
All women at high risk for pyelonephritis or renal impairment should be screened (see Table 50–2).	III	B	39,40,43, 44,45
Prenatal Treatment			
Initial diagnosis of acute pyelonephritis is clinical (symptoms: back/loin ache, fever, rigors, nausea, and vomiting; signs: pyrexia, tachycardia, costovertebral angle tenderness).	—	GPP	—
If acute pyelonephritis is suspected, admit to hospital (if septic shock, admit to HDU/ITU).	—	GPP	—
Investigate: CBC (thrombocytopenia, hemolysis), serum creatinine, BUN, LDH (hemolysis), urine culture, blood culture, ultrasound renal tracts	—	GPP	—
Intravenous fluid if vomiting and/or shocked.	—	GPP	—
Monitor with CVP/PAWP if renal impairment and/or shocked.	—	GPP	—
IV antibiotic; cefuroxime 750 mg–1.5 g q8h or gentamicin 1.5 mg/kg/q8h.	Ia	A	48,50
Switch to oral antibiotic for 7–10 days when apyrexial for 24 h and bacterial sensitivities are known.	—	GPP	—
Repeat MSU 7–10 days after antibiotic course completed.	IV	C	58
Repeat MSU every 4 wk.	IV	C	58
If recurrent UTI:	III	B	53,58,60

BUN, blood urea nitrogen; CBC, complete blood count; CVP/PAWP, central venous pressure/pulmonary artery wedge pressure; HDU/ITU, hemodialysis unit/intensive therapy (care) unit; LDH, lactate dehydrogenase; MSU, midstream urinalysis; UTI, urinary tract infection.

ACUTE RENAL FAILURE IN PREGNANCY

General

Acute renal failure (ARF) is now a rare, but serious complication of pregnancy. In early pregnancy ARF is associated with septic abortion (a complication now largely confined to the developing world) and dehydration related to hyperemesis gravidarum. Around the time of delivery, ARF is most commonly caused by gestational syndromes such as preeclampsia/hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome and abruptio placentae (Table 50–3). Pregnancy is, however, a prothrombotic state, associated with heightened inflammation[62] and major changes to the vascular endothelium,[63] in particular the glomerular capillary endothelium.[64] These physiologic changes predispose pregnant women to acute glomerular capillary thrombosis. Whereas nonpregnant patients who suffer an acute prerenal insult, such as hemorrhage, dehydration, or septic shock, may develop transient acute tubular necrosis (ATN) if inadequately treated, the same prerenal insult in pregnancy is more likely to develop into renal cortical necrosis with permanent renal impairment. This is even more likely to occur if a prerenal insult coexists with a pregnancy-related condition that induces a consumptive coagulopathy or endothelial damage (e.g., preeclampsia/HELLP syndrome).

TABLE 50-3

Causes of Acute Renal Failure in Pregnancy

Most common causes	Placental abruption
	Severe preeclampsia/HELLP
	syndrome
Early pregnancy	Septic abortion
	Hyperemesis gravidarum
	Ovarian hyperstimulation syndrome
Rare causes	Amniotic fluid embolus
	HUS/TTP
	Acute fatty liver of pregnancy.
	Acute obstruction of renal tracts

HELLP, hemolysis, elevated liver enzymes, low platelets; HUS, hemolytic uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

The principles of management are aimed at identification and correction of the precipitating insult and optimal fluid resuscitation, which is best guided by monitoring the central venous pressure (CVP) and ideally pulmonary artery wedge pressure. If oliguria persists despite euvolemia, with deteriorating renal function or fluid overload, then fluid restriction followed by renal replacement therapy is indicated (Table 50-4).

Acute Renal Failure Associated with Preeclampsia (See also Chapters 36 and 80)

General

Preeclampsia rarely causes ARF severe enough to require dialysis.[65] In a cohort of South African women with severe preeclampsia and renal impairment, 7 of 72 (10%) required temporary dialysis and none developed chronic renal failure.[65] All women who needed dialysis either had hemorrhage due to abruptio placentae or HELLP syndrome.[65] Preeclampsia causing mild transient renal impairment (SCr up to 125 μmol/L; 1.41 mg/dL) is common, but with appropriate management, recovery of renal function should be complete (see next section).

Women with preexisting renal disease are more vulnerable to preeclampsia, especially when it is associated with chronic hypertension.[66] A meta-analysis of trials investigating the effectiveness of low-dose aspirin (50–150 mg/day) in pregnant women with moderate to severe renal disease revealed a significant reduction in the risk of preeclampsia and perinatal death.[67]

TABLE 50-4

Indications for Renal Replacement Therapy (RRT), (Dialysis)

Hyperkalemia (K >7.0 mmol/L), refractory to medical treatment
Pulmonary edema, refractory to diuretics
Acidosis producing circulatory problems
Uremia (there is no absolute level of uremia above which dialysis is mandatory for new-onset acute renal failure, but a serum urea over 25–30 mmol/L or SCr >500–700 mmol/L (5.65–7.91 mg/dL) usually indicates a need for dialysis).

Conversely, 2% to 5% of women with preeclampsia have been found to have underlying renal disease when assessed more than 3 months postpartum.[68] Women who have had preeclampsia should therefore be checked for persistent postpartum hypertension and proteinuria. Gestational hypertension usually resolves within 3 months of delivery, but heavy proteinuria due to preeclampsia can take up to 12 months to disappear. Women who have had preeclampsia are more likely to have persistent microalbuminuria compatible with microvascular disease and an increased risk of cardiovascular disease in later life.[69,70]

Women who develop high levels of proteinuria (>10 g/24h) tend to have earlier onset preeclampsia and deliver at an earlier gestational age as compared with preeclamptic women who have less marked proteinuria (<5 g/24h).[71] It is of note, that after correction for prematurity, however, massive proteinuria (>10 g/24h) has no significant effect on neonatal outcome.[71] Increasing proteinuria per se is not therefore an indication for delivery. Pregnant women who develop proteinuria greater than 1 to 3 g/24h (the threshold influenced by other maternal risk factors for thrombosis) should be started on thromboprophylaxis with enoxaparin 40 mg SC (optimal dose) or fragmin 5000 units SC (optimal dose).

The diagnosis of preeclampsia is difficult if there is chronic hypertension and preexisting proteinuria, especially as these two parameters become more marked in late pregnancy. Furthermore, hyperuricemia and IUGR are common features of both preeclampsia and chronic renal impairment, but the presence of raised hepatic transaminases and thrombocytopenia support a diagnosis of preeclampsia.[72]

Management Options for Acute Renal Failure with Preeclampsia

The cure for severe preeclampsia is delivery of the baby and placenta. Delivery may halt the general progression of preeclampsia, but postpartum maternal renal function usually deteriorates before improving.[65] Dialysis is very rarely necessary, but is most common in preeclamptic women who have HELLP syndrome or placental abruption and who double their SCr in the first 24 to 48 hours after admission.[65] Women with preeclampsia who have a rise in SCr from approximately 70 μmol/L (0.79 mg/dL) to greater than 120 μmol/L (1.36 mg/dL) should be delivered to prevent ongoing renal impairment.

Fluid balance is critical to the management of ARF during pregnancy. Too little intravascular fluid leads to prerenal failure, which is especially damaging to chronically impaired kidneys, whereas too much fluid risks pulmonary edema, adult respiratory distress syndrome, and maternal death.[73] Furthermore, transient oliguria (<100 mL over 4 hr) is a common observation in the first 24 hours immediately after a healthy pregnancy. If a preeclamptic woman is not obviously hypovolemic and

has a serum urea less than or equal to 5 mmol/L (14 mg/dL) and SCr less than or equal to 90 μmol/L (1.02 mg/dL) repeated fluid challenges to increase urine output are unnecessary and will only increase the maternal risk of pulmonary edema. Women with severe preeclampsia and renal impairment (SCr >120 μmol/L; 1.36 mg/dL) should have their fluid balance guided by either a CVP catheter or, when available, a pulmonary artery flotation catheter on a intensive care unit familiar with this equipment.[74] The rate of fluid replacement should take account of central venous filling pressure, pulmonary wedge pressure, hourly urine output, and insensible losses. Once euvolemic, the rate of IV fluid replacement should equal the previous hours' urine output plus insensible losses—usually 30 mL/hour, if afebrile. The amount of IV fluid replacement can be reduced, once the mother can take oral fluid and her renal impairment starts to improve. IV fluid regimens that stick to a fixed hourly replacement can lead to fluid overload in oliguric woman and to reduced intravascular volume in those undergoing diuresis. Fluid replacement should include blood to replace blood loses, then isotonic sodium chloride or compound sodium lactate (Hartmann's solution). Dextrose solutions are hypotonic and lead to maternal hyponatremia (5% dextrose contains only 30 mmol/L NaCl, compared with 150 mmol/L NaCl in 0.9% NaCl solution).

Low dose "renal" dopamine infusion (3 μg/kg/min) was previously used to increase renal blood flow in people with ARF. However, a group of 60 South African women with severe preeclampsia and ARF had a similar improvement in urine output and renal function following furosemide infusion (5 mg/hr) as compared with dopamine infusion.[100] Because furosemide has fewer side-effects than dopamine, it is recommended that once hypovolemia has been corrected, as judged by the CVP or pulmonary wedge pressure, preeclamptic women with oliguria (<200 mL/12 hr) and a serum urea greater than 14 mmol/L (39.2 mg/dL) and SCr greater than 500 μmol/L (5.65 mg/dL) may benefit from a furosemide infusion in an effort to avoid hemodialysis.[75] Despite a combination of furosemide followed by low-dose dopamine infusion and vice versa, 13/60 preeclamptic women with oliguric renal failure required temporary dialysis.[75]

Once ATN is established, with oliguria and a rising SCr, despite adequate intravascular volume and BP, fluid intake should then be restricted to avoid fluid overload. Under these circumstances, renal replacement therapy is indicated (see Table 50–4). No good studies have followed women with ARF related to preeclampsia, but those with the most severe renal impairment will undoubtedly be left with a degree of permanent renal impairment that might not manifest until later in life.[65]

Hypertension due to preeclampsia is caused by vasoconstriction around a reduced plasma volume.[72] For this reason and despite the lack of evidence from randomized trials,[76] women with severe preeclampsia often receive plasma volume expansion prior to therapeutic vasodilatation.[77] Unless signs of pulmonary edema are present, (basal crackles and PO_2 <95% on air), 500 mL of colloid or crystalloid given over 30 to 60 minutes, or 250 mL/hour until the pulmonary wedge pressure is 10 to 12 mm Hg, can improve both maternal and fetal well-being in severe preeclampsia.[78,79] A vasodilator given alone can cause profound hypotension that may threaten maternal renal, cerebral, and uteroplacental blood flow.

Acute Renal Failure Associated with the Hemolytic Uremic Syndrome/Thrombotic Thrombocytopenic Purpura

Hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP) are very similar syndromes (from here on designated HUS/TTP). They are characterized by microangiopathic hemolytic anemia and thrombocytopenia. Both congenital and acquired forms of HUS/TTP are more common in late pregnancy.[80] Women with HUS/TTP develop platelet thrombi attached to von Willebrand factor multimers in end-organ microvessels. This typically results in a multiorgan disorder with gastrointestinal ischemia and renal or neurologic impairment.[81] A recently discovered plasma metalloproteinase (ADAMTS13), which normally cleaves von Willebrand factor multimers to prevent microthrombi, is deficient in some women with congenital HUS/TTP,[82] and antibodies that neutralize ADAMTS13 have been found in women with acquired HUS/TTP.[83]

HUS/TTP is more common in women (approximately 70% of all cases) and more common in association with pregnancy (approximately 13% of all cases).[80] During pregnancy, the levels of ADAMTS13 progressively fall.[84] This may explain why women with a congenital deficiency of ADAMTS13 or with other risk factors for thrombosis (e.g., obesity or a thrombophilia) are predisposed to peripartum HUS/TTP.

Hemolytic Uremic Syndrome/Thrombotic Thrombocytopenic Purpura and Preeclampsia

Preeclampsia shares many similarities with HUS/TTP, not least that both syndromes occur most frequently in the third trimester or immediately postpartum. It is, however, most important to differentiate between them, because their management is different. Women with HUS/TTP often present with gastrointestinal or neurologic abnormalities,[80] and they are more likely to have severe renal impairment, hemolysis, and thrombocytopenia compared with women who have preeclampsia. Disseminated intravascular coagulation (DIC) is rare in HUS/TTP, so prothrombin time and kaolin clotting time are usually normal.[81] Women with preeclampsia are more likely to have elevated hepatic transaminases, heavy proteinuria, and abnormal clotting compared with women with HUS/TTP.[72] However, in many women the

distinction between preeclampsia and HUS/TTP can only be determined by the course of the illness following delivery,[85] but here again ARF due to preeclampsia usually gets transiently worse before improving.[65]

Management Options for Acute Renal Failure with Hemolytic Uremic Syndrome/Thrombotic Thrombocytopenic Purpura (See also Chapters 42 and 80)

Maternal survival from HUS/TTP has greatly improved since treatment with plasmapheresis—infusion of fresh plasma and removal of old plasma.[86] Until recently it was unclear why plasmapheresis worked, but the recent discovery of antibodies to ADAMTS13 (removed with old plasma) and a congenital deficiency of ADAMTS13 (replenished with infusion of fresh plasma), gives reason to this process. However, a severe deficiency in ADAMTS13, which is not currently a routine laboratory measurement, is not present in all cases of HUS/TTP, and plasmapheresis is effective in pregnant women who have milder deficiencies of ADAMTS13.[87]

Steroids are often added to the plasma exchange regime and are a rationale choice for acquired HUS/TTP with an autoimmune pathology, but there are no randomized controlled trials of their use. Antiplatelet regimes with aspirin and dipyridamole may also be beneficial in conjunction with plasma exchange.[88] Conversely, administration of platelets to thrombocytopenic patients with HUS/TTP can result in a precipitous decline in clinical status.

Acute Renal Failure due to Acute Renal Cortical Necrosis

Risks and Management Options

In the developed world, acute renal cortical necrosis (ARCN) has become a rare complication of pregnancy. The reduced incidence of septic abortion and improved management of peripartum obstetric emergencies has prevented prerenal impairment developing into ATN and then renal ARCN. In the developing world, however, obstetric emergencies are still responsible for the majority of cases of ARCN.[89] ARF following septic abortion or peripartum obstetric emergencies developed into ARCN in 20% of women following a prolonged period of ATN.[90]

ARCN is most commonly caused by abruption of the placenta with hemorrhage, amniotic fluid embolus, and sepsis associated with DIC.[91] Following hemorrhage or sepsis with hypotension, prerenal failure will, without adequate resuscitation, lead to ATN. If anuria persists for longer than a week, then ARCN should be suspected. A definitive diagnosis can be made with renal biopsy, but is often missed due to the patchy nature of cortical necrosis. Selective renal angiography will also confirm the diagnosis, but introduces another nephrotoxic agent and is usually unnecessary. Due to the serious nature of the precipitating illness and the limited availability of renal replacement therapy in the developing world, maternal mortality is still high.[90] However, for those women who survive the acute illness, renal function usually returns slowly over the next 6 to 24 months. Long-term renal function depends on the extent of cortical necrosis, which is often incomplete. Hyperfiltration through remnant glomeruli usually leads to a subsequent progressive decline in renal function.

Acute Renal Failure Due to Acute Fatty Liver of Pregnancy (See also Chapters 48 and 80)

Risks and Management Options

Acute fatty liver of pregnancy (AFLP) causes reversible peripartum liver and renal impairment in 1:5000 to 1:10,000 pregnancies.[92] The diagnosis is made on clinical and laboratory findings of impaired liver and on renal and clotting function, rather than on histologic or radiologic evidence of a fatty liver.[92] Women with AFLP usually present with nausea, vomiting, and abdominal cramps. Impaired renal function and reduced plasma antithrombin levels are early findings of AFLP that may precede liver dysfunction.[92] In established cases of AFLP, depressed function of the liver with prolonged prothrombin time, hypoglycemia, and DIC are more markedly abnormal than liver transaminases, which may only be moderately elevated.[92] In a series of 28 women with AFLP, other ubiquitous laboratory findings at the time of delivery were elevated serum total bilirubin (mean 128 μmol/L; 7.5 mg/dL), creatinine (mean 205 μmol/L; 2.32 mg/dL), and uric acid levels (mean 654 μmol/L; 11mg/dL).[92]

A recessively inherited fetal inborn error of mitochondrial fatty acid oxidation may explain up to 20% of AFLP.[93] Mitochondrial fatty acid oxidation is important for both normal renal and liver function and may therefore explain the dual vulnerability of these organs in women with AFLP.

In women with AFLP, maternal renal impairment is aggravated by hypotension secondary to hemorrhage, which is itself most likely to follow an emergency operative delivery.[92,94] The combination of renal dysfunction, hemorrhage, and DIC secondary to liver failure during pregnancy or postpartum requires intensive care with a multidisciplinary team of hepatologists, nephrologists, intensivists, and obstetricians. Management is supportive, aimed at maintaining adequate fluid balance for renal perfusion, replacing blood, correcting the coagulopathy with fresh frozen plasma and possibly with antithrombin concentrate and fresh platelets. Hypoglycemia should be corrected with 10% dextrose solutions. Temporary dialysis may be necessary, but with good supportive care, recovery of normal renal and liver function is usual.[92] Perinatal survival in association with AFLP is improving, but depends on the early recognition of the maternal condition, close fetal surveillance, timely delivery, and excellent neonatal care.

Acute Renal Failure due to Nephrotoxic Drugs During Pregnancy

Risks and Management Options

Nonsteroidal anti-inflammatory drugs (NSAIDs), including the more selective COX-2 inhibitors, when given to the mother peripartum, reduce renal blood flow and can cause acute renal impairment to both mother and fetus.[95,96] Women with reduced intravascular volume, especially with preexisting renal impairment, are particularly vulnerable and should be prescribed NSAIDs with caution. Aminoglycosides are also nephrotoxic and should be prescribed with care and attention to drug plasma levels in women with mild renal impairment.

Acute Renal Failure due to Renal Obstruction in Pregnancy

Risks and Management Options

Obstruction of the renal tracts during pregnancy may be due to renal calculi (see later discussion), congenital renal tract abnormalities or a gestational overdistension syndrome. Women born with congenital obstructive uropathies at the pelvo- or vesico-ureteric junction (PUJ or VUJ) are at increased risk for urine outflow obstruction in the second half of pregnancy, even if they have had surgical correction in childhood[97] (Fig. 50–1). Congenital abnormalities of the lower urinary tracts including the bladder and urethra are varied and usually require extensive surgical correction in childhood. During pregnancy, these women are at increased risk of recurrent urine infections and, less commonly, of outflow obstruction requiring either temporary nephrostomy or ureteric stent.[98]

Women with a single kidney and urologic abnormalities are particularly vulnerable to developing postrenal failure in relation to gestational obstruction of their solitary kidney (see Fig. 50–1). An incomplete obstruction can cause renal impairment with an apparently good urine output. High back-pressures compress and damage the renal medulla, leading to a loss of renal concentrating ability and production of dilute urine that is passed through an incomplete obstruction. It is also important for the obstetrician to remember that a congenitally single kidney is often associated with other abnormalities of the genital tracts, such as a unicornuate uterus.[99]

During pregnancy the renal tracts can rarely and spontaneously become grossly overdistended. If untreated this overdistension can very rarely lead to rupture of the kidney or renal tracts.[100] Women with overdistension of the renal tracts initially present with severe loin pain, most commonly on the right side and radiating to the lower abdomen. The pain is positional and inconstant; it is characteristically relieved by lying on the opposite side and tucking the knees up to the chest. A palpable tender

FIGURE 50–1
A postpartum nephrostogram of a dilated collecting system in a solitary cross-fused left kidney that obstructed at 22 weeks' gestation. This 28-year-old primigravida presented with nausea and mild left loin pain and was admitted with severe hypertension 180/110 mm Hg. Her SCr rose from 162 μmol/L (1.83 mg/dL) to 298 μmol/L (3.37 mg/dL) in 3 days, despite a urine output of 4 L/24 hr. Pelvicaliceal dilatation (36-mm diameter) was noted on renal ultrasound, indicating partial urinary outflow obstruction. Within days of a nephrostomy, her symptoms dissipated and the hypertension and SCr had returned to normal; the pregnancy went to 37 weeks. Labor failed to progress and a caesarean section was complicated by an abnormal unicornuate uterus. The nephrostomy remained in situ until 6 weeks postpartum, at which time a ureteric stent was inserted. (Figure shows stent and nephrostomy tube.)

flank mass may suggest renal tract rupture.[100] Rupture of the kidney almost always occurs in a previously diseased kidney, usually in association with a benign hamartoma or renal abscess.[100] Urinalysis will reveal either gross or microscopic hematuria. A renal ultrasound will detect a hydronephrotic kidney with a grossly dilated pelvicaliceal system (see previous discussion for physiologic pelvicaliceal dimensions). Occasionally a urinoma will be evident around the kidney, indicating rupture of the renal pelvis that can sometimes seal spontaneously.

The pain from the overdistension syndrome varies from mild to very severe. Women with mild symptoms can usually be treated with advice on positional relief and regular analgesia. Women with severe unremitting pain, hematuria, and grossly distended renal tracts on ultrasound, in the absence of structural or infected masses, usually have immediate pain relief following decompression of the system with either a ureteric stent or nephrostomy. Rupture of the kidney necessitates immediate surgery and almost invariably an emergency nephrectomy.[100]

Acute Renal Failure

Management Options	Quality of Evidence	Strength of Recommendation	References
Identify and Treat Precipitating Cause			
Severe Preeclampsia			
Delivery	III	B	65
Fluid balance	III	B	74
Furosimde if necessary	Ib	A	75
Dialysis in rare cases	Ib	A	75

Correct clotting, hypoglycemia, and fluid balance			
Urinary Tract Obstruction	III	B	98,100
Correction of obstruction			
Nephrotoxic Drugs	III	B	95,96
Stop			
Monitoring and Optimising Fluid Balance			
Clinical assessment; thirst, urine output (catheter), skin turgor, JVP (difficult in pregnancy).	III	B	150–152
Biochemical SCr, BUN, urine chemistry (but rarely useful).			
If SCr >120 µmol/L (1.36 mg/dL) and clinical uncertainty of fluid balance, use invasive monitoring (CVP/PAWP).			
In severe preeclampsia/HELLP in the absence of pulmonary edema (Po$_2$ > 95% on air), give fluid to expand plasma volume prior to vasodilator.			
Treatment			
Recognize deteriorating renal function despite euvolemia and need for RRT (see Table 50-4).	III	B	150–152
If new onset proteinuria (>10 g/24h and SCr >120 µmol/L) remote from term (i.e., < 30–32 wk), consider diagnostic renal biopsy.			
Proteinuria >1–3 g/24h, give thromboprophylaxis with LMW heparin until 6 wk postpartum or until proteinuria resolves.			

ARCN, acute renal cortical necrosis; BUN, blood urea nitrogen; CVP/PAWP, central venous pressure/pulmonary artery wedge pressure; FFP, fresh frozen plasma; HELLP, hemolysis, elevated liver enzymes, low platelets (syndrome); HUS/TTP, hemolytic uremic syndrome/thrombotic thrombocytopenic purpura; JVP, jugular venous pressure; LMW, low molecular weight; RRT, renal replacement therapy; SCr, serum creatinine.

CHRONIC RENAL DISEASE IN PREGNANCY

General

The effect of pregnancy-related changes on women with preexisting renal disease depends on the type of renal disease; the level of renal impairment; and complications such as hypertension, proteinuria, and infection (Table 50–5). Advice to women with renal impairment regarding pregnancy must take into account all these parameters in an effort to answer the two most important questions:

• What effect will the pregnancy have on the mother's kidney disease?
• What effect will the mother's kidney disease have on the pregnancy?

The Effect of Pregnancy on the Mother's Kidney Disease—Risks and Management Options

The gestational increment in GFR is attenuated in women with moderate renal impairment and absent in those with a SCr greater than 200 μmol/L (2.26 mg/dL).[101-104] Similarly, the gestational increase in blood volume and erythropoiesis is inversely related to the preconception SCr.[103] However, the anemia of renal impairment can be safely corrected during pregnancy with human recombinant erythropoeitin.[105] At all levels of preconception renal impairment, the likelihood of renal damage as a consequence of pregnancy is increased by the coexistence of other factors, in particular, hypertension, proteinuria, and infection.[101-108]

Effect of Pregnancy on Maternal Kidney Disease in Women with Preexisting Mild to Moderate Renal Impairment

Women who become pregnant with renal disease, but with normal or near normal renal function at conception and a SCr <120 μmol/L (1.36 mg/dL) carry only a slightly increased risk of long-term damage to their kidneys from pregnancy compared with women with mild renal disease who had never become pregnant.[102,109] However, more accurate data using creatinine clearance instead of SCr is still needed.

In a large multicenter series, 40% of women with moderate renal impairment (SCr 124–168 μmol/L; 1.49–1.90 mg/dL) had a pregnancy-related deterioration in renal function, which persisted after delivery in about half of the cases.[110,111] In one series, only 1 of 49 (2%) pregnancies in women with an initial SCr below 177 μmol/L (2.00 mg/dL) rapidly declined to ESRF.[110]

Effect of Pregnancy on Maternal Kidney Disease in Women with Preexisting Severe Renal Impairment

Two-thirds of women with a SCr greater than 177 μmol/L (2.00 mg/dL) have a gestational deterioration in renal function that nearly always persists postpartum.[110] Unlike women who have mild to moderate renal impairment, those with severely impaired renal function do not tend to recover their renal function postpartum. One-third of women with a SCr above 177μmol/L (2.00 mg/dL) (creatinine clearance <25 mL/min) will develop ESRF during or following pregnancy.[110]

There is no guarantee that aborting the pregnancy will reverse a decline in renal function. Indeed, women with severe renal impairment who have a gestational decline in renal function requiring dialysis, might consider continuing the pregnancy, (in the absence of other complications), as there is an 80% chance of a live birth outcome when dialysis is started after conception.[112] Women who are established on dialysis with ESRF have no further renal function to lose, but they put themselves at high risk of morbidity from pregnancy complications such as preeclampsia (see following section).

Effect of Pregnancy on Maternal Kidney Disease in Women with Preexisting Proteinuria and Hypertension

Asymptomatic proteinuria (>500 mg/day) detected in early pregnancy, usually indicates underlying renal impairment.[113] These women have an increased risk of preeclampsia (30%), which increases further in those who also have chronic hypertension.[113] Limited postpartum follow-up of women with proteinuria identified in early pregnancy has shown that they have an increased

---

TABLE 50–5

Features Detrimental to Long-term Maternal Renal Function and Pregnancy Outcome

Impaired Renal Function
Preconception SCr >177 μmol/L (2.00 mg/dL) or GFR <25 mL/min. Two thirds of mothers have an accelerated decline in renal function and one third develop ESRF in association with pregnancy. Increased risk of preterm labor, IUGR, and preeclampsia.

Hypertension
Increased risk of preeclampsia, IUGR, and preterm labor and an accelerated decline in maternal renal function

Proteinuria
Nephrotic levels associated with maternal thromboembolism. Variable reports of IUGR, preterm labor, and poorer long-term maternal renal prognosis

Urinary Tract Infections
Increased maternal and fetal morbidity with acute pyelonephritis and preeclampsia and probable increased risk of preterm labor

Reduced Plasma Volume
IUGR

Hyperglycemia
Large-for-gestational-age babies, but with microvascular disease there is an increased risk of IUGR

ESRF, end-stage renal failure; GFR, glomerular filtration rate; IUGR, intrauterine growth restriction; SCr, serum creatinine.

risk of progressive renal impairment.[113] It is therefore most important that women with proteinuria recognized during early pregnancy are investigated for previously occult renal disease and monitored serially throughout pregnancy for changes in renal function, level of proteinuria, BP, and occult urinary infection. Chronic hypertension and preconception proteinuria usually worsen in the third trimester[110] and in most series provoke an accelerated decline in renal function postpartum.[101–108]

Effect of the Mother's Kidney Disease on the Pregnancy—Risks and Management Options

Improved neonatal and obstetric care over the last few decades are responsible for the impressive improvement in neonatal outcome from women with impaired renal function.[101,104,110] However, women with the most severe renal impairment still have the worst fetal outcome.[101,103,110] Furthermore, early pregnancy losses are often ignored in analyses of pregnancy outcome, but are also more common in women with severe renal impairment.[101,114,115]

Effect of Preexisting Mild to Moderate Renal Impairment on Pregnancy Outcome

Women with normal or near-normal renal function have a higher incidence of preterm delivery and IUGR.[102] In a retrospective study of 240 pregnancies in 166 Japanese women who delivered between 1970 and 1988, the perinatal mortality rate was significantly higher if the GFR was less than 70 mL/minute (22%; versus 4% if GFR > 70 mL/min).[116]

Effect of Preexisting Severe Renal Impairment on Pregnancy Outcome

A ubiquitous observation is that a SCr greater than 220 μmol/L is associated with more preterm deliveries and lower birth weights than a lower SCr.[110] In one series, 73% of women with a preconception SCr greater than 221 μmol/L were delivered before 37 weeks and 57% had IUGR, compared with 55% and 31%, respectively, for women who had a SCr less than 221 μmol/L.[110] Neonatal survival was an impressive 100% in the group with severe renal insufficiency.[110]

A cesarean section rate of around 60% is a consistent finding in most series with women who have markedly impaired renal function, but relatively good perinatal outcome.[101,106,110] Therefore, when the fetus is put at risk by maternal disease, it seems inadvisable to prolong pregnancy beyond a point when intact neonatal survival is expected. Although it is difficult to dissect apart the independent contribution to poor fetal outcome of maternal hypertension, proteinuria, and renal impairment, the balance of evidence suggests that each parameter is individually and cumulatively detrimental to fetal outcome.[101-103,114]

Effect of Hypertension on Pregnancy Outcome

In one study, women with moderate to severe renal impairment (SCr 110–490 μmol/L; 1.24–5.54 mg/dL) who were hypertensive at conception or in early pregnancy had a 10.6 times higher relative risk of fetal loss than normotensive women with the same level of renal function.[101] Another study found that if the preconception BP was greater than 140/90 mm Hg, perinatal mortality was 23% versus 4% for normotensives with renal disease.[116] Furthermore, treatment of chronic hypertension before conception reduces the incidence of fetal and maternal complications toward that of normotensive women.[114]

Outside of pregnancy, hypertension related to chronic renal disease is often treated with angiotensin-converting enzyme (ACE) inhibitors or angiotensin II antagonists. These drugs are particularly useful for women with diabetic nephropathy and can be taken up to the sixth week of pregnancy, but due to their effect on fetal renal development and other teratogenic effects, they should be stopped as soon as pregnancy is diagnosed. Some women have continued these drugs throughout the first trimester, without apparent harm to the neonate, but without any detailed assessment of neonatal renal function.

Antihypertensive medications that can be safely used to control hypertension in pregnant women with renal impairment include methyldopa, labetolol, nifedipine SR, or alpha antagonists. Thiazide diuretics mildly attenuate gestational plasma volume expansion and show a trend toward mild fetal IUGR.

Effect of Preexisting Proteinuria on Pregnancy Outcome

One series of women with primary glomerulonephrosis demonstrated a linear relationship between increasing proteinuria and decreasing infant weight,[117] and in another that included 398 pregnancies, there were 34 stillbirths (9%), all associated with significant proteinuria.[114] In another series, women with asymptomatic proteinuria (>500 mg/24 hr) in early pregnancy had 53/57 live births, but 45% were preterm, 23% were complicated by IUGR, and 62% had superimposed preeclampsia.[113] However, in a further series of 82 pregnancies affected by moderate to severe renal impairment, high-grade proteinuria had no effect on pregnancy outcome.[110]

Patients with nephrotic syndrome are at increased risk of thromboembolism, but outside of pregnancy this risk is not usually considered high enough to warrant thromboprophylaxis with heparin. Pregnant women, however, are already in a prothrombotic state, and thromboembolism is a major cause of maternal death.[73] Thromboprophylaxis with low-molecular-weight (LMW) heparin (e.g., enoxaparin 40 mg SC once daily) is therefore essential for all pregnant women with more than 3 g proteinuria per 24 hours, including those with proteinuria due to preeclampsia. In women with 1 to 3g proteinuria per 24 hours, heparin thromboprophylaxis should be considered,

especially if additional risk factors exist, such as obesity (BMI >30), maternal age older than 35 years, cigarette smoking, and immobility. Thromboprophylaxis with LMW heparin should continue for at least 6 weeks postpartum if the proteinuria persists.

Women with heavy proteinuria will often have a low plasma albumin concentration and massive systemic edema. This is particularly seen in some pregnant women with diabetic nephropathy. In order for them to tolerate the pregnancy, small doses of a loop diuretic, furosemide, may be necessary to reduce edema. Thromboprophylaxis with LMW heparin is essential for this group of women.

Prophylactic Low-Dose Aspirin and Pregnancies Complicated by Renal Disease

Women with renal disease often hyperfilter through remaining glomeruli and have microalbuminuria. During healthy pregnancy women develop a prothrombotic and proinflammatory state, which, even if preeclampsia does not occur, is often associated with a degree of glomerular endothelial swelling.[64] If preeclampsia does emerge, the glomerular capillary endothelial cells swell and the narrowed lumen is filled with thrombus.[64] Thrombosis and infarction within a glomerular capillary lead to the loss of a functioning nephron and loss of renal function. Subclinical cortical necrosis due to glomerular capillary thrombosis is a possible explanation for the gestational loss of renal function associated with pregnancies complicated by moderate to severe renal impairment, especially in relation to sepsis due to recurrent UTIs.[104] In an attempt to prevent glomerular capillary thrombi, preserve maternal renal function, and reduce the risk of preeclampsia,[67] the author prescribes prophylactic low-dose aspirin (75 mg/day) throughout pregnancy to all women with a history of renal disease, especially those who have recurrent UTIs and who are immunosuppressed with renal transplants.

SUMMARY OF MANAGEMENT OPTIONS
Chronic Renal Failure

SPECIFIC RENAL DISEASES IN PREGNANCY

Risks and Management Options

Primary Glomerulonephritis

The histologic type of primary glomerulonephritis does not affect pregnancy outcome as much as the clinical parameters, hypertension, proteinuria, level of renal impairment, and incidence of UTIs.[116] Suggestions that certain histopathologic diagnoses have a worse fetal or maternal outcome probably reflect the increased incidence of these clinical complications in certain histopathologic diagnoses.[108,116] However, the presence of severe vessel lesions on renal biopsy has been associated with increased perinatal mortality, but had no significant effect on maternal complications during pregnancy.[114] On the rare occasion that sudden renal impairment (SCr >120 μmol/L; 1.36 mg/dL) or new-onset heavy proteinuria (>5 g proteinuria per 24 hr) occurs before 30 to 32 weeks' gestation in the absence of preeclampsia, a renal biopsy is indicated to exclude a steroid-responsive glomerular disease.

IgA Disease

IgA nephropathy is the most common type of chronic primary glomerulonephritis in young people and is consequently highly represented in pregnant women. Most women with IgA nephropathy who are normotensive and have a GFR above 70 mL/minute have a good obstetric and renal outcome following pregnancy.[108,116] Those women who have a preconception SCr greater than 120 μmol/L (1.36 mg/dL; GFR <50 mL/min), hypertension, heavy proteinuria, and the most severe histologic lesions on renal biopsy are more likely to have an accelerated deterioration in renal function.[108,116]

Women who had Henoch-Schönlein purpura (HSP) with IgA glomerulonephritis as children are at an increased risk of recurrent proteinuric hypertension dur-ing their pregnancies (70% in one series).[118] There are also reports of pregnancy triggering recurrent HSP.[119]

Autosomal Dominant Polycystic Kidney Disease

Women with autosomal dominant polycystic kidney disease (ADPKD) who have normal renal function and BP, usually have a successful, uncomplicated pregnancy.[120] However, preexisting hypertension is a significant risk factor for preeclampsia and fetal prematurity.[120] In one study of 468 live births from women with ADPKD there were no more fetal complications compared with 200 live births from family members who did not have ADPKD.[120] As this is an autosomal dominant condition, the parents must be aware before pregnancy that there is a 50% chance of their offspring being affected.

Reflux Nephropathy

Reflux nephropathy is one of the most common renal conditions in women of childbearing age. Women who had vesicoureteric reflux (VUR) in childhood are at risk of reflux nephropathy in later life. Reflux nephropathy is characterized by renal scarring, reduced GFR, recurrent UTIs, proteinuria, and hypertension. This combination of clinical features makes pregnancy in women with reflux nephropathy particularly high risk. Pregnancy complications include superimposed preeclampsia (≤75%), recurrent UTIs (28%–65%), deterioration of renal function (≤13% have an irreversible decline in renal function), gestational ureteric obstruction requiring drainage (2/47), and increased fetal morbidity and mortality influenced by maternal hypertension and SCr at conception.[104,121,122] Women with reflux nephropathy who have impaired renal function (SCr >110 μmol/L; 1.24 mg/dL) at conception are at particularly high risk of poor pregnancy outcome.[104]

All women with reflux nephropathy, even those who have had VUR successfully treated by ureteric

reimplantation during childhood, should be screened for asymptomatic bacteriuria every 4 to 6 weeks throughout pregnancy (see Table 50–2). Acute pyelonephritis is twice as common in women with persistent VUR than in those who have had spontaneous or surgical resolution of VUR.[104] Following one UTI, low-dose prophylactic antibiotics, chosen according to the sensitivity of the most recent UTI, would reduce the risk of further UTIs and may therefore preserve renal function. Women with persistent VUR, especially those with a history of upper UTI and those who are contemplating pregnancy, should consider prepregnancy correction of VUR to reduce maternal and fetal morbidity.

Women with congenital urologic defects, including reflux nephropathy or PUJ obstruction, are at increased risk of upper renal tract obstruction requiring nephrostomy or stenting, even if they have had urologic correction as children.[121] Throughout pregnancy they should be monitored regularly with serial assessment of renal function (blood urea nitrogen, BUN), midstream urine, and BP. Ultrasonography of the renal pelvis at the end of the first trimester will provide a useful baseline measurement with which to compare future measurements. A repeat ultrasound scan is indicated if there is renal pain suggestive of obstruction, persistent infection, or a rise in SCr in a woman with a single kidney.

VUR is a familial disorder, which affects 20% of infants who have a parent with a family history of VUR, compared with a 1% to 2% frequency of VUR in the general population.[123] Prevention of damaging reflux nephropathy requires diagnosis and treatment before the neonate develops a UTI.[124] Fetal VUR can be detected antenatally by obstetric ultrasound[124] or in newborn babies soon after delivery using cystography, not renal ultrasonography.[123] Evidence for renal scarring can safely be sought in those positive for VUR using a dimercapto-succinic acid (DMSA) radioisotope scan at 3 months of age.[123]

Nephrolithiasis

The incidence of symptomatic renal stone disease during pregnancy is similar to that in the nongravid state.[125] One large series has shown that symptomatic nephrolithiasis affects 1 in 244 pregnancies,[126] despite an apparently ideal environment for renal stone formation that includes gestational renal tract dilatation, urinary stasis, and hypercalciuria. However, during pregnancy there is also increased excretion of inhibitors of stone formation, such as magnesium, citrate, and nephrocalcin, an acidic glycoprotein. Symptomatic renal calculi are, however, more common in whites than African Americans and in multigravidas than primigravidas.[125,126] Renal colic is also more common in the second and third trimester.[125,126]

One large series including 90 pregnancies in 78 women with renal stones, found an increased frequency of UTIs.[127] UTIs associated with renal stones should be treated for longer than isolated UTIs and followed up with antibiotic prophylaxis. Another large series found that women with symptomatic renal stones had an increased risk of preterm rupture of membranes,[126] possibly related to the increased frequency of urinary infection.

Acute Renal Colic

Pregnant women in the process of passing a renal calculus usually develop severe colicky lumbar pain, associated with fever, lower UTI, and hematuria. An ultrasound of the renal tracts will identify a renal calculus in about half of these women.[128] In those women with a normal ultrasound, but symptoms still suggestive of a renal calculus, a kidneys, ureters, bladder (KUB) and single-shot IVU radiocontrast study can identify most other renal calculi.[129] However, in an effort to avoid even a small dose of radiation to the fetus, magnetic resonance urography has recently been used to differentiate between physiologic urinary tract dilatation and obstruction due to calculi.[60]

Initial conservative management of renal colic during pregnancy will result in up to 75% of women passing their stones spontaneously.[128,129] Women must be well hydrated, given pain relief with meperidine (pethidine) and antibiotics. Continued symptoms may necessitate passage of a ureteric stent, but this is difficult to do without radiologic guidance. A percutaneous nephrostomy is another option, especially for an obstructed single kidney, but the nephrostomy is likely to have to remain in place for the rest of the pregnancy.

Recent advances in fiberoptics have allowed the development of holmium laser lithotripsy. This technique allows a ureteroscope to be passed into the upper renal tracts, facilitating direct stone crushing energy to within 0.5 mm of the laser fiber tip. This technique has been successfully and safely used in all stages of pregnancy.[130]

Women who are recurrent stone formers with persistent gross hypercalciuria, despite increased fluid intake, can use thiazide diuretics in pregnancy to increase distal tubular reabsorption of calcium. Uric acid and cystine stones rarely form in pregnancy owing to the physiologic alkalinization of the urine. If problematic, both conditions may be controlled by increasing urine output and further alkalinizing the urine to a pH above 6. During pregnancy, xanthine oxidase inhibitors for uric acid stones and D-penicillamine for cystine stones should probably be avoided, especially during the first trimester.

SUMMARY OF MANAGEMENT OPTIONS
Nephrolithiasis, Renal Colic

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Identify women with renal calculi; for 4–6 weekly MSU during pregnancy; consider definitive treatment to remove calculus.	III	B	60,127–129
Prenatal			
If UTI with renal calculi, treat for 10 days then give prophylactic antibiotics.	IV	C	127
If renal colic:	III	B	128,129
• Give IV NS and pain relief (pethidine rather than NSAID even in first or second trimester).			
• Identify renal calculus with KUB, or single-shot IV urography, or MRU, if available.			
• Most (75%) renal calculi will pass spontaneously.			
Renal calculi causing obstruction, especially in a single kidney, need treatment with a uretric stent or nephrostomy, or ureteroscopic holium laser lithotripsy, if available.	III	B	128–130
Postnatal			
Definitive removal of obstructing calculus	III	B	128–130

IV, intravenous; KUB, kidneys, ureter, bladder; MRU, magnetic resonance urography; NS, normal saline; NSAID, nonsteroidal anti-inflammatory drug; UTI, urinary tract infection.

Diabetic Nephropathy (See also Chapter 45)

Diabetic nephropathy eventually affects about 30% of all patients with type 1 (insulin-dependent diabetes mellitus, IDDM). Before the onset of renal impairment and proteinuria, there is glomerular hyperfiltration and increased urinary albumin excretion—microalbuminuria. The hyperfiltration of early diabetic nephropathy is damaging to the glomerulus, as it is mediated by an increase in glomerular capillary pressure. The increase in renal blood flow due to pregnancy further augments the hyperfiltration of early diabetic nephropathy, but this only partly explains the transient rise in microalbuminuria (30–300 mg albuminuria) and preexisting proteinuria during the third trimester.[131]

Microalbuminuria in early pregnancy is, however, associated with an increased prevalence of preeclampsia and as a consequence preterm delivery.[132] An elevated glycosylated hemoglobin (HbA_{1c}) in the first trimester,[132] prepregnancy duration of diabetes,[132] and maternal blood pressure[133] are all independently associated with an increased risk of preeclampsia. However, improved perinatal care is allowing approximately 95% perinatal survival.[133]

Pregnancy in women with type 1 diabetes does not precipitate the onset of diabetic nephropathy, and those who have established diabetic nephropathy with well-preserved renal function do not progress more rapidly to ESRF as a consequence of pregnancy.[134] Conversely, the majority of women with diabetic nephropathy and moderate to severe renal impairment (SCr >124 μmol/L; 1.4 mg/dL) have more than a 40% chance of an accelerated decline in renal function associated with an exacerbation of hypertension or preeclampsia.[135]

Due to the risk of an accelerated decline in maternal renal function, pregnancy should be discouraged in women with diabetic nephropathy who have a GFR lower than 70 mL/minute, (SCr >124 μmol/L; 1.4 mg/dL), especially in association with uncontrolled hypertension. If pregnancy occurs in this group of women, they must understand the risks to their own renal function and the importance of regular antenatal care. Good control of maternal blood glucose levels and hypertension before conception and during pregnancy will improve both perinatal and maternal outcome.[133] If maternal BP remains persistently over 130/90 mm Hg, a calcium-channel blocker can be safely used throughout pregnancy to lower systemic pressures to protect maternal kidneys and reduce the risk of preeclampsia. Low-dose aspirin (50–150 mg/day) also has a role in reducing the risk of preeclampsia in women with diabetic nephropathy.[67]

Women with diabetic nephropathy who develop nephrotic syndrome are at increased risk of thromboembolism during pregnancy and for 6 weeks postpartum. These women should receive thromboprophylaxis with LMW heparin if proteinuria exceeds 1 to 3 g/24 hours, depending on the presence of other risk factors, such as obesity, smoking, age older than 35 years, history of thrombosis, and immobility. Diuretics used with caution may have a role in the symptomatic relief of gross edema.

SUMMARY OF MANAGEMENT OPTIONS
Diabetic Nephropathy (See also Chapter 45)

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Advise that pregnancy with diabetic nephropathy and SCr >124 µmol/L; 1.4 mg/dL at conception is associated with a 40% risk of gestational decline in renal function	III	B	134,135
Advise that increased risk of adverse pregnancy outcome	III	B	132
Try and achieve euglycemia	III	B	133
Prenatal			
Every 4–6 wk monitor BP, BUN, Glucose, MSU until 24 wk, then every 2 wk until 32 wk, then weekly	III	B	132,134,135
Try and achieve euglycemia	III	B	133
Give aspirin 75 mg once daily to reduce risk of preeclampsia	Ia	A	67
Control hypertension to <140/90 mm Hg	III	B	133
Screen for preeclampsia; fetal surveillance	III	B	132,134,135
Give LMW heparin when >1–3 g proteinuria/24h and hypoalbuminemia	–	GPP	–
A diuretic may be necessary for symptomatic relief of gross edema with nephrotic syndrome	–	GPP	–
Postnatal			
Reassess renal function (GFR) postpartum	III	B	134,135

BP, blood pressure; BUN, blood urea nitrogen; GFR, glomerular filtration rate; LMW, low molecular weight; MSU, midstream urinalysis; SCr, serum creatinine.

Lupus Nephritis (See also Chapter 44)

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disorder that predominantly affects young women and is characterized by a relapsing and remitting course. Renal involvement (lupus nephritis) is recognized by proteinuria, elevated SCr, hypertension, and often thrombocytopenia and hyperuricemia. Consequently, a relapse of SLE during the second half of pregnancy is difficult to distinguish from preeclampsia. Clinical features that may be discriminatory are the presence of hematuria and red cell casts in active lupus nephritis, as well as extrarenal manifestations affecting the skin and joints. The laboratory findings of active SLE include consumption of complement (C3 and C4), which is not consumed during preeclampsia,[136] and a rising titer of double-stranded DNA antibody. The erythrocyte sedimentation rate (ESR) can reach as high as 70 in healthy pregnancy and is therefore not useful in identifying a flare of lupus nephritis during pregnancy. The C-reactive protein (CRP) level is unchanged in active lupus. If there is clinical doubt remote from term (before 32 weeks' gestation), a renal biopsy may help to differentiate between active lupus nephritis and preeclampsia.

Women with quiescent lupus nephritis, absent antiphospholipid antibodies (APL ab), normal or near normal renal function (SCr <120 µmol/L), limited proteinuria (< 500 mg/24 hr), and controlled hypertension for at least 6 months before conception can expect a good fetal and maternal outcome.[137,158] Relapses of SLE are more common in pregnant women who have had more than three flares before pregnancy, who have APL ab, C3 hypocomplementemia, and hypertension. Women with active lupus nephritis at conception, especially in association with proteinuria, hypertension, and APL ab, have an increased risk of early pregnancy loss, IUGR, preterm

delivery, preeclampsia, and perinatal and maternal mortality.[138] The presence of maternal APL ab is specifically associated with an increased risk of early pregnancy loss and extractable nuclear antibodies (ENA: anti-Ro and anti-La) are associated with an increased risk of congenital fetal heart block.

Prednisolone, azathioprine, and hydroxychloroquine have all been safely used to control SLE during pregnancy for many years. A flare of lupus nephritis during pregnancy is usually treated with IV methylprednisolone 500 mg daily, for 3 days, and an increase of oral prednisolone to around 40 mg daily. Steroid-resistant and progressive lupus nephritis has been successfully treated during pregnancy with IV cyclophosphamide. However, when a severe flare of lupus nephritis occurs during pregnancy, the effects of this life-threatening condition on the mother need to be balanced against the likelihood of a successful fetal outcome. Difficult decisions regarding continuation of the pregnancy sometimes need to be made. Additional treatment includes antihypertensive medication to control BP to ≤140/90 mm Hg and thromboprophylaxis with low-dose aspirin and LMW heparin, especially in the presence of APL ab and proteinuria greater than 1 g/24 hours. Lupus nephritis is slightly more likely to flare postpartum, but the consensus is not to use prophylactic steroids peripartum, unless there are signs of disease activity.[137]

SUMMARY OF MANAGEMENT OPTIONS

Lupus Nephropathy (See also Chapter 44)

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Advise to postpone pregnancy until at least 6 months in remission	III	B	138
Advise increased risk of adverse pregnancy outcome, if previous frequent relapses, (SCr >120 μmol/L; 1.36 mg/dL), BP >140/90 mm Hg	III	B	137,138
Advise of significance of ENA to fetus	III	B	138
Prenatal			
Prednisolone, azathioprine, hydroxychloroquine to be used to treat lupus nephritis as necessary	III	B	137
Recognize lupus nephritis flare—rise in dsDNA antibodies and consumption of complement	III	B	136
Treat lupus flare with prednisolone/methylprednisolone	III	B	137
Surveillance for	III	B	138
• Preeclampsia			
• Poor placental function			
• Fetal congenital heart block if ENA positive			
Thromboprophylaxis with LMW heparin if >1 g proteinuria	—	GPP	—
Postnatal			
Advise increased risk of postpartum lupus flare, but no need for prophylactic increase in immunosuppression	III	B	137
Some advise limited breast-feeding if on azathioprine but no strong evidence to support this	—	GPP	—

dsDNA, double-stranded DNA; ENA, extractable nuclear antibodies; LMW, low molecular weight; SCr, serum creatinine.

CHRONIC DIALYSIS AND PREGNANCY

Women with ESRF have reduced fertility, but improvements in hemodialysis and the use of erythropoietin to treat chronic renal failure-induced anemia have increased the likelihood of women conceiving and of producing a surviving infant.[139] The incidence of pregnancy in women on hemodialysis is variably reported between 0.44% and 7%, depending on the criteria that define the female dialysis population.[140] Up to 60% of reported pregnancies now result in a live infant,[105,140] but 80% of pregnancies are preterm at around 32 weeks.[105,140] High fetal urinary urea causes an osmotic diuresis, which probably explains why polyhydramnios affects more than 50%

of such pregnancies. Premature rupture of membranes and maternal hypertension are other causes for preterm delivery.

Women on peritoneal dialysis (PD) are less likely to conceive than women on hemodialysis.[140] Furthermore, as pregnancy progresses the physiologic demands of pregnancy are increasingly difficult to meet by increasing the number of PD exchanges. There are, however, many case reports of successful pregnancies in women on PD.[141] Complications include peritonitis that should be treated in the same way as for nonpregnant patients with intraperitoneal antibiotics and awareness of drug levels.

The key to a successful pregnancy for women with ESRF is that their renal replacement therapy should match as closely as possible the healthy gestational changes to kidney function. This requires knowledge of the timing and extent of these pregnancy-related changes and a willingness by the woman to eventually have almost daily hemodialysis and monitoring. Frequent dialysis should aim to keep the predialysis serum urea at less than 17 mmol/L (BUN <50 mg/dL). This strategy will also reduce the need for large volumes of fluid to be removed at any one time and is therefore less likely to compromise uteroplacental blood flow. In those women who have some residual renal function or who can still produce urine, fluid balance is easier to manage, which increases the likelihood of a successful pregnancy outcome.

Women who increase their dialysis regimen to more than 20 hours per week are also more likely to have a successful pregnancy outcome.[141] Further improvements are likely with more than 24 hours per week.[139] Fluid balance and weight gain should recognize an average gestational weight gain of 1 pound (0.5 kg) per week during the second and third trimesters.[142] Maternal BP should be kept just under 140/90 mm Hg. Rises in BP might initially respond to extra fluid removal, but resistant hypertension in a euvolemic woman may herald gestational hypertension requiring antihypertensive medication.

Increased dialysis will, however, lead to hypokalemia and a higher concentration of potassium in the dialysate, or potassium supplements may be necessary. Furthermore, a gestational reduction in serum sodium concentration necessitates a concomitant reduction in dialysate sodium concentration to around 135 mmol/L, and the gestational reduction in serum bicarbonate concentration (18–22 mmol/L) should be matched with a low bicarbonate dialysate.[143] Increased dialysis frequency will also allow for a greater protein intake, which is variably recommended to be between 1.2 and 1.8 g/kg/day.[140]

Anemia and hemorrhage are common in the dialysis population. Serum iron and Hb levels need to be monitored monthly, and iron supplements with erythropoietin given to maintain a Hb between 10 and 11 g/dL. The dose of erythropoietin needs to increase by 50% to 100% in pregnancy. It does not cross the placenta, to consequently there have been no reports of teratogenicity or polycythemia in the infant.[141,144] The dialysis circuit should be heparinized as usual. Folate supplementation (2–5 mg/day) is recommended throughout pregnancy, and low-dose aspirin (75 mg/day) taken from shortly after conception may reduce the risk of preeclampsia.[67] The requirement for calcium and vitamin D supplements is also likely to change as pregnancy progresses, and therefore plasma levels of calcium and phosphate need to be monitored and doses of phosphate binders adjusted or stopped accordingly.

Cesarean section is necessary in approximately 50% of pregnancies in women on dialysis. After cesarean section women on peritoneal dialysis will need to have a temporary rest from PD for up to 72 hours, after which time, small 1-L volumes can be used, gradually building back up to 2 L.

SUMMARY OF MANAGEMENT OPTIONS
Chronic Dialysis

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Women on dialysis have reduced fertility, but pregnancy is more likely if optimal Hb and iron status and if hemodialysis rather than PD	III	B	114,140
Advise increased risk of adverse pregnancy outcome (preterm labor, IUGR, hydramnios, and preeclampsia)	III	B	105,140
Prenatal			
Hemodialysis regime to mimic physiological renal changes of pregnancy	III	B	139–141
After 1st trimester, increase the dialysis regime to almost daily (20–24 h/wk) to keep predialysis BUN <50 mg/dL (17 mmol/L).	III	B	139–141
Increase erythropoietin and iron (may need IV iron) to keep Hb 10–11 g/dL	III	B	141,144

SUMMARY OF MANAGEMENT OPTIONS
Chronic Dialysis (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal—Continued			
Recognize gestational weight gain, approximately 0.5 kg/wk in 2nd and 3rd trimester	IV	C	142
Recognize hypertension may be caused by fluid overload before using antihypertensive medicines	—	GPP	—
Give aspirin 75 mg and folic acid 5 mg/day throughout pregnancy	Ia	A	67
Adjust calcium and phosphate binders according to serum chemistry	—	GPP	—
Screen for complications (preterm labor, IUGR, hydramnios, and preeclampsia)	III	B	105, 140
Labor and Delivery			
Cesarean section most likely	—	GPP	—
Women on PD will need temporary hemodialysis	—	GPP	—
Fetal monitoring for last 30 min of hemodialysis	—	GPP	—
Postnatal			
Keep close monitoring of BP and fluid balance	—	GPP	—
Gradually return to nonpregnant dialysis regime over 2 wk	—	GPP	—

BP, blood pressure; BUN, blood urea nitrogen; Hb, hemoglobin; IUGR, intrauterine growth restriction; IV, intravenous; PD, peritoneal dialysis.

RENAL TRANSPLANT PATIENTS AND PREGNANCY (See also Chapter 54)

After renal transplantation a women's fertility usually returns toward normal.[145] Pregnancy should, however, be delayed for around 2 years after transplantation or until renal function and immunosuppressive therapy is stabilised.[145] About 1 in 20 women of childbearing age who have a functioning kidney transplant will become pregnant, and of those that go beyond the first trimester, 90% will end successfully.[146] These pregnancies are, however, more likely to be complicated by preterm labor (50%), preeclampsia (30%), and IUGR (20%).[146] Despite these complications the majority of controlled studies have shown that pregnancy has no influence on long-term maternal renal function if SCr is less than 133 μmol/L (1.5 mg/dL).[145] However, as for all renal disease, obstetric and maternal outcome is worse if there is hypertension, recurrent UTIs, proteinuria, and renal impairment (SCr >133 μmol/L).

Pregnancy does not appear to affect the rate of rejection.[145] However, the plasma levels of cyclosporine usually decrease in pregnancy, and controversy has arisen as to whether the dose of cyclosporine should be adjusted according to plasma levels. Small studies suggest that it is unnecessary to increase the dose of cyclosporine to prevent rejection,[147] and it is the author's practice to keep the

level of immunosuppression the same as prepregnancy levels. Women taking cyclosporine appear to have small-for-gestational-age babies compared with women who take prednisolone and azathioprine.[148] However, cyclosporine is otherwise well tolerated in pregnancy with no increased risk of teratogenesis.

Prednisolone (5–10 mg) rarely causes problems for the neonate, as only small amounts cross the placenta as judged by maternal-to-cord blood ratios of approximately 10:1. Azathioprine passes easily across the placenta, but it is not converted to its active metabolite, 6-mercaptopurine, by the immature fetal liver. It has been taken by thousands of pregnant women over 3 decades and appears to be safe. A series of 100 pregnancies in which the mother took tacrolimus revealed a similar side effect profile to cyclosporine.[149] At present very few women have been treated with mycophenolate mofetil, but successful pregnancies and healthy offspring have been reported. Too few women have received ornithine ketoacid transaminase 3 (OKT3) or antithymocyte globulin (ATG) to recommend their use in pregnancy, but sometimes difficult decisions need to be made between treating steroid-resistant rejection and continuing the pregnancy.

Pregnant women on immunosuppression should receive prophylactic antibiotics for all surgical interventions, including delivery. Furthermore, monthly urine cultures should be taken to screen for asymptomatic bac-

teriuria, which should be treated when isolated. Just one UTI during pregnancy in a transplant patient would be an indication for long-term low-dose antibiotic prophylaxis.[150] During labor, the pelvic kidney does not obstruct labor; therefore, a spontaneous vaginal delivery should be the aim if the maternal and fetal condition remain satisfactory. Cesarean section is, however, necessary in 50% of women with renal transplants.[145] Furthermore, the dose of steroids should be temporarily increased at this physically stressful time. The presence of azathioprine and cyclosporine in breast milk suggests that breastfeeding should be limited, although additional exposure for a few weeks postpartum is unlikely to be harmful compared with in utero exposure over the previous 9 months.

SUMMARY OF MANAGEMENT OPTIONS
Renal Transplant (See also Chapter 54)

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Advise to delay pregnancy until 2 yr post-transplantation	III	B	145
Advise increased risk of adverse pregnancy outcome, though pregnancy does not increase likelihood of rejection	III	B	145,146
Prenatal			
Advise aspirin 75 mg once daily throughout pregnancy	Ia	A	67
Keep maintenance immunosuppression the same as before pregnancy, despite dilutional fall in cyclosporine level	III	B	147,149
Monitor BP, BUN, MSU, proteinuria 4–6 weekly throughout pregnancy	–	GPP	–
Screen for preeclampsia and fetal compromise	III	B	146,148
Labor and Delivery			
Peripartum prophylactic antibiotics	–	GPP	–
Spontaneous vaginal delivery usually possible, despite pelvic kidney	III	B	145
Temporary increase in steroid dose to cover stress of delivery	–	GPP	–
Postnatal			
No good evidence that limited breastfeeding while taking azathioprine and cyclosporine is harmful (≤ 4 weeks)	–	GPP	–

BP, blood pressure; BUN, blood urea nitrogen; MSU, midstream urinalysis.

CONCLUSIONS

Women with chronic renal disease who continue with their pregnancy need extra prenatal screening for and management of:

- Urine infections—The aim is to keep the urine sterile.
- Hypertension—The aim is to keep the BP below 140/90 mm Hg.
- Proteinuria—If it is above 1 g–3 g/24 hour (depending on presence of other risk factors for thrombosis e.g. BMI >30, age >35 years), the aim is to implement thromboprophylaxis with LMW heparin or low-dose aspirin.
- Deteriorating renal function—The aim is to remove or treat the cause of acute renal impairment, effect a timely delivery, and implement dialysis in specific cases.
- Preterm labor—If this is a risk, the aim is to implement tocolytic therapy and management in a center with appropriate neonatal facilities.
- Fetal well-being—The aim is to try and achieve maximum fetal maturity while avoiding irreversible maternal injury or acute fetal compromise.
- Severe acute gestational syndromes need removal or treatment of the nephrotoxic insult, intensive monitoring of fluid balance, and awareness of the need for dialysis.
- Women with ESRF are far more likely to have a successful pregnancy outcome if they have a renal transplant compared with those on dialysis.

Spine and Joint Disorders

Ralph B. Blasier / Michael J. Mendelow

INTRODUCTION

During pregnancy, maternal anatomic changes present mechanical challenges to the musculoskeletal system. Hormonal changes occur that modify the connective tissues and their response to mechanical stress. Complaints of musculoskeletal discomfort during pregnancy are common[1–5] and may be temporarily disabling.[6] These problems usually do resolve spontaneously with completion of pregnancy, but occasionally they may remain as chronic disorders. Some musculoskeletal conditions that exist prior to pregnancy may affect the course of the pregnancy.

LOW BACK AND PELVIC PAIN

General Considerations

Back and pelvic pain has been reported to occur in 48% to 90% of pregnancies.[1–12] Of 855 women followed prospectively throughout pregnancy by Ostgaard, 49% complained of back pain. Of these, 22% noted ongoing back pain at the time they became pregnant, leaving a true incidence rate of 27%. In this series, the back and posterior pelvic pain prevalence rate was 22% to 28% throughout pregnancy, and pain was often present before the 12th week. Kristiansson and colleagues followed 200 women prospectively through pregnancy. They noted prevalence rates of pain of 19% at week 12, gradually increasing to 47% at week 24, with a peak prevalence of 49% at week 36. If mechanical factors were predominant in causing pain, a greater increase in prevalence would be expected with advancing gestation.[1,8] Overall prevalence of back pain with onset before or during pregnancy was 81.5%, but prevalence rates during pregnancy were two to three times greater than those before. Studies of non-pregnant women of similar demographics report prevalence rates of back pain of 20% to 25%. Lumbar pain may be more common during pregnancy in women who noted back pain before pregnancy, whereas onset during pregnancy is more commonly described as sacral pain.[1,8] The findings of Berg, in a study of the pregnancies of 862 women, are similar, with pain in the sacroiliac area being most common (67% of women with pain).[9] The pain has been noted to be so severe that patients are unable to continue to work in 9% to 10% of women and work function and daily routine are compromised in 30% to 36% of pregnant women.[1,8]

The many terms used in the literature such as *sacroiliac joint dysfunction*, *pelvic girdle relaxation*, *pelvic insufficiency*, and even *sacroiliac joint pain* allude to an unjustified knowledge of pain mechanisms and describe a mixed group of patients.[13] More recent prospective studies incorporating pain diagrams, serial interviews, and provocative physical examination[1,10,12,13] have been helpful in our understanding and progress toward rational management. Berg and associates differentiate a *muscular insufficiency*, usually noted by patients having *mild back pain*, from a diagnosis of *sacroiliac dysfunction* made in two thirds of women with severe back pain.[9] The former diagnosis was made in patients with tender paravertebral muscles who had normal range of motion and no neurologic signs. The latter term was applied to patients with evidence of sacroiliac pain or decreased sacroiliac motion on provocative or functional testing (or both). Ostgaard and colleagues suggest the terms *low back pain* and *posterior pelvic pain*.[13]

Hormonal Considerations

Relaxin is a polypeptide hormone. In the human female, production sites for relaxin are the corpus luteum, deciduas, and chorion. Postulated receptor sites and target

organs are the pubic symphysis, myometrium, cervix, placenta, breasts, and skin fibroblasts.[14] Relaxin is thought to relax connective tissue and relax myometrium. The association of estrogen and relaxin with separation of the pubic symphysis has been demonstrated in three orders of mammals, including Rodentia, Primatia, and Chiroptera, presumably those with narrow pelves relative to the size of their offspring.[15] Relaxin values in humans peak in the first trimester.[7,16] The effect of relaxin is remodeling of connective tissue, a side effect of which may be pelvic pain.[7]

MacLennan found relaxin levels to be higher in the first half of pregnancy and decreasing toward the end of gestation. In early labor, levels increase again, but by the third day postpartum, relaxin is almost undetectable.[16] Relaxin levels are higher in the patients with symptoms, and the highest levels were found in women most affected clinically. Moreover, patients with the highest levels took longer to recover after the pregnancy, and some had recurrent high levels and symptoms with subsequent pregnancies. The relationship between hormone levels and joint pain in pregnancy is unclear. Marnach and associates found pain to be associated with elevated levels of estradiol and progesterone, but not relaxin, cortisol, or measured joint laxity.[17]

Mechanical Explanations for Back and Pelvic Pain in Pregnancy

Load on the spine is increased by general weight gain and the weight of the uterus, fetus, and breasts.[11] Theories of increasing lumbar lordosis occurring in response to the more anterior center of mass, and producing increased shear stresses across the motion segments of the lumbar spine have long been entertained.[2,11] The contribution of abdominal musculature to support of the spine may be diminished, and postural adjustments and response to increased loads are required.[18,19] General changes in laxity of supporting soft tissues occur under hormonal influences, and, because of higher receptor concentration, may be concentrated in the pelvic area. A generalized systemic effect on ligaments may cause lower back and posterior pelvic pain, because muscle forces are concentrated in the lumbar and lumbosacral region.[8,11]

Radicular symptoms are commonly noted in pregnancy.[20] This may be caused by direct pressure of the uterus on nerve roots and lumbar and sacral plexi. Bushnell is credited with describing the "parietal neuralgia of pregnancy" as mechanical pressure on nerve roots by ligamentous structures of an increasingly lordotic spine.[21] With descent of the fetus into the pelvis in late pregnancy, radicular symptoms attributed to pressure on the lumbosacral plexus may be experienced.

Ostgaard and colleagues[11] provided a biomechanical analysis, which demonstrates that the flexion moment caused by the more anterior center of increasing mass of the fetus and uterus can be accommodated with large increases in extensor muscle forces and consequential lumbar spine compression forces. Extension of the upper trunk, head, and neck can offset the increase in flexion moment by maintaining a new center of gravity closer to the spine. Ostgaard and colleagues analyzed biomechanical factors and low back pain in 855 pregnant women and found that lumbar lordosis did not increase during gestation. In two separate prospective studies, no correlation was found between spinal configuration and complaints of back pain.[11,22] Hip joint extension, rather than lumbar spine extension, must be a major mechanism used by pregnant women to cope with the increased flexion moment produced by pregnancy.[11] Whether a population of women with back pain has intrinsic limitation of hip extension, or whether women with hip flexion contractures have a greater tendency toward back pain with pregnancy, remains to be studied.

A correlation has been identified between back pain and prepartum lumbar lordosis, suggesting that women with increased lumbar lordosis for any reason prior to pregnancy may be at higher risk for back pain when pregnant.[11] Fast and associates found that, despite expectedly significant differences in abdominal length and in the ability to perform a sit-up, there was no correlation with apparent decrease in abdominal strength and back pain.[18] Ostgaard found that no biomechanical parameter correlated with sick leave for back pain during pregnancy. Sick leave taken correlated with pain intensity and with pain in the sacroiliac joint areas, as opposed to other areas of back pain, suggesting that posterior pelvic pain is more disabling than back pain.[1,23]

Peripheral laxity, followed throughout pregnancy in the prospective back pain study by Ostgaard of biomechanical factors, was measured by presence of *striae distensae*, by serial measurement of ulnar deviation angle of the fourth finger to a defined force, and by Bishop score (a 1–10 scale of cervix "ripeness"). Peripheral laxity was seen to significantly increase from weeks 12 through 20 in primiparous women. Laxity in multiparous women was the same at 12 weeks as that in primigravidas at 36 weeks and did not change during pregnancy. The correlation between increased peripheral laxity and increased abdominal sagittal diameter was strong. These data suggest that an increase in laxity after an initial pregnancy does not necessarily return to normal. All persons lose stature (total height) with physical exertion. Control individuals and pregnant women without back pain regain stature after exertion faster than pregnant women with symptoms of back pain.[24]

A presumed common inheritable disorder called benign joint hypermobility syndrome has been recognized in the medical literature since 1967. At times linked to entities such as fibromyalgia, osteogenesis imperfecta, and Ehlers-Danlos and Marfan syndromes, recent investigation has suggested the underlying pathophysiology for this ill-defined condition may relate to altered colla-

gen synthesis. Grahame and colleagues[25] have attempted to establish specific clinical diagnostic criteria for this constellation of joint-related symptoms. Their revised Brighton criteria for diagnosis include major and minor articular and extra-articular symptoms or physical examination findings. Several lines of investigation have noted an increased incidence of genitourinary relaxation and pelvic prolapse in women with this condition. Relative to spine and joint disorders in pregnancy, this underlying syndrome may add risk to those affected individuals and requires further study.

Lumbar Disc Disease

The association of lumbar disc disease and pregnancy has been suggested by several authors. Relaxin may weaken the annulus of the intervertebral discs.[2,19] LaBan found five patients in a very large series of deliveries to have clinical, electromyographic, and surgically proven findings of herniated lumbar discs, a rare event.[26] Magnetic resonance imaging (MRI) evaluation of pregnant and nonpregnant women revealed the same prevalence of disc abnormalities in both groups. No prospective, controlled studies have related lumbar disc disease to pregnancy. However, the potential for disc herniation and lumbar nerve root compression, with radicular pain and definite neurologic loss, should be considered in the evaluation of the pregnant patient with back pain. Electromyographic studies may be helpful in diagnosis and management. Progressive paralysis or loss of bowel and bladder control require urgent imaging studies, usually with MRI, and urgent surgical decompression.

Vascular Congestion and Night Backache

Back pain in pregnancy has been shown to be common in the evening.[5,12] It has been proposed that this pain is due to increased venous flow through lumbar veins, the vertebral plexus, and paraspinal and azygous veins occurs at night in response to redistribution of an already-large extracellular and venous fluid volume, and that this may be worsened due to mechanical vena caval compression in the supine patient. Edema and increased pressure occur with subsequent pain.

Pain during menstruation, which may be associated with pelvic venous congestion, has been relieved by dihydroergotamine, which causes venous constriction. Patients with symptomatic lumbar stenosis and congestive heart failure have increased symptoms at night, which are relieved with management of heart failure. Venous congestion may be relieved by positional changes, and beyond a search for other musculoskeletal causes, pain that persists should be investigated as a sign of venous pathology, such as proximal venous thrombosis.[2,12]

Sacroiliac Pain, Osteitis Condensans Illii, and an Association with the Inflammatory Processes

Inflammatory changes in the sacroiliac joints are suggested as a cause for sacroiliac pain.[27] "Osteitis condensans illii," as described by Wells, is a "fairly uniform area of increased density in the lower iliac bone, adjacent to the sacroiliac joint, unilateral or bilateral."[28] This finding is most common in women, particularly those who have been pregnant. Of the 67 patients reported by Wells, all were females, 80% had been pregnant, and 30 patients had had low back pain.[28] Shipp and Haggart, in 1950, suggested that the motion or strain associated with pregnancy on the sacroiliac ligaments may explain the finding of osteitis condensans illii most commonly in postpartum women.[29] Wells concluded that there is likely little relationship between back pain and oteitis condensans illii and that the association with pregnancy is due to some unknown mechanism.[28]

Risk Factors

Risk factors for back pain during pregnancy include increasing parity, younger age, back pain before pregnancy, increased lordosis before pregnancy, smoking, and physically strenuous work.[1,8,11,23] Specifically, perceived physical heaviness of work, frequency of twisting and forward bending, and sitting work posture are important risk factors. Housewives had the same prevalence of back pain as working women. Women without previous back pain and women who believed they had a "normal or strong back" were less likely to experience back pain. Pain intensity tends to increase more and to be more severe in younger women.[8]

Risk factors for postpartum pain include twin pregnancy, first pregnancy, higher age at first pregnancy, increased weight of the baby, forceps or vacuum extraction, fundus expression, and a flexed position of the women at childbirth. Cesarean section is negatively associated with persistent postpartum pain.[30]

GENERAL LOW BACK AND PELVIC PAIN

Management Options

Evaluation

History and physical examination can give some insight into pain mechanisms and direct the management of back and pelvic pain. Extraskeletal causes for backache must be considered. Obstetric complications and urologic disorders may present with symptoms ranging from vaginal discharge, flank pain, nausea, vomiting, and dysuria.[31] Atypical presentations of refractory pain may indicate more significant and rare pathology such as disc herniation,

infection, or tumor. Spinal cord tumors, including schwannomas, presenting during pregnancy have been reported. Sacroiliac joint infection has been diagnosed using MRI.[32] Although complaints of back pain are common, vigilance must be maintained if serious diagnoses are not to be missed.

For example, a history of pain at night, a radicular pain distribution, paresthesias, and bowel or bladder dysfunction may herald radiculopathy from nerve root irritation by lumbar disc disease. Differentiation from similar symptoms related to direct fetal pressure on nerve roots, such as paresthesias in the distribution of the ilioinguinal and iliofemoral nerves and even of quadriceps weakness and "giving-way" episodes is necessary.[31] The patient with sacroiliac pain will complain of pain, either unilaterally, or bilaterally. Unilateral pain is more commonly sacroiliac pain than pain from other causes.

Straight-leg raise testing (Lasègue's sign) is performed with the "patient supine, noting the presence and distribution of pain and the angle of lower limb elevation at which it occurs as the examiner raises the straight leg from the examining table by flexion at the hip only." In the normal patient, the angle between the leg and the examining table should reach 70 degrees or more without pain, and the maneuver should not cause any pain beyond hamstring discomfort with stretching. A positive test reproduces the patient's radicular pain and suggests nerve root compression.

Specific provocative tests for assessment of lumbosacral or sacroiliac pain have been described that correlate with, and discriminate more effectively between, specific sources of pain. Being more reproducible, such provocative tests may have greater clinical value.[10,13,27] Posterior superior iliac spine pressure in the standing patient may provoke pain in the sacroiliac region. Sacrospinous and sacrotuberous ligament tenderness by direct pressure during vaginal examination suggests a pelvic contribution to the patient's pain. Symphyseal pain is provoked by direct pressure over the pubic symphysis.

The femoral compression test, or posterior shear or "thigh thrust" test,[10,27] is performed with the patient supine and the hip in 90 degrees of flexion. Axial pressure is applied to the femur. The test is positive if pain is produced in the sacral area or ipsilateral buttock.

The iliac or ventral gapping test involves lateral opening pressure against the medial aspect of the anterosuperior iliac spine, that is, the pelvis of the supine patient is pressed apart.

The iliac compression or dorsal gapping test involves compressive or closing pressure against the lateral iliac

wings of the patient in a lateral decubitus or supine position. Pain provoked in either right or left sacral and or buttock area denotes a positive test.

The Patrick test is performed on the supine patient by flexing, abducting, externally rotating, then extending the hip, placing the ankle of the side being tested across the thigh of the opposite leg. The examiner places one hand on the contralateral pelvis to stabilize it. The test is positive if pain is provoked in the sacroiliac area with the pelvis stabilized. Pain with the pelvis free to roll may be of lumbar origin.

Pelvic torsion, or the Gaenslen test, performed on the supine patient positioned near the edge of the examining table, involves maximum flexion of one hip and simultaneous maximal extension of the other hip held over the edge of the table.[27]

The "Fortin finger test"[33] is considered positive if the patient can localize pain with one finger immediately inferomedial to, and within 1 cm from, the posterior superior iliac spine and if the patient consistently points to this area.

Pain provoked in the groin with rotation suggests the hip itself as a source of the pain, whereas posterior pelvic or symphyseal pain indicates sacral or symphyseal causes. Limitation of extension (flexion contracture) may be associated with increased lumbar lordosis, likely of long duration (before pregnancy) and predisposing to low back pain with pregnancy.[11]

Radiographic evaluation, undesirable during pregnancy, may be warranted if pain cannot be explained by the hormonal, mechanical, and vascular mechanisms, especially if neoplasm or infection is being considered. No harm to the fetus has been demonstrated with fetal exposure of less than 10 rads, a dose much greater than that incurred in a routine spine radiography series or bone scan.[31] MRI may be helpful in diagnosis of tumor and infection, although safety in pregnancy has not been established by long-term follow-up. Mass lesions impinging on nerve roots, such as disc herniations, can be evaluated with electromyographic and nerve conduction studies.[31,32]

Treatment

Most complaints regarding back and pelvic pain during pregnancy require only symptomatic care. Lumbar disc disease, urologic disorders, venous thrombosis, or other vascular or visceral causes for back pain must be considered in refractory or atypical cases.

SUMMARY OF MANAGEMENT OPTIONS
Back and Pelvic Pain—General

Management Options	Quality of Evidence	Strength of Recommendation	References
Evaluation			
Consider extraskeletal causes for backache (e.g., obstetric complications and urologic disorders).	IV	C	1,2
Atypical presentations or pain refractory to the usual care may indicate more significant, although rare, pathology (e.g., disc herniation, infection, tumor).	IV	C	3,63
Differentiation from similar symptoms from direct fetal pressure on nerve roots (e.g., paresthesias in the distribution of the ilioinguinal and iliofemoral nerves and even of quadriceps weakness and "giving-way") is necessary.	–	GPP	–
Routine examination includes inspection of the patient while she is standing, then while bending forward, followed by palpation about the spine, paraspinal area, and sacrum.	–	GPP	–
Radiographic evaluation, although undesirable during pregnancy, may be warranted if insidious causes for pain are suspected.	IV	C	3
MRI may be particularly helpful in the diagnosis of tumor and infection.	–	GPP	–
Mass lesions compressing nerve roots, such as disc herniations, can be initially evaluated with electromyographic and nerve conduction studies without exposure to radiation.	–	GPP	–
Treatment			
Daily low back exercises help develop abdominal tone with standing, lateral bending, and rotational trunk exercises.	IV III	C B	1,2 76
The pelvic tilt exercise, anecdotally provides marked relief of low back pain.	IV III	C B	1,2 76
Simple measures taught in back care programs, such as placing one foot on a foot stool when standing for a prolonged period, can give some relief.	IV III	C B	1,2 76
For mild to moderate pain, general comfort measures including rest, activity modification, and physical therapy, including massage and pelvic and low back exercises, as well as general back care are helpful.	IV III	C B	1,2 76
For night pain, the use of a "maternity cushion" may give relief.	Ib	A	77
Elastic compression stockings worn throughout the day may, by limiting lower extremity edema, diminish the fluid shifts and venous engorgement that occur at night.	–	GPP	–
Analgesic options are limited, and nonsteroidal anti-inflammatory drugs (NSAIDs) should be specifically avoided because of concern for potential adverse fetal effects.	–	GPP	–
Persistent pain, including discogenic pain, not responsive to rest, may benefit from lumbar epidural steroids.	–	GPP	–
Transcutaneous electrical nerve stimulation (TENS) may be helpful.	–	GPP	–
Muscle weakness is a concern, but only acute loss of bowel and bladder function or acute paralysis would indicate a need for decompressive surgery during pregnancy.	IV	C	63
Mobilization techniques applied to the sacroiliac area have been reported to provide relief, commonly permanent, in some women.	IV III	C B	1,2 8,76
Treatment with a trochanteric belt provides relief, particularly for women with posterior pelvic pain.	IV III	C B	1,2,13 8
Sacroiliac injection with corticosteroids and local anesthetic may be indicated in severe cases.	–	GPP	–

SPONDYLOLYSIS AND SPONDYLOLISTHESIS

Spondylolysis is a bony insufficiency at the pars interarticularis of the spine. The condition can cause instability and pain. Spondylolisthesis is the slipping forward of one vertebra on another. This can result from a spondylolytic defect, or from degenerative change in the facet joints.[19,34] Depending on the cause and the nature of the defect, the disorder is classified into five different types. Dysplastic and isthmic spondylolisthesis represent congenital and developmental disorders, which have a high familial incidence. These slips are more common in males than females (2:1), although females have a higher chance of progression. These slips most commonly occur at the L5–S1 level. The condition probably develops or presents in the first two decades of life with the diagnosis most often being made in adolescence.[18,29,30]

Risks

The influence of pregnancy on spondylolisthesis is an interesting issue, but little has been written on the subject. Saraste[35,36] provided a long-term review of 255 patients with isthmic and dysplastic spondylolysis, diagnosed at between 9 and 40 years old, with average age at diagnosis of 24 years. The length of follow-up ranged from 20 to 44 years. A comparison of the 171 men, 21 nulliparous women, and 63 parous women, showed no significant differences in symptomatology, impairment, degree of slip, or progression of slip. Moreover, spondylolysis, with or without spondylolisthesis, was not a risk factor for pregnancy complications.

Degenerative spondylolisthesis usually occurs at the L4–L5 level and presents later in life and more commonly in women than in men (4:1). Sanderson and Fraser found, in a review of radiographs of 949 women, that those who had borne children had a significantly higher incidence of degenerative spondylolisthesis than those who had not. Nulliparous women had twice the incidence of degenerative slips as men. Proposed explanations for their findings include the generalized increase in laxity of pregnancy and residual relative joint relaxation, and the effects of relaxin on the collagen of the facet joint capsules and of the annulus of the intervertebral disc.[19]

Women have generally greater joint laxity than men. Possibly, compromised abdominal musculature in parous women may allow perpetually increased sheer and rotatory stresses at the L4–L5 joints.[19]

Management Options

The management of spondylolysis and spondylolisthesis during pregnancy differs little from that in the nonpregnant patient. Symptomatic relief can be obtained by rest and immobilization. The choice of analgesic is limited in pregnancy and should not include aspirin or nonsteroidal anti-inflammatory agents. In the event that significant neurologic impairment is suspected, consultation should be obtained emergently.

SCOLIOSIS

Scoliosis is a three-dimensional deformity of the spine, most prominently manifested by curvature in the coronal plane. The disorder is usually idiopathic, commonly familial, and presents and progresses most dramatically during the adolescent growth spurt. Spinal curvature may also be due to congenital defects in the vertebral bodies, to spinal cord disorders, to intracranial pathology, or to muscle spasm and back pain. Scoliosis is more common in females than in males.

Risks

The influence of pregnancy on preexisting scoliosis, particularly with regard to curve progression, has been controversial. An increase in curve progression during pregnancy has been demonstrated in scoliosis patients in small series. In particular, those treated with bracing who have multiple pregnancies before age 23, those with curves greater than 25 degrees, and patients who already had ongoing curve progression at the time of the pregnancy, have been found to have increases in their curves during pregnancy. Subsequent reviews have not found the same associations.[37–39]

Betz and colleagues[32] retrospectively reviewed 355 women with idiopathic scoliosis who had reached skeletal maturity. Two groups, 175 who had had at least one pregnancy and 180 who had never been pregnant, were compared. No effects on curve progression during pregnancy were demonstrated with regard to age of the patient at the time of pregnancy, ongoing progression of the curve at the time of pregnancy, the number of pregnancies, or the presence of a spinal pseudarthrosis (incidence 77%). Those having severe back pain during pregnancy (12%) may be slightly higher in unfused patients with scoliosis than in nonscoliotic patients. In patients who had undergone posterior spinal fusion, no progression of the unfused portion of the curve was demonstrated. In these patients, no problems during the pregnancy were attributed to the scoliosis.

In 159 deliveries of women who had scoliosis without a spinal fusion, spinal anesthesia could not be administered in two because of the scoliosis, and cesarean section was necessary in 12 (7.4%) for reasons unrelated to the scoliosis. In patients who had undergone posterior fusion, two patients had minor problems during delivery related to the fusion. In one, spinal anesthesia could not be administered, and in the other, proper positioning was difficult. The incidence of complications or deformity in the newborn was not increased.

In the series by Betz and colleagues,[37] postpartum back pain in scoliotic women or women with scoliosis who had

not been pregnant was no greater than in the general population. As in other series, potential for progression of curves greater than 30 degrees during adulthood at a general rate of 1 degree per year was seen. However, increased progression, especially of the 6 to 8 degrees per pregnancy previously reported, was not found. They recommend that, for women of childbearing age with curves greater than 30 degrees, radiographs should be done soon after each delivery to minimize the potential for fetal exposure.[37,39]

Management Options

Prepregnancy and Prenatal

The influence of pregnancy on preexisting scoliosis, particularly with regard to curve progression, has been controversial. The affected patient should be counseled that no significant increase in the rate or incidence of curve progression during pregnancy has been demonstrated in large series of pregnant scoliosis patients compared with nonpregnant ones. In patients who had undergone posterior spinal fusion, no progression of the unfused portion of the curve is seen in the majority.

Labor and Delivery

In patients who had undergone posterior fusion, 1.5% have minor problems during delivery related to the fusion. In one report, spinal anesthesia could not be administered, and in another, proper positioning for delivery was difficult. Overall, less than 3% of deliveries in women who had undergone posterior spinal fusion for scoliosis had problems requiring cesarean section. The indications for section were unrelated to the fusion or the scoliosis. The incidence of complications or deformity in the newborn was not increased in patients who had undergone posterior fusion for scoliosis.

Postpartum

Scoliotic women show no increase in postpartum back pain compared with women with scoliosis who had not been pregnant. Therefore, no specific postpartum recommendations are offered. In general, for women with curves greater than 30 degrees, radiographs should be done every 2 years up to age 25, and every 5 years thereafter. Appropriate radiographic and clinical evaluation by a surgeon who manages scoliosis should be considered in the months following delivery, taking the opportunity to have a radiograph when pregnancy is unlikely.

PELVIC ARTHROPATHY AND RUPTURE OF THE PUBIC SYMPHYSIS

Pelvic arthropathy usually occurs in two recognizable syndromes, though there may be overlap between them:

- Abnormal mobility of the pelvic joints may lead to pain and a waddling gait; or
- After a difficult delivery, there may be a rupture of the symphysis.

PELVIC ARTHROPATHY

The increased lumbar lordosis caused by the weight and position of the developing fetus increases the stress on the lumbosacral junction and the sacroiliac joints. In patients with a more sagittal than oblique orientation of these joints, there is less inherent stability, and there may be a predisposition to pelvic laxity. Under hormonal influence, the ligaments of the pubic symphysis and the sacroiliac joints relax during the first half of pregnancy, returning to normal in the typical patient at 6 months postpartum. Excessive relaxation of the ligaments of the pelvis may cause symptoms at about the sixth or seventh month, consisting of pain with walking, turning in bed, or other exertion. There may be a unilateral limp or even a bilateral waddling gait. The pain may rarely be so severe that standing or walking is precluded. Asymmetrical sacroiliac laxity (right different from left) is much more strongly associated with pelvic pain than is the absolute amount of laxity.[40–42]

In some cases, symptoms appear only during labor, due to excessive loosening of the symphysis and sacroiliac joints. Separation of the pubic symphysis during pregnancy is common, varying between 0 and 35 mm (average 7–8 mm). Separation over 8 to 9 mm is considered pathologic. Rupture of the ligaments of the pubic symphysis may occur during labor as a result of forceps delivery, especially in case of fetal/pelvic disproportion. Patients often complain of prelabor pain in the pubis and sacroiliac joints. During and after labor, the patient may complain of pain over the symphysis and sacroiliac joints, radiating down the thighs. The lower limbs are externally rotated, and she may be unable to walk normally for weeks or months. The diagnosis is made with a history of pregnancy, pain at the pubic symphysis or the sacroiliac joints, tenderness at the pubic symphysis or the sacroiliac joints, and excessive laxity of the ligaments. A gap may be felt at the symphysis externally or by vaginal examination. Relaxation of the symphysis can be ascertained by placing the examiner's fingers on the superior edges of the pubic bones and noting vertical translation during walking. A prevaginal examination of the symphysis can be made while an assistant pulls down on one of the patient's ankles while pushing up on the other.

Ultrasonography has been used to confirm the diagnosis, with symptomatic patients having a symphyseal gap of 20 mm (range 10–35 mm) and asymptomatic controls 4.8 mm (range 4.3–5.1 mm).[43,44] MRI has been used to diagnose postpartum pubic and pelvic pin, but its clinical benefit has not been established.[45,46]

Management Options

Treatment is generally by rest, with or without a pelvic band or girdle. Some investigators report treatment with early injection of steroid or local anesthetic or use of oral anti-inflammatories. A limited number of reports mention pelvic arthropathy with onset 1 to 2 days after delivery, characterized by pain and tenderness at the symphysis, but without swelling or bruising and without widening or abnormal mobility of the symphysis. Symptoms abate within a week or two with rest and analgesics. It has been speculated that this is caused by swelling and pressure within the fibrous confines of a relatively normal pubic symphysis.[47]

RUPTURE OF THE PUBIC SYMPHYSIS

Separation of the pubic symphysis in association with labor and delivery is rare and is sometimes unrecognized when it does occur. Some widening of the pubic symphysis has been noted as being necessary for normal delivery, and some widening normally does occur. Rarely, the separation is greater than 10 mm, and this is usually symptomatic.[48] The pubic symphysis comprises a thick fibrocartilagenous disc between two thin layers of hyaline cartilage covering the articular surfaces of the bone. It is held together by four ligaments: the anterior pubic (strong), the superior and inferior arcuate, and the posterior pubic (weak). Progesterone and relaxin are known to increase the elasticity of the pubic ligaments. A slight widening of the symphysis occurs during a normal pregnancy, but not normally more than 8 to 9 mm. Occasionally, actual rupture of the pubic symphysis may occur.[48] Occasionally, the onset of pain may be abrupt and may even be accompanied by an audible "crack."[49] Associated factors may include hard labor, precipitous labor, difficult forceps delivery, cephalopelvic disproportion, abnormal presentation, multiparity, forceful abduction of the thighs, or previous pelvic trauma.[30,48,50–54] Estimates of incidence range between 1/500 and 1/30,000.[48,49] The incidence appears to be decreasing over time, as many difficult vaginal deliveries are being replaced by cesarean section.[48] Separations of as much as 120 mm have been reported, and the sacroiliac joints become affected with more than 40-mm separation.[48]

Management Options

Treatment may begin with tight pelvic binding and rest in the lateral decubitus position. Symptoms may last as little as 2 days, typically 8 weeks, or (reportedly) up to 8 months.[48] For inadequate reduction, recurrent diastasis, or persistent symptoms, external skeletal fixation is the treatment of choice to maintain stability while the ligaments heal.[55,56] Pin tract infections in association with the external fixation pins are common and are usually readily manageable.[55,56] Internal fixation by plate and screws or cerclage wire have also been reported.[56,57] One case has been reported of anterior plate fixation of the pubis with simultaneous posterior fixation by sacroiliac screws.[58]

Complications of separation of the pubic symphysis include nonunion (failure to heal with reduction), pubic degenerative joint disease, osteitis pubis, and hemorrhage. The separation may occur in association with a connecting vaginal laceration, and there have been reports of these being complicated by suppurative arthritis, abscess of the vulva, and abscess of the space of Retzius.[48] Some investigators report irrigation and immediate closure of such a connecting vaginal laceration, under the belief that lack of a cortical fracture, unexposed bone ends, and coverage of the bone by articular cartilage may decrease the chance of wound infection.[59]

POSTPARTUM OSTEITIS PUBIS

Osteitis pubis is a self-limited, apparently noninfective, osteonecrosis that begins at the pubic symphysis and extends into the pubic bones. It is rarely associated with pregnancy, either antepartum or postpartum. It is similar to pelvic arthropathy in its presentation, with accompanying pubic tenderness and pain that may prevent ambulation. It is differentiated from pelvic arthropathy and symphyseal disruption by radiographic rarefaction of the pubic bones, without symphyseal widening. It is differentiated from septic symphysitis by its lack of fever, leukocytosis, and radiographic bony sequestrum. Steroids and nonsteroidal anti-inflammatories have been recommended for treatment.[60] Treatment of symptomatic osteitis pubis with intravenous pamidronate has been reported.[61]

SEPTIC PUBIC SYMPHYSITIS AND SACROILITIS

Osteomyelitis in or adjacent to the pubic symphysis has rarely been reported in association with pregnancy. Fever is not universal, though leukocyte count, erythrocyte sedimentation rate, and C-reactive protein levels are usually elevated. Surgical drainage and antibiotics should be curative.[62,63]

STRESS FRACTURES OF THE PUBIC BONE

Stress fracture of the body of the pubic bone have rarely been reported during pregnancy, unrelated to athletics or physical training. In the few cases reported, no underlying pathologic process has been found. The cause is thought to be due to ligament laxity, muscle imbalance, and increased load. Pain is usually insidious in onset. There is tenderness at the fracture. Radiography is diagnostic, but not usually until some healing has occurred. MRI has been suggested to diagnose pelvic stress frac-

tures immediately.[64,65] Management is usually directed toward symptomatic relief.

PELVIC TRAUMA AND PREGNANCY

In a study of 34 women who had had a displaced pelvic ring fracture, all of whom had at least one full-term pregnancy after healing, only two required elective cesarean section, and the need for the cesarean section was determined at the first presentation by pelvimetry. Of these 34 women, 17 had healed with displacement of the fracture involving the birth canal. Of eight who had had previous traumatic pubic symphyseal disruption, two had recurrence of pain during pregnancy.

In a case of trauma very shortly after delivery, there is a report of a very wide traumatic diastasis of the pubic symphysis, which was "surprisingly easy" to reduce, with apparently no lasting injury to the sacroiliac ligaments. It was reasoned that the physiologic relaxation of the pelvis during pregnancy protected the ligaments from gross disruption during the injury.[66] Successful surgical fixation of a severely displaced acetabular fracture has been reported in a patient 20 weeks pregnant, without affecting the pregnancy.[67]

TRANSIENT OSTEOPOROSIS OF THE HIP

Transient osteoporosis of the hip is a rare condition. It has been defined by multiple case reports over the last 41 years.[68] It is characterized by a gradually developing pain in the hip with weight bearing.[69] Symptoms begin in the third (or late second) trimester. The pain is predominantly in the anterior thigh and the groin. For unknown reasons, the left hip is affected more often than the right, though both may be affected.[68] The pain is relieved by rest. There is no associated history of trauma or illness. Musculoskeletal examination is normal, except for discomfort at the extremes of hip motion and a slight decrease in total range of hip motion.[69] Joints other than the hip may become involved, and the process may regress at one joint and progress at another.[70] Other areas affected may include knee, ankle, foot, ribs, shoulders, and spine.[68,71]

Radiographic osteopenia can occur, beginning 2 to 4 weeks after onset of symptoms. Radiographically, the joint space is preserved.[68,69] The indistinctness of the subchondral cortical bone is "striking."[70] MRI of the involved joint reveals a joint effusion and diffuse signal abnormalities in the marrow, suggestive of marrow edema (decreased signal on T_1-weighted images and increased signal on T_2-weighted images).[68,72] The differential diagnosis includes joint infection, rheumatoid arthritis, pigmented villinodular synovitis, and osteonecrosis.[70] Radionucleide bone scanning shows an increased uptake in the affected femoral head and often the acetabulum.[70,73] One report of a case followed by serial dual-photon x-ray absorptiometry (DXA) over a period of 4 years showed a loss of 20% of bone mineral density (compared with age-matched controls), which resolved rapidly in the first year and returned to the normal range after cessation of lactation.[68]

Management Options

The condition is self-limiting. Treatment is conservative, including protection from weight bearing, maintenance of joint motion, and analgesic medications.[69] Bone and synovial biopsies are not necessary.[69] In cases in which joint aspiration has been performed, the effusion is sterile, and the joint fluid is normal.[68–70] Some cases report associated pathologic fracture of the pubic rami or the femoral neck.[55]

Various treatments have been used, including limitation of weight bearing by wheelchairs, crutches, or canes. Corticosteroids, phenylbutazone, and calcitonin have been tried without beneficial effect.[69,71] After delivery, symptoms completely resolve over 3 to 9 months.[69]

The cause of transient osteoporosis of the hip is unknown.[70] Some hypothesize that the cause may be neurovascular and perhaps related to reflex sympathetic dystrophy. However, lack of trauma; lack of the characteristic burning, pulsing pain; lack of changes in skin color, temperature, and moisture; and failure to respond to sympathetic blockade all mitigate against this explanation.[65] Some authors have speculated about other causes, including abnormalities in local blood flow, viral infection, rheumatic and other inflammatory conditions, and metabolic abnormalities, but none of these explanations has been convincingly upheld.[73] Other investigators have speculated that mechanical compression of the obturator nerve in pregnancy may be a causative factor, but animal experimentation has failed to produce hip osteoporosis by this mechanism.[71] It appears that by an unknown stimulus, intense bone resorption is initiated in the femoral head. Later, during resolution, osteoid is laid down and mineralized. Between resorption and remineralization, the bone is weak and susceptible to microtrauma, thus explaining the pain with weight bearing. If the microtrauma accumulates faster than it can be repaired, a pathologic fracture may ensue. For this reason, weight bearing should be limited until resolution of osteopenia.[71]

AVASCULAR NECROSIS OF THE HIP

It is not entirely clear that there is any difference between pregnancy-related transient osteoporosis of the hip and pregnancy-related avascular necrosis of the hip. Some authors have defined aseptic necrosis of the femoral head during pregnancy as an entity separate from transient osteoporosis of the hip in pregnancy, but the clinical presentation is very similar to transient osteoporosis.[74] Symptoms begin in the third trimester; the hip is painful with weight bearing; the pain is

relieved by rest; there is no associated history of trauma or illness; and the musculoskeletal examination is normal, except for discomfort at the extremes of hip motion and a slight decrease in total range of hip motion. Radiographs show osteoporotic changes, and radionucleide bone scanning shows an increased uptake in the affected femoral head.[74] Unlike nonpregnancy-related aseptic necrosis of the hip, which often mandates operative treatment and often leads to predictable degenerative joint disease, it has been observed that aseptic necrosis of the hip in pregnancy gives good results with conservative treatment, consisting of reduction in weight bearing.

One radiographic finding that may differentiate aseptic necrosis of the femoral head during pregnancy from transient osteoporosis of the hip has been a "crescent sign," with subchondral lucency or subchondral collapse of the weight-bearing dome of the femoral head. Actual bone necrosis, dead osteocytes, or empty osteocyte lacunae have not been well documented. The crescent sign of the femoral head radiographically resembles other proven cases of aseptic necrosis that occur without pregnancy, and this has been the basis for calling the osteoporotic hip with a crescent sign in pregnancy, "aseptic necrosis during pregnancy." However, the crescent sign might as well be a pathologic fracture in osteoporotic bone, making the distinction between these two entities questionable. MRI should be able to differentiate between these two entities if they actually differ; however, this has not been studied to date.

HIP ARTHROPLASTY

Generally, hip joint replacement should not occur in a woman of childbearing age, as this operation is typically reserved for patients with limited physical activities and relatively short expected life span. However, there are a few rare indications for hip joint replacement in the young, such as avascular necrosis of the hip, severe rheumatoid disease, or certain aggressive tumorous conditions. Reckling has reported a completely normal impregnation, labor, and delivery in a 19-year-old girl who had had a prior total hip replacement.[75]

A prosthetic hip does not have as much inherent joint stability as a biologic hip. Dislocation during positioning is a theoretical concern. However, hip flexion with abduction or external rotation ought to be relatively safe. The dangerous positions are hip flexion with internal rotation and, to a lesser extent, hip extension with external rotation. Neither of these positions would be likely to occur during delivery, with or without stirrups, or squatting with a birthing chair. Other preexisting hip conditions, such as severe slipped capital femoral epiphysis, especially bilateral, or hip fusion, may make positioning for delivery challenging. They do not otherwise preclude vaginal delivery.

SUMMARY OF MANAGEMENT OPTIONS			
Back and Pelvic Pain—Specific Conditions			
Management Options	Quality of Evidence	Strength of Recommendation	References
Scoliosis			
Prepregnancy and Prenatal	–	GPP	–
Curvature does not usually worsen.			
Compromise of respiratory function may occur in some (see Chapter 38).			
Labor and Delivery	–	GPP	–
Regional analgesia may not be possible.			
Positioning for delivery may have to be individualized.			
For respiratory compromise, see Chapter 38.			
Pelvic Arthropathy			
Rest, with or without a pelvic band or girdle.	–	GPP	–
Analgesia and anti-inflammatory drugs.	III	B	54
If this fails, consider injection of steroids and local anesthetic.	III	B	54

SUMMARY OF MANAGEMENT OPTIONS
Back and Pelvic Pain—Specific Conditions (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Rupture of the Pubic Symphysis			
Treatment is generally nonsurgical, and complete recovery is to be expected.	–	GPP	–
Steroids and anti-inflammatory drugs.	IV	C	60
Treatment may begin with tight pelvic binding and rest in the lateral decubitus position.	–	GPP	–
Symptoms may last as little as 2 days, typically 8 weeks, or reportedly up to 8 months.	–	GPP	–
For inadequate reduction, recurrent diastasis, or persistent symptoms, external skeletal fixation is the treatment of choice to maintain stability while the ligaments heal.	–	GPP	–
Internal fixation by plate and screws or metallic cerclage wire only considered in extreme cases.	–	GPP	–
Hip Problems			
Transient Osteoporosis—Conservative Approach	IV	C	69
Limit weight bearing.			
Encourage movement.			
Analgesia.			
Avascular Necrosis	–	GPP	–
Manage as for transient osteoporosis.			
Hip Arthroplasty	–	GPP	–
Usually no significant problem encountered nor special management required.			
Normal birthing position can be used.			
Avoid flexion to more than 90 degrees and internal rotation or adduction of the hips, which can provoke dislocation.			

CONCLUSIONS

- Back and pelvic pain are common complaints in pregnancy.
- Risk factors for back pain during pregnancy include increasing age, increasing parity, younger age, back pain before pregnancy, increased lumbar lordosis before pregnancy, smoking, physically strenuous work.
- Risk factors for persistent pain postpartum include twin pregnancy, first pregnancy, higher age at first pregnancy, increased weight of the baby, forceps or vacuum extraction, fundus expression, a flexed position of the women at childbirth.
- Cesarean section is negatively associated with persistent postpartum pain.
- Extraskeletal causes should always be remembered in the initial evaluation.
- Atypical presentations, or pain refractory to the usual care, may indicate more significant, although rare, pathology.
- Radiographic evaluation, although undesirable during pregnancy, may be warranted if insidious causes for pain are suspected.
- MRI may be helpful in the diagnosis of tumor and infection.
- Lesions compressing nerve roots, such as disc herniations, can be initially evaluated with electromyographic and nerve conduction studies, without exposure to radiation.

Skin Disease

George Kroumpouzos / Lisa M. Cohen

INTRODUCTION

Skin problems in pregnancy can be categorized as follows[1]:

- physiologic skin changes of pregnancy
- preexisting skin diseases and tumors affected by pregnancy
- pruritus in pregnancy
- specific dermatoses of pregnancy.

Prompt recognition and correct classification of the skin problem are essential for treatment, when necessary. The pregnant woman should be counseled about the nature of her skin condition, possible maternal or fetal risks associated with it, and management options.

PHYSIOLOGIC SKIN CHANGES OF PREGNANCY

The skin undergoes changes during pregnancy that are caused by the profound endocrine and metabolic alterations during the gestational period. The physiologic skin changes of pregnancy include pigmentary changes such as hyperpigmentation and melasma, vascular changes such as spider angiomas (Fig. 52–1), palmar erythema, nonpitting edema and varicosities, stretchmarks *(striae gravidarum)* (Fig. 52–2), as well as mucosal, hair (Fig. 52–3), nail, and glandular changes.[1–3] These changes are not associated with any risks for the mother or fetus and are expected to resolve postpartum.

The types of pigmentation seen in pregnancy are summarized in Table 52–1. The most common pigmentary changes of pregnancy are hyperpigmentation and melasma (Fig. 52–4). Uncommon pigmentary patterns, such as pseudoacanthosis nigricans (Fig. 52–5) and dermal melanocytosis (Fig. 52–6), can also be seen.[4–8] Furthermore, postinflammatory hyperpigmentation secondary to specific dermatoses of pregnancy

(Fig. 52–7) is particularly common in skin of color. A mild form of localized or generalized hyperpigmentation occurs to some extent in up to 90% of pregnant women[1,3] and shows accentuation of the areolae, nipples, genital skin, axillae, and inner thighs. The most familiar examples are darkening of the linea alba *(linea nigra)* (see Fig. 52–2) and periareolar skin *(secondary areolae)*.

Melasma *(chloasma,* or *mask of pregnancy)* is a type of facial melanosis reported in up to 70% of pregnant women[2] and one third of nonpregnant women taking an oral contraceptive.[9] Although the malar pattern is common, the entire central face is affected in most patients *(centrofacial pattern)* (see Fig. 52–4) and less often the ramus of the mandible *(mandibular pattern)*.[10] Melasma results from melanin deposition in the epidermis (70%, accentuated by Wood's lamp examination), dermal macrophages (10% to 15%) or both (20%). This type of melanosis is thought to be associated with the hormonal changes of gestation and worsens with exposure to ultraviolet and visible light.[10–11] Melasma usually resolves postpartum but may recur in subsequent pregnancies or with the use of oral contraceptives. The dermal type of melasma is less responsive to treatment than the epidermal. Mild gestational melasma can be treated with azelaic acid, which is safe during pregnancy. Persistent melasma can be treated postpartum with topical hydroquinone 2% to 4% and a broad-spectrum sunscreen, with[12] or without a topical retinoid and mild topical steroid. Melasma, whether caused by pregnancy or oral contraceptives,[3] is resistant to treatment in 30% of patients. Combination therapies, including laser treatment[13,14] and chemical peels,[15] may be effective to some extent in resistant cases.

The physiologic vascular, connective tissue, mucosal, glandular, hair, and nail changes of pregnancy are summarized in the Summary of Management Options box. The oral pyogenic granuloma of pregnancy *(granuloma gravidarum,* or *pregnancy epulis)* is discussed under Skin Tumors.

Physiologic Skin Changes of Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Pigmentation			
Follow-up for spontaneous resolution in postpartum period.	–	GPP	–
Sun protection mandatory in all cases.	–	GPP	–
For persistent cases postpartum, consider:			
• Hydroquinone 2%-4% cream with or without tretinoin and mild topical steroids	IV	C	12
• Combination therapies including laser treatment (erbium: YAG, Q-switched ruby, or Q-switched Nd:YAG)	IIa	B	13,14
• Combination therapies, including chemical peels (glycolic acid and Jessner's solution)	IIb	B	15
Spider Nevus (see Fig. 52–1)			
Reassure (occurs in 67% of white women, in the second to fifth months; resolves within 3 months' postpartum); persistent lesions can be treated with fine-needle electrocautery, cryotherapy, or laser.	–	GPP	–
Palmar Erythema			
Reassure (occurs in 70% of white and 30% of African American women).	–	GPP	–
Varicosities			
Explain (occurs in 40% of women; thrombosis in <10%); recommend leg elevation, compression stockings.	–	GPP	–
To treat symptomatic hemorrhoids, recommend stool softeners, hot sitz baths, topical anesthetics, suppositories, laxatives.			
Nonpitting Edema			
Reassure; exclude preeclampsia. Recommend leg elevation; compression stockings, diuretics if severe.	–	GPP	–
Striae Gravidarum (see Fig. 52–2)			
Reassure (occurs in 90% of white women; less common in other groups; less apparent postpartum but may never disappear); prescribe antipruritics, topical steroids if itchy; laser can improve the color changes.	–	GPP	–
Pyogenic Granuloma (Granuloma Gravidarum)			
Reassure (occurs in 2% of pregnant women at second to fifth months; typically on the gingivae; postpartum shrinkage).	–	GPP	–
Recommend good dental hygiene; excision if excessive discomfort or bleeding.			
Gum Hyperemia/Gingivitis			
Seen in most pregnant women in the third trimester; resolves postpartum.	–	GPP	–
Reassure; recommend good dental hygiene.			

Continued

Physiological Skin Changes of Pregnancy *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendations	References
Hair Changes (see Fig. 52–3)			
Mild hursutism regresses within 6 months' postpartum.	–	GPP	–
Postpartum hair shedding (*telogen effluvium*) lasts 1 to 5 months.			
Frontoparietal hair recession and diffuse thinning also reported.			
Exclude pathologic androgen production if hirsutism.			
Follow-up postpartum hair changes.			
Glandular Changes			
Reassure (enlargement of sebaceous glands of the areolae); axillary sweating can be controlled with aluminum chloride solution (20%).	–	GPP	–
Nail Changes			
Reassure (start in the first trimester; onycholysis, subungual hyperkeratosis, transverse grooving, brittleness).	–	GPP	–

FIGURE 52–1
Spider angioma (telangiectasia) on the arm (see Color Plate 42).

FIGURE 52–2
Stretchmarks (striae gravidarum) on the lateral aspects of the abdomen and hyperpigmentation of the linea alba, causing development of the *linea nigra* (see Color Plate 43).

PREEXISTING SKIN DISEASES AND TUMORS AFFECTED BY PREGNANCY

The pregnant woman is susceptible to aggravation or less often to improvement of skin diseases and tumors.[16] The conditions that may improve during pregnancy are listed in Table 52–2.

Inflammatory Skin Diseases

Risks and Management Options

ATOPIC DERMATITIS (ECZEMA)

Eczema is the most common pregnancy dermatosis, accounting for 36% of total cases.[17] Atopic dermatitis

FIGURE 52–3
Telogen effluvium, which developed in the immediate postpartum period, with typical temporal recession and thinning (see Color Plate 44).

TABLE 52–1

Patterns of Pigmentation in Pregnancy

PATTERNS

- **Common hypermelanoses**
  - Hyperpigmentation
  - Melasma
- **Uncommon hypermelanoses**
  - Pseudoacanthosis nigricans
  - Dermal melanocytosis
  - Vulvar melanosis
  - Verrucous areolar pigmentation
  - Localized reticulate pigmentation
- **Darkening of preexisting pigmentation**
  - Acanthosis nigricans
  - Pigmentary demarcation lines
- **Darkening of benign skin lesions**
  - Scars
  - Melanocytic nevi
  - Skin tags; seborrheic keratoses
- **Postinflammatory hyperpigmentation**
  - Secondary to specific dermatoses of pregnancy (see specific section in text)
- **Jaundice** (see specific section in text)

FIGURE 52–6
Grayish-brown ill-defined patches of dermal melanocytosis may develop in pregnancy and persist in the postpartum period (see Color Plate 47).

FIGURE 52–4
Melasma of the entire central face (see Color Plate 45).

FIGURE 52–7
Extensive postinflammatory hyperpigmentation secondary to pruritic urticarial papules and plaques of pregnancy in an Asian female (see Color Plate 48).

FIGURE 52–5
Pseudoacanthosis nigricans may develop in skin of color during pregnancy and manifests itself as hyperpigmented velvety plaques on the axillae (as shown) and neck (see Color Plate 46).

TABLE 52–2

Preexisting Disorders That May Improve in Pregnancy

- Atopic dermatitis
- Acne vulgaris
- Chronic plaque psoriasis
- Fox-Fordyce disease
- Hidradenitis suppurativa
- Linear IgA disease
- Rheumatoid arthritis
- Sarcoidosis

is more likely to worsen than remit in pregnancy, although remission has been reported in up to 24% of cases. There is a personal history of atopy in 27% of pregnant females with atopic dermatitis, a family history of atopy in 50% of cases, and infantile eczema in 19% of offspring. There have been no adverse effects on the fetal outcome. Maternal smoking may be implicated in the development of atopic eczema during pregnancy and lactation.[18] The effect of breast-feeding on atopic eczema has been debated. Gestational atopic eczema is treated with moisturizers and low- to mid-potency topical steroids. A short course of oral steroid may be required for severe eczema. Systemic antibiotics, such as erythromycin base or penicillin, are necessary in superinfected eczema. Systemic antihistamines, such as diphenhydramine, are often required for severe pruritus. Ultraviolet B light (UVB) is a safe adjunct in treating chronic eczema. Irritant hand dermatitis and nipple eczema are often seen postpartum.[1] Nipple eczema can show painful fissures and be complicated with bacterial infection, most commonly from *Staphylococcus aureus*.

ACNE VULGARIS

The effect of pregnancy on acne vulgaris is unpredictable. Some patients may develop acne for the first time during pregnancy, and acne conglobata may worsen during pregnancy. Comedonal acne can be treated with topical keratolytic agents, such as benzoyl peroxide, whereas inflammatory acne can be treated with azelaic acid, topical erythromycin, topical clindamycin phosphate, or oral erythromycin base. All these medications are safe to use during gestation.[19]

Urticaria may worsen in pregnancy, whereas hidradenitis suppurativa and Fox-Fordyce disease may remit during gestation as a result of reduced apocrine gland activity.[1]

CHRONIC PLAQUE PSORIASIS

Chronic plaque psoriasis is the most common type of psoriasis to develop or exacerbate during pregnancy.[20] It is more likely to improve (40% to 63%) than worsen (14%) during gestation; it commonly flares, however, within 4 months of delivery. Psoriatic arthritis may develop or worsen during pregnancy, and often starts postpartum or perimenopausally (30% to 45%).[21] Topical steroids and topical calcipotriene as well as topical anthralin and topical tacrolimus appear to be safe treatment options for localized psoriasis in pregnancy.[22] UVB is the safest treatment for severe psoriasis that has not responded to topical medications. A short course of cyclosporine can be administered for psoriasis that has not responded to UVB.

GENERALIZED PUSTULAR PSORIASIS/IMPETIGO HERPETIFORMIS

A very rare variant of generalized pustular psoriasis develops in pregnancy, often associated with hypocalcemia[23]

or low serum levels of vitamin D.[24] When compared with nonpregnant women with various forms of psoriasis, pregnant women with impetigo herpetiformis rarely have a personal or family history of psoriasis, develop the eruption strictly during pregnancy, and improve postpartum. The eruption usually starts in the third trimester. It often persists until delivery and occasionally runs a protracted course postpartum. It can exacerbate with the use of oral contraceptives.[25] Impetigo herpetiformis is manifested as grouped discrete sterile pustules at the periphery of erythematous patches (Fig. 52–8A). The lesions start in the major flexures and extend centrifugally onto the trunk and around the umbilicus, usually sparing the face, hands, and feet. The lesions may become crusted (Fig. 52–8B) or vegetative, and the mucous membranes may show erosive or circinate lesions. Postinflammatory hyperpigmentation commonly develops; nail changes secondary to subungual pustules are exceptionally seen.

FIGURE 52–8

A, Early impetigo herpetiformis: discrete group sterile papules at the periphery of erythematous patch. *B*, Generalized advanced lesions of impetigo herpetiformis show crusting or vegetations.(see Color Plate 49.) (Photographs courtesy of Aleksandr Itkin, MD.)

Skin histopathology shows features of pustular psoriasis, and direct immunofluorescence is negative. The laboratory workup reveals leukocytosis, elevated erythrocyte sedimentation rate, and occasionally hypocalcemia or decreased serum vitamin D levels. Impetigo herpetiformis is thought to be an outbreak of psoriasis probably triggered by a metabolic milieu, such as pregnancy or hypocalcemia.[1] The latter is known to exacerbate generalized pustular psoriasis and can develop secondary to hypoalbuminemia in pregnancy. A report[26] that showed reduced levels of an inhibitor of skin elastase in a patient with impetigo herpetiformis warrants further investigation. Furthermore, a recent report[27] raised speculation that infections during pregnancy may trigger a flare of pustular psoriasis in an individual with psoriatic tendency.

Impetigo herpetiformis can be treated with systemic steroids at daily doses up to 60 mg/day of prednisone. Calcium and vitamin D replacement therapy should be undertaken if necessary and can lead to remission of the eruption.[23] A severe case was treated with cyclosporine.[28] Impetigo herpetiformis has been treated postpartum with oral retinoids[29] or PUVA[30] (psoralens with ultraviolet A light). Systemic antibiotics should be administered in superinfected cases. The eruption commonly resolves postpartum but recurs in each successive pregnancy with earlier onset and increased morbidity.[25,31] There are serious risks for the mother and fetus. Maternal risks include tetany, seizures, delirium, and exceptionally death from cardiac or renal failure. Fetal risks[25] such as stillbirth, neonatal birth, and fetal abnormalities may result from placental insufficiency, which often complicates impetigo herpetiformis, and have been reported even when the skin disease was well controlled.[31] Maternal and fetal monitoring is of utmost importance. In severe cases termination of pregnancy is warranted, the timing of which depends on the maternal and fetal status. The eruption resolves promptly afterwards.

Infections

Risks and Management Options

Pregnancy can affect the vast majority of common infections, causing an increase in the prevalence or exacerbation of candida vaginitis, *Trichomonas*, *Pityrosporum* folliculitis, and papillomavirus infections.[1,16] Other infections, such as recurrent genital herpes simplex virus infection, are not exacerbated in pregnancy but are of critical interest because they significantly increase fetal morbidity and mortality[32] (see Chapter 31). Disseminated infections are more likely to occur during gestation and may have devastating effects for the fetus. Viral exanthems can have significant maternal and/or fetal complications; their management options are summarized in Table 52–3. The consequences for the mother and fetus are also reviewed in Chapters 30 to 33.

The prevalence of candida vaginitis increases during pregnancy. The infection has been reported in 17% to 50% of pregnant women[33]; of those, 10% to 40% are asymptomatic.[34] *Candida albicans* has been associated with intra-amniotic infection.[35] The organism can be cultured from up to 50% of neonates born to infected mothers.[16] Neonatal candidiasis can result from passage of the infant through an infected birth canal and congenital candidiasis from an ascending infection in utero. The latter is characterized by generalized skin lesions that appear within 12 hours of delivery.[16] *Trichomonas* infection is seen in 12% to 27% of pregnant women.[36] An association with preterm delivery and low birth weight[37] has been debated.[38] *Pityrosporum* folliculitis and tinea versicolor (Fig. 52–9), both caused by yeasts of the *Malassezia* species, occur with greater frequency in pregnant women.[39] Papillomavirus infections may worsen during gestation, and condylomata acuminata can show accelerated growth, blocking the birth canal.[16]

Early studies showed exacerbation of leprosy during pregnancy or within the first 6 months of lactation,[40] a finding that was debated by a recent study.[41] Leprosy reactions are triggered by pregnancy: type 1 (reversal) reaction occurs maximally postpartum,[42] when the cell-mediated immunity returns to prepregnancy levels, and type 2 reaction (*erythema nodosum leprosum*) throughout pregnancy and lactation.[43] The increased incidence of erythema nodosum leprosum in pregnant women has been associated with early loss of nerve function secondary to "silent neuritis."[44] Multidrug therapy of rifampin, dapsone, and clofazimine is the treatment of choice during pregnancy. Leprosy reactions should be treated with oral steroids and not thalidomide which is contraindicated in pregnancy. Patients with leprosy should be counseled about the effects of pregnancy on the disease before they become pregnant, and pregnancies should be planned when the disease is well controlled. Leprosy has been associated with increased fetal mortality and low birth weight.[40] Approximately 20% of children born to mothers with leprosy will develop the disease by puberty.

Autoimmune Disorders

Risks and Management Options

SYSTEMIC LUPUS ERYTHEMATOSUS

Chronic discoid lupus is not affected by pregnancy. The data[45–47] as to whether flares of systemic lupus erythematosus (SLE) are more common during pregnancy are conflicting. The discrepancy among previous studies is due to methodologic differences,[48] including the definition of lupus flare, and the fact that several typical manifestations of active SLE, such as facial erythema (Fig. 52–10), alopecia, fatigue, edema, anemia, musculoskeletal pain, mild proteinuria, and elevated ESR, are common findings in pregnancy. In most studies the frequency of flare during pregnancy was higher than 57%.[48]

TABLE 52-3

Viral Exanthems: Maternal and Fetal Risks and Management Options

VIRUS	MATERNAL RISKS	FETAL RISKS	MANAGEMENT OPTIONS	LEVEL OF EVIDENCE	GRADE OF RECOMMENDATION
Varicella-Zoster	Pneumonitis (14%) Death (3%)	0–20 weeks: congenital varicella syndrome → skin lesions or limb hypoplasia to severe multisystem involvement	Give VZIG to seronegative mother within 72 hours postexposure; treat confirmed maternal varicella early with acyclovir for pneumonitis or other complications.	Ib	A
		13–40 weeks: herpes zoster in infancy (1–2%) −1 to +1 week from delivery: neonatal varicella	Provide VZIG prophylaxis if mother has varicella or infant of seronegative mother has maternal or other VZV contact before 28 days; treat neonatal varicella with intravenous acyclovir.	Ib	A
Rubella	None	0–8 weeks: spontaneous abortion (20%)	HNIG may be offered to seronegative pregnant contacts of rubella for whom termination is unacceptable.	III	B
		0–12 weeks: congenital rubella syndrome (85%) → sensorineural deafness, congenital heart defects, retinopathy, cataract, microphthalmia, psychomotor retardation 13–16 weeks: congenital rubella → sensorineural deafness, retinopathy	Recommend therapeutic abortion.	III	B
Erythema Infectiosum (Parvovirus B19)	Aplastic crisis in patients with hemoglobinopathy	0–20 weeks: midtrimester abortion 4–6 weeks later (↑ by 9%) 9–20 weeks: hydrops fetalis after 12 weeks (3%) Congenital red cell aplasia?	Monitor for hydrops fetalis; consider intrauterine transfusion	IIa	B
Enteroviruses (Echo Virus, Coxsackie Virus)	None	Perinatal maternal infection: neonatal infection of variable severity symptomatic → fulminant multisystem disease: pneumonitis, hepatitis, meningoencephalitis, myocarditis, pancreatitis, disseminated intravascular coagulation	Give HNIG to neonates born within 5 days of maternal infection (efficacy unproven).	III	B
			Provide infection control measures to prevent nosocomial spread from index case.	IIb	B
Measles	Increased mortality from pneumonia (3%), encephalitis, hepatitis, myocarditis, nephritis, appendicitis, mesenteric adenitis, thrombotic thrombocytopenic purpura	Preterm labor; ↓ birth weight within 2 weeks of rash; fetal death in utero uncommon Congenital infection to the neonate ranges from mild disease to death	Provide prophylactic IG within 6 days postexposure.	IIb	B
			Offer symptomatic treatment.	GPP	GPP
			Give MMR postpartum to susceptible women.	Ib	A

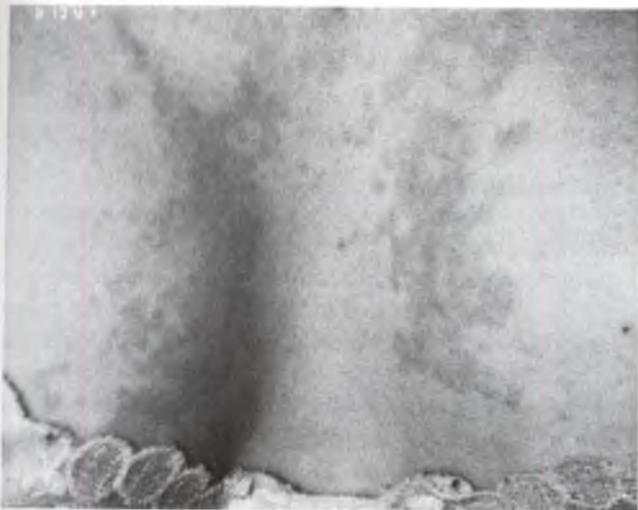
HNIG, human normal immunoglobulin; VZIG, varicella zoster immune globulin.
Table modified from Mahon E, Ruiter A, Lockwood D: Infectious diseases in pregnancy. In Black M, McKay M, Braude P, et al (eds): Obstetric and Gynecologic Dermatology, 2nd ed. London, Mosby, 2002, pp 80–81.


FIGURE 52–9
Hyperpigmented minimally scaly patches on the chest in a pregnant female with tinea versicolor (see Color Plate 50).

Pregnancy is well tolerated by mothers in remission for at least 3 months before conception, but if conception occurs during the active stage of disease 50% of gravidas will worsen during pregnancy and may experience life-threatening progression of the renal disease.[45] When SLE first appears during pregnancy it may show severe manifestations but usually remits postpartum. Cutaneous flares and arthralgias are the most common manifestations of SLE in pregnancy. Flares are not more severe during than outside of pregnancy and can be treated with

FIGURE 52–10
Malar erythema in a butterfly distribution in a pregnant woman with systemic lupus erythematosus. (see Color Plate 51). (Photograph courtesy of Cameron Thomas, Campbell Kennedy, and Phillipa Kyle from second edition.)

oral steroids. Yet, steroids do not prevent flares and should not be prescribed prophylactically.

The effects of lupus on fetal outcome correlate with the severity of maternal lupus, active disease at the time of conception or first presentation of SLE during pregnancy, and presence of anticardiolipin antibody or lupus anticoagulant. Preterm delivery occurs in 16% to 37% of pregnancies, and spontaneous abortion rates are two to four times normal; other risks include fetal death, intrauterine growth restriction (IUGR), and preeclampsia.[48] These obstetric complications have been associated with uteroplacental hypoperfusion, defective placentation, and chronic inflammation. The antiphospholipid syndrome[49] may complicate SLE, but many patients have primary antiphospholipid syndrome without lupus. It presents with manifestations that can worsen or lead to its initial diagnosis during gestation, such as recurrent miscarriage, thrombosis, livedo reticularis, migraine, stroke, and thrombocytopenia. Treatment with low-molecular-weight heparin or aspirin and close antenatal surveillance for maternal and fetal complications is warranted.

NEONATAL LUPUS

Neonatal lupus[50] can develop due to transplacental passage of maternal anti-Ro (SS-A), and less commonly anti-La (SS-B) or anti-U1-RNP antibody. The risk is 5% if anti-Ro positive, and the incidence is 1.6% of all lupus pregnancies. An association with HLA DR2 and DR3 positivity in the mother has been reported. The female-to-male ratio is 3:1. Neonatal lupus is characterized by a transient skin eruption and systemic manifestations, including congenital heart block (15% to 30%), cytopenias, hepatosplenomegaly, and pericarditis/myocarditis. The eruption become manifest several weeks into postnatal life and resolves by 6 to 8 months of age, coincident with the clearance of maternal autoantibody from the infant's circulation. The skin lesions frequently affect the face and scalp, with a predilection for the eyelids. Other sun-exposed areas may be also affected; occasionally the eruption becomes generalized. The lesions are papulosquamous or annular/polycyclic, indistinguishable from subacute cutaneous lupus of the adult. Skin histopathology shows interface dermatitis and superficial dermal mononuclear cell infiltrate. Immunofluorescence shows a particulate pattern of IgG in the epidermis.

Congenital heart block carries a substantial neonatal morbidity and mortality, and can be detected in utero at 18 to 20 weeks' gestation. Twenty-two percent of affected infants die in the perinatal period, and 62% of the infants require a pacemaker. The risk of bearing a second child with heart block is 25%, rising to 50% after two or more affected infants. The maternal and fetal anti-Ro, anti-La, and anti-U1-RNP status should be determined, and the newborn should be screened for heart block. Survivors of neonatal lupus may be at

increased risk of developing connective tissue disease in adulthood.

DERMATOMYOSITIS/POLYMYOSITIS

Dermatomyositis/polymyositis may show a flare of the heliotrope rash, worsening of proximal muscle weakness, or subcutaneous calcification in approximately half of the affected individuals.[51] When the disease is in remission during pregnancy there are no maternal or fetal risks involved. Nevertheless, when the disease starts or relapses during gestation, it can be detrimental to the mother and/or fetus. High doses of oral steroids may be required to control the disease. Fetal demise due to abortion, stillbirth, or neonatal death has been reported in over half of the cases of active disease, and prenatal surveillance is crucial. An assisted vaginal delivery may be required in case of active myositis during labor. If the disease is diagnosed in the first trimester, the option of therapeutic abortion should be offered to the mother because of the high risk of maternal and/or fetal complications.

SYSTEMIC SCLEROSIS

The course of scleroderma is not significantly altered by pregnancy. Gravidas with limited scleroderma without systemic disease do better than those with diffuse scleroderma.[52] Women with early (less than 4 years) diffuse scleroderma are at high risk for hypertension, renal failure, premature delivery, and small full-term infants. The risk of hypertension and renal failure is greatest during the third trimester and postpartum period. Nevertheless, renal crisis during gestation is less common than previously thought. Successful pregnancy is now reported in 70% to 80% of patients. The skin disease usually does not progress during pregnancy, whereas reflux esophagitis and articular disease worsen. Raynaud's phenomenon usually improves secondary to gestational vasodilation and increased blood flow.

BULLOUS DISORDERS

Pemphigus vulgaris, vegetans, or foliaceus may present or worsen during gestation.[53] Linear immunoglobulin A (IgA) disease may improve in pregnancy and relapse postpartum.[54] Pemphigus vulgaris is rare during pregnancy; it usually worsens in the first or second trimester. Skin immunofluorescence studies are required to differentiate pemphigus from herpes gestationis (see Herpes Gestationis in this chapter). Neonatal pemphigus can develop from transplacental transfer of IgG antibodies. Most neonates require no therapy as the blisters heal spontaneously within 2 to 3 weeks. Eight out of 26 documented pregnancies in 22 women with pemphigus resulted in stillbirth or abortion. Stillborn infants have been found to have skin lesions and immunofluorescence findings consistent with pemphigus. Pemphigus during pregnancy can be controlled with high doses of oral steroids.

Metabolic Disorders

Risks and Management Options

PORPHYRIA

Porphyria cutanea tarda, acute intermittent porphyria, and variegate porphyria can present problems in pregnancy because they are adversely affected by estrogen. Patients with porphyria cutanea tarda demonstrate bullous lesions, skin fragility, and milia on sun-exposed areas, such as the dorsa of the hands and forearms; other skin changes include facial hypertrichosis, periorbital hyperpigmentation, scarring alopecia, and dystrophic calcification with ulceration. Reports of porphyria cutanea tarda and pregnancy have been scarce in the literature; these reports have provided conflicting results.[55] Symptomatic exacerbation of the disease has been often reported during the first trimester followed by improvement later in pregnancy. These changes parallel a rise in serum estrogen and porphyrin excretion in the first trimester and a fall in serum iron levels and urinary porphyrins later in gestation. Nevertheless, some authors reported exacerbation of the disease with oral contraceptives and not in pregnancy. The fetal prognosis is not usually affected by this disorder. Lists of drugs that are safe and unsafe for porphyria patients have been published.[56] Management of porphyria cutanea tarda during pregnancy includes sun protection, avoidance of alcohol and iron, and repeated phlebotomies in retractable cases. Chloroquine is contraindicated in pregnancy because of its teratogenicity. The newborn should be assessed and screened for porphyria cutanea tarda in the immediate postpartum period, both for genetic counseling and avoidance of inducing factors in the child.

ACRODERMATITIS ENTEROPATHICA

Acrodermatitis enteropathica is a rare autosomal disorder of zinc deficiency characterized by dermatitis, diarrhea, and alopecia. The skin lesions are vesiculobullous and eczematous and are distributed on the extremities and periorificial sites, such as the mouth, anus, and genital areas. The disease usually flares during gestation, because serum levels decrease early in pregnancy.[57] This decline is not attributed to fetal demands only, because acrodermatitis enteropathica can also flare with oral contraceptive use. The skin lesions in pregnancy need to be differentiated from pemphigoid gestationis and impetigo herpetiformis. Most often, having first appeared in childhood, the skin disease reappears during pregnancy, worsens until delivery, and clears postpartum.[57] The disorder usually has no effect on fetal outcome. Fetal malformations and neonatal death have been reported in a few cases of untreated maternal disease.

Connective Tissue Disorders

Risks and Management Options

EHLERS-DANLOS SYNDROMES I TO X

Ehlers-Danlos syndromes I to X are a group of inherited disorders of collagen metabolism that manifest with skin fragility, easy bruising, joint hypermobility, and skin hyperelasticity. Women with Ehlers-Danlos syndromes type I (classic, or gravis) and IV (ecchymotic, or arterial) are particularly likely to develop complications during pregnancy. The risks include premature rupture of the membranes; postpartum bleeding; rupture of major vessels (especially in type IV), including the aorta and pulmonary artery; poor wound healing and dehiscence; uterine lacerations; bladder and uterine prolapse; and abdominal hernias.[58] The reported maternal mortality in type IV disease is 20% to 25%. The risks are such that women with Ehlers-Danlos syndromes types I or IV should be counseled against pregnancy. A favorable outcome of pregnancy, however, has been reported for types II (mitis) and X (fibronectin abnormality).

PSEUDOXANTHOMA ELASTICUM

Gestation may worsen the vascular complications of pseudoxanthoma elasticum. The main complication is massive hematemesis from gastrointestinal (particularly gastric) bleeding, but repeated epistaxis and congestive heart failure with ventricular arrhythmia have been also reported.[59] Hypertension is frequent and should be treated aggressively. An increased risk of first-trimester miscarriage and IUGR secondary to placental insufficiency has been reported.

Skin Tumors

Risks and Management Options

MISCELLANEOUS LESIONS

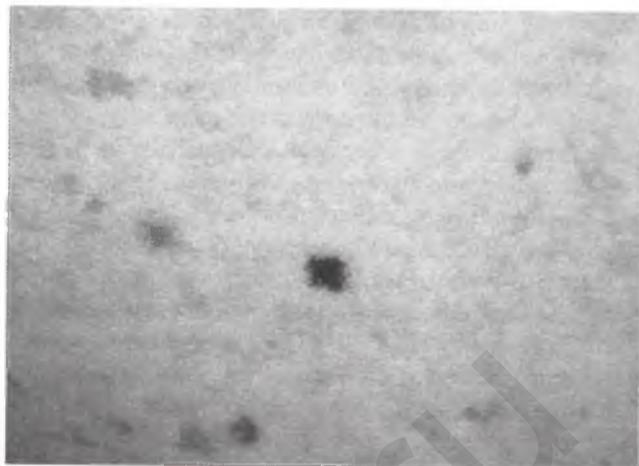
Most benign skin tumors can appear for the first time, increase in number, or enlarge during gestation as a result of the effects of high estrogen levels on vascular and soft tissues. The most common lesions that change during pregnancy are melanocytic nevi, seborrheic keratoses, and skin tags. Melanocytic nevi may develop, enlarge, or darken during pregnancy (Fig. 52–11). The pigmentary changes observed in melanocytic nevi during pregnancy are thought to be due to the melanogenic effects of high estrogen levels and increased levels of melanocyte-stimulating hormone. An increase in estrogen and progesterone receptors in melanocytic nevi in pregnancy has been demonstrated. A mild degree of histopathologic atypia has been reported in a few studies but there is no evidence that pregnancy induces malignant transformation of preexisting nevi. Seborrheic keratoses may also enlarge or darken during gestation. Skin tags (*molluscum fibrosum gravidarum*) usually appear during the later months of preg-


FIGURE 52–11
Melanocytic nevus that became darker and developed a mild border irregularity during gestation (see Color Plate 52).

nancy and may partially or completely disappear postpartum. In all these cases, the pregnant woman needs to be reassured that these skin lesions are common during pregnancy and may improve postpartum.

Vascular tumors may also be affected or present during pregnancy. The pyogenic granuloma of pregnancy (*granuloma gravidarum*, pregnancy tumor, or pregnancy epulis) is a benign proliferation of capillaries within the gingivae that appears between the second and fifth months of pregnancy. The prevalence of *granuloma gravidarum* is estimated to approach 2% of all pregnancies. It may be caused by trauma to inflamed mucosa and presents as a vascular deep-red or purple nodule between the teeth or on the buccal or lingual surface of the marginal gingiva. Occasionally, pyogenic granulomas can develop on the lip or extramucosal sites (Fig. 52–12). Typical histopathologic features of a pyogenic granuloma are seen in all cases. Spontaneous shrinkage of the tumor usually occurs postpartum, and most cases do not require

FIGURE 52–12
Pyogenic granuloma of pregnancy (*granuloma gravidarum*), typically seen on the gingivae, can also develop on extramucosal sites (see Color Plate 53).

treatment. Surgical excision, however, is necessary in cases of excessive bleeding. An increased frequency of other vascular tumors, such as hemangioma, hemangioendothelioma, glomus tumor, and glomangioma, has been reported in pregnancy. Large hemangiomas that exceptionally cause arteriovenous shunt and high-output cardiac failure in pregnancy partially regress postpartum, tending to enlarge again in subsequent pregnancies.

Dermatofibromata, dermatofibrosarcomata protuberans, leiomyomata, and keloids may develop or enlarge during pregnancy (Fig. 52–13). Desmoid tumors often develop in the rectus abdominis muscle. Neurofibromas may enlarge or arise *de novo* during gestation, often complicated with massive hemorrhage within the tumor; these lesions may partially resolve postpartum.

NEUROFIBROMATOSIS

Women with neurofibromatosis are at high risk for vascular complications during pregnancy such as hypertension and renal artery rupture.[60] A higher prevalence of maternal and fetal risks, such as first-trimester spontaneous abortion, stillbirth, IUGR, and perinatal complications, has been reported in neurofibromatosis.

MALIGNANT MELANOMA

Malignant melanoma accounts for 8% of malignant neoplasms during pregnancy. Most studies[61-63] have showed that melanomas that develop during pregnancy are thicker than melanomas in nonpregnant women and show a trend toward shorter disease-free survival. These findings are thought to be due to a delay in the diagnosis of melanoma during gestation, but the data to support this speculation is insufficient. Grin and colleagues[64] reviewed controlled clinical trials in pregnant women with melanoma and indicated that pregnancy does not influence the 5-year survival rate. These results were confirmed by a recent study[65] in pregnant women with stage I to II melanoma, which did not reveal any difference in the 10-year disease-free survival and overall survival between pregnant and nonpregnant women. Moreover,

FIGURE 52–13
Keloid that developed during pregnancy without previous trauma (see Color Plate 54).

no differences were found in the histologic subtype, tumor location, ulceration, and vascular invasion between the two groups. There was a trend toward shorter disease-free survival in pregnant women that did not reach statistical significance. The authors concluded that the overall survival for women with melanoma during pregnancy is dependent only on the tumor thickness and ulceration.

Surgery is the treatment of choice in patients with early melanoma. Correct staging is crucial, and sentinel lymph node biopsy using preoperative intradermal injection of technetium-99m-sulfur colloid is considered safe during pregnancy.[66] For pregnant women with advanced disease the prognosis, risks, and benefits from systemic therapy should be discussed. Systemic chemotherapy during the second and third trimesters does not usually cause fetal abnormalities, except in the case of alkylating agents.[67] Nevertheless, given that the effectiveness of chemotherapy in advanced melanoma is at present limited, systemic chemotherapy should not be given in pregnancy in other than exceptional circumstances. In some cases, termination of pregnancy may be the least damaging course of action to allow systemic therapy to be offered.

There are currently no standard guidelines for patients who desire a pregnancy after the diagnosis and treatment of melanoma. Based on the fact that 50% of recurrences develop by 3 years in patients with thick lesions, MacKie[67] suggested that women who have melanoma should not become pregnant not should they take oral contraceptive or postmenopausal hormonal replacement therapy for 2 years after initial treatment unless there are exceptional circumstances. The recommendation of other authors[66] about how long to wait before becoming pregnant after a diagnosis of melanoma is on case-by-case basis, depending on tumor thickness and stage, age of the patient, and desire to become pregnant. Although placental and/or fetal metastasis is extraordinarily rare (19 cases),[66] melanoma is the most common type of malignancy to metastasize to the placenta and fetus, representing 30% of placental metastases and 58% of fetal metastases. Maternal and fetal death invariably occurs; 80% of maternal deaths occur within 3 months of delivery. When a gravida is diagnosed with melanoma the placenta should be sent for histologic examination. Some authors[67] suggested that blood from both the mother and umbilical cord be examined cytologically.

Miscellaneous Skin Disorders

Risks and Management Options

A variety of skin disorders have been reported to start or flare during pregnancy, but large series are missing for most of them. Sarcoidosis of the skin is one of the most studied and has been shown to improve in pregnancy. Figure 52–14 demonstrates minimal residual skin lesions of sarcoidosis in a pregnant female who demonstrated generalized skin sarcoidosis before gestation. Exacerbation or new onset of erythema nodosum (adversely affected by

FIGURE 52–14

female who showed severe generalized skin sarcoidosis before
gestation (see Color Plate 55).

estrogen), keratosis pilaris, erythema multiforme, bowenoid papulosis, mycosis fungoides, Langerhans cell histiocytosis, mastocytosis, erythrokeratodermia variabilis, hereditary angioedema, tuberous sclerosis, Marfan syndrome, and hereditary hemorrhagic telangiectasia during pregnancy have been reported. The serious maternal risks related to vascular complications of tuberous sclerosis, Marfan syndrome, and hereditary hemorrhagic telangiectasia should be promptly assessed. The management of the rest of the aforementioned conditions should be individualized.

SUMMARY OF MANAGEMENT OPTIONS
Preexisting Skin Disorders

Management Options	Quality of Evidence	Strength of Recommendation	References
Atopic Dermatitis (Eczema)			
• Emollients	–	GPP	–
• Low- or mid-potency topical steroids			
• Oral antihistamines			
• UVB phototherapy			
• Short-course oral steroid for severe disease			
Acne Vulgaris

PRURITUS IN PREGNANCY

Pruritus has been reported in 17% of pregnancies. As shown in Table 52–4, a broad differential diagnosis needs to be considered, and the constellation of clinical and laboratory findings is the most helpful approach to establishing a diagnosis and reaching management decisions. In summary, a patient with pruritus in pregnancy should be evaluated as follows:

• A detailed history, past medical history, obstetric history, and physical examination are imperative for deter-

mining the cause of pruritus. The laboratory workup should be directed by the clinical findings. The constellation of clinical and laboratory data will help identify pruritic skin diseases that are not specifically related to pregnancy, such as scabies, or systemic disorders with skin manifestations (see previous section).

• In the patient with pruritus and no eruption, one should consider systemic causes of pruritus such as lymphoma and liver, renal, and thyroid disease.

• In the patient with pruritus, jaundice, and no eruption, one should consider hepatitides, obstetric cholestasis, hyperbilirubinemic states, and other liver diseases.

• In the patient with pruritus and eruption, one should consider specific dermatoses of pregnancy (see following section), allergic reactions, drug eruptions, and urticarial lesions of hepatitis B.

• In the patient with pruritus, no jaundice, no eruption, no systemic disease, and no specific pregnancy dermatosis, one should consider intrahepatic cholestasis of pregnancy, pruritus associated with striae gravidarum and hyperemesis gravidarum complicated with cholestasis.

TABLE 52–4

Etiology of Pruritus in Pregnancy

COMMON CAUSES

• Intrahepatic cholestasis of pregnancy
• Preexisting skin diseases
• Specific dermatoses of pregnancy
• Systemic diseases with skin involvement
• Allergic reactions
• Drug eruptions
• Pruritus associated with striae gravidarum

UNCOMMON CAUSES

• Systemic causes of pruritus (lymphoma; liver, thyroid, or renal disease)
• Viral hepatitis
• Hyperbilirubinemic states
• Hyperemesis gravidarum

Obstetric Cholestasis (See also Chapter 48)

Risks and Management Options

Generalized pruritus without a skin rash often results from obstetric cholestasis, the most common pregnancy-

induced liver disorder. The condition manifests itself with jaundice (*intrahepatic jaundice of pregnancy*) or without (*pruritus gravidarum*). Viral hepatitis is the most common cause of jaundice in pregnancy with obstetric cholestasis second. Obstetric cholestasis is very common in Chile, Bolivia, and Scandinavia.[68] The incidence of obstetric cholestasis is lower in Europe (0.1% to 1.5%), the United States, Canada, and Australia. This geographic variation is thought to be due to environmental and/or dietary factors. Obstetric cholestasis recurs in 60% to 70% of subsequent pregnancies.[69] Oral contraceptives can cause a recurrence of pruritus and cholestasis. In half of the cases there is a family history of this condition or an association with multiple-gestation pregnancy.[68] Some authors suggested that obstetric cholestasis occurs more frequently and at an earlier gestational age in pregnant women who are positive for hepatitis C virus.[70]

Obstetric cholestasis manifests itself in 80% of cases after the 30th week of pregnancy,[68] although initial presentation as early as 6 weeks' gestation has been reported. The pruritus, which may precede the liver function abnormalities of the condition, affects the palms and soles and extends to the legs and abdomen. Excoriations due to scratching are invariably seen. Obstetric cholestasis is occasionally preceded by a urinary tract infection. Mild nausea and discomfort in the upper right quadrant may accompany the pruritus. Mild jaundice (20%) usually develops 2 to 4 weeks after the onset of itching and may be associated with subclinical steatorrhea and increased risk of hemorrhage.[69] Up to 50% of patients develop darker urine and light-colored stools. The symptoms and biochemical abnormalities of obstetric cholestasis usually resolve within 2 to 4 weeks postpartum. An increased risk of cholelithiasis has been debated.

Elevated serum bile acids, especially postprandial elevations, are the most sensitive marker of obstetric cholestasis[69] and correlate with the severity of the pruritus. Mild abnormalities on liver function tests are commonly found, namely elevated cholesterol, transaminases, alkaline phosphatase, and lipids. The conjugated bilirubin is mildly to moderately elevated (2 to 5 mg/dL) in jaundiced patients. Malabsorption of fat may cause vitamin K deficiency, resulting in a prolonged prothrombin time. Skin biopsy is unnecessary because there are no primary skin lesions. Liver biopsy is not indicated, but if performed shows centrilobular cholestasis, bile thrombi within dilated canaliculi, and minimal inflammatory changes.

Hormonal, immunologic, genetic, environmental, and probably alimentary factors may play a role in the etiology of obstetric cholestasis.[68] It has been suggested that the relative decrease in hepatic blood flow during gestation causes decreased elimination of toxins and estrogens. Estrogens interfere with bile acid secretion and increase biliary cholesterol secretion. Progestins inhibit hepatic glucuronyltransferase, thus reducing the clearance of estrogens and amplifying their effects. Monosulfated or disulfated progesterone metabolites, in particular the 3α, 5α-isomers, are substantially increased in obstetric

cholestasis secondary to decreased biliary and fecal excretion. The increased serum levels of sulfated progesterone metabolites may saturate the maximal transport capacity of membrane transport proteins of the hepatocyte. Recent immunologic studies[71] showed a predominance of Th1 cytokines (cell-mediated immune reaction) and decreased maternal-fetal lymphocyte reaction in obstetric cholestasis. These findings show that immunologic mechanisms may be implicated in the pathogenesis of obstetric cholestasis.

Genetic factors have been suggested by the existence of familial cases and geographic variation of obstetric cholestasis. A high prevalence of the HLA haplotype Aw31B8 has been reported. A higher incidence of obstetric cholestasis has been observed in mothers of patients with progressive familial intrahepatic cholestasis (PFIC) or benign recurrent intrahepatic cholestasis. Patients with PFIC type 3 show mutations of the multidrug resistance 3 (MDR3) gene, which encodes the canalicular phosphatidylcholine translocase, a biliary transport protein. Recently, in a family of PFIC type 3 patients, 6 women with a history of obstetric cholestasis were heterozygous for the familial mutation in the MDR3 gene.[72] Environmental factors, as indicated by the geographic variation of obstetric cholestasis and its higher incidence during the winter, and alimentary factors have been implicated in the pathogenesis of obstetric cholestasis; the importance of these factors, however, has been debated.

Fetal risks in obstetric cholestasis include fetal distress, stillbirth, and preterm delivery. Malabsorption of vitamin K increases the risk of intracranial hemorrhage. The pathogenesis of fetal complications is associated with decreased fetal elimination of toxic bile acids, which can cause vasoconstriction of human placental chorionic veins. Furthermore, a higher incidence of meconium passage has been reported in stillbirths in obstetric cholestasis. Meconium can cause acute umbilical vein obstruction. The incidence of meconium passage was increased with the infusion of cholic acid in animal studies. The risk of serious fetal complications in obstetric cholestasis makes intensive fetal surveillance mandatory. Obstetric management should weigh the risk of preterm delivery against the risk of sudden death in utero.

Mild cholestasis can be treated symptomatically with topical antipruritics and emollients; oral antihistamines are rarely effective. Epomediol and silymarin have been helpful in mild cases.[68] The effectiveness of intravenous S-adenosylmethionine was not confirmed by a randomized, placebo-controlled study.[73] Treatment with activated charcoal has met limited success. Phenobarbital has shown minimal effect on the pruritus of obstetric cholestasis and variable effects on the biochemical abnormalities of the condition.[74] UVB has been variably effective and can be safely used when pharmacologic treatments fail. Dexamethasone suppression of fetoplacental estrogen production was effective (uncontrolled) and deserves further evaluation.[75]

Cholestyramine decreases the enterohepatic circulation of bile acids. It needs to be administered (up to 18 g/day) for several days before a clear benefit for pruritus can be obtained and does not improve the biochemical abnormalities of obstetric cholestasis.[74] Furthermore, it has the disadvantage of precipitating vitamin K and should be administered in conjunction with weekly vitamin K supplementation.[68] A case of severe fetal intracranial hemorrhage during treatment with cholestyramine for obstetric cholestasis has been reported. Vitamin K and cholestyramine should be given at different times of the day so that cholestyramine does not interfere with vitamin K absorption. A decrease in pruritus has been reported in approximately half of the patients studied (uncontrolled), but recurrence of itching was common after the first week of treatment. Patients with high serum bile acids may not respond to cholestyramine,[74] and several patients who did not respond to cholestyramine subsequently responded to other agents, such as ursodeoxycholic acid and dexamethasone. It may be concluded that cholestyramine can be effective only in mild to moderate obstetric cholestasis.

Ursodeoxycholic acid, a naturally occurring hydrophilic bile acid, protects against injury to bile ducts by hydrophobic bile acids and stimulates the excretion of these and other hepatotoxic compounds as well as sulfated progesterone metabolites. The medication has been shown to reduce bile acid levels in colostrum, cord blood, and amniotic fluid. A meta-analysis[69] of randomized controlled trials indicated that ursodeoxycholic acid, when administered in doses between 450 and 1200 mg daily, was highly effective in controlling the pruritus and liver dysfunction associated with obstetric cholestasis.[70,76,77] Ursodeoxycholic acid may have a synergistic effect with S-adenosylmethionine.[76] Ursodeoxycholic acid has been safe for both mother and fetus, and may decrease the fetal mortality associated with obstetric cholestasis.[78] Compared to cholestyramine, ursodeoxycholic acid is safer, works faster, has a more sustained effect on pruritus, and shows higher efficacy in improving the biochemical abnormalities of obstetric cholestasis.[68] Data that are available support the use of ursodeoxycholic acid as a first-line agent and cholestyramine as a second-line agent in the treatment of moderate to severe obstetric cholestasis.

SUMMARY OF MANAGEMENT OPTIONS
Pruritus in Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Establish the Diagnosis			
Consider:	–	GPP	–
• **Specific systemic diseases** with skin involvement (see previous sections)			
• **No eruption:** other systemic diseases with pruritus (lymphoma; liver, renal, thyroid disease)			
• **No eruption and jaundice:** hepatitides, obstetric cholestasis, hyperbilirubinemic states, and other liver diseases			
• **Eruption:** specific dermatoses of pregnancy (see following section), allergic reactions, drug eruptions, and urticarial lesions of hepatitis B			
• **No eruption/jaundice/systemic disease or dermatosis:** obstetric cholestasis, pruritus associated with striae gravidarum, and hyperemesis gravidarum complicated with cholestasis			
Management depends on cause—see below for Obstetric Cholestasis

Options for Overall Management	–	GPP	–
• Initiate fetal surveillance.			
• Perform elective delivery at 37–38 weeks.			
• Perform elective delivery at 36–37 weeks if fetal lung maturity and favorable cervix.			
• Consider maternal treatment with URSO.			
• Monitor LFTs and bile acids every 2–4 weeks.			

LFTs, liver function tests; URSO, ursodeoxycholic acid; UVB, ultraviolet light B.

SPECIFIC DERMATOSES OF PREGNANCY

Specific dermatoses of pregnancy are encountered predominantly during gestation or in the puerperium and include only those skin diseases that result directly from the state of gestation or the products of conception.[17] The classification of specific dermatoses of pregnancy into herpes gestationis, pruritic urticarial papules and plaques of pregnancy (PUPPP), prurigo gestationis, and pruritic folliculitis of pregnancy that was proposed by Holmes and Black[79] is now accepted by most authors.

Herpes (Pemphigoid) Gestationis

Risks and Management Options

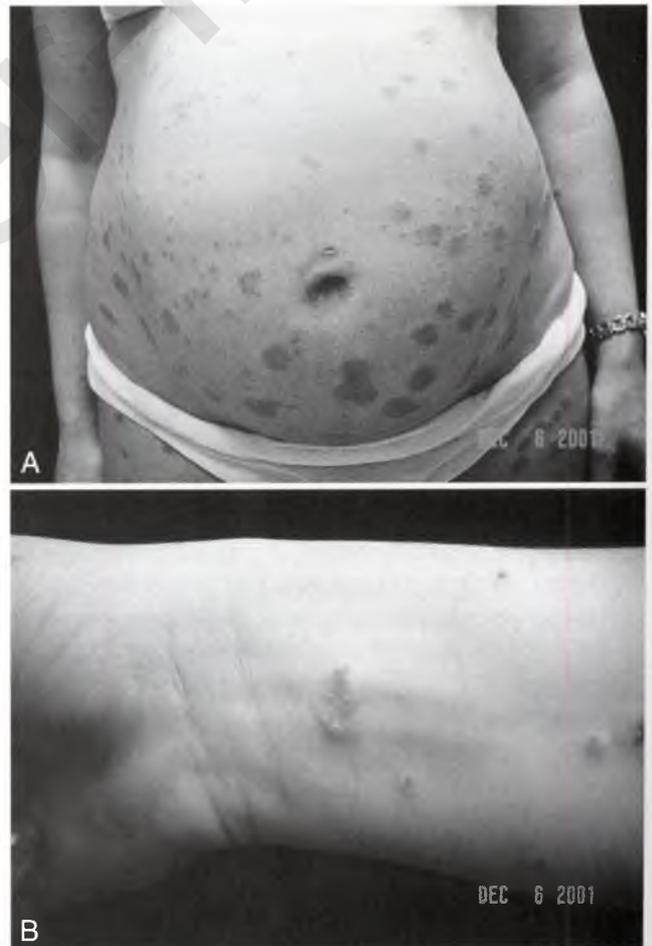
Herpes gestationis is a rare autoimmune bullous disease of pregnancy and the puerperium. It has been rarely associated with choriocarcinoma and molar pregnancy.[80] The disease is more prevalent in white females, and its incidence is estimated between 1 in 10,000 and 1 in 50,000 pregnancies.[80] Herpes gestationis usually starts in the second or third trimester, with an average onset at 21 weeks' gestation, although initial onset in the immediate postpartum period occurs in about 20% of cases.[80,81] Herpes gestationis starts with severely pruritic urticarial abdominal lesions in half of the cases (Fig. 52–15A). The lesions do not spare the umbilicus. A generalized bullous eruption rapidly ensues (Fig. 52–15B), which may affect the palms and soles; facial and mucosal involvement is rare. Bullous lesions arise in both inflamed and clinically normal skin and, unless superinfected, heal without scarring.


FIGURE 52–15

A, Pruritic abdominal urticarial lesions usually develop in the early phase of herpes gestationis. *B,* Characteristic tense vesicles on an erythematous base on the forearm in a patient with herpes gestationis (see Color Plate 56.). (Photographs courtesy of Jeffrey Callen, MD.)

A flare at the time of delivery, preceded by a period of quiescence in late pregnancy, is typically seen (75%).[80] The disease spontaneously resolves in the postpartum period, although a protracted course and "conversion" to bullous pemphigoid have been reported. Cases with overlapping features of herpes gestationis and bullous pemphigoid have been described. Herpes gestationis often recurs in subsequent pregnancies, usually appearing at an earlier gestational age and more severely. Nevertheless, skip pregnancies occur (8%).[81,82] The postpartum duration of herpes gestationis may increase with the number of involved pregnancies. Recurrence with menses or ovulation or subsequent use of oral contraceptives has been reported.[82] The effects of breast-feeding and prolactin on prolonging the duration of herpes gestationis deserve further clarification. The above data underscore the importance of hormonal factors in the pathogenesis of the disease.

Histopathology of early urticarial lesions shows a spongiotic epidermis, marked papillary dermal edema, and a mild perivascular infiltrate of lymphocytes, histiocytes, and characteristically many eosinophils. Focal necrosis of the basal keratinocytes leads to subepidermal blister formation. Direct immunofluorescence of perilesional skin shows linear C3 along the basement membrane zone.[1] In salt-split skin specimens, the antibody binds to the roof of the vesicle. Concomitant IgG deposition is detected in about 25% to 30% of patients. However, IgG is always positive when indirect complement-added immunofluorescence is used.[1] Deposition of IgG1 has been found in virtually all patients studied with monoclonal antibodies. Linear deposition of C3 and IgG1 has also been seen in the skin of neonates of affected mothers and in the basement membrane zone of amniotic epithelium.[80]

The antibody in herpes gestationis belongs to the IgG1 subclass and is believed to activate complement through the classical pathway. The major pathogenic antigen is the bullous pemphigoid 180 kd hemidesmosomal glycoprotein.[83] Reactivity against both the 180 kd and 240 kd bullous pemphigoid antigens is detected in 10% of cases—the reactivity against the 240 kd antigen is thought to develop later during the disease process as a secondary response to basal keratinocyte injury[80] *(epitope spreading)*. Serum antibody levels and eosinophilia do not correlate with the severity of disease. Antibody titers and immunofluorescence for C3 may remain positive even after clearance of the skin lesions or in subsequent disease-free pregnancies. The major antigenic epitopes (A1, A2, A.25, and A3)[84] are located in the noncollagenous domain (NC16A) of the transmembrane 180 kd antigen. Autoantibodies and autoimmune T lymphocytes from herpes gestationis patients recognize the NC16A2 (MCW-1) epitope[84]; these T cells express a Th1 cytokine profile. Several authors postulate that an immunologic insult occurs against class II placental antigens of paternal haplotype, and the antibody then cross-reacts with a maternal skin basement membrane epitope.[85]

The association of herpes gestationis with alleles of the human leukocyte antigens HLA-DR3 (61% to 80%), HLA-DR4 (52%), or both (43% to 50%)[86] and with the C4 null allele indicates that genetic factors may play an important role in the pathogenesis of the disease. Nonetheless, the finding of anti-HLA antibodies in all patients with herpes gestationis is considered an epiphenomenon in the disease process.[80] A change in partner has been occasionally associated with the onset of the disease,[82] and an increased prevalence of HLA-DR2 among husbands has been associated with herpes gestationis among their wives, particularly females positive for HLA-DR3/DR4. Yet, an association between change in consort and development of herpes gestationis has not been consistently found,[81] and skip pregnancies despite having the same partner[81,82] would argue against this association. The role of paternal factors is intriguing but not yet entirely understood.

The differential diagnosis of herpes gestationis includes drug eruptions, erythema multiforme, allergic contact dermatitis, PUPPP, and preexisting bullous disease with exacerbation during gestation, such as bullous pemphigoid. A careful history and clinical examination are usually sufficient to rule out allergic contact dermatitis, drug eruptions, and preexisting bullous disease with flare during pregnancy. Of note, bullous pemphigoid has not been reported during gestation, usually affects the elderly, and is equally common among males and females. The lesions in bullous pemphigoid are more prominent on the lower abdomen and thighs, and do not cluster around the umbilicus. Erythema multiforme can be differentiated by histopathologic and immunofluorescence studies. PUPPP is the most common specific dermatosis of pregnancy that needs to be differentiated from herpes gestationis. Interestingly, PUPPP can manifest with urticarial and/or vesicular lesions almost indistinguishable from those of herpes gestationis. The two diseases, however, can be distinguished by direct immunofluorescence, which is negative in PUPPP.

Herpes gestationis is associated with no maternal risks other than an increased risk of Graves' disease. Neonatal vesiculobullous lesions occur in 10% of cases[87] secondary to passive transplacental transfer of herpes gestationis antibody. The eruption is usually mild and resolves spontaneously in a few weeks as the maternal antibodies disappear from the infant's blood. Superinfection of bullous lesions warrants prompt treatment with systemic antibiotics. Monitoring for evidence of adrenal insufficiency is necessary for infants of mothers treated with oral steroids. Although an association with small for gestational age infants and preterm delivery has been reported,[88] no increase in fetal morbidity or mortality has been documented, with the exception of one case of fetal cerebral hemorrhage. The fetal complications may not be altered by the use of systemic steroids and are thought to be due to low-grade placental insufficiency.[80]

Early urticarial lesions may respond to topical steroids with or without an oral antihistamine, but most cases require oral steroids. Even though doses of prednisone up to 180 mg daily have been reported, most patients respond to lower doses (20 to 40 mg daily). The dose should be tapered 7 to 10 days after control is achieved. Most patients can be maintained on 5 to 10 mg of prednisone daily. The dosage should be increased at the time of delivery to control postpartum exacerbation. Plasmapheresis or chemical oophorectomy with goserelin have been used in recalcitrant herpes gestationis with some success.[80] Plasmapheresis can be considered for patients who do not respond to high doses of oral steroids or when oral steroids are contraindicated. High-dose intravenous immune globulin combined with cyclosporine has been used to treat herpes gestationis with some success.[89] Early delivery may be warranted in refractory cases. A case report indicated some benefit from minocycline in postpartum herpes gestationis. Intractable cases may respond to postpartum administration of cyclophosphamide, pyridoxine, gold, methotrexate, or dapsone.[1,80] Nevertheless, these agents have not been consistently effective, and their use is limited to patients who are not breastfeeding.

Pruritic Urticarial Papules and Plaques of Pregnancy

Risks and Management Options

Pruritic urticarial papules and plaques of pregnancy is the most common specific dermatosis of pregnancy, affecting between 1 in 130 and 1 in 300 gravidas.[79] The term *PUPPP* was coined by Lawley and colleagues,[90] who reported a specific pruritic urticarial eruption in 7 pregnant women. *Polymorphic eruption of pregnancy* is the term used in the British literature. PUPPP occurs predominantly in primigravidas in the third trimester, with a mean onset at 35 weeks' gestation, and occasionally postpartum.[79,91] Familial occurrence and recurrence in subsequent pregnancies, with menses, or with oral contraceptive use are uncommon. The lesions start in the abdominal striae in two thirds of the cases (Fig. 52–16A), and characteristically show periumbilical sparing.[1] The eruption is polymorphous, showing urticarial and at times vesicular, purpuric, polycyclic, or targetoid lesions[91] (Fig. 52–16B). Lesions can spread over the trunk and extremities, usually sparing the palms and soles. Involvement of the face is rare (G. Kroumpouzos, unpublished observation); dyshidrosis-like lesions on the extremities are unusual. When generalized, PUPPP may resemble a toxic erythema (Fig. 52–16C) or resolving atopic eczema. On resolution of PUPPP, extensive postinflammatory hyperpigmentation can be seen, especially in skin of color (see Fig. 52–7).

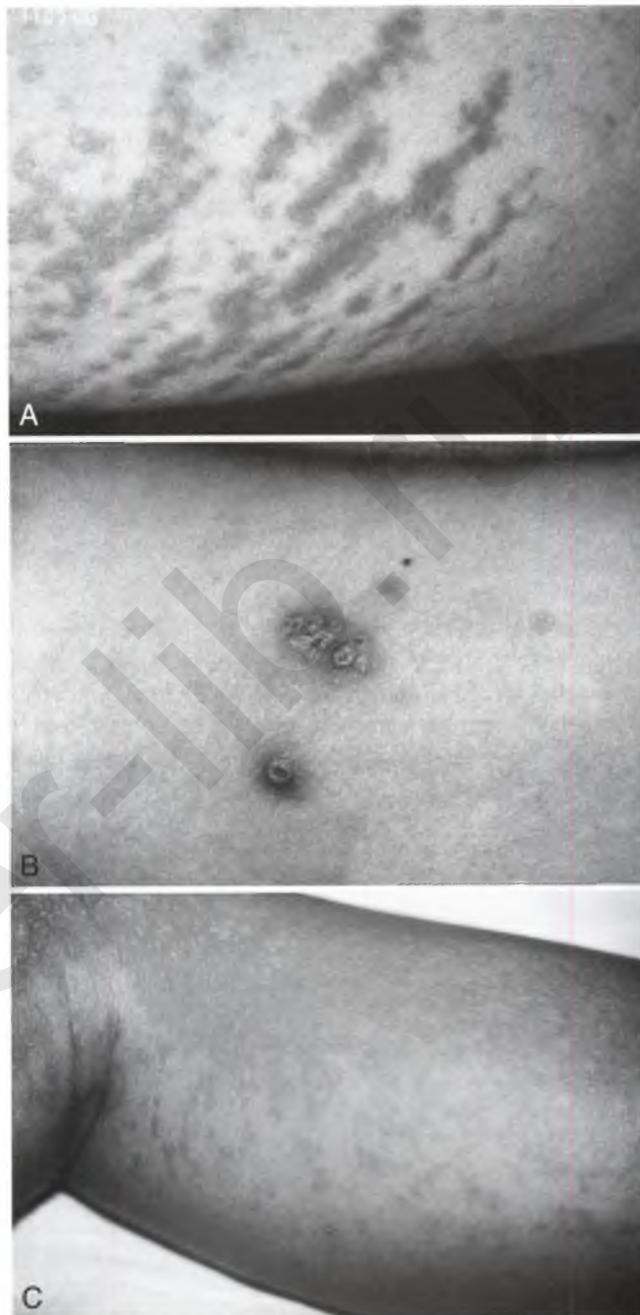
Pruritic urticarial papules and plaques of pregnancy is a clinical diagnosis because it lacks pathognomonic


FIGURE 52–16
A, Early PUPPP showing typical urticarial lesions in the abdominal striae. *B*, Lesions with microvesiculated appearance on the forearm in PUPPP. *C*, Widespread PUPPP may resemble a toxic erythema (see Color Plate 57.). (Photograph courtesy of Helen Raynham, MD.)

histopathologic features and laboratory abnormalities. The histopathology shows spongiotic dermatitis, a perivascular or upper dermal inflammatory cell infiltrate with variable numbers of eosinophils, and occasionally mild epidermal changes such as parakeratosis, acanthosis, and exocytosis.[1] Results from immunofluorescence and serology studies are negative. Differentiation from the urticarial prebullous phase of herpes gestationis requires

immunofluorescence studies (positive in herpes gestationis). Mild PUPPP requires symptomatic treatment with antipruritic topical medications, topical steroids, and oral antihistamines. Rarely, a short course of oral prednisone may be necessary. UVB can be effective.[79] The maternal and fetal prognosis is not affected. Early delivery in refractory cases is not indicated because there are no maternal or fetal risks.

The pathogenesis of PUPPP has not been fully clarified. The clinical presentation and immunohistologic profile suggest a delayed hypersensitivity reaction. No immunologic or hormonal abnormalities have been found, with the exception of a decrease in serum cortisol in one study.[17] A role for estrogen and/or progesterone has been suggested by clinical observations. It has been postulated that rapid abdominal wall distention in primigravidas may trigger an inflammatory process. This hypothesis was proposed by Cohen and colleagues,[92] who first reported an association with twin pregnancy and abnormal weight gains in the mother and fetus. Our recent meta-analysis[92] of 282 PUPPP cases revealed 29 multiple gestation pregnancies (11.7%). This prevalence is at least 10-fold higher than the prevalence of multiple gestation in the USA (1%). The association of PUPPP with multiple gestation is also supported by the recent study of Elling and colleagues.[93] Furthermore, multiple gestation is characterized by higher estrogen and progesterone levels, and progesterone has been shown to aggravate the inflammatory process at the tissue level. Interestingly, increased progesterone receptor immunoreactivity has been detected in skin lesions of PUPPP.[94]

Immunohistochemical studies[95] showed an infiltrate composed predominantly of T-helper lymphocytes. Activated T cells (HLA-DR+, CD25+, LFA-1+) were found in the dermis associated with increased numbers of CD1a+, CD54+ (ICAM+-1+) dendritic cells, and CD1a+ epidermal Langerhans cells in skin lesions, as compared to unaffected skin. This immunohistologic profile may imply a delayed hypersensitivity reaction to an unknown antigen. Fetal DNA was recently detected in skin lesions of PUPPP by Aractingi and colleagues.[96] The authors suggested that fetal cells can migrate to maternal skin and cause PUPPP because pregnancy is associated with peripheral blood chimerism, particularly during the third trimester. The importance of microchimerism in the pathogenesis of PUPPP awaits further clarification.

Prurigo Gestationis

Risks and Management Options

Prurigo gestationis affects between 1 in 300 and 1 in 450 pregnant females.[79] The condition usually begins at

FIGURE 52–17
Prurigo gestationis: excoriated papules and nodules on the extensor surfaces of the extremities (see Color Plate 58.). (Photograph courtesy of Cameron Thomas, Campbell Kennedy, and Phillipa Kyle from second edition.)

about 25 to 30 weeks' gestation and manifests itself with grouped excoriated or crusted pruritic papules over the extensor surfaces of the extremities (Fig. 52–17) and occasionally on the abdomen and elsewhere.[1] Prurigo gestationis commonly resolves in the immediate postpartum period but may occasionally persist for up to 3 months. On resolution of the lesions, postinflammatory hyperpigmentation develops. Recurrence in subsequent pregnancies has not been adequately studied. Serology may show an elevated IgE.[17] Results of immunofluorescence studies are negative; the histopathology is nonspecific. Although Spangler and colleagues[97] reported a dismal fetal outcome in their series, fetal or maternal risks have not been confirmed by any other studies. The differential diagnosis includes other specific dermatoses of pregnancy, pruritic dermatoses unrelated to pregnancy, drug eruptions, arthropod bites, and infestations such as scabies. The treatment is symptomatic with moderately potent topical steroids, if necessary intralesional or under occlusion, and oral antihistamines.[1]

Prurigo gestationis is the least studied of the specific dermatoses of pregnancy. Although its clinical presentation is indistinguishable from that of prurigo nodularis in nonpregnant women, a flare of prurigo nodularis during pregnancy has not been reported. Prurigo gestationis has been associated with a family history of obstetric cholestasis. Vaughan Jones and colleagues[17] postulated that prurigo gestationis and obstetric cholestasis are

closely related conditions, being distinguished only by the absence of primary lesions in obstetric cholestasis. The authors reported an association with personal or family history of atopic dermatitis and elevation of serum IgE, and suggested that prurigo gestationis may be the result of obstetric cholestasis in women with an atopic predisposition. The strong association of prurigo nodularis in nonpregnant women with atopy and psychosomatic factors supports the hypothesis of Vaughan Jones and colleagues. Yet, the association with atopy was not confirmed by other studies. The role of atopy and psychosomatic factors in prurigo gestationis definitely warrants further study.

Pruritic Folliculitis of Pregnancy

Risks and Management Options

Pruritic folliculitis of pregnancy is a rare specific dermatosis of pregnancy first described by Zoberman and Farmer.[98] In 2 of the original 6 cases, pruritic folliculitis of pregnancy had occurred in previous pregnancies. Since the original description, 24 cases have been reported.[79] Decreased awareness of the condition and the fact that many cases may be misdiagnosed as infectious folliculitis or PUPPP may have contributed to an underestimate of its true prevalence. The lesions are pruritic follicular erythematous papules (Fig. 52–18A) and pustules (Fig. 52–18B) that predominate on the trunk.[99] The eruption develops during the second or third trimester and clears spontaneously at delivery or in the postpartum period. The histopathology is that of a sterile folliculitis. Results of immunofluorescence and serology tests are negative. The differential diagnosis includes infectious folliculitis and specific dermatoses of pregnancy. An infectious folliculitis can be ruled out with special stains and cultures from the pustules. The largest series[17] of pruritic folliculitis of pregnancy patients showed a decreased birth weight and a male-to-female ratio of 2:1. Preterm delivery was reported in one case. No other maternal or fetal risks have been documented.

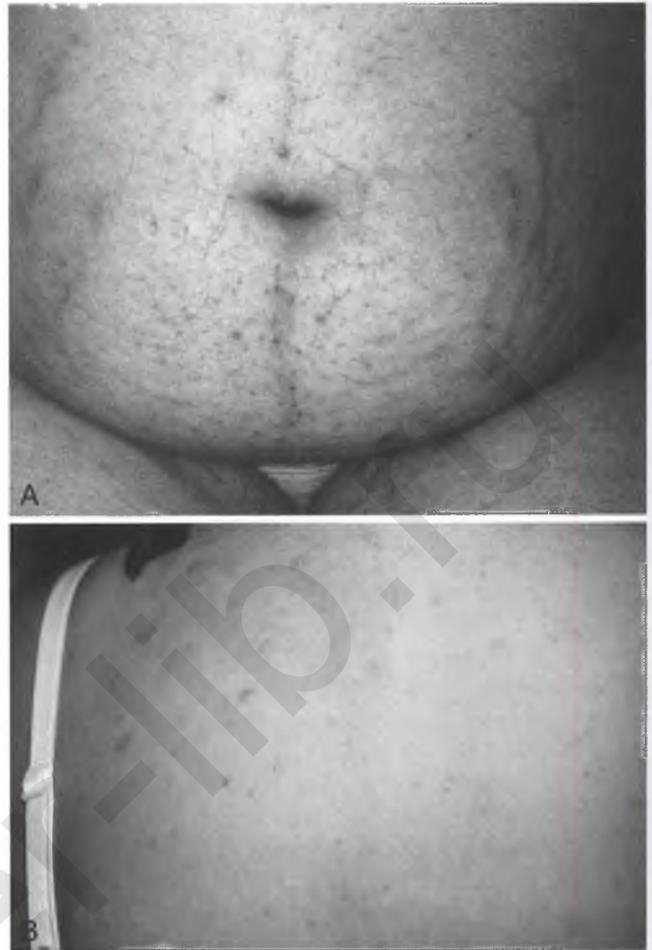
The patient should be reassured that the eruption resolves after delivery and has not been associated with substantial fetal risks. Symptomatic pruritic folliculitis of pregnancy can be treated with low- or mid-potency topical steroids, benzoyl peroxide, and UVB therapy.[1] The pathogenesis of pruritic folliculitis of pregnancy has not been determined. No immunologic or hormonal abnormalities have been found. Associations with increased serum levels of androgens or obstetric cholestasis have


FIGURE 52–18
A, Pruritic folliculitis of pregnancy: typical follicular erythematous or pigmented papules on the abdomen. B, Follicular acneform pustules and papules on the upper back in pruritic folliculitis of pregnancy (see Color Plate 59).

been reported but were not confirmed in the majority of published cases. It has been suggested[79] that pruritic folliculitis of pregnancy may be a form of hormonally induced acne, similar to the monomorphic type of acne that develops after the administration of systemic steroids or progestogens. This intriguing hypothesis has not been supported by any data. Other authors[100] have considered pruritic folliculitis of pregnancy to be a variant of PUPPP. Although follicular lesions have been reported in PUPPP, the clinical presentation and histopathology of pruritic folliculitis of pregnancy differ from that of PUPPP. For the time being, pruritic folliculitis of pregnancy can be considered a specific dermatosis of pregnancy until further data about the condition becomes available.

SUMMARY OF MANAGEMENT OPTIONS
Rashes in Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Establish the Cause—Two Possibilities:			
• Preexisting skin conditions	–	GPP	–
• Dermatoses of pregnancy	–	GPP	–
Herpes (Pemphigoid) Gestationis			
• Perform skin immunofluorescence to confirm the diagnosis.	IV	C	80
• Give topical steroids with or without an oral antihistamine (e.g., diphenhydramine) for early urticarial lesions.	IV	C	80
• Give oral steroids in most cases.	IV	C	80
• Perform plasmapheresis if oral steroids fail.	IV	C	80
• Cyclosporine with IVIG may be beneficial.	IV	C	89
• Immunosuppressants postpartum in non–breastfeeding mothers can be considered.	IV	C	80
• Maintain fetal surveillance (growth and health).	III	C	88
• Maintain vigilance for neonatal herpes gestations.	IV	C	87
PUPPP (Polymorphic Eruption of Pregnancy)			
• Perform skin biopsy if herpes gestation is a consideration.	III	B	91
• Reassure that there are no fetal risks.	III	B	91
• Prescribe topical steroids and/or antipruritic medications with or without an oral antihistamine.	III	B	91
• Give oral steroids in severe cases.	III	B	91
• UVB can be tried.	IV	C	90
Prurigo of Pregnancy			
• Reassure that there are no fetal risks.	IV	C	1
• Give topical steroids with or without an oral antihistamine.	IV	C	1
• Give oral steroids in severe cases.	–	GPP	–
Pruritic Folliculitis of Pregnancy			
• Perform cultures and special stains to rule out infectious folliculitides.	IV	C	1
• Reassure that there are no fetal risks.	–	GPP	–
• Topical benzoyl peroxide, low- or mid-potency topical steroids, and UVB can be tried.	IV	C	1

UVB, ultraviolet light B.

CONCLUSIONS

- **Physiologic skin changes of pregnancy:** no risks for the mother or fetus
- **Preexisting skin disorders:** more likely to worsen than improve during pregnancy
- **Melanoma:** prognosis not adversely affected by pregnancy
- **Impetigo herpetiformis:** form of pustular psoriasis associated with decreased calcium or vitamin D and serious maternal and fetal risks
- **Obstetric cholestasis:** check serum bile acids; ursodeoxycholic acid effective; fetal risks: distress, stillbirth, preterm delivery

CONCLUSIONS

- **Herpes gestationis:** flare at delivery; treatment with oral steroids; fetal risks: small for gestational age infants, preterm delivery, neonatal herpes gestationis
- **PUPPP:** starts in the abdominal striae and shows periumbilical sparing; associated with multiple gestation pregnancy; no maternal or fetal risks
- **Prurigo gestationis** and **pruritic folliculitis of pregnancy:** no maternal or fetal risks

Malignant Disease

Adnan R. Munkarah / Robert T. Morris / Veronica L. Schimp

INTRODUCTION

Cancer is the second leading cause of death in women of reproductive age, and fortunately, a rare cause of maternal mortality.[1,2] Between birth and 39 years of age, 1 in 52 females has invasive cancer, and approximately 3500 women between the ages of 15 and 34 years die annually of cancer in the United States.[2] It is estimated between 1 in 1000 and 1 in 1500 women will be affected by cancer while pregnant each year. The predominant malignancies associated with pregnancy are cervical cancer, breast cancer, melanoma (see Chapter 52), hematologic cancer (See Chapter 50), thyroid cancer (see Chapter 46), and colorectal cancer (Table 53–1).[3] No convincing data show that pregnancy adversely influences the biology, natural history, prognosis, or treatment of maternal cancer.[4,5]

The evaluation and treatment of pregnant women with cancer is similar to that of nonpregnant women, with a few exceptions, and both maternal and fetal outcomes should be considered when planning therapy during pregnancy. One major dilemma encountered in the treatment of pregnant women with cancer is the timing of therapeutic intervention with regard to fetal growth, development, and viability. For most malignancies, the presence of the cancer does not adversely affect the fetus; the major risk to fetal survival and normal development is the toxic effect of the various treatment modalities. Conversely, continuation of pregnancy has not been associated with accelerated tumor growth for most malignancies; therefore, elective abortion offers no therapeutic advantage to the mother. Intuitively, however, any cancer left untreated is being given an optimal opportunity to grow and metastasize. It is a therapeutic challenge for the medical team to weigh the need for immediate intervention for maternal indications against the need to delay therapy for fetal indications.

RADIATION

Radiation therapy is an effective treatment modality for a variety of cancers encountered during pregnancy. In addition, many diagnostic procedures, such as regular x-rays, radioisotope scans, and computed tomography, used in the pretreatment evaluation of malignancies are associated with radiation exposure to the mother and potentially to the fetus (Table 53–2).[6] The effects of radiation on tissues are the result of multiple cellular events that include mitotic delay, cytogenetic abnormalities, and mutagenesis and apoptotic cell death.

The effects of radiation on the fetus depend on the dose of radiation delivered as well as the stage of gestation during which exposure occurred. The dose to the embryo or fetus depends on several factors. These include the teletherapy machine used and its leakage, the target dose, the size of the radiation fields, the distance from the edge of the field to the embryo or fetus, and the use of wedges, lead blocks, compensators, and other scattering objects. Factors that decrease the radiation dose to the embryo or fetus include less leakage, a lower target dose, smaller irradiation fields, greater distance between the edges of the radiation fields and the embryo or fetus, and avoidance of wedges and other scattering objects. A distance of more than 30 cm between the edges of the radiation fields and the embryo or fetus yields a fetal exposure of only 4 to 20 cGy. Lead shielding can further reduce exposure.[7]

Before implantation, the embryo is a multicellular organism that is mostly sensitive to the lethal effects of radiation.[8,9] Exposure to high-energy radiation at that stage may induce cytogenetic abnormalities that will result in an abortion.[10-12]

The teratogenic effects of radiation are a significant risk if the fetus is exposed during organogenesis, which usually lasts for 10 days to 7 weeks after conception. The congenital malformations that are most frequently described with exposure to high-dose radiation involve the central nervous system, skeleton, and genitals. Microcephaly is the most common malformation reported.[13] Other malformations include eye abnormalities, such as microphthalmia, retinal changes, and cataracts. Growth retardation and abortion can also occur during this period.

Later in gestation, except for the central nervous system, the fetal organs become more resistant to the teratogenic effects of radiation. Exposure to high-dose radiation at that stage mainly results in growth retardation and neurophysiologic and behavioral changes that may become obvious in infancy or childhood. Data show that central nervous system malformations and growth retardation have occurred after acute exposure to more than 50 rad.[13] Fetal exposure to less than 5 rad has not been associated with such effects. In utero exposure to radiation may result in an increased risk of leukemia in childhood.[13–16] This effect, however, is the subject of debate among investigators. Ample evidence shows that radiation therapy delivered to the abdomen and pelvis results in fetal exposure to dangerous radiation doses.

CHEMOTHERAPY

Chemotherapy is an essential part of the treatment of many malignancies that can occur during pregnancy, such as breast and ovarian cancers, lymphomas, and leukemias.[17–22] Before the initiation of treatment with an antineoplastic agent in a pregnant woman, the potential benefits to the mother should be weighed against the potential risks to the mother and fetus. When cure is a realistic goal, appropriate treatment should be initiated as needed, without modifications that may adversely affect maternal outcome.

The physiologic changes that accompany pregnancy may alter the pharmacokinetics of various drugs, including many chemotherapeutic agents.[23] For water-soluble drugs, the increase in plasma volume and decrease in albumin concentration may lead to a decreased concentration of the drug after bolus administration; however, its half-life will be longer. On the other hand, an increase in the activity of the hepatic oxidases and an increase in glomerular filtration may lead to an increase in the hepatic or renal clearance of some agents. Like other substances, the transfer of antineoplastic agents to the fetus through the placenta is controlled by the molecular weight, lipid solubility, and protein binding of the agents. For example, the highly protein-bound nature of vinca alkaloids makes transplacental passage to the fetus inefficient.

The timing of fetal exposure to the chemotherapeutic agents is one of the most important determinants of pregnancy outcome. In the first trimester, exposure to chemotherapy can result in congenital malformations or abortion.[22–24] The risk of congenital malformations has been reported to be as high as 17%. The folic acid antagonists aminopterin and methotrexate, when used in the first trimester, seem to be more teratogenic than other antineoplastic agents. Syndromes of congenital anomalies that include cranial anomalies, cleft palate, anencephaly, and micrognathia have been associated with the use of aminopterin. Similarly, the use of methotrexate has led to skull abnormalities known as cloverleaf skull, or oxycephaly.[25–30] First-trimester use of alkylating agents and procarbazine is also associated with an increased risk of fetal malformations.[31]

Second- and third-trimester exposure to chemotherapy does not seem to result in an increased risk of congenital malformations. This exposure has been associated with low birth weight, intrauterine growth retardation, spontaneous abortion, premature birth, microcephaly, and mental retardation and impaired learning behavior.

Myelosuppression is a side effect common to many chemotherapeutic agents. Maternal thrombocytopenia or leukopenia at the time of the delivery can result in significant complications, including massive hemorrhage and serious infections. Therefore, the timing of delivery should be well planned in a woman who is receiving chemotherapy.

SUMMARY OF MANAGEMENT OPTIONS
Cancer Treatment

Management Options	Quality of Evidence	Strength of Recommendation	References
Radiation			
Fetal exposure from imaging doses are given in Table 53-2	III	B	6
Lead screening reduces embryo/fetal exposure and risk	III	B	7
Main risk to early embryo is miscarriage	III	B	10–12
Main risks between 10d and 7w is teratogenesis (? only if >50 rads)	III	B	13
After embryogenesis main risks are	III	B	13–16
growth restriction			
impaired neurobehavioral development (? only if >50 rads)			
Chemotherapy			
Physiological changes of pregnancy may alter the pharmacokinetics of chemotherapeutic agents	III	B	23
In first trimester the main risks are	III	B	22–30
miscarriage			
fetal abnormality (?17%) especially with the folate antagonists			
In second and third trimester the main risks are	III	B	29
growth restriction			
preterm delivery			
impaired neurobehavioral development			

CERVICAL CANCER

Cervical cancer is the most common malignancy diagnosed in pregnancy, with a frequency of 1.6 to 10.6 cases per 10,000 pregnancies.[32] The wide variability in the incidence reported in the literature seems to be caused by the inclusion of patients with postpartum cancer and carcinoma in situ. It is estimated that between 1% and 3% of patients with cervical cancer are pregnant at the time of diagnosis.[33] The mean age of pregnant patients at the time of diagnosis of cervical cancer is 31.6 years (range, 31–36.5 years).[34] As in nonpregnant patients, the most common histologic type is squamous cell carcinoma, which accounts for more than 80% of all cervical cancers.[35] More than 70% of patients have early-stage disease, which includes FIGO (International Federation of Gynecology and Obstetrics) stage I and IIA lesions.[35–38] Diagnosis may be made at an earlier stage in pregnancy because pregnant women are seen frequently by health care providers and undergo routine examinations and Papanicolaou (Pap) smears. One third of pregnant patients who are diagnosed with cervical cancer are asymptomatic, with diagnosis made at the time of an abnormal Pap smear result.

The interpretation of Pap smears obtained during pregnancy can be problematic, because several common physiologic changes associated with the gravid state can lead to false-positive results. For example, eversion of the transformation zone and exposure of columnar cells to the acid pH of the vagina cause squamous metaplasia that may be falsely interpreted as dysplasia. The Arias-Stella reaction can resemble an adenocarcinoma.[39,40] In one study of gravid hysterectomy specimens, Arias-Stella reaction was reported in 9% of specimens examined.[41] Another false-positive cause of low-grade dysplasia on Pap smear is retrieval of trophoblastic cells. It is essential to inform the cytopathologist interpreting the Pap smear that the patient is pregnant.

Historically, it was believed that pregnancy had an adverse effect on the natural history of cervical cancer. Recent studies, however, showed no difference in survival between pregnant and nonpregnant women with cervical cancer when matched by age, stage, and year of diagnosis.[33–35,38,39,42–44] In addition, several studies show that, contrary to a common misconception, the mode of delivery does not seem to affect outcome.[32,44,45]

Management Options

Colposcopy is a safe and reliable method for evaluating pregnant patients with abnormal cervical cytologic findings.[46–50] Colposcopy-directed biopsy can be performed

during any trimester, although most colposcopists suggest delaying biopsy until the second trimester. The main complication associated with cervical biopsy during pregnancy is bleeding; however, this usually can be controlled with the application of Monsel's solution and pressure. Endocervical biopsy must be avoided during pregnancy because of the risk of premature rupture of the membranes, preterm labor, and uncontrollable bleeding.[51]

During pregnancy, diagnostic cervical conization is reserved for selected indications that include the finding of minimal stromal invasion on a colposcopically directed biopsy and persistent cytologic suggestion of invasive carcinoma on Pap smear.[52,53] Fortunately, eversion of the squamocolumnar junction during pregnancy improves access to the endocervix and decreases the necessary volume of tissue to be removed. The risks of immediate and delayed bleeding after conization are 8.9% and 3.7%, respectively.[43] Other infrequent complications include premature labor, chorioamnionitis, and fetal loss.

Pregnant women who are diagnosed with invasive cervical cancer should be counseled extensively about treatment options as well as the effect of the treatment on the mother and fetus. Many factors should be considered in treatment planning, including gestational age, tumor size and stage, and the patient's desire to preserve the pregnancy. Few recent studies have evaluated the effect of delaying definitive therapy until fetal maturity is reached.[36–38,45,54–56] In these reports, treatment delays ranged from 53 to 212 days and did not result in decreased maternal survival. However, the number of patients in these series is too small to allow definite conclusions to be drawn. Treatment delay seems to be a reasonable option in a patient who is more than 20 weeks' pregnant when diagnosed with early-stage disease (FIGO IA1–IB1). In patients who elect to continue with the pregnancy and delay treatment, cervical cancer does not seem to adversely affect the fetus; the incidence of intrauterine growth restriction and stillbirth is not increased in these cases.[42] Repeat examination every 6 to 8 weeks (including col-poscopy) is recommended until surgery. For patients with more advanced disease, such as International Federation of Gynecology and Obstetrics (FIGO) stages IB2 and IIA, early treatment is suggested.[33,57]

The choice of treatment modality for pregnant patients with cervical cancer is based on the same principles that are used in the nonpregnant state. Patients with early-stage disease can be treated surgically with radical hysterectomy and bilateral pelvic lymphadenectomy.[54,55,58,59] Depending on the time of diagnosis, surgery can be done early in gestation, with termination of the pregnancy, or at cesarean delivery. Except for increased blood loss, there is no significant increase in other perioperative complications compared with nonpregnant patients, and the cure rates are comparable.[55]

Radiation therapy is used to treat advanced disease that is not amenable to surgical management. When radiation is administered in the first trimester, spontaneous abortion usually occurs at a cumulative dose of 30 to 50 Gy. Treatment in the second trimester results in abortion at a higher cumulative dose and less reliably. If abortion did not occur by the end of the external radiation therapy, surgical evacuation can be performed before brachytherapy.[60] For patients who are treated after delivery, most radiotherapists wait a few weeks for the uterus to involute before starting treatment.

Tumor stage is an important predictor of survival in cervical cancer. The outcome of patients with early-stage disease is excellent, with 5-year survival rates exceeding 90%.[35] However, in a recent report, the survival rate was worse in women who were diagnosed postpartum than in those diagnosed during pregnancy, and women diagnosed postpartum were at significant risk for recurrent disease, particularly if delivery was vaginal.[45] One site of tumor recurrence when cervical cancer occurs in pregnancy is in the episiotomy site.[61–63] It is believed that tumor cells can implant at the site of episiotomy incision after vaginal delivery. Treatment usually includes local excision and radiation.

SUMMARY OF MANAGEMENT OPTIONS
Cervical Cancer

Management Options	Quality of Evidence	Strength of Recommendation	References
Diagnosis			
Physical examination and cervical smear at first prenatal visit in high risk and those without smear in previous 3 years	III	B	46–50
Colposcopy and directed biopsies for suspicious lesions though measures needed to deal with increased bleeding risk	III	B	43,51
Cone biopsy when microinvasion suspected on directed biopsies; loop excision may be associated with increased preterm births	III	B	52,53

SUMMARY OF MANAGEMENT OPTIONS
Cervical Cancer *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Treatment			
Cervical Intraepithelial Neoplasia:			
follow-up with colposcopy during pregnancy	III	B	51
Micro-Invasive Cancer:			
after careful maternal counseling consider delaying definitive therapy until fetal maturity reached (enhance with steroids) and delivery completed	III	B	36–38
Invasive Cancer:			
Use same therapy guidelines as for non-pregnant patient:			
before 20 weeks: Consider termination and immediate therapy	III	B	54, 55, 58, 59
after 20 weeks: consider awaiting fetal maturity (enhance with steroids), then deliver and implement therapy postnatally	III	B	54, 55, 58, 59
Elective cesarean hysterectomy can be considered with early stage disease	III	B	9
Careful patient counseling required with either presentation	III	B	54, 55, 58, 59
Prognosis			
Recent studies suggesting worse prognosis when diagnosed after pregnancy	III	B	45
Reports of recurrences in episiotomy sites after vaginal birth	III	B	63

OVARIAN CANCER

Ovarian cancer occurs in between 1 in 12,000 and 1 in 20,000 pregnancies.[64–66] It is the second most common malignancy diagnosed in pregnancy.[67] During pregnancy, most ovarian masses are diagnosed incidentally at the time of obstetric ultrasound. Most adnexal masses are nonmalignant and usually are functional cysts (17%), dermoid cysts (36%), or cystadenomas (27%).[57] The risk that an ovarian neoplasm in pregnancy is malignant ranges from 2% to 5%, compared with 20% outside of pregnancy.[68–70]

The histologic distribution of ovarian cancers in pregnancy is different from that seen in the general population, partly because pregnant women are relatively young and have a higher incidence of germ cell tumors. Germ cell tumors account for 33% to 40% of malignant neoplasms complicating pregnancy, epithelial malignancies account for 33% to 53%, and gonadal stromal tumors account for 9% to 20%.[71–74] The distribution of subtypes of germ cell tumors diagnosed during pregnancy is a matter of debate. Whereas some series indicate that dysgerminomas are the most common subtype,[69,73,74] others indicate that malignant teratomas[71,72] and endodermal sinus tumors[75] are more common. Most ovarian malignancies diagnosed in pregnancy are stage I, as would be expected with germ cell tumors.

Management Options

Management of an adnexal mass during pregnancy depends on the ultrasonographic characteristics of the mass and the gestational age. Current recommendations are to proceed with surgical exploration with a midline incision at 16 to 18 weeks for masses that are larger than 6 cm, have a significant solid component, are bilateral, or persist after 14 weeks' gestation.[76,77] The serum cancer antigen 125 level can be elevated in normal pregnancies, especially in the first trimester, and should not be used to decide on surgical intervention.[78] Ovarian neoplasms, even when benign, are associated with increased risk of complications during pregnancy. Adnexal torsion is reported in up to 25% of patients[79,80]; other complications include rupture and hemorrhage. The risk of pregnancy loss or preterm labor is increased if surgery is performed for one of these acute complications.

Unilateral salpingo-oophorectomy with staging biopsy is the recommended surgery for stage I germ cell tumors. Patients with dysgerminomas and stage IA, grade 1 immature teratomas do not require further adjuvant therapy. The remaining germ cell tumors behave more aggressively and should be treated with adjuvant chemotherapy. Treatment of advanced germ cell tumors of any histologic subtype includes chemotherapy. In anecdotal reports of pregnant patients treated with combination chemotherapy regimens (bleomycin, etoposide,

cisplatin, and vinblastine), good maternal and fetal outcomes were achieved.[81,82]

In epithelial carcinomas, patients with early-stage disease can be treated successfully with conservative surgery, including salpingo-oophorectomy and staging biopsy. Advanced disease presents a management problem. Tumor debulking surgery is often extensive and may result in adverse pregnancy outcome. Cisplatin-based chemotherapy is usually used postoperatively. Few case reports describe successful treatment of advanced ovarian cancer in pregnancy with surgery and chemotherapy.[16,20,77]

Gonadal stromal tumors are uncommon in pregnancy. They are often confined to the ovary and have an indolent course. Treatment involves unilateral salpingo-oophorectomy.

SUMMARY OF MANAGEMENT OPTIONS

Ovarian Cancer

Management Options	Quality of Evidence	Strength of Recommendation	References
Diagnosis			
Often diagnosed as chance finding during an obstetric ultrasound examination	III	B	76, 77
CA-125 levels are unhelpful as can be raised in normal pregnancy	III	B	78
MRI helpful	IV	C	67
Treatment			
Surgical exploration ideally performed in second trimester	III	B	71–73
Pregnancy preservation and conservative surgery with unilateral salpingo-oophorectomy and staging biopsies are possible in most early stage ovarian cancers (uncommon)	III	B	71–73
Chemotherapy, if needed, has risks (see above and Chapter 50)	III	B	16, 20, 23–30
Salvage of the pregnancy may not be possible with advanced disease	III	B	71–73

OTHER GYNECOLOGIC MALIGNANCIES

Vulvar carcinoma in pregnancy is extremely rare. The most common histologic varieties are invasive squamous cell carcinoma and melanoma.[83] Radical excision of the primary lesion with inguinofemoral node dissection is the treatment of choice for stage I and II tumors. The timing of treatment and mode of delivery are usually dependent on the time of diagnosis during pregnancy.

The current recommendation is to proceed with definitive surgical treatment at any time during pregnancy, up to 36 weeks' gestation.[83–85] Patients can be allowed to deliver vaginally if the wounds have healed.

Twelve cases of endometrial carcinoma have been reported during pregnancy.[86–88] Surprisingly, five cases were associated with a viable fetus.[71,72] The remaining cases were diagnosed at the time of dilation and curettage performed for abnormal bleeding.

SUMMARY OF MANAGEMENT OPTIONS

Other Gynecological Malignant Disease In Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Vulval Carcinoma			
Rare; histological varieties most commonly encountered are invasive squamous cell carcinomas and melanomas	III	B	83, 85
Radical excision of the primary lesion and inguinal femoral node dissection is the treatment of choice for stage I and II squamous cell cancer	III	B	84, 85
Timing of treatment and mode of delivery are usually dependent on the time of diagnosis during pregnancy. It has been recommended to proceed with	III	B	83, 85

Other Gynecological Malignant Disease In Pregnancy (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Vulval Carcinoma—Continued			
definitive surgical treatment at any time during pregnancy up to 36 weeks of gestation. Patients can be allowed to deliver vaginally provided the wounds have healed			
Endometrial Carcinoma			
There have been twelve cases of **endometrial carcinomas** reported during pregnancy. Surprisingly five cases were associated with a viable fetus. The remaining cases were diagnosed at the time of dilatation and curettage performed for irregular bleeding	III	B	86–88

BREAST CANCER

Pregnancy-associated breast cancer is usually defined as carcinoma that is diagnosed during pregnancy or within 1 year postpartum.[89,90] It is the most common tumor in women of reproductive age. Approximately 3% of breast cancers occur in pregnancy, for a rate of 10 to 40 cases per 100,000 deliveries. The incidence is approximately 3 in 10,000 pregnancies.[4,91,92] Approximately 15% of breast cancers occur in women of childbearing age, and there is evidence that the incidence of premenopausal breast cancer is on the rise. Traditionally, it was believed that pregnancy adversely affected the outcome of patients with breast cancer. Many older reports showed poor survival in women with pregnancy-associated breast cancer.[93–95] In contrast, more recent data show identical survival rates in pregnant women and nonpregnant cohorts, when matched for disease stage.[57,90] The 5-year survival rate is reported to be 90% for patients with stage I disease, 37% for those with stage II disease, 15% for those with stage III disease, and 0% for those with stage IV disease.[96] One explanation for the lower survival rates in earlier reports is that pregnant women are more likely to be diagnosed at advanced stages.[90,97–99] Between 53% and 74% of pregnant women who are diagnosed with breast cancer have evidence of lymph node metastases. Physiologic changes that affect the breast during gestation make clinical examination difficult and inaccurate. In addition, physicians may be reluctant to perform breast biopsy during pregnancy and lactation because of the increased risk of bleeding, infection, and milk fistulas. Delays of several months between the diagnosis of breast mass and biopsy are common.[90] Delay in the diagnosis contributes to the advanced disease and poor prognosis associated with gestational breast cancer.

Management Options

Pregnant women should have a baseline breast examination at the first prenatal visit. Mammography can be performed safely during pregnancy; however, it may not be done routinely because of concern about fetal irradiation. A bilateral mammogram performed with modern equipment yields less than 500 μGy to the human embryo, which is well below the 100-mGy toxic level.[7] The mammogram may have limited diagnostic utility because of the hyperemia and edema that affect the mammary tissues and contribute to the generalized radiographic density of the breasts. Ultrasound is accurate in differentiating between cystic and solid masses. The detection of a mass necessitates prompt evaluation with fine-needle aspiration or surgical biopsy. An experienced cytologist should evaluate the cells obtained from aspirates because hyperproliferative physiologic changes in the mammary tissue may be mistaken for malignancy. The increased risk of complications associated with breast biopsy during pregnancy should not deter the surgeon from performing these procedures when clinically indicated.[90]

As in the nonpregnant patient, staging of breast cancer during pregnancy involves a complete physical examination, blood testing, and chest x-ray with abdominal shielding. Ultrasonographic evaluation of the liver should be performed only if the patient has localizing symptoms or abnormal liver chemistry findings.[100] A radionuclide bone scan can cause significant fetal exposure to radiation. Because of their low yield in early-stage disease, bone scans should be limited to patients with more advanced disease. Magnetic resonance imaging during pregnancy is safe for the mother and fetus; it is being used with increasing frequency to diagnose bone, liver, and brain metastases.

Stage I and II breast cancers are best treated with surgery. Modified radical mastectomy is the standard treatment.[90,101–103] It can be performed safely during pregnancy under general anesthesia. Treatment modalities that include breast preservation with radiation therapy should be avoided in pregnant women because of the risk of fetal exposure to a potentially mutagenic and lethal radiation dose. The standard breast radiation therapy course of approximately 5000 cGy exposes the fetus to a radiation dose that varies according to gestational age and the associated anatomic changes. Early in pregnancy, when the uterus is still in the pelvis, fetal exposure may be as low as 10 cGy. However, in late pregnancy, when the fetus moves up into the mother's abdomen, fetal exposure can reach 200 cGy. Conversely, for some women diagnosed with early breast cancer in the third trimester, delaying treatment until after parturition is an acceptable option with minimal maternal risks and obvious fetal benefit.[104,105]

Adjuvant chemotherapy is indicated in patients with lymph node metastases and in some with large tumors and negative lymph nodes. During organogenesis in the first trimester, the risks of teratogenicity and fetal malformations should be weighed carefully against the potential benefits. Later in pregnancy, regimens that include cyclophosphamide and doxorubicin can be given relatively safely.[57] Methotrexate should be avoided, when possible, because of its associated teratogenicity. In addition to fetal effects, a course of chemotherapy during pregnancy may result in possible maternal complications, including sepsis and hemorrhage, with unplanned labor and delivery.

Advanced-stage disease requires both chemotherapy and radiation therapy. The prognosis is poor, and maternal survival is limited. Management of these patients during pregnancy presents ethical and medical dilemmas and should be planned on an individual basis.

Recent literature does not support the role of routine therapeutic abortion in pregnant patients with breast cancer.[90] Many authors showed that survival is not improved by pregnancy termination for maternal indications.[97,101,106] In some cases, therapeutic abortion may be strongly recommended because of potential fetal damage from the proposed chemotherapy or radiation treatments. In early pregnancy, treatment is greatly simplified with therapeutic abortion.[90]

Subsequent pregnancy in women who have been treated for breast cancer does not seem to confer a worse prognosis than that in patients who did not get pregnant.[107] Population-based studies show that a subsequent pregnancy results in an improvement in survival, with favorable relative risks of 0.2 (range, 0.1–0.5)[89] to 0.8 (range, 0.3–2.3).[104,105] However, it is difficult to draw definite conclusions from available studies because of the small number of patients reported and the associated selection bias. Because recurrence is most likely in the first 2 years, most investigators recommend delaying conception for 2 to 3 years after treatment.

SUMMARY OF MANAGEMENT OPTIONS
Breast Cancer and Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Diagnosis			
Physiologic changes of pregnancy reduce the sensitivity of physical examination and mammography	IV	C	90
Fine needle aspiration of any suspicious lesion	IV	C	90
Open biopsy if the results of needle biopsy are equivocal	IV	C	90
Treatment			
Radical mastectomy is the preferred treatment for early cancers	III	B	91
Adjuvant chemotherapy may be indicated for some patients with high risk cancers. Both maternal benefits and potential risks to the fetus should be weighed carefully	III IV	B C	91 90
If diagnosis is made late in pregnancy and chemotherapy or radiation treatment are indicated, consider delaying therapy until after delivery	IIb	B	102
Routine therapeutic abortions are not indicated	III	B	91,96
Termination of pregnancy may be considered in patients with advanced disease if chemotherapy and/or radiation treatment are indicated in early pregnancy	IIb	B	102
Recommend delaying conception for 2–3 years after treatment	IIa	B	97

PLACENTAL METASTASES

Metastasis of maternal malignancy into the placenta is rare. Malignant melanoma is the most common maternal malignancy associated with placental metastasis; it accounts for nearly one third of reported cases.[106] Next in frequency are hematopoietic malignancies and breast carcinoma.[106,107] Fetal metastasis is extremely rare, even when the maternal surface of the placenta contains evidence of metastatic tumor. The low incidence of fetal metastasis has been attributed to two factors: inherent resistance of the trophoblast to tumor invasion and possible immune rejection by the fetal immune system.[107] Interestingly, after delivery, some infants with metastatic melanoma have complete tumor regression and long-term survival.

CONCLUSIONS

- Between 1 in 1000 and 1 in 1500 gravidas will be affected by cancer each year.
- Cervical cancer is the most common malignancy diagnosed in pregnancy, followed by ovarian cancer.
- Abnormal Pap smears should be thoroughly evaluated in pregnant women; colposcopy is a safe and reliable method for evaluating cytologic abnormalities in pregnancy.
- Treatment of cervical cancer in pregnancy is based on disease stage and gestational age; the same principles should be applied as in the nonpregnant state.
- The histologic distribution of ovarian cancers in pregnancy is different from that seen in the general population, partly because of the younger age group and the higher incidence of germ cell tumors.
- Management of the asymptomatic adnexal mass in pregnancy is dependent on size, ultrasonographic characteristics, and gestational age at diagnosis.
- Surgical exploration (optimally in the early second trimester) for ovarian cancer diagnosis and staging are established recommendations; early-stage disease can be treated successfully with conservative surgery. Extensive surgical debulking can be problematic in pregnancy.
- Adjuvant chemotherapy has been used during pregnancy with good maternal and fetal outcomes.
- Routine breast examination is recommended in pregnancy. Breast masses can be further studied by mammography, ultrasonography, and fine needle aspiration or biopsy.
- Stage I and II breast cancers are best treated by a surgical approach.
- The recommendation for routine therapeutic abortion in breast cancer patients in the interest of maternal survival is not supported by current literature.
- Malignant melanoma is the most common maternal malignancy associated with placental metastases.

Pregnancy After Transplantation

Vincent T. Armenti / Michael J. Moritz / John M. Davison

INTRODUCTION

Transplantation is now an accepted therapeutic option for patients with end-stage organ failure. The first successful human kidney transplant took place in 1954.[1] However, it was not until the 1960s that immunosuppression became available and not until the 1980s, with the introduction of cyclosporine, that consistently acceptable graft and patient survival was achieved. With the restoration of organ function, patients experience an overall improvement in their health, increased libido, and return of fertility.

The first post-transplant pregnancy occurred in March 1958 and was reported in 1963. It occurred in a patient who had received a kidney from her identical twin.[2] This pregnancy resulted in cesarean delivery of a healthy boy. As transplantation has progressed, with improvements in surgical techniques and medical therapy and advances in immunosuppression, pregnancies have been reported in recipients of each organ type. Most outcomes reported are in kidney transplant recipients. Issues that must be considered include maternal graft function and maternal health, the effect of pregnancy on graft function, and the effect of the medications and graft function on the developing fetus. There is also concern about the long-term effects of pregnancy on graft function. Finally, there is the question of whether more subtle and long-term effects, although not apparent at birth, may affect the growth and development of the offspring of these recipients or future generations. These issues are discussed in this chapter.

ORGAN TRANSPLANTATION

Patients with end-stage renal disease who are receiving or will soon need dialysis are candidates for renal transplantation. Common indications for renal transplantation are glomerulonephritis, diabetes, polycystic kidney disease, and hypertension. In 2002 in the United States, 14,710 kidney transplants were performed. The 1-year graft survival rate was 90% for deceased donor kidneys and 95% for donor kidneys.[3] Recent technical advances that allow laparoscopic removal of living donor kidneys have helped to make living donation more acceptable, removing disincentives.[4] In 2001, the number of kidney transplants from living donors exceeded the number from deceased donors.[5] Standard requirements for donor–recipient pairs for kidney transplantation are ABO compatibility and a negative pretransplant cross-match (i.e., absence of preformed anti-donor antibodies). Efforts to increase the number of kidney transplants include the use of methods to use ABO-incompatible donors as well as treatment protocols to reduce antibody levels in patients with antidonor antibodies, making transplantation possible.

Patients with both type I diabetes and end-stage renal disease are candidates for simultaneous kidney–pancreas transplantation. These patients may opt for a kidney transplant first, especially if they have a living donor, and later undergo a pancreas transplant. Patients who do not have diabetic nephropathy, but have other severe complications of diabetes, such as hypoglycemic unawareness, may be candidates for pancreas transplantation alone. In 2002, there were 771 pancreas–kidney transplants performed in the United States, with a 1-year graft survival rate of 76%.[3]

Patients with end-stage liver disease are candidates for liver transplantation. The first successful human liver transplant was performed in 1967.[1] Of candidates for liver transplantation, 95% have chronic liver disease (i.e., cirrhosis) and 5% have fulminant hepatic failure, a disorder that progresses rapidly. Chronic diseases that require transplantation include cirrhosis as a result of hepatitis C, hepatitis B, alcohol use, biliary cirrhosis, or primary sclerosing cholangitis. In children, the most common cause of liver failure is biliary atresia. Complications of end-stage liver disease that suggest the need for transplantation

include ascites, encephalopathy, and bleeding as a result of esophageal varices. In 2002, in the United States, 5040 liver transplants were performed, with a 1-year graft survival rate of 80% to 85%.[3] Living donation, in which part of an adult liver is donated, is now an option for both adult and pediatric recipients.

Although most pregnancies reported in the literature and to the registries have been in kidney or liver recipients, numbers are starting to accrue in the other groups as well, except for small bowel recipients. Candidates for heart transplantation have end-stage heart disease. Cardiomyopathy and coronary artery disease are the most common indications. On average, these adults are older than patients in other organ groups, which is likely part of the reason why fewer pregnancies have been reported. In the United States, 1975 heart transplants were performed in 2002, with a 1-year graft survival rate of 85%.[3] Fewer heart–lung and liver–kidney transplants are performed, and few pregnancies have been reported in these recipients.

Patients with end-stage lung disease and an anticipated survival of less than 2 years without transplantation are candidates for lung transplantation. Three common indications are emphysema or chronic obstructive pulmonary disease, including α_1-antitrypsin deficiency, primary pulmonary hypertension, and cystic fibrosis. The 1-year graft survival rate is the lowest of all of the groups discussed, at 76%, with 957 transplants performed in the United States in 2002.[3] Living donation is an option.

SUCCESS OF TRANSPLANTATION

Medication regimens to maintain graft survival and prevent rejection have been evolving since the 1960s. In general, these can be divided into the following three categories:

- Induction regimens are used in the first week after transplantation. These include agents such as antilymphocyte sera and interleukin-2-receptor blockade antibodies.
- Antirejection regimens are used to treat episodes of rejection. They typically include high-dose, short-term treatments with either corticosteroids or antilymphocyte sera.
- Maintenance regimens are initiated soon after transplantation to prevent acute rejection episodes and provide long-term immunosuppression. The goal of this treatment is to minimize acute rejection episodes and toxicity. Combination therapies are used to balance benefits against side effects and toxicities.

A major goal of therapy is to avoid acute rejection episodes, which affect graft survival. Different organs show different effects of acute rejection, but the result can be chronic rejection, which has no effective treatment and ultimately leads to graft demise.

Maintenance regimens in the early 1960s included azathioprine and prednisone. In the 1980s, the mainstay of immunosuppression was cyclosporine, either in combination with azathioprine and prednisone or with prednisone alone. Tacrolimus, introduced in the 1990s, is another calcineurin inhibitor that is similar to cyclosporine, but more potent and with different side effects. Mycophenolate mofetil was introduced in the mid-1990s, and like azathioprine, belongs to the antimetabolite class. This agent essentially replaced azathioprine, and in most cases, is used with a calcineurin inhibitor. A newly introduced agent is sirolimus, which has a different mechanism of action and the added advantage of not being nephrotoxic. Two drugs of the same class are not used in combination (e.g., cyclosporine and tacrolimus). Table 54–1 summarizes the current agents and their mechanisms of action and side effects, including agents used for induction and rejection.[6] The U.S. Food and Drug Administration (FDA) categories for these drugs are shown in Table 54–2, including information on published reproductive or clinical outcome data.[7]

RISKS OF TRANSPLANTATION

Immunosuppressive Agents and Teratology

Corticosteroids

In animal studies, corticosteroids have caused cleft palate.[8] Clinically, these agents are associated with an increased risk of premature rupture of the membranes and adrenal insufficiency in newborns.[9] Prednisone has been used for more than 40 years for maintenance therapy, and intravenous methylprednisolone is used for induction and treatment of rejection. At current doses, it is considered an adjunctive drug. More recently, given the many side effects, steroid withdrawal and steroid avoidance have been attempted.

Azathioprine

Azathioprine (1.5–3 mg/kg/day), a primary drug used for immunosuppression before the introduction of cyclosporine, is now an adjunctive agent at doses of 0.5 to 1.5 mg/kg/day. Clinical data do not support early concerns about teratogenicity in animal studies, nor has a predominant structural malformation pattern been identified. It is listed as a category D agent, and reviews show attributable newborn problems, including thymic atrophy, transient leukopenia, anemia, thrombocytopenia, chromosomal aberrations, sepsis, and reduced immunoglobulin levels.[10,11]

Cyclosporine

As the first calcineurin inhibitor, cyclosporine became the mainstay of immunosuppression and remains a commonly

TABLE 54–1

Immunosuppressive Drugs

DRUG	USES	EFFECTS	SIDE EFFECTS	COMMENTS
Cyclosporine	Maintenance	Profound inhibitor of helper T cell function	Nephrotoxicity, hypertension, tremor, hirsutism	Relatively selective for alloimmune responses; cannot be used with tacrolimus because of synergistic nephrotoxicity
Tacrolimus	Maintenance, antirejection	Profound inhibitor of helper T cell function	Nephrotoxicity, neurotoxicity, diabetes	
Corticosteroids (oral prednisone, IV methylprednisolone)	Maintenance, antirejection	Inhibits all leukocytes; high doses cause lymphocytosis	Cushingoid fascies, diabetes, excessive weight gain, aseptic necrosis of the hip	Many troublesome side effects; nonspecific immunosuppressant
Azathioprine	Maintenance	Inhibits clonal proliferation of T cells	Leukopenia	Nonspecific
Muromonab-CD3 (OKT3)	Antirejection, induction	Disables or depletes all T cells	First dose can cause fever, chills, or bronchospasm as a result of cytokine release	Low frequency of development of anti-OKT3 antibodies; maximum duration of therapy 2–3 weeks
Antithymocyte globulin	Antirejection, induction	Depletes T cells	Fevers, chills	Maximum duration of therapy 2–3 weeks
Mycophenolate mofetil (CellCept)	Maintenance	Akin to azathioprine	Diarrhea, leukopenia	More lymphocyte-selective than azathioprine
Sirdimus (Rapamune)	Maintenance	Inhibits helper T cells	Potential thrombocytopenia and hyperlipidemia	Some similarities to cyclosporine and tacrolimus; synergistic only with cyclosporine
Basiliximab (Simulect)	Antirejection prophylaxis	Inhibits interleukin-2-mediated activation of lymphocytes	Possible anaphylactoid reaction	Immunosuppressive chimeric monoclonal antibody
Daclizumab (Zenapax)	Antirejection prophylaxis	Inhibits interleukin-2-mediated activation of lymphocytes	Possible anaphylactoid reaction	Immunosuppressive chimeric humanized antibody

used agent. Cyclosporine was originally available as Sandimmune, which was later reformulated as Neoral. Generic versions are available. It is usually used with one or two adjunctive agents. Maternal problems include hypertension and nephrotoxicity. Although fetal toxicity and abnormality have been reported in animal studies, these occurred at dosages higher than those used clinically.[12,13] Some early clinical reports suggested a greater risk of fetal growth restriction,[14] but the magnitude of teratogenic risk appears minimal and no predominant pattern of newborn malformations is evident.

Tacrolimus

Tacrolimus, which was approved for use in the United States in 1995, is more potent than cyclosporine. In animal studies, fetal resorption occurred at doses higher than those used clinically.[15] Transient neonatal hyperkalemia has been reported,[16] as has a higher incidence of diabetes. Tacrolimus can be used alone or with an adjunctive agent.

Mycophenolate Mofetil

Mycophenolate mofetil, which was approved for use in 1995, is typically used in combination with a calcineurin inhibitor. In contrast to the calcineurin inhibitors, there is greater concern about the potential risk of teratogenicity, based on reproductive toxicity studies in animals. Developmental toxicity in rats and rabbits included malformations and intrauterine growth restriction. Death occurred at dosages that appeared to be within the recommended clinical dosages based on body surface area.[17] Limited clinical data show no particular pattern of malformation.[18,19] Given these concerns, when a patient who is taking mycophenolate mofetil becomes pregnant or is considering pregnancy, the dosage may be decreased or mycophenolate mofetil is discontinued and another agent substituted.

Sirolimus

Sirolimus, which was approved for use in the United States in 1999, is an antiproliferative agent of its own class. It is used in combination with cyclosporine or tacrolimus, or with prednisone alone (European and U.S. labeling). There are concerns about its use in pregnancy, but teratogenicity has not been noted in animal studies, although decreased fetal weight and delayed ossification have been reported.[20] When it was used with cyclosporine in pregnant animals, resorption and fetal mortality rates were increased, suggesting increased toxicity; however, insufficient data on clinical outcome are available.[19]

Other agents used for short-term induction or rejection have a minor role in pregnancy. In a small series of patients, muromonab-CD3 (OKT3)[7] and corticosteroids were used for rejection in pregnancy (discussed later).

Maternal Risks

Transplant recipients have varying degrees of post-transplant recovery. One difficulty in assessing pregnancy risk in this population overall is that many of the conclusions have been derived from experience in kidney transplant recipients. In 1976, a management plan was suggested in a detailed case report of a renal transplant recipient during pregnancy.[21] Based on this information and a survey of literature at the time, the following criteria were derived for counseling renal recipients who are contemplating pregnancy:

- Good general health for at least 2 years after the transplant
- Stature compatible with good obstetric outcome
- No proteinuria
- No significant hypertension
- No evidence of renal rejection
- No evidence of renal obstruction on excretory urogram or ultrasound
- Stable renal function
- Stable immunosuppressive therapy

Most of these guidelines still apply, although recipients can safely become pregnant sooner than 2 years post-transplant and hypertension is now much more prevalent. It has been more difficult to identify criteria for recipients of other organs, but good, stable graft function is essential for pregnancy to be well tolerated. The appropriate interval after transplant and the features of good, stable graft function for each group of organ recipients are harder to define. For renal recipients, graft function can be assessed by measuring the serum creatinine level or creatinine clearance. Extensive studies in both clinical and animal models in the nontransplant population have evaluated the effect of pregnancy on renal function. Renal function is unaffected if the kidney is stable.[22] In the transplant population, this finding is supported by well-designed case–control studies showing that pregnancy does not cause deterioration of graft function when prepregnancy graft function is stable.[23–25] Factors that must be considered in nonrenal recipients are the nephrotoxic effect of calcineurin inhibitors on native kidney function and the increased likelihood of hypertension. Thus, nonrenal recipients who receive calcineurin inhibitor therapy often have renal impairment.

Literature surveys from the azathioprine era of the 1970s and 1980s attest to thousands of successful post-transplant pregnancies in renal transplant recipients. The spontaneous abortion rate was approximately 14%, and the therapeutic abortion rate was approximately 20%. Of pregnancies that continued beyond the first trimester, more than 90% were successful. Renal impairment occurred in approximately 15% of women, and hypertension complicated approximately 30% of pregnancies. Preterm delivery was common, affecting 45% to 60%

of pregnancies, with fetal growth restriction occurring in approximately 20%.[26,27]

Initial reports of cyclosporine exposure during pregnancy raised concern because a higher rate of fetal growth restriction, which may have been related to higher doses, was noted.[14] Also apparent was a higher incidence of hypertension than was previously noted in the azathioprine era.[28] With the advent of cyclosporine, it was suggested that this drug might not be optimal for use in pre gnancy and that patients be switched back to azathioprine-based regimens because of the longer experience with these drugs. Given the need to provide more consistent and effective surveillance for the transplant community, the National Transplantation Pregnancy Registry (NTPR) was established in 1991, with the goal of maintaining an ongoing database to assess the safety of pregnancy in transplant recipients as well as pregnancies fathered by male transplant recipients. A National Transplant Pregnancy Register was established in the United Kingdom in 1997, but discontinued in 2002.[29] After the introduction of cyclosporine, case and individual transplant center reports and registry data reported successful pregnancies in female transplant recipients while highlighting consistent risks to mothers and newborns. Most conclusions came from data on renal recipients, but information is accruing from other organ recipients with differences evident among the groups.

Overall, compared with the general population, female transplant recipients are at greater risk for preeclampsia and hypertension during pregnancy. A higher percentage of cesarean deliveries is reported as well. The balance between graft function and management of immunosuppression during pregnancy is crucial. Fortunately, in organ recipients, the incidence of rejection during pregnancy is no higher than that in the nonpregnant population, and graft loss within 2 years of delivery does not appear to be affected by pregnancy. When irreversible, unpredictable graft events occur, they more often happen in patients with impaired prepregnancy graft function. Many recipients have had successful successive pregnancies, and some have had successful outcomes with multiple gestations and in vitro fertilization.[30–32]

Current data for each organ recipient group reported to the NTPR are summarized in Tables 54–3 to 54–7.[19] High incidences of prematurity and low birth weight are reported and are more apparent among pancreas–kidney recipients and less apparent in liver and heart recipients. Pancreas–kidney recipients usually tolerate pregnancy without gestational diabetes. Most infectious complications involve the urinary tract. Rejection during pregnancy is associated with poorer outcomes for the newborn and for graft survival (Tables 54–8 and 54–9). Rejection should be biopsy-proven, if possible; treatment is with steroids, antilymphocyte sera or adjustment of baseline immunosuppression.

TABLE 54–3

Pregnancies in Female Transplant Recipients

Fetal Risks

Two large reports on the two primary calcineurin inhibitors, cyclosporine and tacrolimus, examined the overall prevalence of malformations in newborns. In the offspring of cyclosporine-treated recipients, the malformation rate was 4.1% (14 of 339 births), based on a meta-analysis.[33] NTPR data on the offspring of cyclosporine-treated liver or kidney recipients showed malformations in 3% to 5% of a total of 425 liveborn infants.[34] The types of malformations varied among different systems, with no predominant type noted. No structural malformations were noted in newborns of pancreas–kidney (21 liveborn infants), heart (27 liveborn infants), or lung recipients (3 liveborn infants). In a report of patients treated with tacrolimus during pregnancy (84 women, 100 pregnancies), 4 of 71 liveborn infants analyzed (5.6%) had evidence of structural malformations, but no specific pattern was evident.[35] Transplant recipients, on average, delivered 1 month early, with birth weights of 2200 to 2800 g reported. Differences were seen among organ recipient groups. Genetic considerations must be taken into account. They may contribute to organ failure in the mother and must be considered in the assessment of risk to the newborn. Table 54–10 summarizes the incidence of malformations reported to the NTPR in transplant recipients receiving the newer immunosuppressants. Of concern is the potential for more subtle effects that may not be apparent at birth, but may affect long-term growth and development as well as the next generation.[36] Clinical reports noted that children of recipients are developing well, although there is concern that alterations in T cell subpopulations may affect vaccinations or long-term immunity.[37,38] A large series of 175 newborns of cyclosporine-treated kidney recipients reported to the NTPR showed no evidence of an increased incidence of developmental delays over that expected, given the high percentage of premature offspring in this group.[39]

Childhood transplant recipients who subsequently become pregnant in adulthood are of increasing relevance (Table 54–11).[40] The risk of malformations in newborns of these patients is not increased, but a small percentage of recipients have graft rejection, dysfunction, or even loss within 2 years of delivery. Consistent features of obstetric outcome are higher incidences of prematurity and low birth weight, depending on the type of organ transplant. These rates are always much higher than in the general population.

MANAGEMENT OPTIONS

Prepregnancy and Prenatal

Recommendations for the management of pregnancy after transplantation have been published.[41–56] Transplantation restores fertility, and patients must be advised about appropriate birth control. For all organ recipients, an interval from transplant to conception is advisable to allow establishment of stable graft function and reduction of immunosuppression to maintenance levels, with concomitant reduction of the risk of more serious posttransplant infections. NTPR data showed a higher incidence of pregnancy termination and peripartum rejection with transplant-to-conception intervals of less than 6 months compared with longer intervals in cyclosporine-treated kidney recipients. Waiting at least 6 months, and preferably, 1 year from transplant seems advisable.[57] It is important to note whether the recipient has been rejection-free (and for how long) as well as the level and stability of graft function.

No specific combination of immunosuppressive agents is known to be teratogenic, although there is concern about the newer agents mycophenolate mofetil and sirolimus, given their mechanisms of action. Clinical data are sparse, and there are no definitive recommendations for switching a recipient from one regimen to another prepregnancy or for a specific regimen for women of reproductive age. Pregnancy should be considered high risk, and there should be close communication among the transplant surgeons, transplant physicians, and obstetricians.

A significant percentage of recipients have hypertension and may be receiving a combination of antihypertensive medications. Angiotensin-converting enzyme

*Some recipients had a subsequent pregnancy while receiving a different regimen; two recipients with five pregnancies that occured while they were receiving no immunosuppression are not included in this table.
†Includes twins.
From Armenti VT, Radomski JS, Moritz MJ, et al: Report from the National Transplantation Pregnancy Registry (NTPR): Outcomes of Pregnancy after Transplantation. In Cecka JM, Terasaki PI (eds): Clinical Transplants 2002. Los Angeles, UCLA Immunogenetics Center, 2003, pp 121–130.

inhibitors and angiotensin II receptor antagonists are contraindicated during pregnancy, but their adverse effects have been noted from midpregnancy onward, so it can be argued that they may be continued until conception.[45,58] If dosage adjustments or changes to hypertensive agents are needed, these changes can be made in anticipation of pregnancy. In addition to hypertension and preeclampsia, attention should be focused on other comorbid conditions that are likely to occur, including infections and gestational diabetes.

Rejection, although not common, must be considered in the face of graft dysfunction. The etiology of graft dysfunction in any solid organ recipient must be investigated. There are special clinical considerations for each organ group. In the renal transplant group, the group with the most data, the usual pattern for the serum creatinine level is a slight decrease in early pregnancy, with a return to baseline postpartum. Increases during pregnancy and postpartum should be evaluated. Pancreas–kidney recipients usually can tolerate pregnancy without problems with glucose control, but additional comorbid conditions caused by cardiovascular disease must be considered. Lung recipients appear to have a higher incidence of peripartum problems in terms of both graft function and patient survival.

Infectious complications during pregnancy are most often urinary tract infections. Therefore, monthly urine culture should be performed. Occasionally, more serious yeast infections, pneumonia, sepsis, or unspecified viral infections complicate pregnancy. Cytomegalovirus is usually asymptomatic and is detected by serologic, antigen, or viral monitoring. If a primary infection occurs during pregnancy, there is a risk of transmission with fetal sequelae, but the effectiveness of treating the mother's infection in preventing or ameliorating fetal sequelae is uncertain.

The rate of hepatitis C transmission from mother to child in the nontransplant population is 5%,[59] with one case reported to the NTPR. Recipients with acute hepatitis B infection may transmit it to their offspring. Administration of hepatitis B immune globulin and hepatitis B virus vaccine to the newborn within a few hours of birth usually prevents transmission. Estimates of the incidence of acute infection with toxoplasmosis are 0.2% to 1%, with most cases undiagnosed and asymptomatic. Congenital toxoplasmosis can have severe consequences, and the diagnosis is dependent on culture, direct antigen detection, or serologic tests.[60]

Scrutiny for hypertensive changes and preeclampsia is essential, although the diagnosis of preeclampsia may be difficult because serum uric acid levels and urinary

protein excretion may be well above expected normal ranges without preeclampsia, as a result of drug nephrotoxicity or the renal allograft. Other complications include HELLP syndrome, ureteral obstruction, and complications of cesarean delivery. Peripartum ultrasound assessment to exclude urinary obstruction is warranted if the serum creatinine level increases.

Unless obvious immunosuppressive toxicity or rejection occurs, it is best to maintain baseline immunosuppressive dosing. Blood concentrations are likely to decrease during pregnancy, given the increased maternal volume of distribution as well as fetal metabolism of drugs. Some recipients are noncompliant, choosing to stop taking medications during pregnancy for fear that the medication will harm the fetus. Reports to the registry show that, in most pregnancies, immunosuppressive doses have been kept the same or increased during pregnancy. Regardless of dosing during pregnancy, many changes that occur peripartum mandate that postpartum immunosuppressive dosing should be directed by blood level, when possible.

Significant unexplained deterioration in graft function should be assessed with biopsy. For heart recipients to avoid x-ray exposure, biopsy can be done with echocardiographic guidance.[49] If the diagnosis of acute rejection is made, then appropriate antirejection regimens are necessary. Given the risk of rejection and preeclampsia, more frequent monitoring is warranted from midpregnancy onward, including blood pressure measurements, assessment of graft function, and measurement of immunosuppressive drug levels.

In liver recipients, worsening liver function with chronic rejection or hepatitis C has been noted, with further deterioration in subsequent pregnancies.[61] Whether such deterioration is time-linked or pregnancy-induced requires further study. Recipients with stable graft function have tolerated subsequent pregnancies. Data to support this observation have been noted in each recipient group but are more easily quantified among kidney recipients.

Labor and Delivery

A high incidence of cesarean delivery is reported in all organ recipient groups. Cesarean delivery is performed for obstetric indications only. Immunosuppression must not be interrupted during labor and delivery.

TABLE 54-10

Reported Birth Defects in Offspring of Female Kidney Recipients Taking Cyclosporine (Neoral) or Tacrolimus during Pregnancy

DEFECT	N	REGIMEN
Cleft lip and palate and ear deformity	1	Tacrolimus, mycophenolate mofetil, then sirolimus and prednisone
Hypoplastic nails and shortened fifth fingers	1	Tacrolimus, mycophenolate mofetil, and prednisone
Renal cystic dysplasia	1	Tacrolimus, alone
Submucosal cleft palate	1	Neoral, azathioprine, and prednisone
Tongue-tied	1	Neoral, azathioprine, and prednisone
Pyloric stenosis	1	Neoral, azathioprine, and prednisone
Imperforate anus, clubbed feet, hypospadias	1	Neoral, azathioprine, and prednisone
Total number of live-born infants with birth defects	7/140 (5%)

Postnatal

Most oral maintenance agents are easily absorbed, and treatment can usually be resumed shortly after cesarean delivery. When oral treatment cannot be resumed, intravenous formulations are available for most, but not all, agents. Immunosuppressive drug levels should be monitored and dosage adjusted appropriately, which may affect blood pressure, renal function, and other toxicities.

One must be aware of postpartum depression among transplant recipients, as medications may be missed or not taken. Therefore, close monitoring is required for several months postpartum.

Breastfeeding is controversial.[61-64] Although exposure of the newborn to an immunosuppressive drug may be detrimental, a newly emerging view is that the benefits of breastfeeding outweigh the minimal risk. Further study of potential long-term effects is needed.

CONCLUSIONS

- Successful pregnancy is possible after transplantation.
- Before becoming pregnant, recipients should have stable graft function and optimal control of comorbid conditions.
- Although the shortest safe interval between transplant and conception has not been established, 1 year is a reasonable milestone, given the prerequisites of stable, adequate graft function and maintenance-level immunosuppression.
- Stable medical regimens should be changed as little as possible, and close maternal and fetal surveillance is required during pregnancy.
- These pregnancies are high risk and require coordinated care by perinatal specialists and transplant personnel.

Pregnancy after Transplantation

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Patients should defer conception for at least 1 year after transplantation, with adequate contraception.	IIb	B	26,55,57,65
Assessment of graft function:	III	B	26,46,65
• Recent biopsy	III	B	66
• Proteinuria	III	B	66
• Hepatitis B and C status	IV	C	44
• Cytomegalovirus, toxoplasmosis, and herpes simplex status	IV	C	44, 46
Maintenance immunosuppression options:	IV	C	7,19,28,33, 35,41,42,44, 49,54,67,68
• Azathioprine			
• Cyclosporine			
• Tacrolimus			
• Corticosteroids			
• Mycophenolate mofetil			
• Sirolimus			
The effect of comorbid conditions (e.g., diabetes, hypertension) should be considered and their management optimized; nonrenal recipients should have their baseline kidney function assessed.	III	B	22,26,45,69
Vaccinations should be given, if needed (e.g., rubella).	IV	C	26,44
Explore the etiology of the original disease; discuss genetic issues, if relevant.	IV	C	26,70
Discuss the effect of pregnancy on renal allograft function.	IIa	B	23–26
Discuss the risks of intrauterine growth restriction, prematurity, and low birth weight.	III	B	19,26–28,56
Prenatal			
Accurate early diagnosis and dating of pregnancy	IV	C	26
Clinical and laboratory monitoring of the functional status of transplanted organs and immunosuppressive drug levels:	III	B	26,44,46, 49,71,72
• Every 4 weeks until 32 weeks			
• Every 2 weeks until 36 weeks			
• Then weekly, until delivery			
Monthly urine culture	IV	C	26,44,47
Surveillance for rejection, with biopsy considered if it is suspected	III	B	19,26,44,61
Surveillance for bacterial or viral infection (e.g., cytomegalovirus, toxoplasmosis, hepatitis)	IV	C	26,44,46
Fetal surveillance	IV	C	26,46,55
Monitoring for hypertension and nephropathy	IV	C	26,28,44,48,69
Surveillance for preeclampsia	IV	C	26,46
Screening for gestational diabetes	IV	C	26
Labor and Delivery			
Vaginal delivery is optimal; cesarean delivery is used for obstetric reasons.	IV	C	26,47
For kidney recipients, episiotomy is performed on the side opposite the allograft.		GPP	
For heart, lung, or heart–lung recipients:		GPP	
• Vigilance for poor or absent cough reflex and the need for airway protection			
• Unpredictable response to vasoactive medications			
• Judicious use of intravenous fluids			

SUMMARY OF MANAGEMENT OPTIONS
Pregnancy after Transplantation (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Postnatal			
Monitor immunosuppressive drug levels for at least 1 month postpartum, especially if dosages were adjusted during pregnancy.	III	B	44,49,67,71
Surveillance for rejection, with biopsy considered if it is suspected	III	B	19,26,61
Breastfeeding	III	B	61–64
Contraception counseling	IV	C	26

Trauma

Renee A. Bobrowski

INCIDENCE AND RISKS

General

Trauma occurs in 6% to 7% of all pregnancies and is the leading cause of nonobstetric maternal death.[1,2] Motor vehicle accidents (MVAs) are the most frequent cause of injury, followed by falls, direct assault to the abdomen, and penetrating trauma. Although most injuries during pregnancy are minor, 2% to 8% of victims have a life-threatening injury and require admission to an intensive care unit.[3] Maternal mortality from trauma approximates 10%, but is the same as for nonpregnant patients, when matched for injury severity.[4]

Trauma places the mother and fetus at increased risk, and fetal loss occurs in at least 40% of critically injured gravidas. Injury severity score, increasing fluid requirement during resuscitation, Glasgow coma score, and maternal acidosis and hypoxia appear to predict an increase in fetal loss.[3–7] The rate of adverse pregnancy outcome, however, is approximately 4%, even when maternal injuries are minor.[8] Because 90% of all trauma in pregnant women is minor, more fetuses die as a result of lesser injuries than as a result of catastrophic trauma.

The obstetrician must be prepared to work in concert with the trauma team to evaluate and treat an injured pregnant woman. It is imperative to understand the physiologic changes of pregnancy and the implications for managing gravid trauma patients. The presence of a fetus may be extremely unnerving to even the most experienced emergency team, and obstetric consultation can be invaluable. The basic principles of trauma management apply to injured pregnant women, and maternal resuscitation is the first priority under all circumstances. Once the maternal condition is stable, diagnostic evaluation, fetal assessment, and treatment can proceed.

Physiologic Changes of Pregnancy and Trauma

Among the many physiologic changes that occur during pregnancy, some assume greater importance in trauma. Understanding a pregnant woman's response to injury will facilitate her care from the moment of arrival in the emergency department. Table 55–1 outlines changes that are pertinent to the care of gravid trauma victims and their clinical implications.

The fetal response to trauma depends on the severity of maternal injury and the adequacy of placental perfusion. Uterine perfusion depends on maternal blood pressure because the uterine arteries lack autoregulation and are maximally dilated during pregnancy. Maternal hypotension and hypoxia increase the secretion of catecholamines, which are potent vasoconstrictors of the uterine artery. Normal maternal heart rate and blood pressure do not ensure adequate placental perfusion and fetal oxygenation. Therefore, these vital signs are poor indicators of fetal well-being.[4]

MANAGEMENT OPTIONS—GENERAL

Basic Principles of Trauma Resuscitation During Pregnancy

Emergency department evaluation and treatment of the injured gravida should proceed in a timely and organized fashion. Ideally, each member of the trauma team is assigned specific tasks to avoid confusion and duplication of services. Patients with minor injuries should receive routine medical treatment and appropriate fetal assessment. The management of gravidas with moderate to severe injuries can be divided into the following steps:

- Primary survey
- Resuscitation

TABLE 55–1

Clinical Implications of the Physiologic Changes of Pregnancy in the Patient with Traumatic Injury

PHYSIOLOGIC CHANGE	CLINICAL IMPLICATION
Blood volume increases 50%	Blood loss may exceed 30% before clinical signs of hypovolemia occur
	Aggressive volume replacement is needed
Systemic vascular resistance decreases	Misinterpreted as hemodynamic instability
Heart rate increases	Misinterpreted as early decompensation
Respiratory rate and tidal volume increase	Normal P_{CO_2} = 30 mm Hg
Minute ventilation and oxygen consumption increase	More susceptible to hypoxemia with apnea
Diaphragm is elevated	Perform thoracostomy 1–2 interspaces higher than normal
Gastrointestinal motility decreases	Aspiration risk increases
Distended abdomen occurs with advancing gestation	Sensitivity of peritoneal signs decreases
Uterine enlargement occurs	Protects bowel with lower abdominal penetrating trauma
Uterine blood flow increases	Risk of hemorrhage and retroperitoneal bleeding increases
Bladder is displaced into the abdomen	More susceptible to injury
Renal blood flow increases	Normal serum blood urea nitrogen and creatinine levels = 12 and 0.8 mg/dL, respectively
Hypomotility of the renal collecting system occurs	Ureteral dilation and mild hydronephrosis (right > left)
White blood cell count increases	Nonspecific for injury
Levels of fibrinogen and factors VII, VIII, IX, and X increase	Hypercoaguable state; risk of thrombosis increases

- Secondary survey
- Laboratory and diagnostic studies
- Definitive treatment (Table 55–2)[9,10]

The steps in this algorithm may occur simultaneously in the emergency department.

Primary Survey

The primary survey focuses on identifying life-threatening injuries and initiating resuscitative measures. Details of the event, the mechanism of injury, resuscitation attempts in the field, and the patient's medical history should be obtained from the transporting paramedics. The components of the primary survey include the ABCs of resuscitation (airway, breathing, and circulation), an initial physical examination with adequate exposure to identify injuries, and a brief neurologic assessment.

The highest priority is to establish that the patient has an adequate airway. This can be accomplished in many cases by talking to the patient. A patient who can speak in complete sentences, in a normal voice, and can respond appropriately has a patent airway as well as adequate oxygenation and brain perfusion. If there is evidence of airway compromise, endotracheal intubation should be performed without delay.

Once the airway is deemed adequate, breathing must be assessed. The chest should be examined for expansion, breath sounds, crepitus, subcutaneous emphysema, and open wounds. Supplemental oxygen, 100% by mask, is administered until respiratory assessment is completed. Pulse oximetry can objectively confirm normal oxygen saturation unless the patient has hypotension, peripheral

TABLE 55–2

Summary of General Principles of Trauma Resuscitation

Primary Survey
Identify and treat life-threatening conditions
    Airway
    Breathing
    Circulation
        Venous access
        Fluid and blood component therapy
        Left lateral positioning
    Initial neurologic assessment
    Appropriate exposure for initial physical examination

Resuscitation
Response to initial treatment
    Pulse rate and blood pressure
    Urinary output
    Continue resuscitative measures

Secondary Survey
Initiate once patient is stabilized
    Complete physical examination
    Obstetric evaluation
        Fundal height
        Uterine tone, contractions, and tenderness
        Fetal assessment: fetal heart rate, nonstress test, ultrasonographic examination
        Pelvic examination
    Laboratory studies (See Table 55–3)
    Diagnostic studies
        Focused assessment with sonography for trauma
        Computed tomography
        Diagnostic peritoneal lavage

Definitive Treatment
Consult with appropriate specialists for treatment of specific injuries
Assess the need for transport
Provide deep vein thrombosis prophylaxis
Give tetanus immunization as needed
Administer Rh-immune globulin if the patient is Rh-negative

vasoconstriction, or severe anemia. If there is evidence of maternal hypoxia, arterial blood gas analysis should be obtained while the patient breathes room air (when possible). Oxygen can be weaned based on the clinical assessment and the patient's condition. When a nasogastric tube is required for gastric decompression, it should be placed after adequate ventilation is established.

Endotracheal intubation and mechanical ventilation may be required when a patient cannot maintain adequate ventilation or oxygenation. Intubation should not be delayed with the expectation that a patient's respiratory status will quickly and spontaneously improve. Blood gas analysis can be helpful in the decision-making process, but clinical judgment is equally important. Indications for intubation and mechanical ventilation include airway obstruction, inability to protect the airway, hypoxia, coma, shock, flail chest, open chest wounds, and ineffective ventilation. Adequate preoxygenation before intubation and prompt reoxygenation afterward are important because oxygen consumption increases during pregnancy. Because lower esophageal sphincter tone is decreased during pregnancy, rapid-sequence induction with cricoid pressure should be performed. Postintubation chest radiography is mandatory to confirm proper tube placement.

Circulation is the third component of the ABCs that requires immediate assessment. The hemodynamic changes of pregnancy can result in a misleading impression of maternal stability. Blood volume increases 50% during pregnancy, and gravid women tolerate a greater degree of acute blood loss before hemodynamic compromise occurs. Pulse rate and blood pressure may not change until 30% to 35% of blood volume has been lost.[11] Tachycardia and hypotension therefore are absent in a pregnant woman during the early phase of shock. Conversely, a gravida who has tachycardia and hypotension has lost a significant proportion of her blood volume and will need aggressive resuscitation with fluids and blood products.

A pregnant patient who is lying supine should have a left lateral tilt, particularly during the second and third trimesters. Left lateral positioning maximizes cardiac output by reducing uterine pressure on the inferior vena cava and allowing adequate venous return. If a spine injury is suspected or documented, a rolled towel or blanket can be placed beneath the spine board at the level of the hips without risking neurologic compromise.

The physical examination during the primary survey should be thorough and efficient. In patients with moderate to severe injuries, all clothing must be removed to allow adequate visualization and assessment of injuries. Obvious hemorrhage should be controlled with direct pressure to the wound. A rapid neurologic assessment is included, and the initial examination includes determination of orientation and responsiveness, pupillary reaction, motor response, and the Glasgow Coma Scale.

Concurrent with the initial evaluation of a moderately to severely injured patient, intravenous access must be established. A large-bore (14–16-gauge) peripheral catheter is preferred because it allows the quickest infusion of fluids and blood products. The number of peripheral catheters placed should increase as injury severity increases; patients with moderate injuries should have two secure catheters in place. Central venous access is required when peripheral access cannot be established because of absent veins, hypotension, or large surface area burns. Subclavian line placement in hypotensive trauma patients, however, carries a 12% complication rate, including pneumothorax, hemothorax, thrombosis, and infection.[12] Additionally, the infusion ports of a double- or triple-lumen central venous catheter are generally 18-gauge, and the maximum flow rate is slower than with a large-bore peripheral intravenous line. Another option for central access is placement of a large-bore (8.5 Fc) central catheter; if needed, this line can be converted over a guidewire to a triple-lumen catheter after resuscitation.

Crystalloid (lactated Ringer's solution) is the fluid of choice for initial resuscitation for many physicians. Replacement should be at a rate of 3:1 crystalloid to blood lost. Others use colloid or plasma expanders. If the patient remains hypotensive despite infusion of 2 to 3 L crystalloid, transfusion of packed red blood cells should begin. In the emergency setting, type O negative blood is administered until blood type and crossmatch are obtained. When possible, a warming device helps to prevent hypothermia as a result of infusion of crystalloid and blood products. Coagulation products should be administered based on abnormal laboratory parameters.

Military antishock trousers are controversial in the management of traumatic shock. They have not been well studied nor widely used in pregnant women. In the injured gravida, the lower extremity compartments can be inflated, but this may increase bleeding from injured pelvic structures. Generally, the abdominal compartment should not be inflated in the second and third trimesters, because it can compromise venous return and precipitate or exacerbate respiratory compromise from increased intra-abdominal pressure. Military antishock trousers are recommended for an injured pregnant woman only when major pelvic fractures are accompanied by uncontrollable hemorrhage.[9,10]

Resuscitation

The goal of the resuscitation phase is to monitor the patient's response to initial treatment and optimize intravascular volume and oxygen delivery. Adequate maternal resuscitation is of paramount importance to fetal survival. Blood pressure and pulse rate are frequently monitored, although these parameters are not reliable in detecting early shock in the gravida.[4]

Measurement of central venous pressure has been used in the acute setting, but absolute values should be viewed with great caution because central venous pressure is lowered by pregnancy. A pulmonary artery catheter is rarely indicated during initial resuscitation attempts. Vasopressors are contraindicated in hemorrhagic shock unless the patient has cardiogenic shock as a result of cardiac contusion or neurogenic shock associated with spinal cord injury.[10]

A urinary catheter is diagnostic and therapeutic; it allows accurate measurement of urine output and assessment of the urine for hematuria, and provides adequate drainage. The kidney is sensitive to the effects of hypotension, and urine output decreases as the kidney attempts to conserve fluid and maintain intravascular volume. An output of 30 mL/hr or more indicates adequate renal perfusion. Evidence of blood at the urethral meatus or difficulty in passing a catheter suggests bladder or urethral injury. If no urine is obtained through the catheter, bladder rupture must be considered. This condition is most commonly associated with a pelvic fracture. Gross or microscopic hematuria mandates evaluation to exclude urinary tract injury.

If an injured patient in shock is unresponsive to aggressive resuscitative measures, immediate operative intervention must be considered. A number of causes of refractory shock should be eliminated, however, before proceeding to the operating room. In the pregnant woman who is seriously injured, volume replacement may be inadequate, particularly in the third trimester, when blood volume is at its peak. Concealed hemorrhage associated with abruptio placentae can result in maternal shock, and amniotic fluid embolism is a rare but potential cause of cardiovascular collapse. Additional causes of persistent shock include tension pneumothorax, cardiac tamponade, neurogenic shock, uncorrected hypothermia, significant electrolyte and acid–base disturbances, and hypoxia.[11]

Secondary Survey

The secondary survey is performed once the maternal condition is stabilized. A complete physical examination should be conducted in an ordered fashion. Particular attention must be given to sites of bleeding, injured limbs, and entrance and exit wounds in cases of penetrating trauma. Head injuries account for nearly 50% of deaths in trauma patients. A complete neurologic assessment should be performed and compared with the initial examination.[13] The most common underlying etiologies of central nervous system impairment in a trauma patient include alcohol intoxication, diabetic ketoacidosis, narcotic and barbiturate overdose, hypovolemic shock, and cerebrovascular accidents. All neck injuries should be presumed to be life-threatening until excluded by appropriate evaluation. Tension and open pneumothorax, flail chest, and massive hemothorax are thoracic injuries that require rapid diagnosis and treatment. A chest tube should be placed one to two interspaces higher in pregnant patients to compensate for diaphragm elevation.[14] Although an abdominal examination should be conducted on all injured patients, the absence of findings does not exclude an acute intra-abdominal process. A rectal examination should be performed in patients with moderate to severe injuries to exclude gastrointestinal bleeding and document normal sphincter tone.

A complete obstetric examination is included in the secondary survey. Fundal height should be measured and fetal heart tones auscultated. Uterine tone and the presence of contractions and tenderness are assessed. Pelvic examination should be performed on all gravidas unless contraindicated. A sterile speculum examination assists in identifying membrane rupture or genitourinary bleeding. Contraindications to the pelvic examination include unstable spine, pelvic, and femur fractures because positioning may risk additional injury. Examination may be possible after orthopedic consultation. Digital examination can be performed if there is no vaginal bleeding or, in the presence of bleeding, once placenta previa has been excluded by ultrasonographic examination.

Fetal assessment begins with estimating gestational age by last menstrual period, fundal height, and ultrasonography. If the gestational age is uncertain, ultrasonographic measurements can quickly approximate dating of the pregnancy. When the potential for fetal survival must be determined urgently, a biparietal diameter of 54 mm or greater measured by ultrasonography has been suggested as more predictive than estimated fetal weight.[15] Fetal heart tones can be auscultated intermittently by Doppler in a previable fetus.

Continuous fetal heart rate monitoring of a viable fetus should be instituted in the emergency room as soon as possible, once initial resuscitation of the mother has begun. Changes in the fetal heart rate pattern may be the first sign of compromise and may occur despite normal maternal vital signs. Fetal tachycardia, bradycardia, late decelerations, and decreased beat-to-beat variability can indicate deterioration in fetal status. The tocodynameter can be helpful in detecting contractions that may not be perceived by an injured patient. Obstetric staff must be immediately available to interpret the fetal heart rate tracing before the patient is transferred to the obstetrics unit.

A variety of laboratory studies and diagnostic modalities are available to assist in evaluating and managing an injured gravida. Diagnostic peritoneal lavage (DPL), abdominal–pelvic computed tomography (CT) scan, and focused abdominal sonography of trauma (FAST) can be helpful in determining whether a patient requires operative intervention for intra-abdominal injuries. The study or combination of studies performed should be tailored to the clinical situation (discussed later).

Laboratory Studies in the Gravid Trauma Victim

Complete laboratory evaluation must be initiated quickly for patients with moderate to severe injuries. Suggested studies are listed in Table 55–3. Additional tests should be ordered as dictated by the patient's condition and the clinical situation.

Pregnant women have a physiologic anemia because plasma volume increases to a greater degree than red cell volume. Nevertheless, the hemoglobin level during pregnancy is normally 10 g/dL or higher. An initial hemoglobin level of less than 8 g/dL has been associated with ongoing hemorrhage and an increased mortality rate in nonpregnant trauma patients.[16] A normal hemoglobin level, however, does not exclude excessive bleeding because several hours may be required for equilibration to occur. Activated partial thromboplastin time (aPTT) and prothrombin time (PT) are unaffected by pregnancy. Fibrinogen increases during pregnancy, and a low-normal fibrinogen level (200–250 mg/dL) suggests a consumptive coagulopathy.[17]

Serum chemistry values provide additional information. Although electrolyte levels are usually normal in young, healthy gravidas, a decreased bicarbonate level is correlated with fetal demise in pregnant trauma patients. Determining a baseline creatinine level is helpful in case renal complications develop. Elevation of the aspartate aminotransferase (AST) or alanine aminotransferase (ALT) level above 130 IU/L is associated with a sixfold increase in the risk of intra-abdominal injury and is an indication to pursue diagnostic imaging in the stable nonpregnant patient.[18]

The Kleihauer-Betke stain determines the presence of fetal blood cells in the maternal circulation as well as the degree of fetomaternal hemorrhage (FMH). Determining the amount of FMH is important to ensure that Rh-negative gravidas receive an adequate dose of anti-D immunoglobulin to prevent isoimmunization. Fetal cells and ghost maternal cells are counted after acid elution and staining of the maternal blood sample. A normal maternal blood volume of 5 L (5000 mL) is commonly assumed. The laboratory reports the ratio of fetal to maternal cells, and the volume of FMH is calculated:

$$\frac{\text{Fetal cells}}{\text{Maternal cells}} \times \text{Maternal blood volume}$$

Unfortunately, alcohol and illicit substance use is common in trauma patients, and urine and blood toxicology screens should be performed. The results of testing provide information that is important for both medical and legal reasons. The physiologic effects of illicit substances can alter a patient's response to the stress of trauma. Alcohol lowers sympathetic response, whereas cocaine can cause sympathetic stimulation or paradoxical depression. Cocaine use has been associated with placental abruption and should be considered in the gravid trauma patient with an adverse fetal outcome. Organic pathology should be excluded in patients with neurologic compromise, but their condition may reflect the effects of an illicit substance.

Diagnostic Studies in the Gravid Trauma Victim

Diagnostic procedures can be pursued once initial resuscitation is completed and the mother and fetus are stable. Radiographic screening of patients with moderate to severe injuries consists of cervical spine, chest, and pelvis films. Cervical spine films exclude cervical spine injury in most patients with blunt trauma. Chest x-ray evaluates the presence of hemothorax, pneumothorax, or ruptured diaphragm. A plain film of the abdomen should be obtained if abdominal injury or a foreign body is suspected.

Radiation exposure should be considered when caring for the pregnant patient. Examinations that assist management should be performed, and necessary tests should not be omitted because the patient is pregnant. Fetal risk is negligible if maternal exposure is limited to less than 5 to 10 rad (5000–10,000 mrad).[19] Abdominal shielding and avoiding duplication of films (e.g., intravenous pyelogram scout film and pelvic film) minimize fetal exposure. The radiation dose to the fetus from common radiologic studies has been estimated at 0.02 to 0.07 mrad per chest radiograph, 100 mrad per abdominal film, 200 mrad per hip film, and 3 to 5 rad per CT scan of the abdomen and pelvis.[19] Studies with the highest radiation dose include pelvic CT, pelvic angiography, and pelvic fluoroscopy.

Intra-abdominal injury must be excluded, as in the nonpregnant patient. Clinical examination of the abdomen in nonpregnant patients with blunt trauma detects only 60% of intra-abdominal injuries. During pregnancy, signs and symptoms of an acute intra-abdominal process are often further obscured as the uterus stretches the anterior abdominal wall. Three diagnostic modalities are available to exclude abdominal injury when the patient does not require emergent laparotomy: DPL, CT scan, and FAST. Each has its advantages, disadvantages, and limitations.

DPL is highly sensitive and accurately detects 94% to 98% of intra-abdominal injuries.[20,21] Traditional indications for DPL include equivocal findings on physical examination, unexplained hypotension, an unresponsive patient, and spinal cord injury. DPL can be performed in a pregnant patient without compromising safety and accuracy.[22,23] Although CT scan and FAST are becoming more common, DPL is still useful for evaluation of unstable blunt trauma or an indeterminate FAST study. DPL is more accurate than CT for early diagnosis of hollow visceral and mesenteric injury, but does not reliably exclude retroperitoneal injury. DPL also cannot assess the specific site of bleeding or the extent of injury. Previous laparotomy, massive obesity, and advanced third-trimester pregnancy are relative contraindications to DPL, although no gestational age cutoff has been defined.[24] The complication rate for DPL is 1% in nonpregnant patients and does not appear to be increased during pregnancy.[22–24]

The standard technique for DPL is modified somewhat for the pregnant patient. As for any DPL, the bladder and stomach must be emptied before the procedure. Location of the incision is dependent on the stage of gestation. During the first trimester, a standard infraumbilical incision may be used. As pregnancy advances, however, the incision must be supraumbilical and above the uterine fundus. Once the peritoneum has been entered under direct visualization, the catheter is placed into the abdominal cavity and aspirated to detect gross blood. One liter Ringer's lactate is infused into the peritoneal cavity, and the fluid is allowed to drain into a sterile bag by gravity. An aliquot of returned fluid is then sent for red blood cell count, white blood cell count, and amylase measurement. A minimum of 200 mL fluid must be recovered to allow accurate interpretation. Standard criteria for a positive DPL finding include aspiration of at least 10 mL gross blood, bloody lavage effluent, red blood cell count greater than $100,000/mm^3$, white blood cell count greater than $500/mm^3$, amylase level greater than 175 IU/dL, and detection of bile, bacteria, or food particles.[9]

CT scanning is recommended when a patient with blunt trauma is hemodynamically stable but has unreliable or equivocal findings on physical examination or findings suggestive of significant trauma. It is the diagnostic modality of choice for nonoperative management of solid viscus injuries and has the advantage of detecting clinically unsuspected injuries. Its negative predictive value is excellent. Experience with abdominopelvic CT in pregnant trauma victims is limited, but a case series of 42 patients undergoing helical CT for trauma has been published. The radiation exposure of 0.87 to 1.75 mrad calculated in this study was less than the traditional amount and was determined by the scan pitch.[25] Disadvantages of CT include a lower sensitivity for hollow viscus injury, possible dye reactions, and lack of

portability, which requires patients to be moved from the resuscitation area of the emergency department.

FAST is a relatively new modality, but it is rapidly becoming the diagnostic study of choice for hemodynamically stable patients.[26,27] It is noninvasive, can be performed at the bedside in the emergency room, and can be repeated easily if the results are equivocal. The examination focuses on identifying fluid in the pericardium, pleural cavity, pararenal retroperitoneum, and peritoneal cavity. The sensitivity of FAST is 73% to 88%, and its accuracy is 96% to 99%.[21] FAST appears to decrease the need for both DPL and CT scan, allowing more selective and cost-effective use of these modalities.[26] A review of FAST in pregnant blunt trauma victims showed sensitivity and specificity similar to nonpregnant patients, suggesting that it can be useful in assessing the need for additional evaluation or emergent laparotomy.[28]

An evidence-based algorithm incorporating hemodynamic status and the findings on physical examination was developed by the EAST Practice Management Guidelines Work Group.[21] FAST is considered the diagnostic examination of choice for patients who are hemodynamically unstable, with DPL as an alternative to exclude hemoperitoneum. Patients who are hemodynamically stable, with a reliable physical examination, undergo serial examinations or diagnostic testing, depending on the findings on initial clinical examination. Patients with an unreliable physical examination should undergo FAST or CT scan, depending on institution and physician preference, with subsequent management determined by results.

Definitive Treatment

Definitive treatment is instituted according to the type and severity of injuries as well as the clinical condition. A patient with hemorrhagic shock and obvious intra-abdominal injury is unlikely to remain in the emergency department longer than necessary and will have undergone minimal diagnostic evaluation before operative intervention. In a patient who is hemodynamically stable, adequate time is available to assess the full extent of injuries. Once diagnostic studies have been completed and interpreted, a treatment plan can be devised in consultation with appropriate specialty services.

Trauma victims are frequently transported to the nearest hospital. However, not all institutions are equipped to care for a patient with major injuries, and transfer to a tertiary care center may be necessary for definitive therapy. Maternal stability and fetal well-being must be ensured before land or air transport. Copies of medical notes and the results of laboratory and radiologic studies should accompany the patient to avoid duplication and unnecessary delays. A patient should not be transferred if there is any sign of hemodynamic compromise, ongoing hemorrhage, severe uncorrected anemia, nonreassuring fetal status, or danger of delivery en route. Personnel

equipped to handle emergencies should always accompany a pregnant patient during transport.

Tetanus immunization is the first of two treatment issues that should be addressed before a patient leaves the emergency department. Tetanus occurs almost exclusively in patients who have been inadequately immunized. Preventing tetanus after injury entails ensuring adequate immunity and local wound care, with elimination of necrotic tissue and foreign bodies. Tetanus toxoid (0.5 mL IM) is administered when a patient has been appropriately immunized, but the most recent booster was longer than 5 years ago. Previously unimmunized patients require both tetanus immune globulin (500 U IM) and the first of three doses of tetanus toxoid. The immune globulin and toxoid must be injected into different sites to ensure adequate protection.

The second issue is the extremely high risk of deep venous thrombosis (DVT) in patients with moderate to severe injuries. Blood transfusion, surgery, femur or tibia fracture, and spinal cord injury are associated with an increased risk of DVT.[29] However, only a small percentage of patients have clinical signs of DVT in the days after the traumatic event. Young patients with injuries are at high risk, and DVT has been reported to occur in 46% of trauma victims younger than 30 years of age.[29] The American College of Chest Physicians[30] recommends DVT prophylaxis for trauma patients with an identifiable risk factor. Low-molecular-weight heparin (LMWH) should be administered if the patient has no contraindications to heparin therapy. If LMWH prophylaxis is contraindicated, mechanical prophylaxis (elastic stockings or intermittent pneumatic compression) should be instituted. An inferior vena caval filter is not recommended for prophylaxis.[30] LMWH has been used successfully during pregnancy, but studies showing its efficacy in gravid trauma victims are lacking. The hypercoaguable state of pregnancy is an additional risk factor for thrombosis, and DVT prophylaxis should be initiated once the injured gravida is stable.

BLUNT TRAUMA

Incidence

MVAs are responsible for 60% to 75% of cases of blunt trauma, making it the most common mechanism of injury and the leading cause of fetal death related to maternal trauma.[4,31] The severity of the crash appears to be the most significant factor in predicting fetal outcome.[32] Although most injuries are minor, each year in the United States, an estimated 1300 to 3900 women experience a fetal loss as a result of an MVA.[33] Obstetric complications associated with blunt trauma include abruptio placentae, preterm labor, uterine rupture, fetomaternal hemorrhage, direct fetal injury, and fetal demise. The incidence of abruptio placentae, direct fetal injury, and fetal death in non-life-threatening blunt abdominal trauma is fortunately low (1.6%, 0.8%, and 1.6%, respectively), but the fetus is nevertheless at risk, even when maternal injuries are minor.[34] The incidence of preterm delivery associated with noncatastrophic blunt trauma is also infrequent, at 0.86%.[35]

Falls are the second most common form of blunt trauma, but direct abdominal assault is occurring with increasing frequency in pregnant women. The prevalence of physical abuse of pregnant women is 6% to 31%. Morbidity and adverse outcomes of pregnancy appear to be more common with direct assaults than with MVAs.[36,37] Physical abuse is often a repetitive event that may prompt multiple emergency room visits. It is important to ask specific questions about abusive relationships because women frequently do not volunteer such information. As the only health care provider many patients sees regularly during pregnancy, the obstetrician has the best opportunity to offer assistance to victims of abuse.

General Management

The initial management of a pregnant woman who has blunt trauma was discussed earlier (see Table 55–2). The trauma team may have performed a primary survey and begun resuscitation efforts before an obstetrician is summoned. This approach is appropriate because maternal stabilization is always the priority. The obstetric consultant should assume comanagement responsibilities for the mother and fetus once notified of the patient's admission to the emergency department.

Injury patterns associated with MVAs vary depending on whether the victim was restrained, the type of safety belt system in use, and the patient's place in the vehicle. Unbelted individuals usually sustain injuries to the head, face, chest, abdomen, and pelvis when they hit the interior of the car or are ejected. A lap belt prevents ejection from the vehicle, but hollow viscus and lumbar spine injuries are common. Those wearing a shoulder harness without the lap component often have cervical spine, clavicular, chest, liver, and spleen injuries. A three-point lap–shoulder system offers optimal protection, but injuries do occur, and include rib, sternum, and clavicular fractures. Air bag deployment may cause face, arm, and chest abrasions, and chemical keratitis has been reported.

Abdominal injuries are common in victims of blunt trauma. Specific injuries sustained during pregnancy change with advancing gestation. By 12 weeks, the bladder has become an intra-abdominal organ and thus is more susceptible to injury. As the uterus enlarges and rises out of the pelvis, the risk of injury increases. Life-threatening retroperitoneal hemorrhage occurs more frequently during pregnancy, when pelvic blood flow is markedly increased.[38] Bowel injuries, however, tend to occur less often because the small intestine is compressed into the upper abdomen.

Accurate and timely diagnosis of intra-abdominal injury requiring surgical intervention is one of the challenges in blunt trauma. Findings on physical examination of the abdomen may be normal initially despite visceral injury. Serial examinations are therefore important to detect deterioration in the patient's condition. Intra-abdominal hemorrhage should be suspected in patients with rib and pelvic fractures. Rib fractures are frequently

associated with liver and spleen injuries, and pelvic fractures are associated with genitourinary injuries and retroperitoneal hemorrhage. FAST, DPL, and abdominal–pelvic CT scan should be used, as previously discussed, to determine the need for operative intervention.

Information on pelvic fracture during pregnancy is limited to a literature review of 101 cases of pelvic and acetabular fracture during pregnancy.[39] Mechanisms of injury included automobile–pedestrian accidents, MVAs, and falls. The overall maternal mortality rate was 9%, and the fetal mortality rate was 35%. Fractures in the third trimester were associated with an 18% incidence of fetal skull fracture. As reported by other authors, increasing severity of maternal injury increased both maternal and fetal mortality rates. The trimester of pregnancy during which the injury occurred did not influence fetal death. Repair of the fracture usually is not performed during pregnancy, and the mode of delivery depends on the type of fracture and the interval between injury and delivery.

Abruptio Placentae

Abruptio placentae occurs in 1% to 5% of gravidas with minor injuries and 6% to 37% of those with major injuries.[34–36,38,40–42] It is the most common cause of fetal death when the mother survives blunt trauma. Placental abruption cannot be predicted based on placental location, severity of maternal injury, or vehicle damage (in the case of an MVA), and it can occur without obvious injury to the mother.[6,8,43,44] A small series reported an increased incidence of abruption in patients involved in MVAs at speeds of 30 mph and greater and those with a higher injury severity score.[7]

When a gravida is involved in an MVA, intrauterine pressure at the time of impact is estimated to be 10 times greater than the forces generated with labor.[45] Although the uterus is considered more elastic than the placenta, recent models indicate that their mechanical properties are similar and there is overlap. The uteroplacental interface appears to fail at a lower strain than either the uterus or the placenta.[32] The increase in intrauterine pressure generated on impact may propagate placental separation, with subsequent formation of a retroplacental hematoma.[45]

Placental abruption usually occurs soon after the traumatic event. Classic signs and symptoms include vaginal bleeding, abdominal pain, and fundal tenderness as well as uterine irritability, high-frequency contractions, and increased tone. Back pain and vaginal bleeding may be the most prominent symptoms in women with separation of a posterior placenta.[46] The absence of vaginal bleeding, however, does not exclude the diagnosis. Bleeding can be concealed within the uterus and may be detected only by increasing fundal height, fetal heart rate abnormalities, or maternal hypovolemia. A hypertonic uterus and evidence of fetal compromise are highly suggestive of abruptio placentae. Cardiotocographic monitoring is the most sensitive method of surveillance after a traumatic event (discussed later).[8,35,36]

Management of a patient with abruptio placentae after traumatic injury is similar to that of an uninjured gravida with this complication. As soon as abruption is suspected, intravenous access must be established. A urinary catheter allows accurate measurement of output. Complete blood and platelet counts, fibrinogen level, aPTT, and PT should be obtained and repeated every 4 to 6 hours to detect disseminated intravascular coagulation. A minimum of two units of packed red blood cells must be crossmatched and immediately available in the blood bank. Fresh frozen plasma and packed red blood cells should be administered based on abnormal laboratory findings and estimates of ongoing hemorrhage. Obstetric management depends on the maternal condition, fetal status, and severity of abruption. If there are signs of maternal hypovolemia or shock, fluid resuscitation and administration of blood products should begin promptly. Disseminated intravascular coagulation is not an indication to proceed with cesarean section, and abdominal delivery only increases the risk of bleeding complications.

Fetal status and the severity of abruption direct the clinical course once the mother is stable. When the fetus is alive, gestational age and plans for intervention must be established quickly. Hysterotomy offers no benefit to either mother or fetus if a previable fetus shows signs of compromise. Continuous fetal monitoring and close observation are reasonable approaches for a preterm gestation when the heart rate pattern is reassuring. Corticosteroids should be administered to minimize the complications of prematurity if the gestational age is 24 to 34 weeks. As always, the risks of prematurity must be weighed against the risks of continuing the pregnancy. Delivery is generally indicated in a term pregnancy with abruptio placentae, but cesarean delivery is unnecessary if the fetal status is reassuring. If the fetus has died, induction of labor and vaginal delivery can be anticipated because this is the safest method of delivery for the mother.

Preterm Labor

Preterm labor requiring tocolysis occurs in 11% to 28% of gravidas who have blunt trauma.[35,37,47] Delivery before 34 weeks' gestation, however, is uncommon and experienced by only 0.86% of gravidas with blunt trauma.[35] Extravasation of blood into the myometrium appears to be a stimulus for uterine contractions associated with traumatic events. Uterine muscle injury can also cause release of lysosomal enzymes, generation of prostaglandins, and subsequent uterine activity.

When uterine contractions occur after blunt trauma, it may be difficult to determine whether they represent placental abruption or isolated preterm labor. Tocolysis is

discouraged by those who believe that uterine activity is an indication of the former. Uterine contractions developing after blunt trauma abate without treatment in 90% of gravidas.[40] On the other hand, successful tocolysis has been reported after blunt trauma.[47] Regardless of whether pharmacologic inhibition of labor is used, fetal heart rate and uterine contractions should be monitored continuously during observation of the patient.

If a tocolytic is administered, the agent should be selected with an awareness of its potential complications. β-Mimetic preparations (ritodrine, terbutaline) are relatively contraindicated in patients at risk for hemorrhage because drug-induced tachycardia may mask early signs of hypovolemia. Magnesium sulfate has fewer cardiac side effects than the β-mimetics. However, patients with renal dysfunction are at increased risk for toxicity because magnesium is excreted through the kidneys. Indomethacin may be used to inhibit preterm labor, although it can cause transient or premature closure of the fetal ductus arteriosus and oligohydramnios. Additionally, nonsteroidal anti-inflammatory agents, such as indomethacin, may be contraindicated in severely injured patients because the drug can adversely affect platelet and renal function. Calcium channel blockers (e.g., nifedipine) have also been used successfully as an oral tocolytic. This class of drugs may cause maternal hypotension, however, and may imitate early shock in a gravid trauma patient.

Uterine Rupture

Uterine rupture occurs in 0.6% to 1% of gravidas who have blunt trauma and is most frequently associated with maternal pelvic fracture.[48–50] It is an uncommon complication of trauma because uterine muscle retains its elasticity and resistance to rupture, even at advanced gestation. When the uterus ruptures, however, the site is often fundal.[51] A scarred uterus has a greater propensity to rupture than an unscarred uterus. Uterine rupture usually occurs as a result of direct abdominal trauma during the late second and third trimesters. It is much more devastating for the fetus than for the mother, with a 10% maternal mortality rate, but a fetal mortality rate of nearly 100%.[47]

The diagnosis of uterine rupture can be difficult. Signs and symptoms may be limited to vague abdominal pain. Uterine tenderness, a nonreassuring fetal heart rate pattern, absence of the presenting part, palpable fetal parts outside the uterus, fetal demise, and maternal shock are more dramatic presentations. When fetal death occurs after a serious accident, uterine rupture must be considered. Rupture of the uterus may first be suspected when induction of labor is unsuccessful. DPL results are generally positive when the uterus has ruptured and major vessels have been damaged.

If rupture of the uterus is suspected, exploratory laparotomy should be performed to control maternal hemorrhage. Ideally, a trauma surgeon will be in attendance to explore the abdomen for additional injuries. A vertical abdominal incision allows maximum exposure, particularly if surgical repair of intra-abdominal injuries is required. Conservation of fertility is always a consideration because a patient's wishes may be unknown or uncertain at the time of the accident. However, uterine repair should be undertaken only if the patient is hemodynamically stable and hemorrhage can be controlled. When the uterus is extensively damaged and repair is impossible or the patient is in hemorrhagic shock, hysterectomy is indicated.

If the uterus is to be repaired, the site of rupture should be assessed after delivery of the fetus and once hemostasis is achieved. Necrotic tissue along the rupture site may be excised to allow reapproximation of well vascularized tissue. The uterine defect can then be repaired in layers. The risk of uterine rupture in future pregnancies is certainly present, but not prohibitive. It would seem prudent to offer elective cesarean delivery in subsequent pregnancies, especially if the rupture site was fundal or damage was extensive.

Fetal Injury

The exact incidence of fetal injury as a result of maternal trauma is unknown. An incidence of 0.49% has been noted in gravidas with noncatastrophic trauma.[35] Fetal skull fractures, long bone fractures, intracranial hemorrhage, and soft tissue injury have been reported. Skull fracture or head injury is most commonly described and is associated with maternal pelvic fracture late in gestation, when the fetal head is engaged.[39]

The management of fetal injuries must be individualized, and experience is limited. If the fetus is alive and without signs of distress, delivery may be delayed in very premature gestation. Serial ultrasonography and frequent assessment of fetal well-being may be beneficial until maturity is reached. If pregnancy is advanced or delivery is indicated for fetal compromise, a pediatrician should be consulted and in attendance for the delivery. Accurate and unbiased documentation is always important, given the medicolegal ramifications of fetal injury.

Fetal Assessment

The prediction of adverse fetal outcome after a traumatic event has been a controversial subject. Cardiotocographic monitoring is currently the most sensitive method of immediate fetal surveillance.[40] Clinical risk factors for fetal death include injury severity score, severe abdominal injury, hypotension, hemorrhagic shock, DIC with or without abruption, and gestational age less than 23 weeks.[52–56] Because almost all patients who have placental abruption after trauma manifest signs soon after the event, it is important to institute fetal heart rate and uterine activity monitoring once the mother is stable. Delayed

abruption several days after an accident is described, but has been questioned. The few patients reported were not monitored immediately after the event, and early signs of abruption may have been overlooked.[57,58]

Uterine activity appears to be the most sensitive indicator of abruption after blunt trauma.[35,36,59,60] The presence of six to eight or more contractions per hour identifies a patient who is at risk for adverse pregnancy outcome.[8,35,36] Approximately 14% of women who had contractions every 2 to 5 minutes immediately after blunt trauma subsequently had abruption. No patient with fever than eight contractions per hour had abruption.[8] Similarly, a second study showed that when uterine contractions, tenderness, or vaginal bleeding were present, 19% of patients had obstetric complications compared with 0.9% who did not have these symptoms.[36]

Although obstetric ultrasonographic examination can be helpful in fetal assessment, normal findings do not exclude or reduce the risk of abruption. The sensitivity of ultrasonography in predicting abruption in blunt trauma patients is only 40%.[8,40] Cardiotocographic monitoring appears to be more sensitive than ultrasonography in detecting acute abruption.[48,61] Ultrasonography is useful to exclude placenta previa, document fetal viability, establish gestational age, estimate fetal weight, measure amniotic fluid volume, and assess fetal well-being.

Guidelines for monitoring pregnant trauma victims have been suggested. If a patient does not have uterine tenderness, contractions, or vaginal bleeding on presentation, 2 to 6 hours of cardiotocographic monitoring is sufficient.[35–37,47,48] Patients may be released home if they do not have symptoms, the fetal heart rate pattern is reassuring, and maternal injuries have been appropriately evaluated and treated. These patients are not at increased risk for adverse pregnancy outcome compared with uninjured control subjects.[8] They should be instructed about the symptoms and signs of preterm labor and abruption as well as indications to return to the hospital.

Approximately 52% of gravidas have uterine tenderness, irritability or contractions, or vaginal bleeding after blunt trauma.[37] These patients require additional observation and continuous fetal monitoring; a minimum of 24 hours has been recommended, even if symptoms resolve.[35] A more recent study recommends at least 24 hours of fetal monitoring if the maternal heart rate is greater than 110 beats/min, the injury severity score is greater than 9, the fetal heart rate is less than 120 beats/min or greater than 160 beats/min, or there is evidence of placental abruption, and for victims of ejections or motorcycle or pedestrian collisions.[62] The hospital stay should be extended as maternal and fetal conditions dictate. Seriously injured patients who require surgery or transfer to the intensive care unit present a challenge to the obstetrician. If the fetus is viable, continuous monitoring should be used; obstetrics personnel must be readily available to evaluate the fetal heart rate tracing.

Fetomaternal Hemorrhage

Fetomaternal hemorrhage (FMH) occurs in a significant number of gravidas who are victims of blunt trauma. The incidence is 8.7% to 30% in gravid trauma patients compared with 1.8% to 8% in pregnant control subjects.[8,36,37,60,63] The mean volume of transfusion was reported in two studies as 12 mL and 16 mL, with a range of 5 to 69 mL.[8,63] Although no clinical signs reliably predict FMH, an increased incidence is noted in women who have an anterior placenta or uterine tenderness.[8,36] Most fetuses with FMH have a normal outcome, but anemia, supraventricular tachycardia, and fetal demise are recognized complications.[8,63]

The most important role of Kleihauer-Betke (KB) testing in trauma patients is to identify a large volume of fetomaternal transfusion in the Rh-negative gravida. Massive FMH occasionally occurs, even with relatively minor maternal injuries, so all Rh-negative gravidas should undergo KB testing after any trauma. Although routine testing of all gravid blunt trauma victims has been suggested, the clinical utility of this approach is uncertain.[37] Unfortunately, the KB result does not correlate with the occurrence of placental abruption or fetal distress.[35,60] The KB test predicted obstetric complications in only 27% of pregnant trauma patients in one study, and the sensitivity for adverse outcome was only 18% in a second series.[37,60] Testing may, however, identify FMH as the cause of an otherwise unexplained fetal death.

Isoimmunization can occur very early in pregnancy because the Rh antigen is present on fetal red blood cells 34 days after conception. The amount of fetal blood required to stimulate maternal antibody formation may be as little as 0.01 mL. The KB test, however, is not sensitive enough to detect such a small amount of fetal blood in the maternal circulation. Because an undetectable amount of fetal blood can lead to sensitization in early pregnancy, all unsensitized Rh-negative women who have trauma should be considered candidates for Rh immune globulin.[35,48]

The amount of immune globulin administered depends on the volume of FMH as calculated from the KB stain results. Anti-D immunoglobulin (300 µg or 1500 IM) IU administered within 72 hours of the event protects against maternal antibody formation for transfusion of up to 15 mL fetal red blood cells (30 mL whole blood). If KB testing is unavailable, 300 µg is adequate in most women and can be administered empirically.[36,40] The precise doses used should be in accordance with local guidelines.

Seat Belt Use

Passenger restraint systems have saved thousands of lives. The use of lap–shoulder belts reduces the likelihood of fatal injury by 45% and the likelihood of moderate to

critical injury by 50%.[64] Safety belts minimize injuries by limiting passenger contact with the interior of the vehicle, preventing ejection, and spreading the force of deceleration over a larger area. Although air bags have augmented the reduction in rates of injury and death, they do not offer protection in lateral collisions and do not prevent ejection. Combined lap–shoulder restraint systems must continue to be worn for optimal crash protection. Air bags should not be disconnected during pregnancy.

MVAs are the most common mechanism of fetal death associated with maternal trauma.[31] The leading cause of fetal death in MVAs is maternal death, and the most common cause of maternal death is ejection from the vehicle.[65] The maternal mortality rate is 33% when the woman is ejected from the vehicle versus only 5% when she is not. When the mother is ejected, the fetal mortality rate is 47% compared with 11% when the mother remains in the vehicle. The rate of fetal death is decreased by seat belt use because seat belts prevent ejection and decrease the maternal mortality rate.[65]

The addition of a shoulder harness to the lap belt reduces the risk of maternal head injury and fetal death. The shoulder component decreases the maternal morbidity rate by preventing jack-knifing of the mother's torso over the lap belt and increasing the area over which deceleration forces dissipate. Decreasing force over the abdomen reduced the fetal mortality rate in animal studies from 50% with a lap belt alone to 12% with the three-point restraint system.[66] Crash simulation with a pregnant crash dummy also provides evidence that the three-point restraint system decreases the likelihood of injury.[67]

Despite the benefits of safety belts, pregnant women often hesitate to use them; 30% of gravidas either do not wear a safety belt or wear it incorrectly.[33] The perception of increased risk of fetal injury with seat belt use is a major factor contributing to the reluctance of pregnant women to use restraint systems. During the first antenatal visit, all pregnant women should be counseled on the importance and proper use of safety belts. Unfortunately, only 42% to 55% of gravidas receive information on the use of restraint systems during pregnancy.[33,68,69] It is equally important to give patients correct information.[68] Women should be instructed to place the lap portion of the belt under the abdomen and across both the anterior and superior iliac spines. The belt should be snug, but comfortable. The shoulder restraint should cross the shoulder without rubbing the neck and should be positioned between the breasts.[70] Lap and shoulder belts should be worn together because neither is as effective as the combination.[66,71] It is helpful to remind women during the course of pregnancy that safety belts should be worn and that they save the lives of both mother and fetus.

PENETRATING TRAUMA

Incidence

Pregnant women are the victims of penetrating trauma with increasing frequency. Gunshot and stab wounds are the most common, but injury occurs by other mechanisms as well, and may be self-inflicted.[72] Firearm injuries are the second most common mechanism of fetal death associated with maternal trauma.[31] The exact incidence of these injuries in pregnancy, however, is uncertain because some cases may not be reported. The mortality rate associated with penetrating injury in nonpregnant victims increases with the number of organs injured, but the rate of visceral injury and the mortality rate are lower during pregnancy.

The mother usually fares much better than the fetus when the injury is caused by a gunshot or stab wound.[10,73] The maternal mortality rate is 0% to 9% for gunshot wounds during pregnancy, whereas the perinatal mortality rate is 41% to 71%.[73] When the mother is stabbed, fetal injury and fetal death occur in 93% and 50% of cases, respectively.[74] Although direct fetal injury is responsible for most perinatal deaths, some deaths results from premature delivery, with it attendant complications.[75] Fetal survival is affected by several factors, including the severity of fetal and maternal injury, the presence and extent of placental hemorrhage, and gestational age at delivery.

General Management Options

Maternal injury patterns change with advancing gestation. Penetrating trauma in the first trimester causes wounds similar to those in nonpregnant victims. As the uterus enlarges and occupies more space in the abdominal cavity, it is more likely to be injured than any other intra-abdominal organ. The uterus offers relative protection to

other abdominal organs by the third trimester. Hence, bowel injury is uncommon when a pregnant woman has a penetrating injury to the lower abdomen, but the small bowel is at high risk for injury when entry is in the upper abdomen. Multiple bowel wounds are more common in pregnant victims than in their nonpregnant counterparts because the intestine is compressed in the upper abdomen with advancing gestation.

As with other forms of trauma, the emergency team, trauma surgeon, and obstetrician must coordinate the care of a pregnant woman. Maternal resuscitation and hemodynamic stability are a priority, and the leading cause of early death from gunshot wounds is hypovolemia as a result of major vessel injury. The injured woman must be thoroughly examined and each entrance and exit wound noted. If exploratory laparotomy is indicated, a midline vertical incision offers optimal exposure to the abdomen.

An indication for exploratory laparotomy, however, is not an indication to empty the uterus. Abdominal delivery concurrent with exploratory laparotomy increases operative time and blood loss. A patient may undergo induction of labor and vaginal delivery postoperatively without increased risk of morbidity.[76] The only indication for hysterotomy is to provide adequate surgical exposure for repair of maternal injuries. Cesarean hysterectomy is indicated when damage to the uterus is extensive or uterine injury is associated with uncontrollable hemorrhage. Specific guidelines for treating pregnant women with gunshot and stab wounds are discussed later, but these guidelines should be individualized based on obstetric and surgical needs.

Gunshot Wounds

The size of the entrance wound does not predict the internal damage caused by a bullet. If no exit wound is found, radiographic studies are performed to localize the bullet. A flat plate and lateral film usually suffice. Intra-abdominal bullet wounds may be managed in one of the following ways:

- Observation
- Exploratory laparotomy with cesarean delivery
- Exploratory laparotomy without delivery

Surgical exploration has been considered standard practice for managing bullet wounds of the abdomen and flank. However, careful observation of a wounded gravida has been suggested as an alternative in the following situation:

- The mother is hemodynamically stable
- The bullet has entered below the uterine fundus
- The bullet can be localized to within the uterus
- There is no evidence of maternal genitourinary or gastrointestinal injury[77]

Additionally, the fetus should be free of injury or compromise, or dead, if the mother is managed conserva-

tively.[78,79] Broad-spectrum antibiotic coverage is prudent, at least initially. This conservative approach should be considered only in trauma centers in which experienced surgeons manage trauma care. With this approach, it has been suggested that fewer than 20% of gravidas require surgical intervention for visceral wounds.[77]

Although this type of nonoperative management has been reported, this approach has not been prospectively tested in gravidas with penetrating injuries. Radiologic studies may give a false impression of the location of the bullet in the uterus when significant maternal injury has occurred.[80] DPL can be performed to exclude intra-abdominal hemorrhage. Exploratory laparotomy, however, is the most reliable means for detecting intra-abdominal injury should doubt exist. The ultimate decision about the need for operative intervention rests with the surgical team.

The decision to deliver the fetus is based on gestational age, fetal status, and exposure required for surgical exploration and repair of maternal injuries. If the fetus is alive and, near term and the uterus is injured, cesarean delivery with uterine repair is reasonable. When a viable fetus is alive but remote from term, suggested indications for delivery include evidence of fetal hemorrhage, uteroplacental insufficiency, and infection.[73]

Although fetal injury can occur when a bullet enters the mother's lower abdomen, the risks of prematurity may outweigh the risk of delaying repair of fetal injuries. Although obstetric ultrasonography and radiography may be helpful, the diagnosis of in utero injuries can be difficult. Neonatal and pediatric surgical consultation is invaluable in planning care.

If the fetus has died, vaginal delivery is preferred if there is no evidence of uterine hemorrhage. Options include awaiting spontaneous labor and induction of labor with prostaglandins or oxytocin. If laparotomy is required and the uterus prevents exposure for repair of maternal injuries, evacuation of the dead fetus is indicated.

Stab Wounds

When a patient has a stab wound, attempts should be made to determine the object used and its length. The longer the object, the more likely it is that the peritoneum has been penetrated when the abdomen is wounded. The risk of intestinal injury in nonpregnant stabbing victims is less than that with gunshot injuries because bowel tends to move away from a penetrating object (sliding effect). This effect explains, in part, the lower mortality rate with stab wounds than with gunshot wounds. The sliding effect may be less during pregnancy because bowel is compressed into the upper abdomen with advancing gestation.

Traditionally, all abdominal stab wounds have been regarded as an indication for exploratory laparotomy. More recently, nonoperative management has been considered for some patients.[72] Two of the most impor-

tant factors in assessing the need for laparotomy in injured gravidas are peritoneal penetration and location of the entrance wound. A wound can be probed, and a fistulogram may assist in determining whether the peritoneal cavity has been entered. If a conservative approach is chosen, the patient must be closely monitored and exploration undertaken without delay if the mother has signs of hemorrhage or evidence of sepsis. Contraindications to observation include the following:

- Penetration of the peritoneal cavity
- Entry above the fundus
- Hemodynamic instability of the mother
- Fetal compromise at a viable gestational age

As with gunshot wounds to the abdomen, the surgical consultant should make the final decision about the need for operative intervention.

DPL may be used to identify intra-abdominal injury requiring laparotomy, but it has several limitations in patients with penetrating injuries.[4] First, the findings may be negative in nonpregnant victims, despite hollow viscus injury, because bleeding is usually minimal. Second, the leukocyte response to bowel injury may be delayed, causing a false-negative finding. Finally, the accuracy of DPL in pregnant women with stab wounds is unknown. Although a positive finding would be expected when uterine vessels are injured, the size of a uterine wound and the depth of penetration cannot be ascertained.

FAST was prospectively evaluated in 75 patients with penetrating abdominal trauma and was shown to be useful as the initial diagnostic test.[81] It is not, however, as reliable as in blunt trauma, and a negative result requires additional testing. Additionally, it has not been studied in pregnant victims of penetrating trauma, and its accuracy is unknown in this setting.

A lower abdominal stab wound with adequate force is likely to damage the uterus as well as the fetus. Management options include the following:

- Observation
- Uterine repair with delivery of the fetus
- Uterine repair with the fetus left in utero[82]

No outcome data are available comparing repair of a uterine wound with no repair. The risks of infection and uterine rupture associated with each approach are unknown, given the limited number of patients with these injuries. Indications for delivery are the same as those for gravidas with a gunshot wound.

Based on reported cases of stab wounds to the pregnant uterus, Sakala and Kort[74] proposed the following management plan. A nonperforating injury of the uterus may be repaired without disturbing the pregnancy. Perforating injuries, however, carry a much higher rate of fetal injury. A fetus at or near term should be considered for cesarean delivery and uterine repair. If the fetus is premature, alive, and not compromised, the uterus may be repaired, with vaginal delivery anticipated. When the fetus has died, both perforating and nonperforating injuries should be repaired and the fetus delivered vaginally. The injured uterus maintains its ability to labor and deliver an infant.[83] Antibiotic prophylaxis seems reasonable in these cases, although no data are available to support this recommendation.

Stab wounds to the upper abdomen are three times more frequent than lower abdominal wounds. Upper abdominal wounds that penetrate the peritoneum require surgical exploration because of the high likelihood of small bowel injury. If doubt exists, exploratory laparotomy is the safest approach to exclude intra-abdominal injury. When the peritoneum of the upper abdomen has been penetrated, laceration of the diaphragm must be excluded because it can result in bowel herniation, strangulation, and sepsis. After diaphragm repair, labor and second-stage Valsalva efforts should be avoided and cesarean delivery should be performed, presumably to avoid increasing intra-abdominal pressure.[74]

BURNS

Incidence

Fortunately, most burns sustained during pregnancy are minor, and more severe burns are uncommon. Most burns occur in the home and are the result of a house fire, hot water or flammable liquids, and gases. Pregnant women account for 0.4% to 7% of all patients who are hospitalized with major burns.[84-88]

Maternal survival is dependent on the percentage of total body surface area (TBSA) burned.[87,89-91] When 20% to 39% of TBSA has been burned, 97% to 100% of gravidas survive. The mortality rate increases when 40% to 59% of TBSA is burned, and ranges from 27% to 50%. Burns exceeding 60% of TBSA are associated with an increasing maternal death rate.[86,87,90-93] Survival in pregnant women with burn injuries is comparable to that in their nonpregnant counterparts, when matched for burn severity.[89] Concurrent inhalation injury, however, is associated with an increased mortality rate in nonpregnant patients.

Fetal survival is also affected by the percentage of maternal TBSA involved. The fetal mortality rate is negligible when the burn affects less than 20% of maternal TBSA. When 20% to 39% of the mother's TBSA is involved, the fetal loss rate ranges from 11% to 27%. The fetal mortality rate increases to 45% to 53% with burns that affect 40% to 59% of maternal TBSA. When a pregnant woman has a burn that involves greater than 60% of TBSA, fetal loss approaches 100%.[86,87,90-93] The largest reported burn survived by both mother and fetus is 58% of TBSA.[94]

Classification of Burns

The depth of a burn is classified by degree. A first-degree burn is confined to the epidermis. Second-degree burns are superficial and deep partial-thickness burns. Adequate epithelial cells remain and allow skin to regenerate. Clinically, blistering, erythema, and pain characterize superficial partial-thickness burns. Deep partial-thickness lesions are characterized by blisters; a pale, white appearance; and no pain sensation. Full-thickness burns, previously known as third-degree burns, destroy all epithelial elements. Regeneration is not possible without grafting. The burned area appears charred and leathery, without blisters; thrombosed superficial vessels may be visible; and pain sensation is absent. Fourth-degree burns involve structures beneath the skin.

Burn size estimates the extent of injury. The "rule of nines" is a method used to estimate the percentage of body surface area involved. Each upper extremity and the head and neck are 9% of TBSA. The lower extremities and the anterior and posterior surface's of the trunk are 18% each. This system was devised for nonpregnant patients, however, and does not account for the pre-sumed increase in abdominal surface area with advancing gestation.

Burns severity is defined as minor, moderate, or major. A minor burn is a superficial, or partial-thickness, burn that covers less than 15% of TBSA or a full-thickness burn that covers more than 2% of TBSA. Major burns include partial-thickness burns covering more than 25% of TBSA, full-thickness burns covering more than 10% of TBSA, and burns meeting the criteria for admission to a burn unit (discussed later). Major burns are classified according to the TBSA involved: moderate (10% to 19% of TBSA), severe (20%–39% of TBSA), and critical (>40% of TBSA).[92]

Management of Minor Burns

Minor burns may be treated on an outpatient basis if the burn does not affect an area of critical function (i.e., hand, across a joint) or an area in which cosmesis is a concern (i.e., face). Superficial (first-degree) burns do not require specific treatment beyond keeping the area clean and protected. A mild analgesic may be prescribed. A narcotic, such as oxycodone, may be required for pain control in patients with partial-thickness burns. The burned area should be cleansed with sterile saline and devitalized tissue removed. Large blisters may be incised and debrided. Blisters should not be aspirated because this practice can introduce bacteria into a closed space. A nonadherent sterile dressing can be used to protect the burned area. Patients with partial-thickness burns should be re-evaluated in 24 hours. At this time, the wound is evaluated and the dressing changed. Complete healing can be expected in 2 to 3 weeks, with no adverse effects on the pregnancy.

Management of Major Burns

The basic principles of resuscitation also apply to the patient with a major burn injury. Fluid administration is the most important initial treatment. Venous access should be established with a 14- to 16-gauge catheter placed through unburned skin, when possible. Immediate removal of clothing prevents continued burning by smoldering synthetic fabric. All skin surfaces must be examined, burned areas assessed for depth and surface area involved, and additional injuries excluded. Inhalation injury should be suspected and 100% oxygen given by face mask. Arterial blood gas analysis and carbon monoxide level measurement are standard features of laboratory evaluation. A burn specialist should be consulted. Admission to a burn unit is considered for patients with any of the following injuries[95]:

- Partial-thickness burn affecting greater than 10% of TBSA
- Burns of the face, hands, feet, genitalia, perineum, or skin over major joints

- Third-degree burns
- Electrical injury, including lightning injury
- Chemical burns
- Inhalation injury
- Burn injury in patients with preexisting medical disorders that could complicate management or affect the risk of death
- Burns and associated trauma
- Burn injury in a patient who requires special social, emotional, or long-term rehabilitation

The systemic response to a major burn is a massive release of vasoactive mediators that cause a decrease in plasma and blood volumes, shifting intravascular fluid to intracellular and interstitial compartments. Thus, the goal of fluid resuscitation is to correct hypovolemia during the initial 24 to 48 hours. Hypovolemic shock develops in a patient with burns covering more than 15% to 20% of TBSA if fluid resuscitation is not instituted promptly.[96] Hypovolemia in the pregnant patient can also lead to decreased placental perfusion and fetal compromise. Therefore, proper resuscitation is critical for both mother and fetus.

The essential component of fluid resuscitation is crystalloid (normal saline or lactated Ringer's solution). The amount of fluid that a patient requires during the first 24 hours after a burn injury can be estimated with one of several formulas. The Parkland formula estimates fluid requirements during the first 24 hours as 4 mL/kg/% TBSA burned. Edema formation at the burn site is most rapid during the initial 6 to 8 hours after the a burn, and fluid is administered at a rate to compensate for the intravascular loss. One half of the total fluid required is administered during the first 8 hours after the burn (not after admission), and the remaining half is administered over the next 16 hours. The Brooke and Evans formulas are also used to estimate fluid requirements, but differ from the Parkland protocol in their administration of colloid and free water in addition to crystalloid. Additional fluid may be required for adequate resuscitation in pregnant women with major burns because blood volume increases with advancing gestation. Inhalation injury also increases the amount of fluid required during initial resuscitation. Fluid administration is adjusted to maintain urinary output of 0.5 mL/kg/hr. Most patients remain tachycardic despite adequate fluid resuscitation; therefore, heart rate is not a good clinical measure. Pregnant patients also have a baseline increase in heart rate. Electrolyte balance must be closely monitored during and after resuscitation, with imbalances corrected on an ongoing basis.

Diligent wound care is critical to preventing infectious complications. In the emergency department, personnel should wear sterile gloves and gowns while caring for the patient. Once clothing has been removed, burned areas are covered with sterile dry dressings or sterile sheets. An intravenous narcotic should be administered, as needed, for pain control. Debridement and application of antibiotic ointment should not be performed in the trauma room, but under proper conditions in a burn unit. Topical antimicrobial agents delay colonization of the wounded area. Three have established efficacy in the treatment of major burns: 11.1% mafenide acetate, 1% silver sulfadiazine, and 0.5% silver nitrate. Silver sulfadiazine must be used with caution, and long-term use is relatively contraindicated in pregnant women because of the theoretical risk of kernicterus in the newborn. Iodine-containing solutions are frequently used for wound care, but their use must be limited during pregnancy because of the absorption of the iodine and the risk of fetal thyroid dysfunction.[91] All patients with a burn affecting greater than 10% of TBSA should receive tetanus toxoid with immunoglobulin if their previous immunization status is uncertain.

Carbon monoxide (CO) poisoning can occur whenever carbonaceous material is released as a result of incomplete combustion. The affinity of CO for hemoglobin is more than 200 times that of oxygen, and it readily displaces oxygen from hemoglobin.[97] Carbon monoxide causes a left shift of the oxyhemoglobin dissociation curve and increases the affinity of hemoglobin for the remaining bound oxygen. Tissue oxygenation decreases as less oxygen is released from hemoglobin in the periphery. Signs and symptoms of CO poisoning correlate with the blood level. A CO level of less than 10% is unlikely to cause symptoms, whereas levels of 10% to 20% cause a mild headache and palpitations. Once the level reaches 20% to 40%, dizziness, agitation, confusion, and incoordination become apparent. Patients with a CO level of greater than 40% are at risk for progressive dyspnea, lethargy, coma, and death.

CO readily crosses the placenta and may cause fetal malformations, hypoxia, neurologic dysfunction, low birth weight, and death in utero. CO levels rise more slowly in the fetus than in the mother, and continue to increase for up to 24 hours after the maternal level has reached a steady state. Once fetal CO reaches a steady state, the concentration is 10% to 15% higher than the mother's concentration. Likewise, the fetus requires a much longer time for elimination than the mother does. The maternal half-life of CO in a sheep model was 2.5 hours compared with 7 hours in the fetus.[97]

The blood level determines the urgency of treatment for CO poisoning. Observation is sufficient if the CO level is less than 10%. When the level is 10% to 20%, treatment with 100% inspired oxygen is indicated. High-concentration oxygen administered with a tight-fitting face mask decreases the half-life of carboxyhemoglobin in adults from 2 to 3 hours in room air to 45 minutes.[97] Similarly, 100% oxygen decreases the half-life of car-

boxyhemoglobin in the fetus from 7 hours to 2 to 3 hours, but it is still longer than that in the mother. Based on mathematical calculations, a pregnant woman with CO poisoning should receive 100% oxygen for up to five times longer than needed to reduce her own level to normal (<5%).[97,98] This extended period of treatment allows for the longer elimination time required by the fetus.

Hyperbaric oxygen therapy is used for nonpregnant patients with a CO level greater than 25% or with neurologic changes, regardless of the blood level. It has been used to treat pregnant women with CO poisoning, with no adverse fetal effect. Therapy has been recommended for pregnant women with a maternal CO level of more than 20%; neurologic changes, regardless of the CO level; or signs of fetal compromise.[99] However, hyperbaric oxygen therapy in patients with a major burn presents a number of logistic problems, and care must be individualized.

Inhalation injury occurs as a result of exposure to smoke particles and chemicals. Patients who are burned in a closed space are at increased risk, and the incidence increases with burn severity. Two thirds of patients with burns affecting more than 70% of TBSA have concurrent inhalation injury.[96] Singed nasal hair, facial burns, inflamed oropharyngeal mucosa, carbonaceous sputum, and a CO level greater than 15% suggest injury. Laryngeal edema should be suspected in a patient with hoarseness, stridor, or cough. Intubation may be required to maintain a patent airway. The initial chest radiograph, however, may not show the severity of injury. If the diagnosis of inhalation injury is in doubt, laryngobronchoscopy can be performed. Treatment includes warm humidified oxygen, bronchodilators, pulmonary toilet, nebulized heparin, and therapeutic bronchoscopy. Mechanical ventilation is required if respiratory failure occurs.

Patients with major burns are at risk for many complications, including pulmonary edema, pneumonia, wound infections, septic shock, electrolyte disturbances, nutritional deficiencies, and scar formation. Sepsis is the major cause of death in patients with burns, emphasizing the importance of sterile technique.[91] A circumferential burn of the thorax or abdomen may cause respiratory compromise or vena caval compression in pregnant victims. Early escharotomy improves respiratory excursion and relieves increased intra-abdominal pressure. Scar formation can be physically limiting, but successful pregnancies have been reported in patients with significant abdominal scarring after burn injuries. Surgical release and grafting can be performed in a scar that becomes restrictive with advancing pregnancy, and uninvolved expanded abdominal skin has been used as a flap to reconstruct a scar after delivery.[100,101] Clinically significant thromboembolism is an infrequent complication in patients with a major burn. Nevertheless, prophylaxis has been suggested for patients with additional risk factors, including lower extremity trauma, extensive burns, morbid obesity, prolonged bed rest, and central venous lines.[30] Although data on the risk of thromboembolism in pregnant burn victims are not available, pregnancy is an additional risk factor and prophylaxis seems reasonable if no other contraindications exist.

Obstetric complications associated with major burns include spontaneous abortion, premature labor, and fetal death in utero. The first week after injury seems to be the period of highest risk, and medical complications often precede obstetric complications. The physiologic response to burns includes hypovolemia, hypoxia, acidosis, electrolyte imbalance, and sepsis. Each of these, alone or in combination, can lead to uterine activity or fetal compromise.[94] Septicemia is the most common cause of spontaneous abortion in women with burns.[84]

An increased incidence of premature labor has been associated with burns affecting more than 30% to 35% of TBSA.[94] In addition to the mechanisms that can stimulate the uterus (discussed earlier), prostaglandins and leukotrienes are released from macrophages, neutrophils, and platelets at the burn site. Prostaglandin E_2, a uterine stimulant, is produced by scalded skin. Because prostaglandins are associated with uterine activity, pregnant women who have a burn injury should be monitored for uterine contractions. Tocolytic agents, particularly β-mimetics, must be used cautiously, and only after the mother is clinically stable and the fetal heart rate tracing is reassuring.

Intervention on behalf of a viable fetus may be required in a gravida with a major burn. The following recommendations are based on combined experiences of various authors caring for pregnant burn victims. Delivery is suggested when a significant medical complication develops in a woman with moderate burns, because fetal survival in this group appears to be influenced by maternal complications. Likewise, early obstetric intervention has been advocated for a gravely ill woman who has complications that jeopardize the fetus and any woman with extensive burns who is beyond 32 weeks' gestation.[85,89] Fetal death occurs most commonly during the first week after a major burn and is a likely event when a gravida has severe to critical burns.[94,102] Delivery after maternal stabilization is recommended for women at 26 weeks' gestation and beyond with burns affecting greater than 40% to 50% of TBSA.[87,92,93,102] This recommendation is based on older literature, and the gestational age for intervention should be adjusted based on institutional neonatal survival at the limits of viability and on patient and family wishes. Cesarean delivery is reserved for obstetric indications, and vaginal delivery has been accomplished, even in women with perineal burns. If abdominal delivery is indicated, the incision may be performed through burned skin without increasing morbidity.

->40%–50% of the total body surface area is burned			

ELECTRICAL INJURY

Incidence

Reports of electrical injuries in pregnant women are exceedingly uncommon. A total of 21 pregnant women with electrical injury and 11 gravidas struck by lightning have been reported.[103,104] Although one study reported no maternal deaths from conductive and lightning injuries, the fetal mortality rate was 73% and 45%, respectively.[103] The fetal death rate was only 6%, however, in 31 women who were followed prospectively after predominantly household electrical injuries.[104] Minor injuries are less likely to be reported than catastrophic events, however, and the true incidence of electrical injury in pregnancy is likely to be underestimated. Most victims of electrical injury have multisystem trauma, and should be transferred to an experienced center for optimal care.

Management

The direct effects of the current and the heat it generates cause physical damage, as does trauma as a result of electrical injury. Electrical injury can be thermal, conductive, or caused by lightning; conductive injuries are the most common. The type of current, its path through the body, and its voltage also affect the type of injury. Cardiac and respiratory arrest are the main causes of death after injury from domestic alternating current and lightning. The current passing through the body can cause cardiac dysrhythmia, asystole, respiratory arrest, muscle contraction, tetany, skeletal fractures, and neurologic injury. Continuous cardiac monitoring is recommended for patients who have loss of consciousness, cardiac dysrhythmia, abnormal findings on 12-lead

electrocardiogram, abnormal mental status or physical examination findings, or burns or tissue damage expected to cause hemodynamic instability or electrolyte abnormalities.[105] Fractures may be caused by a fall occurring with the shock, and cervical spine injury as a result of muscular contraction must be excluded. Rhabdomyolysis can cause renal failure if adequate intravenous hydration is not maintained until myoglobinuria resolves. Tissue necrosis may be extensive, and antibiotic prophylaxis with penicillin decreases the risk of muscle and fascial infection. Surgical consultation may be required for wound care, debridement, and fasciotomy. Most victims of electrical injury have multisystem trauma and require transfer to an experienced center for optimal care.

Resistance to current varies among tissues of the body. Blood offers little resistance compared with muscle, skin, tendon, fat, and bone. Amniotic fluid, the uteroplacental circulation, and fetal skin offer low resistance to electrical current flow.[103,106] As a result, the fetus is very vulnerable to electrical injury. When the current takes a hand-to-foot path through the mother, it presumably passes through the uterus.[104,106] The current path may therefore be an important factor in fetal outcome, and may account for the difference in mortality rates among reported cases.[103,104]

The severity of maternal injury is not predictive of fetal outcome, and minor exposure can have a profound fetal effect. Significantly less current is required to produce injury in the fetus than in the mother.[103] In cases of fetal demise, cardiac arrest appears to have been the cause of death. This observation is consistent with maternal reports of sudden cessation of fetal movement after the injury. Intrauterine growth restriction and oligohydramnios have been reported in fetuses surviving maternal electrical injury.[103,106] An animal model

also showed growth restriction in 71% of rabbit fetuses subjected to electrically induced thermal injury of the placenta.[107]

The paucity of data makes it difficult to offer management recommendations for a gravida who has an electrical injury. Care of the mother should follow established guidelines. Fetal cardiac activity should be confirmed after electrical injury. If the fetus is alive and viable, continuous cardiotocographic monitoring should be started at the time of initial maternal evaluation. Monitoring for 4 hours is suggested when minor mechanical trauma (i.e., fall to the floor) is associated with electrical injury. Twenty-four hours of maternal and fetal monitoring has been recommended if the results of maternal electrocardiogram are abnormal, maternal loss of consciousness occurred, or there is a history of cardiovascular disease.[105] Monitoring for oligohydramnios and fetal growth restriction throughout the rest of the pregnancy is also recommended for the surviving fetus.[106]

PERIMORTEM CESAREAN SECTION

Incidence

The concept of perimortem and postmortem cesarean delivery dates back thousands of years. Fortunately, it is an uncommon occurrence, and the exact incidence is difficult to calculate.

Management Options

Injuries in a pregnant trauma patient occasionally are so severe that the mother dies, despite maximal resuscitation efforts. The decision to perform perimortem cesarean delivery in an attempt to save the fetus is based on gestational age and the duration of cardiac arrest. The operation should not be performed in anticipation of a

cardiopulmonary arrest, but only once cardiovascular collapse has occurred.

One of the most important questions is the effect of cesarean delivery on the efficiency of cardiopulmonary resuscitation (CPR). Even under optimal conditions, CPR generates a cardiac output that is only 30% of normal.[108] Shunting of 10% of the cardiac output to the uterus and the left lateral tilt recommended to decrease vena caval compression by the uterus further reduce the effectiveness of chest compressions. Oxygen consumption increases during pregnancy as well and predisposes pregnant women to rapid desaturation with hypoventilation. It is presumed that delivery of the fetus allows more efficient CPR by relieving vena caval obstruction and increasing blood volume by autotransfusion.

The sooner the infant is delivered after a maternal arrest, the better the chance of intact neurologic survival. Optimal neonatal outcome is achieved when delivery occurs less than 5 minutes from the arrest. There are no documented cases of intact fetal survival beyond 35 minutes from the onset of cardiac arrest in the mother.[108] Therefore, it seems reasonable to proceed with delivery up to 35 minutes after maternal collapse. If the duration of arrest is unknown, proceeding with delivery is also reasonable.

Once maternal cardiopulmonary arrest has occurred and the decision is made to intervene on behalf of the fetus, the following steps are suggested. Initiate delivery 4 minutes after maternal arrest, with the intention to deliver the fetus 5 minutes after the arrest.[108] Continue CPR throughout the procedure to offer every chance for maternal survival. Do not waste precious time preparing a sterile field or instrument tray or attempting to perform an ultrasound examination. Each surgeon should approach the abdominal incision in the most efficient fashion. Consider a low transverse uterine incision because less blood loss occurs and closure can be achieved more quickly than with a classical incision. If more than 4 minutes have passed, but signs of fetal life are present, proceed with delivery.

SUMMARY OF MANAGEMENT OPTIONS

Perimortem Cesarean Section

Management Options	Quality of Evidence	Strength of Recommendation	References
Perform when maternal cardiopulmonary arrest occurs, not in anticipation of it.	IV	C	108
Initiate delivery 4 minutes after arrest if maternal resuscitation is unsuccessful: The goal is delivery 5 minutes after arrest.	IV	C	108
Continue cardiopulmonary resuscitation during delivery.	IV	C	108
Use time efficiently:	IV	C	108
• Do not prepare a sterile field or a full instrument table.			
• Use the quickest incision possible.			
• Consider a low transverse uterine incision.			
Proceed with delivery if >4 minutes have passed since maternal arrest but signs of fetal life are still present.	IV	C	108

CONCLUSIONS

- Trauma occurs in 6% to 7% of all pregnancies and is the leading cause of non-obstetric maternal mortality.
- Physiologic changes associated with pregnancy can significantly influence the clinical presentation after trauma as well as the response to initial resuscitative attempts.
- The management of gravidas with moderate to severe injuries should follow an organized plan, including a primary survey, an initial resuscitation attempt, a secondary survey, laboratory and diagnostic testing and definitive treatment. With few exceptions, both the diagnostic and therapeutic approach to trauma in pregnancy should differ minimally from that of a non-pregnant patient.
- Gestational age assessment should be determined quickly, and monitoring of the potentially viable fetus should be a component of the initial evaluation.
- Blunt trauma can lead to pregnancy-specific injuries including abruptio placenta, preterm labor, uterine rupture, and fetomaternal hemorrhage.

CONCLUSIONS (Continued)

- With penetrating trauma, exploratory laparotomy is not necessarily an indication for operative delivery of the fetus. This latter decision should be based on gestational age, fetal and maternal stability, and the ability to gain adequate surgical exposure for the repair of maternal injuries.
- Maternal and fetal survival in burn victims are dependent on the percentage of total body surface area burned in the mother.
- With electrical injuries, the severity of maternal injury is not predicitive of fetal outcome. Significantly less current is required to produce injury in the fetus than in the mother.
- A perimortem cesarean delivery should be initiated within 4 minutes after arrest with continuation of the CPR process throughout the surgical procedure.

Psychiatric Illness

Roger F. Haskett

INTRODUCTION

Recognition of psychiatric illness during pregnancy and the postnatal period is vitally important for the health of the mother and infant. Psychiatric disorders, such as depression, are commonly associated with impaired functioning that can significantly interfere with a pregnant woman's ability to care for herself, including participating in optimal prenatal care and maintaining an appropriate diet, as well as increasing the risk of using substances such as tobacco and alcohol. Women with psychiatric and substance use disorders during pregnancy are reported to have at least twice the risk of inadequate prenatal care compared to women without these diagnoses.[1] This association with inadequate prenatal care persists after controlling for other known risk factors and is associated with more adverse pregnancy outcomes and decreased use of pediatric care after birth. These findings are consistent with studies of patients in other primary care settings, noting that depressed individuals are much less likely to comply with treatment recommendations. In addition the presence of mood or anxiety disorders during pregnancy is a strong predictor of psychiatric illness and disability in the postpartum period.

In obstetrics and gynecology practices, the prevalence of psychiatric disorders, including substance abuse disorders, is reported to range from 20% to 48%; this number is even higher in clinics serving low-income women. In particular, the prevalence of major depression in these settings is reported to be as high as 22%. This high prevalence should not be unexpected, considering that adult women suffer from depression and anxiety disorders at rates two to three times higher than men, and that the increased prevalence tends to be most prominent following puberty and throughout the reproductive years.[2] When detected it will be noted that the onset of these psychiatric disorders may predate pregnancy, occur during pregnancy, or most commonly appear during the postpartum period.

In addition to appropriately administering specific treatments,[3] successful management of psychiatric illness in pregnancy and the postpartum period requires effective collaboration between the obstetrician, pediatrician, psychiatrist, and other mental health professionals as well as the participation of relatives and other key social supports.

PREVALENCE OF PSYCHIATRIC ILLNESSES IN PREGNANCY

Recognition of the high frequency of psychiatric symptoms in obstetric and gynecology practices has followed the recent development of screening tools for use in these settings. One study in a university-based obstetric clinic providing prenatal care for low-income minority women reported that 38% of women screened positive for psychiatric disorders including substance abuse.[4] One in five pregnant women screened positive for alcohol or other substance abuse, and more than half of the women who screened positive for a psychiatric disorder (21%) met criteria for a depressive disorder, including 4% with major depression. Other identified diagnoses were anxiety disorder (5%) and eating disorder (5%). Women with psychiatric disorders were more likely to have public insurance, an unexpected pregnancy, and a previous history of psychiatric treatment. More significantly, they tended to be more likely to have received inadequate prenatal care and to be referred to child protective services. Another study of 766 women attending gynecologic practices in Sweden[5] found that 30% met criteria for a psychiatric disorder, although these investigators deleted the screening questions for alcohol abuse. Overall 27% of women screened positive for a depressive disorder, including 10% for major depression, and 12% were positive for an anxiety disorder. Of more concern was the finding that only one out of five women with a psychiatric diagnosis was receiving any treatment, either medication or psychotherapy.

The PRIME-MD Patient Health Questionnaire (PHQ) was the screening instrument used in these studies to assess current psychiatric disorders. The PHQ is a four-page self-report measure that assesses eight common psychiatric diagnoses, including mood, anxiety, eating, alcohol, and somatoform disorders. Although developed in other primary care settings,[6] the validity and utility of the PHQ has been assessed in a multisite sample of 3000 patients attending obstetric/gynecology outpatient clinics or office practices.[7] In addition to assessing the eight psychiatric diagnoses, the PHQ screens for disorders that are more common among or restricted to women, such as premenstrual syndrome, postpartum and menopausal mood disorders, and posttraumatic stress disorder. Information about reproductive history, psychosocial stressors, and severity of impairment is also included. In the validation study, 20% of women met criteria for a psychiatric diagnosis; the majority were unrecognized prior to reviewing the questionnaire. Most physicians and nurse practitioners (89%) reported that the diagnostic information provided by the PHQ was "very" or "somewhat" useful in management or treatment planning.

MAJOR DEPRESSION

General

In 1992 the Global Burden of Disease study reported that unipolar major depression was the most common cause of disease burden in women aged 15 to 44.[8] This heavy burden of depression-related disability in women results not only from the high prevalence of depression, but also from a clinical course that is characterized by early onset, recurrence, chronicity, and comorbidity.[9] Typically major depression is found to be one and a half to three times more prevalent in women than men. This higher prevalence of depression among women has been detected throughout the world using a variety of epidemiologic study designs.[2] Similar gender differences have been found for chronic minor depression or dysthymia and recurrent minor depression. The gender difference in prevalence appears at age 11 to 14 and is consistently found through midlife.[10,11] The literature is inconsistent about the presence of a gender difference in prevalence following menopause, and some reports suggest that the prevalence in men and women converges after age 55 due to an absolute fall in the female prevalence.[12] There does not appear to be a gender difference in the course of depression. The higher prevalence of depression among women is due to a higher risk of first onset, not to a differential risk of recurrence, speed of episode recovery or chronicity of depression.[13] In addition, although limited, research has not found an effect of pregnancy on the onset or recurrence of major depression. Pregnancy does not protect against depression, as

was once believed, nor does it appear to increase the risk of depression compared to nonpregnant controls. An emerging consensus holds that significant distress and impairment is also associated with the presence of "minor depression," or depressive symptoms that do not reach a level of severity to meet criteria for major depression. In a recent systematic review of depression in pregnancy, the prevalence rates were reported as 7.4%, 12.8%, and 12.0% for each trimester of pregnancy, respectively.[14]

Diagnosis

Depression during pregnancy may be difficult to detect because many symptoms characteristic of depression, such as sleep and appetite disturbance, low energy, and diminished libido, are common in pregnant women who are not depressed. Although five of nine symptoms (Table 56–1) must be present over the same 2-week period to meet criteria for major depression, one of the symptoms must be either (1) depressed mood most of the day and nearly every day or (2) markedly diminished interest or pleasure in activities, often referred to as *anhedonia*. Using these symptoms in a two-question case-finding instrument is an effective means for identifying major depression. A positive response to either of the questions (1) "During the past month, have you often been bothered by feeling down, depressed, or hopeless?" or (2) "During the past month, have you often been bothered by little interest or pleasure in doing things?" had a sensitivity of 96% and a specificity of 57%; a negative response made a diagnosis of major depression very unlikely.[15] In women who give a positive response to either question, additional inquiry should be made about the presence of the other seven features of depression—such as change in sleep or appetite, physical agitation, fatigue, worthlessness or guilt, poor concentration, and suicidal thinking. In pregnant women, the most useful confirming symptoms are anhedonia, guilt, hopelessness, and suicidal thinking.

Many pregnant women do not seek treatment; identification of their depression is dependent on adequate screening by their obstetrician during antenatal visits. Risk factors for depression in pregnancy include a

TABLE 56–1
Diagnostic Criteria for Major Depression
1. Depressed mood most of the day, nearly every day*
2. Markedly diminished interest or pleasure in activities*
3. Major change in appetite or weight
4. Decrease or increase in sleep
5. Psychomotor agitation or retardation
6. Fatigue or loss of energy
7. Feelings of worthlessness or excessive or inappropriate guilt
8. Diminished ability to think or concentrate; indecisiveness
9. Recurrent thoughts of death or suicide

American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Washington DC, American Psychiatric Association, 2000.
*Must be present to establish diagnosis

personal and family history of mood disorder, marital conflict, younger age, and limited social support with greater numbers of children. In a recent study of 3472 women at 10 obstetric clinics, who were screened for depression during a prenatal visit,[16] 20% were found to have elevated depressive symptom scores (CES-D ≥16) but less than 1 in 7 of these women was receiving treatment for depression. Among the 28% of women who were positive on the lifetime depression screen items ("you had 2 weeks or more when nearly every day you felt sad, blue, or depressed or in which you lost interest in things like work"), nearly one half (42.6%) reported increased depressive symptoms during pregnancy. Women having a prior history of depression were nearly five times more likely to have elevated depressive symptoms during pregnancy than women without this history. Other factors predicting elevated depression scores were a self-rating of poor overall health, greater alcohol use problems, smoking, being unmarried, being unemployed, and lower educational attainment. Other studies have reported low levels of spousal support predicting depression during pregnancy.[17]

Maternal and Fetal Risks

Recent literature reviews summarize the reported association between depressive symptoms during pregnancy and poor neonatal outcomes, such as low birth weight, increased risk of premature delivery, and maternal preeclampsia.[18–21] In a study of African-American women, who have twice the risk of spontaneous preterm birth relative to white women, an association was found between elevated maternal depressive symptoms and spontaneous preterm birth.[22] In addition there have been reports linking developmental delays, antisocial behavior, and criminality in individuals whose mothers were depressed during pregnancy.[23,24] Pregnant women with depression may have decreased appetite and inadequate weight gain during pregnancy and are more likely to use tobacco, alcohol, or illicit drugs.[25] In addition, depression during pregnancy is a strong predictor of postpartum depression.

Management Options

Screening for depression is feasible and when using self-report instruments does not require clinical staff. In the Marcus study 90% of women approached were willing to be screened[16]; in the study by Scholle, 82% of screened women agreed to a clinical research review of their results.[26] Identification of risk factors for depression in pregnancy can increase the efficiency of screening, for example, women with a past history of depressive illness should be specifically targeted for appropriate screening.

Standard treatments for depression with demonstrated efficacy include psychotherapy, antidepressant medications, and electroconvulsive therapy (ECT).[27] Selection of a specific intervention will be influenced by the severity of depression and level of impairment, specific information related to use of the intervention in pregnancy, and the woman's preferences.[28–30] Nonpharmacologic treatments such as interpersonal psychotherapy have been adapted successfully for use during pregnancy[31] and are sometimes preferred by women concerned about exposing the fetus to antidepressant medications.

When considering pharmacologic treatments for depression in pregnancy, the risks to the developing fetus can be divided into risks of physical malformations (teratogenesis), risks of neonatal toxicity or withdrawal syndromes following delivery, and risks of long-term behavioral effects (behavioral teratogenesis). Although the Food and Drug Administration established a system to advise physicians about the safety of medications in pregnancy, these categories should be used with caution. The majority of psychotropic medications are categorized as Category C, which indicates "human studies are lacking . . . risk cannot be ruled out." No psychotropic medications are in Category A, indicating that they are safe for use in pregnancy, because ethical concerns do not permit the randomized studies needed to generate the data for this classification. Clinicians should note that medications in Category B should not be assumed to be safer than those in Category C because, although the former indicates that there is no evidence of risk in humans, this may be the result of an absence of human studies.

On review of the literature there is no evidence that tricyclic or selective serotonin reuptake inhibitor/serotonin and norepinephrine reuptake inhibitor (SSRI/SNRI) antidepressants are associated with an increased risk of major malformations.[32] Reports have linked exposure to tricyclic antidepressants during the third trimester with neonatal toxicity manifesting as lethargy, hypotonia, and anticholinergic symptoms as well as withdrawal syndromes comprising irritability, tachypnea, tachycardia, and feeding difficulties.[33] Although reports have been inconsistent and generated from small numbers of women, fluoxetine, paroxetine, and sertraline have been linked to transient neonatal difficulties for some women taking these medications in late pregnancy. There is limited data assessing behavioral teratogenesis or neurologic and behavioral developmental outcomes following prenatal exposure of the developing brain to tricyclic and SSRI antidepressants.[34,35] Fortunately the studies that have been published were unable to detect any differences between children exposed to antidepressants in utero and unexposed children at ages varying from 4 months to 7 years.[36]

The treatment of depression during pregnancy raises the following issues, which must be addressed by the treating physician and the patient:

- Risk of exposing the fetus to antidepressant medication
- Risk of untreated depression in the mother
- Risk of relapse of depression in the mother following antidepressant withdrawal.[21]

Obstetricians may encounter these issues in two possible circumstances: a pregnant woman who is recently diagnosed with depression or a woman who is not currently depressed or pregnant and who seeks consultation before conception. In women who present with a new onset or recurrence of depression during pregnancy, the choice of antidepressant treatment will be influenced by the severity of the current episode and any prior episodes of depression. In milder forms of depression, interpersonal or cognitive behavioral psychotherapy alone may be an appropriate treatment. Alternatively, in women who have failed psychotherapy alone or who have severe symptoms, such as weight loss or suicidality, or marked functional impairment, antidepressant medication is likely to be strongly recommended. In these latter women, the risks to the pregnancy associated with their depressive illness will usually exceed the known risks of exposure to an antidepressant medication.[37] Many of the women who seek consultation about antidepressant treatment prior to conception will have suffered prior episodes of depression and may be taking maintenance treatment. In these circumstances, the decision to continue or withdraw antidepressant medications prior to conception will be influenced by the risk for relapse of depression, including the severity and frequency of prior episodes of depression. Up to 75% of women who discontinue an antidepressant during pregnancy will suffer a depressive relapse,[38] although assessing a specific woman's prognosis should focus on the number of prior episodes and the time to relapse after previous attempts at antidepressant discontinuation. Women with a history of rapid and severe relapses following antidepressant discontinuation are likely to be most appropriately treated by continuing medication throughout pregnancy. These risk-benefit discussions with the mother should be documented in the medical record and if possible should occur with the father present.

SUMMARY OF MANAGEMENT OPTIONS

ANXIETY DISORDERS

General

Studies of women in the general population[39] have reported that the 12-month prevalence of anxiety disorders is 4.3% for generalized anxiety disorder (GAD), 3.2% for panic disorder, and 1.8% for obsessive-compulsive disorder (OCD). Prevalence of posttraumatic stress disorder (PTSD) in a recently reported cohort of economically disadvantaged pregnant women was 7.7%, with these women being five times more likely to have a major depressive disorder and three times more likely to have a generalized anxiety disorder.[40] Unfortunately, in contrast to depression, the systematic data on the frequency and course of anxiety disorders during pregnancy are limited. Some of the difficulty in characterizing anxiety disorders in pregnancy results from the frequent overlap of depressive and anxiety symptoms and from the past convention of subsuming all combined presentations under a depressive

diagnosis. Surveys that distinguish between anxiety and depressive disorders, however, find a prevalence of anxiety disorders in obstetrics and gynecology practices that ranges from 5% to 12%.[41] Little is known about the influence of pregnancy on the course of anxiety disorders, although a small number of retrospective accounts and case reports have suggested that symptoms of anxiety and panic disorder decrease and symptoms of OCD increase during pregnancy.[42]

Diagnosis

Anxiety is frequently free-floating, although it may focus on specific pregnancy fears, and is accompanied by symptoms of autonomic arousal. In women with panic disorder, chronic feelings of elevated anxiety are interspersed by the abrupt onset of episodes of pronounced fear, sometimes described as a fear of dying, going crazy, or losing control, which is associated with prominent physical symptoms of distress. These include shortness of breath, dizziness, unsteady feelings or faintness, palpitations or tachycardia, chest pain or discomfort, trembling or shaking, sweating, hot flashes or chills, choking, nausea or abdominal distress, numbness or paresthesias, as well as depersonalization (feeling separated from their body) or derealization (familiar surroundings feel unfamiliar). Episodes of panic usually begin to ease within 30 minutes but may be followed by a lingering period of increased anxiety and impaired function. Women with OCD describe recurrent thoughts that are unpleasant and out of character, often involving personally unacceptable aspects of aggression or sexuality, or repetitive compulsive behavioral rituals that are experienced as

unreasonable; attempts to resist are followed by increased and incapacitating anxiety.

Maternal and Fetal Risks

There is some evidence for a deleterious effect of increased maternal stress and anxiety on birth weight and premature delivery.[43,44] Other obstetric complications associated with increased maternal anxiety include preeclampsia,[45] increased analgesic use,[46] and increased rate of cesarean sections.[47] Adverse effects on the fetus include increased uterine artery resistance, as well as changes in fetal hemodynamics and autonomic reactivity.[48,49]

Management Options

Nonpharmacologic treatments are often effective in decreasing anxiety symptoms and include cognitive behavioral therapy and relaxation techniques. Pharmacologic treatment of anxiety disorders during pregnancy is indicated in women who have severe symptoms and are unresponsive to psychotherapy. Use of SSRI antidepressants is favored, due to their demonstrated effectiveness in anxiety disorders and accumulating evidence for their safety in pregnancy. Because of persistent concerns about an increased frequency of oral clefts as well as signs of toxicity in neonates born to women taking high doses of benzodiazepines in late pregnancy, these medications should be used cautiously and at the lowest effective dose. Abrupt withdrawal of benzodiazepines during pregnancy, however, is not recommended. There are insufficient data to determine the safety of buspirone during pregnancy.

BIPOLAR DISORDER

General

The prevalence of mania and bipolar disorder is about 1%; in contrast to depression, there is no significant gender difference. Despite this, there appears to be a relationship between childbirth and the first episode of mania in women

with bipolar illness, as noted by reports that childbirth predated the first episode of mania in one of four women with this illness.[50,51] In addition, Hunt and Silverstone[52] reported from a study of patients with severe bipolar illness that 39% of the mothers but none of the fathers had their first episode after childbirth. Epidemiologic studies also note a marked excess of postpartum psychosis after the first child

compared to subsequent pregnancies, suggesting that there is a particular change occurring at the first delivery that is less evident at other births. Overall the risk of relapse of mania after delivery is estimated to be between 1 in 3 and 1 in 4.[52] Diagnostic and management issues associated with depressive episodes occurring during the course of a bipolar disorder are similar to those for unipolar depressive episodes described previously.

Diagnosis

The essential criterion for the diagnosis of mania is the presence of abnormally and persistently elevated, expansive, or irritable mood for at least 1 week. This must be accompanied by at least three of the following clinical features: inflated self-esteem or grandiosity, decreased need for sleep, increased talkativeness or pressure to keep talking, flight of ideas or subjective experience of racing thoughts, distractibility, increase in goal-directed activity (socially, at work or school, or sexually) or psychomotor agitation, disinhibited behavior, excessive involvement in pleasurable activities with high potential for painful consequences (engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments). The overall severity must lead to marked functional impairment or need for hospitalization. Women with bipolar illness may also present with less severe forms of mania, diagnosed as *hypomania*, which are of shorter duration and are usually associated with less functional impairment. Although the euphoric or irritable mood changes are usually evident in a patient being followed longitudinally, the most informative diagnostic feature of mania, especially during the assessment of current and past episodes in a new patient, is persistently decreased need for sleep without daytime fatigue or lowered energy.

Maternal and Fetal Risks

Risks to the mother and fetus result from the impulsive, disinhibited, or high risk behavior that is seen in mania, as well as from the commonly associated substance abuse and dependence. In addition, women with untreated mania or hypomania are unlikely to participate in appropriate prenatal care or maintain an adequate diet.

Management Options

Treatment considerations should address two separate groups of women:

- those presenting with mania during pregnancy
- women with an established diagnosis of bipolar disorder requesting advice about a planned or recently confirmed pregnancy.

In the former, the risks to the mother and fetus from untreated mania are prominent, and the risks of failure to treat must be balanced against the risks of effective phar-

macologic treatment.[53,54] Admission to a psychiatric facility is necessary if there is a high risk of imminent harm to the mother or fetus and the woman has reduced insight and is unwilling to cooperate with appropriate outpatient treatment. Medication choices for mania in pregnancy should include lithium carbonate, despite early reports about the risk of Ebstein's anomaly and other cardiovascular abnormalities in infants exposed to lithium during the first trimester.[55] Subsequent studies of lithium in pregnancy suggest a more modest teratogenic relationship, with a risk of cardiovascular abnormalities that is 10 to 20 times higher in exposed children than the normal population, but with an actual occurrence rate that is low (0.05% to 0.1%).[56,57] It is recommended that fetuses who have first-trimester exposure to lithium should be screened for cardiovascular abnormalities by ultrasound in the mid-trimester. Despite these concerns, the risk of lithium for mania must be balanced against the increased teratogenic potential of the anticonvulsants that are the other established pharmacologic treatment for this disorder.[58] Valproate and carbamazepine have been linked to neural tube defects in 2% to 5% of exposed babies; there is insufficient data to assess the risks with the newer, more novel anticonvulsants. It does appear, however, that teratogenic risk is increased by the use of combinations of anticonvulsants and high plasma levels. In addition, a third class of medications is now under consideration for the treatment of mania, the atypical antipsychotics. Olanzapine was the first approved for this indication and is likely to be followed by others in the class. Although currently there is limited safety data available, which limits use of these drugs in pregnancy, studies of small numbers of women taking olanzapine during pregnancy have not revealed any teratogenicity. Finally, ECT should also be considered as an alternative to psychotropic medication exposure. It has demonstrated effectiveness for treatment of mania and depression, and reviews support the relative safety of ECT during pregnancy provided that specific modifications are made to the anesthetic procedure.[59]

Ideally, a woman with well-controlled bipolar illness will address the specific management of pregnancy prior to conception. Unfortunately the rate of unplanned pregnancy in women with bipolar illness is even higher than the 50% seen in the general population.[60] In these women pregnancy will commonly be at an advanced gestational age when diagnosed. As neural tube closure usually occurs by the end of the fourth week and development of the heart by the end of the eighth week, the period of risk for major organ malformation may have passed by the time many women taking maintenance psychotropic medication have confirmed pregnancy. This is particularly important information for women considering a rapid discontinuation of medications once pregnancy is detected. Studies have shown a 50% recurrence rate within 2 to 10 weeks of discontinuation of lithium in patients with bipolar illness, and this is

increased if medication is discontinued abruptly. Considering the lack of data of a clear safety advantage for a specific mood stabilizer and the risks of relapse following a change in treatment, there is little support for switching a woman from one mood stabilizer to another once pregnancy is detected. If the decision is made to continue medication during pregnancy, the minimum

effective dose should be used. In women who are planning pregnancy and report only occasional episodes of moderately severe mania or hypomania, medication discontinuation before conception may be a supportable option, provided that the taper occurs over 2 to 4 weeks' minimum and there is close collaboration between the obstetrician and psychiatrist.

SCHIZOPHRENIA

General

Pregnancy in women with schizophrenia occurs under very different circumstances today compared to a few decades ago.[61] The first and most influential change resulted from the release of patients to the community, instead of confining them to institutions, providing them with increased opportunities to meet partners. Despite this, although the fertility rates for women with schizophrenia have increased, its occurrence remains between 30% and 80% of the general population.[62] Because effective utilization of birth control practices is limited in women with schizophrenia, one important contributing factor for this decrease in fertility is the high prevalence of hyperprolactinemia in patients taking the older class of antipsychotic medications. More recently, the treatment of schizophrenia

has seen an increased utilization of a new generation of atypical antipsychotics that are much less likely to produce elevated prolactin levels. As a result, it is very likely that the frequency of pregnancy in women with schizophrenia will increase.

Diagnosis

The diagnostic criteria for schizophrenia require the presence of at least two of the following over a 1-month period: delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and affective flattening or markedly decreased volition. These features should be associated with prominent social and occupational dysfunction of at least 6 months' duration. The diagnostic evaluation should focus on the chronic and persistent features of the illness because the clinician may have difficulty during a cross-sectional assessment in differentiating psychosis in schizophrenia from

psychotic symptoms in a patient with mood disorder. Particular presentations that may have diagnostic challenges are the delusional denial of the pregnancy or the incorporation of the pregnancy into established delusional systems.

Maternal and Fetal Risks

Prenatal care may not be appropriately sought or maintained by these women, especially in cases in which the pregnancy was not planned and in women with prominent volitional deficits. Individuals with this illness are also noted to have great difficulty maintaining healthy lifestyle choices for diet, exercise, and avoidance of alcohol and tobacco. All of these factors are associated with worse outcomes from pregnancy. The use of older antipsychotic medications conveys some increased risk of teratogenicity, although further examination of this data linked the low-potency phenothiazines, such as chlorpromazine, with an increased risk of malformations. The depot antipsychotics are not recommended during pregnancy because they have been associated with an increased risk of extrapyramidal side effects in the neonate.

Management Options

Although it may be desired by the patient, discontinuation of psychotropic medication during pregnancy in women with schizophrenia is associated with a markedly increased risk of relapse. Considering that treatment of relapse is likely to require higher doses of medication than maintenance treatment, one alternative is to attempt reduction to the lowest effective dosage of medication, especially during the first trimester. Although low doses of the more potent older antipsychotics, such as haloperidol, are preferred for the treatment of schizophrenia in pregnancy, the new atypical antipsychotics are commonly being continued in pregnancy, despite the limited amount of safety data currently available. Any indication of psychotic relapse should be managed by prompt admission to a psychiatric facility for restabilization. A key aspect of management during pregnancy is to evaluate the options for the mother and child after delivery. Assessment of the woman's capacity to provide appropriate care for the infant should begin during the pregnancy; this should include review of the stability of the illness, the woman's adherence to outpatient care, and the quality of psychosocial supports.

SUBSTANCE ABUSE AND DEPENDENCY
(See also Chapter 34)

General

Considering that substance abuse and dependence are chronic relapsing disorders, women with these diagnoses are at particular risk when they become pregnant. Identification of prenatal substance use, including alcohol and nicotine, is a critical public health issue in the care of pregnant women.[63] In 1992 the National Pregnancy and Health Survey reported an estimated prevalence among U.S. women during pregnancy of alcohol (18.8%) and illicit drug use (5.5%). Another report of prospectively screened newborns in an urban population noted that 44% of infants tested positive for opiates, cocaine, or cannabis. Although many women report spontaneously quitting substance use on learning of the pregnancy, maintenance of abstinence is problematic without participation in treatment programs.[64] A key strategy in the accurate identification of affected women is the use of self-report screening instruments. These tend to identify much higher rates of substance use than detected by maternal interview alone. For example, one report contrasted the 65% to 70% correct identification of prenatal drinkers using a questionnaire with the 20% having documentation of alcohol use in the obstetric record.

Diagnosis

One of the strongest risk factors for substance abuse is the presence of other psychiatric disorders. Depression, mania, and schizophrenia are all associated with an increased prevalence of substance use and abuse. Other risk factors identified for frequent drinking in pregnancy were being unmarried, smoking, age ≥25 years, and having a college education, although the applicability of these findings to other populations requires further study.[65] Interviewing individuals who are aware of the mother's behavior, such as the spouse/partner and other relatives, can be informative, although the presence of substance abuse in these individuals may decrease the reliability of their responses. Urine screening of the mother has been controversial, although with the mother's consent it may be a useful strategy for identifying mothers who should be referred for treatment.

Maternal and Fetal Risks

The legality of substances does not lessen their serious implications for the health of the fetus; legal substances are probably associated with more widespread use.[66] The fetal consequences of maternal smoking are well established. These include intrauterine growth restriction, low birth weight, and developmental delays. Fetal alcohol syndrome (FAS) is associated with alcohol consumption during pregnancy. The three critical features are growth deficiency, facial phenotype, and brain damage dysfunction. A recent preclinical study showed that alcohol blocked N-methyl-D-aspartate receptors and excessively activated GABA receptors, leading to extensive neuron degeneration. The damage was dependent on the rapidity of dose administration and the duration of blood alcohol level elevation.[67] This suggests that peak levels during a drinking episode are most critical to developing FAS. Maternal use of benzodiazepines and barbiturates is known to be associated with neonatal withdrawal syndromes, but of more concern is the recent report suggesting that these substances may delete neurons from the developing brain through a mechanism similar to that proposed for alcohol. Considering their relatively common use in pregnant women and infants, there is an urgent need for more systematic examination of these risks.

Maternal use of illicit substances is associated with significant risk of adverse effects on the fetus.[68] Cannabis use during pregnancy has been associated with effects on the exposed infant's cognitive development and behavior, with at least one report linking hyperactivity, inattentiveness, and impulsivity at age 10 with first- and third-trimester exposure to cannabis.[69] Prenatal cocaine use is reported to be associated with a dose-dependent decrease in head circumference and head weight.[70] There has been a report of increased frequency of cardiovascular and musculoskeletal anomalies in infants exposed to methylenedioxymethamphetamine (Ecstasy) during pregnancy,[71] but further study is needed. Opiate withdrawal is the primary risk for infants born to opiate-dependent mothers and is characterized by autonomic dysfunction, as well as gastrointestinal and respiratory symptoms.

Management Options

The key to management of substance abuse is detection. The use of screening instruments is valuable; a questionnaires such as CAGE or T-ACE (Table 56–2) are commonly used for the detection of alcohol misuse.[72] Although the literature suggests that six drinks daily can cause overt FAS, the safe level has not been identified and the comparative risks for binge drinking and daily drinking are not clear. Risk-drinking (enough to *potentially* damage the offspring) has been defined as an average of more than one drink (0.5 oz) per day, or less if massed (binges of >5 drinks per episode).[73] In the United States, a conservative position has been adopted that essentially recommends total abstinence during pregnancy.

Unfortunately there are few screening tools for detection of the use of other substances. When diagnosed, a comprehensive treatment program is indicated, with individual and group therapy, behavioral incentives, and in some situations, pharmacologic agents such as methadone. These interventions have demonstrated positive effects on both maternal and neonatal outcomes.

The Summary of Management Options for this section is found in Chapter 34.

POSTPARTUM DEPRESSION CONDITIONS

General

The psychiatric diagnostic system (i.e., *DSM-IV*) does not recognize postpartum disorders as discrete diagnoses but permits "postpartum onset" to be used as a specifier

---

TABLE 56–2

T-ACE Screening Tool for Pregnancy Risk-Drinking*

Tolerance
"How many drinks can you hold?"
(A positive answer, scored a 2, is at least a 6-pack of beer, a bottle of wine, or 6 mixed drinks. This suggests tolerance of alcohol and very likely a history of at least moderate to heavy alcohol intake.)

Annoyed
"Have people annoyed you by criticizing your drinking?"

Cut Down
"Have you felt you ought to cut down on your drinking?"

Eye Opener
*"Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover?"

* From Sokol RJ, Delaney-Black V, Nordstrom B: Fetal alcohol spectrum disorder. JAMA 2003;290:2996–2999. The first question is scored 0 or 2 points. The last 3 questions are scored 1 point if answered affirmatively. A total score of 2 or more is considered positive for risk-drinking.

for episodes of illness appearing within 4 weeks of childbirth. There is continued debate about this relatively brief interval for the definition of postpartum illness, most epidemiologic studies use a 3-month period, which captures the peak prevalence of psychiatric illness and hospitalization after childbirth, and other researchers and clinicians are extending their focus to the events occurring during the first postnatal year.[74] Postpartum mood changes include three distinct clinical syndromes: postpartum blues, postpartum depression, and postpartum psychosis, although a single cross-sectional evaluation of all three may be indistinguishable. Fortunately, the prevalence of these three disorders varies inversely to their severity.

Postpartum "Blues"

General

Although not actually listed in *DSM-IV* as a psychiatric disorder, this well-recognized, common disorder occurs in 25% to 80% of women following delivery. Sadness may be prominent, but the syndrome is commonly characterized by emotional lability, bursting into tears without apparent cause, increased anxiety, insomnia, and negative thinking. Symptoms usually appear within the first postpartum week and, in the majority of women, peak around day 5 postpartum and resolve within 2 weeks. Given the timing and self-limiting nature of this syndrome, there have been many reports and hypotheses linking its pathophysiology to the rapid and profound changes occurring at parturition, but so far none have achieved wide support.

Diagnosis

The key to the diagnosis of this state is its time course.[75] Distinguishing between postpartum blues and postpartum depression has great clinical significance. Persistence of depressive symptoms past the second week postpartum should result in a careful reassessment of the original diagnosis. In addition, prominent insomnia and mood lability in a woman with risk factors for postpartum psychosis, even if it occurs in the first 2 weeks after childbirth, should prompt an urgent psychiatric consultation.

Maternal and Fetal Risks

Generally this syndrome is not associated with significant functional impairment of the mother and does not significantly increase risks to the infant.

Management Options

Provide support and education about the typically self-limiting nature of this condition, but monitor for progression and development of postpartum depression.

Confirm that this is not postnatal depression and that it resolves within 2 weeks.	–	GPP	–
Offer explanation and support.	–	GPP	–

Postpartum Depression

General

The prevalence of postpartum depression is 10% to 15%; it occurs in 1 of every 7 to 10 women after delivery, making it the most common complication of childbirth. Women with a past history of depression have an elevated risk of postpartum depression, estimated to range from 25% to 50%. Although the psychiatric diagnostic system focuses on depression appearing up to 4 weeks after delivery, a significant body of data emphasizes the importance of depression having an onset up to 1 year after childbirth. Due to its temporal association, the cause of postpartum depression is commonly attributed to the rapid and pro-found hormonal changes occurring after delivery. Other factors that increase the risk of postpartum depression are also seen in women suffering from depression unrelated to childbirth, such as past and family history of depressive episodes, poor marital relationship, low social support, stressful life events, and low socioeconomic status.[17,76]

Diagnosis

The clinical features and diagnostic process for postpartum depression are similar to those for women suffering from depression at other times. The first step is to identify a period of persistent depressed mood or anhedonia lasting at least 2 weeks. Several screening instruments

have been utilized for this purpose. The most commonly reported instrument in the literature is the Edinburgh Postnatal Depression Scale (EPDS), a 10-item self-report instrument designed to assess the presence of depressive symptoms in women after childbirth.[77] Each symptom item is scored from 0 to 3 according to severity. A score >9 on the EPDS should be followed by a brief focused interview to determine the presence of a depressive diagnosis. Other instruments include a two-question case-finding instrument assessing the presence of depressed mood or anhedonia.[15] A positive response to either of the two items suggests that a diagnosis of depression should be explored.

In women who were screened during the second trimester of pregnancy and again during the postpartum year, the two independently predictive risk factors for postpartum depression were high depressive symptoms during pregnancy and a past personal history of depressive disorder.[78] Another study of first-time otherwise healthy mothers found that women reporting high levels of depressive symptomatology at 2 months' postpartum had an increased risk of high levels of depressive symptoms continuing through the first year postpartum.[79] This emphasizes the persistence of depressive symptoms with associated impairment of function and reinforces the importance of identifying depressed mothers soon after childbirth, preferably with routine use of screening instruments, and referring for appropriate interventions.[80]

Considering that bipolar illness can present with an episode of depression, it is essential to ask the depressed woman about the features of past hypomania or mania, particularly when psychotic features are present. This can be done by asking about the past occurrence of at least 3 to 4 days of a markedly decreased need for sleep (i.e., feeling rested after 3 to 4 hours sleep per night, without daytime fatigue or decreased energy). A positive response to this question or one about periods of persistently elevated or irritable mood that others thought were abnormal indicates that further evaluation for possible bipolar disorder is indicated and psychiatric referral is recommended.

Maternal and Fetal Risks

Although the overall risk of suicide in postpartum women is low, those who develop a severe psychiatric illness in the first year after childbirth are at a significantly increased risk. In one study, the long-term risk of suicide in women admitted to a psychiatric hospital in the first year after childbirth was increased 17 times.[81] In these women the risk of completed suicide during the first postpartum year was markedly increased to 70 times greater than the age-specific mortality rate. A recent report from the United Kingdom noted that suicide was the leading cause of maternal death during the first year after childbirth.[82]

Adverse effects of maternal depression on infant development have been widely reported,[83–85] including reports of an association between maternal depression and an increased risk of sudden infant death syndrome.[86] Children of depressed parents are at high risk for anxiety and depressive disorder in childhood, depression in adolescence, and alcohol dependence as adults.[87] Children of depressed mothers are also less likely to benefit from appropriate parental prevention practices.[88] Depressed mothers reported a three times greater risk of serious emotional problems in their children and more functional disability.[89]

Homicide is the leading cause of infant deaths due to injury, 9 per 100,000 live births from 1988 to 1991.[90] This study revealed that children born to young unmarried and poorly educated mothers were several times more likely to be killed. In this group of mothers, the most important risk factors were maternal age <17 years and birth of the second or subsequent child before age 19; these accounted for 17% of the infant deaths. Five percent of homicides occurred on the first day of the infant's life; 95% of these infants were not born in a hospital compared to 8% of all infants killed during the first year of life who were not born in a hospital. Infants killed immediately after birth appeared to be the result of unwanted or disguised pregnancies. Identification of adolescents who have hidden their pregnancies and provision of appropriate prenatal care is particularly important. Maternal depression may play a role in the deaths occurring after the first day of life. The combination of depressed mood, low self-esteem, pessimism and hopelessness may reach delusional levels in some mothers, leading them to believe that their babies and themselves are better off dead.[91] In addition, reports suggest that infants of depressed mothers are more irritable, less easily consoled, and have disrupted sleep and wake cycles, all increasing their risks of being abused.

Management Options

Women receiving a diagnosis of depression after childbirth are commonly treated with antidepressant medication.[92] Uncontrolled studies have reported improvement in postpartum depression after treatment with antidepressants such as sertraline, fluvoxamine, and venlafaxine. Unfortunately only one placebo-controlled trial of antidepressants in postpartum depression has been published. This study compared antidepressant medication (fluoxetine) with psychotherapy (cognitive-behavioral therapy; CBT). Results indicated that fluoxetine was more effective than placebo. With regard to the role of psychotherapy, six sessions of CBT were more effective than one session, but the addition of multiple CBT sessions to fluoxetine did not provide any additional benefit.[93]

Women with postpartum depression appear abnormally sensitive to the withdrawal of high levels of gonadal steroids following parturition. A preliminary placebo-controlled study showed that transdermal estrogen was an effective treatment for women with severe postpartum

depression, although more research is needed to assess the safety of estrogen in the postpartum period.[94]

Due to the reluctance of some postpartum women to take medication, psychotherapy has been studied as an alternative to antidepressant medication as well as an adjunct to medication. In addition to the study noted previously, several randomized controlled trials have shown that individual psychotherapy is an effective treatment for postpartum depression.[95] There was greater improvement of maternal mood and social functioning in women receiving interpersonal psychotherapy than in women in the waiting list control group.[96] Other studies have shown the benefit of including the partner in the psychotherapy sessions, although the results from group therapy are mixed.[97]

Many women who express reluctance to take medication after childbirth identify concern about the possible adverse effects on breastfeeding infants. Because all antidepressants are excreted in breast milk, many studies have evaluated the serum levels of antidepressant in breastfeeding infants. With few exceptions, these reports have found that the serum levels of antidepressants in infants were either very low or undetectable.[98,99] Reports of adverse effects in breastfed infants of mothers taking antidepressants have included increased crying, colic, and decreased sleep in three infants whose mothers were taking fluoxetine and who were found to have serum levels of fluoxetine and its metabolite that were in the adult therapeutic range. Citalopram, sertraline, and doxepin have been identified in case reports with either adverse effects or elevated serum levels. It should be noted that most reports were of one or two cases, methodologies varied, and with the exception of one study the follow-up was brief.

Postpartum Psychosis

General

Postpartum psychosis is the most severe postpartum mood disorder; fortunately it is rare, affecting 1 to 2 women per 1000 deliveries. Current literature generally reflects the view that postpartum psychosis, in the majority of cases, is a presentation of bipolar disorder following childbirth.[52,100] Women with a history of bipolar disorder have a 100-fold higher risk of developing postpartum psychosis than women without bipolar disorder.[101] In addition, women with bipolar disorder and a family history of postpartum psychosis have a rate of postpartum episodes twice that seen in women with bipolar disorder and no family history.[102]

Diagnosis

Symptoms of insomnia, prominent mood lability, restlessness, sadness, and irritability appear within 2 weeks of childbirth, followed by the development of psychotic features, such as delusions, hallucinations, and thought disorder. Insomnia is an early and common symptom and is found in 42% to 100% of women with psychosis.[103] The presence of perplexity and confusion are also noted to be common, unlike in nonpuerperal manic episodes. Some researchers have commented on the role of sleep loss in the precipitation of mania generally[104]; this may be of particular importance following childbirth.[105] Studies of sleep in the later stages of pregnancy show prominent sleep disruption, with prolonged sleep latency, more awakenings, decreased total sleep time, and suppression of stage 4 sleep; recovery of stage 4 sleep and reduction in REM sleep occur in the early postpartum period.[106,107] More importantly a prospective study of sleep in pregnancy revealed a differential effect depending on the presence of a past history of mood disorders. In addition sleep disruption during late pregnancy and the early postpartum period appears to be more pronounced in first-time mothers than in muti-

parous women. This may be relevant for the observed increase in the risk of postpartum psychosis after the first child compared to later deliveries.

Maternal and Fetal Risks

In almost all instances, women with postpartum psychosis are unable to provide adequate care for themselves or their child and require additional support and supervision. Thoughts of harming the infant are common in women with postpartum psychosis; sometimes they act on their thoughts. Postpartum women who commit infanticide or suicide more commonly present with depressed mood than mania.

Management Options

Early identification of sleep impairment is important in the management of women with a history of bipolar disorder or postpartum psychosis. Prevention of sleep loss in vulnerable women by daytime delivery and reduction of nocturnal stimulation may be appropriate. Prompt treatment of decreased sleep in these women, with a high potency benzodiazepine such as clonazepam or a sedating antipsychotic, is essential. Due to the high risk of recurrence, prophylactic treatment of women with a history of postpartum psychosis or bipolar disorder is often considered, although there is no consensus about the optimal time to begin prophylaxis. Many patients prefer to defer starting prophylactic medication until immediately after delivery.

Established postpartum psychosis requires admission to a psychiatric hospital. Mother and baby units are optimal but are relatively uncommon in the United States. Because there are no adequately controlled studies of psychopharmacologic treatment of postpartum psychosis, the standard treatments for a psychotic manic or depressed episode are used, including new generation antipsychotics, lithium, valproate, and antidepressants. If an antidepressant is used, a mood stabilizer such as lithium or valproate should be given in combination. There are numerous reports that ECT is effective in the treatment of postpartum psychosis, but there are no controlled studies of this strategy. A small open-label pilot study of 17β-estradiol in the treatment of postpartum psychosis found encouraging results but requires further investigation.[108]

CONCLUSIONS

PSYCHIATRIC AND SUBSTANCE ABUSE DISORDERS

- Relatively common in women during pregnancy and the postnatal period
- Present in up to 50% of women seen in obstetric and gynecology practices
- Commonly not recognized unless standard clinical assessments are supplemented with screening instruments
- Associated with twice the risk of inadequate antenatal care
- Collaborative care with a psychiatrist or other mental health clinician frequently beneficial

DEPRESSION AND ANXIETY DISORDERS

- Most common in women during the reproductive years
- More likely to develop during pregnancy in women with personal and family history of mood disorder, marital conflict, younger age, and limited social support

Continued

DEPRESSION AND ANXIETY DISORDERS *(Continued)*

- Failure to treat is associated with negative obstetric and neonatal outcomes
- Standard psychotherapeutic and pharmacologic treatments are effective; many can be used in pregnancy
- Withdrawal of treatment is commonly followed by relapse

BIPOLAR DISORDER AND SCHIZOPHRENIA

- Present particular risks during pregnancy
- Untreated mania is associated with impulsive high risk behaviors, often including substance abuse
- Use of effective antimanic treatments during pregnancy requires careful assessment of the risk-benefit relationship
- Psychotic symptoms and volitional deficits in women with schizophrenia may result in major impediments to antenatal care and ability to care for the infant

SUBSTANCE ABUSE

- Associated with adverse effects on the infant
- May be difficult to detect without specific screening and corroborative information
- Responds favorably to comprehensive treatment programs, although they are frequently characterized by a relapsing course before sustained abstinence is achieved

POSTPARTUM MOOD DISORDERS

- Common
- Distinguishing the three forms of disorder is crucial
- Postpartum blues spontaneously remits within 2 weeks of delivery
- Postpartum depression may become apparent at any time during the first year after childbirth; the strongest predictors are a past history of depressive disorder and depression during pregnancy
- Standard antidepressant treatments are indicated for postpartum depression
- Postpartum psychosis is rare but usually appears within 2 weeks of childbirth and requires urgent psychiatric inpatient care
- Postpartum psychosis is most common in women with a history of bipolar illness

SECTION SIX

Prenatal—General

Abdominal Pain

Kassam Mahomed

INTRODUCTION AND OVERVIEW

Abdominal pain during pregnancy presents unique clinical challenges; the differential diagnosis during pregnancy is extensive. The pain may result from three broad sources:

- Physiologic effects of pregnancy
- Pathologic conditions related to pregnancy
- Pathologic conditions unrelated to pregnancy

The clinical presentation and natural history of many abdominal disorders are altered during pregnancy; the diagnostic evaluation is altered and constrained by pregnancy; and finally, the interests of both the mother and the fetus must be considered in pain management.

The initial step in management of abdominal pain is to establish a diagnosis by a detailed history, a thorough physical examination, and specific investigations (Tables 57–1 to 57–4). Details of this process will be covered in sections devoted to specific conditions.

Abdominal assessment during pregnancy is modified by displacement of abdominal viscera by the enlarging gravid uterus, because of which abdominal masses may also be missed on physical examination.

Physiologic changes in laboratory values during pregnancy which need to be remembered in clinical evaluation include mild leukocytosis, dilutional anemia, increased alkaline phosphatase levels, hyponatremia, hypercoagulability, and fasting hypoglycemia with postprandial hyperglycemia.

DIAGNOSTIC IMAGING IN PREGNANCY

Fetal safety during diagnostic imaging is a concern in pregnancy. Ultrasonography is considered safe during pregnancy, although sensitivity for nonobstetric conditions may be decreased.[1] Magnetic resonance imaging (MRI) is preferable to computed tomography (CT) scanning to avoid ionizing radiation.[2,3] Rapid sequence MRI

is preferable to conventional MRI because of briefer exposure.[4] Radiation dosage is the most important risk factor and is worse in earlier gestation. Exposure of more than 15 rads during the second and third trimester, or more than 5 rads in the first trimester, should be of concern because of the associated increased risk of miscarriage, chromosomal and fetal abnormalities, as well as increased likelihood of malignancies in childhood.[5] Diagnostic studies with the most radiation exposure, such as intravenous pyelogram (IVP) and barium enema, typically expose the fetus to less than 1 rad.[2]

Sigmoidoscopy, especially flexible sigmoidoscopy, seems to be relatively safe in pregnancy; it does not induce labor and should be considered in medically stable patients with important indications, as opposed to routine screening.[6] Informed consent, however, should be routine in such cases.

PHYSIOLOGIC CONDITIONS IN PREGNANCY (See Table 57–1)

Round Ligament Pain

Round ligament pain occurs in 10% to 30% of pregnancies and most commonly occurs toward the end of the first trimester and in the second trimester. It is more common in multigravidae than primigravidae and is said to be due to stretching of the round ligaments, but there is no documented evidence for this. The pain, which is usually described as cramplike or stabbing and is made worse by movement, is in the lower quadrant and can radiate to the groin. It is often associated with some tenderness over the area of the round ligaments.

Risks

The main risk is failure or delay in diagnosis of a significant pathologic condition (see later discussion).

TABLE 57–1

Physiologic Conditions in Pregnancy

	ROUND LIGAMENT PAIN	UTERINE TORSION	BRAXTON HICKS CONTRACTIONS	MISCELLANEOUS MILD DISCOMFORT
History				
Pain	Cramplike/stabbing, aggravated by movement	Recurrent attacks, pain can be severe	Irregular tightenings	Mild/varied
Urine	−	± urinary retention		−
Trimester	Late 1st/2nd	3rd	Late 2nd/3rd	3rd
Previous disease	−−	Uterine anomaly, pelvic mass, previous surgery		Fibroids
Examination				
Shock	−	+	−	−
Uterus	Soft	Very tender	Irregular contractions	−
Tenderness	Over area of round ligament insertion	Very tender over adnexa	−−	−
Others	−	Vagina distorted/changed	No show, no cervical change	−
Investigations				
All	Negative or normal	Negative or normal	Negative or normal	Negative or normal

+, Present; −, absent; ±, may be present.

Management Options

Management is conservative and includes reassurance, reducing physical activity, avoiding movements or postures that exacerbate the symptoms, and in some cases analgesics. Failure to respond to conservative measures or worsening of symptoms are indications for further investigations.

Severe Uterine Torsion

Mild asymptomatic axial rotation of the uterus (<40 degrees), usually to the right, is observed in the majority of pregnancies.[7] However, of rotations greater than 45 degrees, 6% occur in the first, 26% in the second, and 49% in the third trimester. The features of pain, shock, intestinal complaints, urinary symptoms, bleeding, and obstructed labor are related to the degree of torsion and can be acute, subacute, chronic, or intermittent.[8] In 80% to 90% of cases, there is a predisposing factor such as a fibroid, congenital anomaly, torsion of a gravid horn of a didelphic uterus,[9] adnexal mass, or a history of pelvic surgery.[10]

Risks

Maternal vasovagal shock and possible fetal asphyxia (both acute and chronic) are the main risks of severe uterine torsion.

Management Options

Conservative measures such as bed rest, analgesia, and altering the position of the mother can be used to try to produce a spontaneous correction of the torsion. Often laparotomy is performed for detorsion of the uterus,

hoping the pregnancy will continue. If the fetus is viable, cesarean section is performed following detorsion of the uterus[8] (level IV, grade C).

Braxton Hicks Contractions

Many women experience Braxton Hicks contractions in the latter half of pregnancy.[11] They are irregular in frequency and inconsistent in intensity. Although in the majority of women these contractions are painless, some women find them painful.

Risks

The main danger is to mistake the uterine activity of true preterm labor for Braxton Hicks contractions.

Management Options

A careful history and examination should be performed to exclude genuine labor. Absence of a "show" or membrane rupture together with a high presenting part would be reassuring. Value of absent fetal breathing movements with true labor is yet to be established. Vaginal examination, perhaps repeated in 4 hours, may be the only satisfactory way to assess the significance of these uterine contractions. Once the diagnosis is made, reassurance is all that is necessary.

Miscellaneous Nonpathologic Causes of Discomfort

Heartburn, excessive vomiting, and constipation are common causes of mild discomfort or pain, especially during

early pregnancy. A full discussion of the risks and management of hyperemesis gravidarum is given in Chapter 48.

During the third trimester, most pregnant women will experience varying degrees of these symptoms, which some will describe as "discomfort" and others as "pain."[11] Normal events causing such symptoms include abdominal wall distention, vigorous fetal activity, engagement of the fetal head, and pressure effect of the fetal head with breech presentation.

Risks

The main risk is to miss a pathologic cause for the pain.

Management Options

Heartburn may be helped by reassurance, avoidance of bending, and lying flat in bed. Antacids[12,13] and H_2 receptor antagonists[14] are of proven benefit if simple measures do not help. If vomiting is excessive and not relieved by reassurance and dietary adjustments, hospital admission may be required, especially if there is dehydration (level Ib, grade A).

Constipation may be relieved by increasing dietary fiber[15] and avoiding iron unless absolutely necessary. In severe cases laxatives may be tried[16] (level III, grade B).

SUMMARY OF MANAGEMENT OPTIONS
Round Ligament Pain

Management Options	Quality of Evidence	Grade of Recommendation	References
Exclude pathologic causes of pain	–	GPP	–
Reassure	–	GPP	–
Reduce physical activity	–	GPP	–
Provide local heat	–	GPP	–

SUMMARY OF MANAGEMENT OPTIONS
Severe Uterine Torsion

Management Options	Quality of Evidence	Grade of Recommendation	References
Exclude pathologic cause of pain	–	GPP	–
Conservative measures	–	GPP	–
Bed rest			
Analgesia			
Alter maternal position			
Screen for acute and chronic fetal hypoxia.			
Surgical measures (diagnosed at laparotomy)	IV	C	8
Correct the torsion			
Deliver by cesarean section during laparotomy or later (either vaginal or by cesarean) if preterm			

SUMMARY OF MANAGEMENT OPTIONS
Heartburn, Excess Vomiting and Constipation

Management Options	Quality of Evidence	Grade of Recommendation	References
Heartburn			
Reassure	–	GPP	–
Avoid bending	–	GPP	–
Avoid lying flat in bed (more pillows/raise head of bed)	–	GPP	–
Antacids	Ib	A	12,13
H₂ antagonists if severe	Ia	A	14
Excess Vomiting			
Exclude pathologic cause	–	GPP	–
Reassure	–	GPP	–
Dietary adjustment	–	GPP	–
Rectal antiemetics (? avoid first trimester)	–	GPP	–
Consider hospital admission (especially if dehydration/ketosis):	–	GPP	–
Nothing else as first measure			
Consider IV fluids and IV antiemetics if continued problem			
See Chapter 48 for discussion of hyperemesis gravidarum			
Give steroids in extreme cases			
Constipation			
Dietary adjustment, increase fiber	IIb	B	15
Stop iron therapy unless absolutely indicated	–	GPP	–
Consider laxatives	III	B	16
Consider suppositories/enema only if severe	–	GPP	–

PATHOLOGIC CONDITIONS RELATED TO PREGNANCY (See Tables 57–2 and 57–3)

Spontaneous Miscarriage
Chapter 4 provides a detailed discussion of risks and management options.

Uterine Leiomyoma
Chapter 58 provides a detailed discussion of risks and management options.

Placental Abruption
Chapter 59 provides a detailed discussion of risks and management options.

Chorioamnionitis
Chapters 27 and 63 provide detailed discussions of risks and management options.

Preterm Labor
Chapter 62 provides a detailed discussion of risks and management options.

Uterine Rupture
Chapter 77 provides a detailed discussion of risks and management options, and Chapters 68 and 75 contain discussions of specific issues.

Ectopic Pregnancy
Chapter 4 provides a detailed discussion of risks and management options.

TABLE 57-2

Pathologic Conditions Related to Pregnancy: Uterine

	ABORTION/MISCARRIAGE	FIBROIDS	PLACENTAL ABRUPTION	CHORIOAMNIONITIS	PRETERM LABOR	UTERINE RUPTURE
History						
Pain	+	Localized ± severe	Mild to very severe	±	+	+

Ovarian Pathology

Chapter 58 provides a detailed discussion of risks and management options.

Abdominal Pregnancy

General

Advanced abdominal pregnancy is a rare event. In the United States it has been estimated that there are 10.9 abdominal pregnancies per 100,000 births, and 9.2 abdominal pregnancies per 1000 ectopic gestations.[17]

It is more commonly seen in patients of low socioeconomic status and in developing countries and in those with a history of infertility or a previous history of pelvic infection.

Advanced abdominal pregnancy has been divided into primary and secondary forms:

- In primary abdominal pregnancy, the tubes and ovaries are normal, and there is no evidence of uteroplacental fistula. The pregnancy is related exclusively to the peritoneal surface very early in pregnancy.
- Secondary abdominal pregnancy occurs after tubal abortion or rupture, with subsequent implantation of the conceptus on a nearby peritoneal surface.

Diagnosis

Early diagnosis requires a high index of suspicion. Abdominal pain is present in 80% of cases, often noticed in early pregnancy, and varies from mild discomfort to severe and unbearable pain. Fetal movements may be painful or absent with fetal death. In 30% of cases vaginal bleeding occurred in early pregnancy. Examination reveals abdominal tenderness, with easily palpable fetal parts.

TABLE 57-3

Pathologic Conditions Related to Pregnancy: Extrauterine

+, Present; −, absent; ±, may be present
hCG, human chorionic/gonadotropin.

Abnormal lie occurs in 15% to 20% of cases. Vaginal examination often reveals a closed, uneffaced cervix occasionally displaced anteriorly. Absence of palpable uterine contractions to oxytocin stimulation or to induction of labor by prostaglandins is one of the most helpful clinical clues to the diagnosis.[18] Even with a high index of suspicion, confirmation of the diagnosis is not always easy.

Ultrasound scan should reveal one or more of the following features: the fetal head is located outside the uterus; the fetal body is outside the uterus, as is the ectopic placenta; failure to demonstrate a uterine wall between the fetus and the urinary bladder; and there is recognition of a close approximation of fetal parts and the maternal abdominal wall.

Radiography should reveal one or more of the following features: absence of a definite uterine shadow around the fetus; maternal intestine shadows intermingling with fetal parts in the anteroposterior view; overlapping of the maternal spine by fetal small parts in the lateral film.

MRI can safely produce images in different planes without the use of ionizing radiation. This method seems to be a very sensitive diagnostic tool where facilities exist.

Risks

Perinatal mortality rate is reported to be greater than 50%.[19] If there is reduced liquor volume there is an increased incidence of fetal malformation, pressure deformities, and pulmonary hypoplasia. Maternal mor-

tality rate depends on availability and accessibility of services but has been reported as 5 per 1000 cases.[17]

Management Options

Management is based on an empiric approach derived from a review of cases[20] rather than evidence from controlled trials (level III, grade B).

Timing and the nature of the intervention will depend on the gestation and viability of the fetus at the time of diagnosis. If the fetus is dead, then surgery is indicated. Some advocate waiting 3 to 8 weeks to allow atrophy of the placental vessels with a possible decrease in intraoperative complications. If the fetus is alive but nonviable (before 24 weeks), immediate surgery is thought to be indicated by many authors. If the pregnancy is 24 or more weeks, a conservative approach may be contemplated to allow time for further development of the fetus. This approach requires thorough and careful counseling of the parents. There are no data that define the risks for the conservative versus surgical options at either gestation.

NATURE OF INTERVENTION

Preoperative preparations should include having several units of blood available and, if possible, carrying out the delivery with a general, vascular, or genitourinary surgeon. A midline vertical incision is always advisable to improve access. The amniotic sac should be carefully incised in an avascular area free of placenta. Removal of the fetus should be done in a way to minimize manipula-

tion of the placenta and surrounding membranes and the likelihood of bleeding.

MANAGEMENT OF THE PLACENTA

If the blood supply to the placenta can be safely secured, complete removal of the placenta usually results in an uncomplicated postoperative recovery, and most authors now agree that removal of the placenta, if straightforward, should be the optimal approach.

If the placenta cannot be removed safely, other options include ligating the cord close to the placenta and leaving it in situ or ligating the placental blood supply and removing the pelvic organ upon which implantation has occurred (e.g., hysterectomy or salpingo-oophorectomy).

Partial removal of the placenta when its whole blood supply cannot be ligated may result in massive hemorrhage, shock, and death. This is not recommended. In such situations it is best that the placenta be left in situ. However, this option is often accompanied by ileus, peritonitis, abscess formation, and prolonged hospital stay.

Some advocate leaving the placenta in situ with later use of methotrexate to increase the rate of absorption/destruction of the retained placental tissue. However, this leads to rapid destruction of the placenta with accelerated accumulation of necrotic placental tissue, which often becomes infected. This is therefore not a recommended method of treatment.

SUMMARY OF MANAGEMENT OPTIONS COVERED IN OTHER CHAPTERS

Pathologic Conditions Related to Pregnancy

Topics	Summary of Management Options Found in Chapter

SUMMARY OF MANAGEMENT OPTIONS

Abdominal Pregnancy *(Continued)*

Management Options	Quality of Evidence	Grade of Recommendation	References
Live Fetus After 24 Weeks–Continued			
Make midline vertical incision in abdomen.			
Incise sac away from placenta.			
Avoid placental manipulation during delivery.			
If blood supply to placenta can be secured, remove placenta completely.			
If blood supply to placenta cannot be secured, ligate cord only (greater postoperative morbidity).			

PATHOLOGIC CONDITIONS UNRELATED TO PREGNANCY (See Table 57–4)

Gastrointestinal Tract

Acute Appendicitis

GENERAL

Acute appendicitis is the most common nonobstetric surgical emergency during pregnancy complicating about 1 in 1000 pregnancies,[21] the same as in nonpregnant women.[22] The incidences are approximately 30%, 45%, and 25% in the first, second, and third trimesters, respectively.[23] The incidence among teenagers is higher than in older age groups.[24]

DIAGNOSIS

The diagnosis is challenging as the typical symptoms, anorexia, nausea, and vomiting mimic normal pregnancy, and the anatomic location of the appendix during pregnancy can be different from that in the nonpregnant patient. Conventional teaching maintains that appendicitis pain "migrates" upward with the growing uterus. However, a recent review of cases over a 10-year period[23] showed that pain in the right lower quadrant of the abdomen is the most common presenting symptom in pregnancy, regardless of gestational age. Appendicitis should always be considered when a pregnant woman presents with persistent abdominal pain and tenderness, nausea, vomiting, and fever. Rebound tenderness and muscle guarding are valuable signs in the diagnosis of appendicitis, but because of the laxity of the abdominal wall, these signs are found less frequently in pregnant women.[25]

Normal pregnant women may have mild leukocytosis, but serial white blood cell counts can prove helpful when evaluating patients over several hours when a shift to the left may be very valuable.[26]

Pyelonephritis is the most common differential diagnosis of abdminal pain that mimics acute appendicitis in pregnancy.[27] Interestingly, a review of 50 women presenting with right lower abdominal pain clinically diagnosed and operated upon for acute appendicitis revealed that 80% of the appendices were histologically normal.[28]

Use of high resolution ultrasound with graded compression technique allows direct visualization of an acutely inflamed appendix[29] with reported 100% sensitivity and 96% specificity.

RISKS

Similarity with normal symptoms in pregnancy can lead to a delay in the diagnosis. Reluctance to operate in a pregnant woman causes further delay and thus increases the risk of perforation, peritonitis, and septicemia as well as a substantial risk of miscarriage, preterm labor, and fetal demise. A review[22] of 56 women who underwent appendectomy during pregnancy showed that 33% aborted after surgery in the first trimester. Second-trimester surgery resulted in preterm delivery in 14%. This is more likely when the inflamed appendix has perforated. Maternal mortality rates have declined from 40% in 1908 to 0.5% in 1977.

MANAGEMENT OPTIONS

Despite the difficulty in making the diagnosis, surgery should not be delayed when the clinical suspicion is high. Laparoscopy can be performed safely in pregnancy especially before 20 weeks (see later discussion)[26] and may be considered during the first two trimesters for nonperforated appendicitis or when the diagnosis is uncertain. Use of ultrasound[30] to guide first trocar insertion to prevent

+, present; –, absent; ±, may be present.

injury to the uterus may be a useful adjunct to improve safety (level III, grade B).

Because the location of the appendix is variable in pregnancy, the incision used with laparotomy needs to be individualized. In the first trimester, as the appendix remains in its usual location and the uterus does not obstruct access to it, a low transverse or McBurney incision can be used. In the second and third trimesters, a right paramedian incision over the area of maximal tenderness allows better access to the appendix and the option of extending the incision if needed. It is thought preferable to extend the incision to gain adequate exposure rather than to extensively compress or manipulate the pregnant uterus. There are, though, no studies that address this issue.

During the postoperative period one must be alert for signs of preterm labor, monitoring for contractions and cervical dilation. Peri- or postoperative use of tocolysis is debatable. Those who are against using tocolysis[31] fear the risk of potential fluid overload and adult respiratory distress syndrome. Others[32] have used prophylactic tocolysis successfully. There are no reported trials to resolve this issue[32,33] (level III, grade B). Postoperative antibiotics are normally recommended. Clindamycin and gentamicin in combination are thought to be effective and safe even though they are both category B drugs in pregnancy (see Chapter 35).

Intestinal Obstruction

Acute intestinal obstruction is the second most common nonobstetric abdominal emergency complicating pregnancy. It occurs in 1 in 1500 pregnancies and is increasingly being reported as a cause of acute abdominal pain requiring surgery in pregnancy.[34] This trend is attributed to a number of factors, including an increase in the number of surgical procedures performed in young women[35] and an increased number of pregnancies occurring in older women.[36,37] Obstruction most likely occurs in the third trimester because of the added mechanical effects of the enlarged gravid uterus.[38]

Clinical presentation is similar to that in the nonpregnant state, with colicky abdominal pain, vomiting, and constipation. Abdominal distention and high-pitched

bowel sounds are found. If the diagnosis is suspected, there should be no delay in requesting an erect abdominal x-ray to demonstrate dilated loops of bowel with fluid levels.

RISKS

Like appendicitis, delay in diagnosis is common and is often the explanation for the morbidity and fatality that accompany intestinal obstruction in pregnancy. High maternal and fetal mortality rates of 10% to 20% and 30% to 50%, respectively, are reported, especially if the obstruction is complicated by strangulation or perforation, or by fluid and electrolyte imbalance.[34,36]

MANAGEMENT OPTIONS

If there are no signs of strangulation, conservative management with intravenous fluids and nasogastric aspiration may be tried for a few hours. Where there is any doubt, however, early surgery after correcting fluid and electrolyte imbalance would be the safest option in view of the high complication rate. A vertical midline incision is usually necessary, and occasionally the definitive surgical procedure may have to be preceded by cesarean section if access becomes a problem and fetal maturity is assured. Use of perioperative tocolysis to prevent preterm labor in a continuing pregnancy is debatable, as discussed earlier[34] (level IV, grade C).

Acute Cholecystitis and Cholelithiasis

Physiologic changes of the biliary system in pregnancy including decreased gallbladder motility and delayed emptying results in an increase in gallbladder disease in pregnancy. In a large ultrasound study in Chile, 12% of pregnant women versus 1.3% of nonpregnant control subjects had gallstones.[39] Most gallstones are asymptomatic in pregnancy, but when symptoms occur they are the same as in nonpregnant women. Acute cholecystitis as a result of cystic duct obstruction complicates about 1 in 1000 pregnancies, and many women will get their first attack during pregnancy.

DIAGNOSIS

Pain is located in the epigastrium and right upper quadrant and can vary in severity. It may be sudden in onset and become intermittent. Colicky pain is often a result of a stone obstructing the common bile duct. There may be nausea, vomiting, pyrexia, tachycardia, and right subcostal tenderness. The tenderness on deep palpation under the right costal margin on deep exhalation is known as positive Murphy's sign. Leukocytosis is common. Serum liver function tests and amylase may be mildly abnormal. The differential diagnosis includes viral hepatitis, pneumonia, appendicitis, acute fatty liver of pregnancy, and shingles. Ultrasound scan of the gallbladder and the common bile duct will demonstrate gallstones in more than 90% of cases.[40] Cholangiography is contraindicated in pregnancy.

It is important to differentiate cholecystitis from the hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome and severe preeclampsia, which are associated with great risk to the mother and fetus. Abnormal renal function, raised serum uric acid levels, and low platelet counts will help to make the correct diagnosis of HELLP syndrome.

RISKS

Spontaneous rupture of the gallbladder may occur. There is a possible risk of miscarriage and preterm delivery when surgery is required during pregnancy.

MANAGEMENT OPTIONS

Management is similar to that in the nonpregnant woman. Initially, and particularly in the first and third trimesters, conservative treatment should be advocated.[41] This approach includes analgesia with meperidine but not morphine, intravenous fluids, and nasogastric suction. Antibiotics may be used. Recurrent attacks, failure to respond to conservative treatment, suspected perforation, empyema of the gallbladder, peritonitis, and doubt about the diagnosis are indications for surgery.

Cholecystectomy is not indicated when asymptomatic gallstones are present. If symptomatic, it is preferable to operate in the second trimester, although more aggressive surgical options have now become more acceptable during all trimesters because of advances in maternal and fetal monitoring and advances in laparoscopic surgery.[42,43] Fever and pulmonary complications can occur postoperatively.[44] Tocolysis prior to surgery has not been generally recommended[45] (level III, grade B).

Inflammatory Bowel Disease

Chapter 48 provides a detailed discussion of risks and management options.

Gastroesophageal Reflux and Peptic Ulcer Disease

Chapter 48 provides a detailed discussion of risks and management options.

Acute Pancreatitis

Although acute pancreatitis is rare in pregnancy (1 in 4000), it is said to be more common in pregnancy because of the higher risk of gallstones. It tends to present in late pregnancy or soon after delivery.[40] Gallstones cause more than 70% of cases by obstructing the sphincter of Oddi. Typical symptoms include fever and often sudden midepigastric pain, which may localize to the left upper quadrant and often radiates into the left flank. Anorexia, nausea, and vomiting are common. There may be mild pyrexia with varying degree of abdominal tenderness. Ultrasonography will demonstrate gallstones in more than 70% of cases. Raised serum amylase and lipase concentrations will confirm the diagnosis.[40] False-

negative results may occasionally occur with hemorrhagic pancreatitis with massive necrosis or when the blood is taken 24 to 72 hours after the attack. A CT scan may be used for severe cases to delineate areas of pancreatic necrosis.[40]

RISKS

Dehydration and shock may contribute to a high maternal mortality rate particularly in the third trimester. An acute episode may be associated with preterm labor.[46]

MANAGEMENT OPTIONS

The recommended treatment is similar to that for the non-pregnant patient and includes taking nothing by mouth, intravenous fluids, gastric acid suppression, analgesia, and possibly nasogastric suction. Meperidine is the traditional choice for analgesia and seems to be relatively safe in pregnancy. In most cases pancreatitis subsides in 3 to 7 days after such treatment. In patients with gallstones and pancreatitis, surgery may be performed as noted earlier after inflammation subsides. Some, however, recommend aggressive surgical intervention[46,47] (level III, grade B).

Urinary Tract Pathology

Chapter 50 provides detailed discussions of risks and management options.

Liver Disease

Acute Fatty Liver of Pregnancy

Chapter 48 provides a detailed discussion of risks and management options.

Severe Preeclampsia and Eclampsia

Chapters 36 and 80 provide detailed discussions of risks and management options.

SUMMARY OF MANAGEMENT OPTIONS

Appendicitis

Management Options	Quality of Evidence	Grade of Recommendation	References
Diagnosis is not easy; risk to mother and fetus greatly increased with perforation.	III	B	32
Laparoscopy can be performed safely especially before 20 weeks.	–	GPP	–
Use of ultrasound scan to guide trocar is a useful adjunct for safety.	III	C	30
Laparotomy performed with right paramedian incision at site of maximal tenderness.	–	GPP	–
There is conflicting evidence for the use of prophylactic tocolysis postoperatively for 2–3 days.	III	B	32,33
Administer postoperative antibiotics.	–	GPP	–

SUMMARY OF MANAGEMENT OPTIONS

Intestinal Obstruction

Management Options	Quality of Evidence	Grade of Recommendation	References
Once diagnosis is made, conservative vs. surgical approach is cause for debate:	IV	C	34
Conservative (nasogastric suction and IV fluids) may be considered for a few hours if no strangulation/perforation is present.			

Continued

Intestinal Obstruction *(Continued)*

Management Options	Quality of Evidence	Grade of Recommendation	References
Surgical approach (laparotomy and surgical correction of obstruction) always indicated if strangulation/perforation, though some would advocate early surgery for all cases.			
If surgical option chosen:	IV	C	34
Obstetrician and surgeon should operate together.			
Make adequate vertical incision.			
Cesarean section may be necessary for adequate surgical field in late pregnancy.			
Give careful attention to fluid and electrolyte balance.	–	GPP	–
Tocolysis for 2–3 days after surgery is common practice.	–	GPP	–
Administer perioperative antibiotics.	–	GPP	–

SUMMARY OF MANAGEMENT OPTIONS
Cholecystitis

Management Options	Quality of Evidence	Grade of Recommendation	References
Prepregnancy			
Consider cholecystectomy prior to conception with symptomatic gallstones.	–	GPP	–
Prenatal			
Conservative approach first:	III	B	42
Bed rest			
Analgesia/sedation			
IV fluids			
Nasogastric suction			
Antibiotics (e.g., amoxicillin, cefradine, or co-amoxiclav) (chenodeoxycholic acid is contraindicated because of possible teratogenic effects)			
Dietary adjustment after attack has subsided (avoiding fatty foods, etc.)			
Indications for cholecystectomy	III	B	43
(preferably in second trimester):	IV	C	41
Recurrent cholecystitis attacks			
Jaundice			
Abnormal liver function			
Empyema of gallbladder			
Bile duct dilatation suggestive of obstruction			
Pancreatitis			
Laparotomy is also indicated if appendicitis cannot be excluded			

SUMMARY OF MANAGEMENT OPTIONS
Acute Pancreatitis

Management Options	Quality of Evidence	Grade of Recommendation	References
Prepregnancy			
Discuss specific measures in women with risk factors:	–	GPP	–
Cholecystectomy in women with known gallstones and previous attacks of cholecystitis or pancreatitis			
Various strategies in women with alcohol abuse (see Chapter 34)			
Change treatment in women taking thiazide diuretics			
Prenatal			
Prevent and treat shock with IV fluids and monitoring of electrolyte, calcium, and glucose concentrations.	III	B	46
Analgesia	–	GPP	–
Administer prophylactic antibiotics (such as amoxicillin, cefradine or co-amoxiclav).	III	B	46
Suppression of pancreatic activity (no Randomized Controlled Trials):	–	GPP	–
Anticholinergic drugs			
Steroids			
Prostaglandins			
Glucagon			
Cimetidine			
Trypsin inhibitors			
Use of nasogastric suction is questioned	–	GPP	–
Prompt recognition and treatment of surgical complications:	–	GPP	–
Laparotomy usually performed with cholecystectomy if conservative measures fail.			
Cholecystectomy can be an early option when pancreatitis occurs with gallstones in first or second trimester.			
Postnatal			
Cholecystectomy possible if pancreatitis with gallstones successfully treated conservatively in pregnancy.	–	GPP	–

MISCELLANEOUS CAUSES (See Table 57–5)

Rectus Hematoma

Bleeding into the rectus muscle and subsequent hematoma formation following rupture of a branch of the inferior epigastric vessels may occur following a bout of coughing or direct trauma, usually in late pregnancy. A large unilateral painful swelling may be confused with an ovarian cyst, degenerating fibroid, uterine rupture, or placental abruption. However, its superficial location in the abdominal wall should enable accurate diagnosis.

Management Options

If diagnosed early, treatment consists of analgesia and bed rest. If, however, diagnosis is only made at the time of surgery, the hematoma can be evacuated and hemostasis secured.

Sickle Cell Crisis

Chapter 39 provides a detailed discussion of risks and management options.

Porphyria (See also Chapter 52)

Porphyrias are rare diseases caused by deficiency of various heme biosynthetic enzymes that result in accumulation of toxic prophyrin precursors. Acute intermittent porphyria is the most common of these diseases, and women present with diffuse abdominal pain, gastrointestinal symptoms, and autonomic nervous system disturbances.[48] Exacerbations

first presenting during pregnancy can mimic various neuropsychiatric disorders and present a challenging diagnosis.[49] Pregnancy itself can precipitate an attack, and so porphyria may present for the first time in pregnancy.

Increased urinary levels of porphobilinogen and delta-aminolevulinic acid are diagnostic. Management includes avoidance of precipitating drugs, avoidance of fasting, and possible administration of parenteral glucose.[49] Genetic counseling would be recommended.

Malaria

Chapter 33 provides a detailed discussion of risks and management options

Arteriovenous Hemorrhage

Miscellaneous, very rare conditions resulting in intra-abdominal hemorrhage can cause abdominal pain in pregnancy. These conditions include rupture of the utero-ovarian veins, rupture of aneurysms (splenic, hepatic, renal, aortic), and spontaneous rupture of the uterine vein.[50] In addition to the abdominal pain, rapidly progressing shock is a feature.

Risks

The main risks of these conditions are maternal and fetal demise.

Management Options

Speed of action is imperative in these cases, and even then, death may not be avoided. In all conditions, the principles of management are the same: namely, surgical control of the hemorrhage, correction of shock, and specific measures for specific problems (such as splenectomy with splenic rupture or insertion of a graft with aortic rupture). If the patient survives long enough for such definitive measures to be considered, practical assistance from a general or vascular surgeon is mandatory.

Tuberculosis

Chapter 33 provides a detailed discussion of risks and management options.

Psychological Causes

About 1% of laparoscopies performed for abdominal pain in pregnancy reveal no cause for the pain.[51] Many of these patients have psychological stress that affects the irritable bowel syndrome. Pregnant women with idiopathic abdominal pain are often single, are smokers, and have financial problems.[52] However, this diagnosis is made by exclusion and requires comprehensive diagnostic evaluation to exclude organic disease and to avoid surgical intervention. Reporting a high number of ailments during antenatal care may be an indication for psychoso-

cial support.[53] Domestic volence should also be considered in these cases (see Chapter 81).

INDICATIONS

Laparoscopy has become an increasingly popular option for many conditions. The most common indication has been laparoscopic cholecystectomy, which though initially reserved for the second trimester, is now being more widely and safely performed in any of the three trimesters as surgeons become more aggressive in their management approach. Other indications include appendicitis and ovarian cyst complications in early pregnancy.

PROCEDURE

In pregnancy patients should be counseled adequately regarding the risks from the procedure. In late pregnancy ultrasound-guided Verres needle insertion has been shown to reduce injury to the uterus.[30] An experienced anesthetist would be recommended to ensure that respiration is not compromised by the pneumoperitoneum.

COMPLICATIONS

Lachman and associates[51] recently reviewed the literature on the subject and cautioned on the lack of adequate data on the possible harmful effect of intra-abdominal pressure as a result of the pneumoperitoneum as well as any possible effect of carbon dioxide absorption on the fetus. The long-term consequences have also been questioned in another review article.[54] Use of ultrasound scan to guide the Verres needle has been suggested to avoid needle injury to the uterus.[30] In terms of short-term risks of miscarriage and preterm labor, the numbers studied to date are too small to be reassured and caution would still need to be exercised.

INDICATIONS

The indications for laparotomy in pregnancy are discussed in the different sections of this chapter. In general, they are the same as in the nonpregnant patient. Obstetricians arguably are more comfortable with the idea of operating on a pregnant woman than are general surgeons. They are also often more familiar with the alterations in disease presentation and differential diagnosis in pregnancy than general surgeons. For these reasons, it is advisable that obstetricians do not simply turn the care of their patients over to surgical specialists for

diagnosis and treatment, but rather remain actively involved in their patients' management throughout the period of evaluation, treatment, and postoperative care.[55]

PROCEDURE

Anesthetic Considerations

The choice of the anesthesia for surgery during pregnancy depends on the operation proposed, the skill of the anesthesiologist, and the preference of the surgeon and the patient. Although it has been suggested that chronic exposure of operating room personnel to anesthetic agents leads to an increased rate of miscarriage, the hazard associated with acute general anesthetic administration to the patient is not well characterized. It seems that the risk is very small. It is probably more important that meticulous attention is paid to maintenance of maternal homeostasis. The fetus is totally dependent on adequate maternal oxygenation and uterine perfusion. Any compromise of maternal oxygenation will potentially affect the fetus. Both conduction or regional anesthesia and general anesthesia can be used in pregnancy with safety for both the mother and fetus.

Operation

Abdominal incisions in pregnancy are the same as those used in nonpregnant patients. McBurney and low transverse incisions are best limited to the first trimester. Later in pregnancy, the enlarged uterus so completely fills the lower abdomen that access to organs other than the anterior, lower uterine segment (as for cesarean section) is extremely difficult. It is generally advisable to make an incision that can be extended if necessary, rather than attempting to use a small and poorly placed incision and being forced to manipulate the uterus in an attempt to accomplish the operation. Midline or paramedian incisions work well. Healing in pregnancy is generally without complications, though there may be some skin scar spreading as the abdomen enlarges through pregnancy and keloid formation in some women. If labor occurs shortly after surgery, the fresh incision may inhibit maternal expulsive efforts during the second stage necessitating an assisted delivery.

COMPLICATIONS

There is an increased risk of miscarriage in association with laparotomy performed during early pregnancy.[55] This risk exists especially in the first trimester and is considerably reduced on planned procedures carried out in the second trimester. Preterm delivery and technical difficulty are problems encountered when laparotomy is carried out during the third trimester. However, although the risks of laparotomy in pregnancy should not be underestimated, the risks to the mother and baby of the condition for which the surgery is required are usually greater than the risks of the operation itself.

CONCLUSIONS

- Abdominal pain in pregnancy is a common complaint.
- There are diverse obstetric, gynecologic, surgical, medical, and psychiatric causes of abdominal pain.
- A careful history and methodical physical examination aided by selective investigations will usually reveal the cause of the pain in most cases.
- Physiologic changes that occur in pregnancy may make diagnosis more difficult.
- Diagnosis of some conditions (e.g., appendicitis) can be delayed or missed during pregnancy; a high index of suspicion together with a knowledge of the ways in which different pathologic conditions present in pregnancy is needed.

CHAPTER 58

Nonmalignant Gynecology

Kassam Mahomed

INTRODUCTION

This chapter discusses the significance of a number of gynecologic problems in association with pregnancy that are not covered elsewhere in the book. For malignant gynecologic problems, see Chapter 53. Nonmalignant topics discussed elsewhere include infection (see Chapter 32), female circumcision (see Chapter 73), previous pelvic floor surgery, and previous third-degree tear (see Chapter 73).

OVARIAN CYSTS IN PREGNANCY (See Chapters 53 and 55)

Introduction

With routine ultrasonographic examination during the first trimester, the discovery of an ovarian cyst has become relatively common early in pregnancy. Ovarian cysts that are 6 cm or larger are estimated to occur in 0.5 to 2 per thousand pregnancies.[1] Most unilocular and anechoic ovarian cysts with thin borders that are seen during the first trimester are corpus luteum cysts. These cysts are not usually present after the end of the first trimester. Three fourths of these cysts are asymptomatic, and most resolve without treatment.[2] Further evaluation or management of cysts in early pregnancy is usually left until the second trimester.[3]

After 16 weeks of amenorrhea, organic cysts are the most common, mainly dermoid cysts. A review of series noted three stage Ia borderline tumors, accounting for 3.6% of cysts and 10% of persisting masses.[4] No prospective studies are available to assess the risk of cancer or the complications associated with a cyst larger than 6 cm in diameter and without malignant criteria.

Risks

The major risk of ovarian cysts in pregnancy is to the mother. Between 10% and 15% of ovarian cysts undergo torsion and cause pain.[4] If the cyst is large enough, it may cause malpresentation or may obstruct labor and increase the risk of cesarean delivery.[5] The most important fetal risk is miscarriage (4.7% risk after elective surgery) or premature delivery (9%), which may be induced by surgical removal.[6]

Management Options

Prepregnancy

Surgical treatment is indicated for cysts that are detected before pregnancy, are larger than 5 cm or contain echogenic material, and persist for longer than 4 weeks or are symptomatic.[7] Aspiration of cysts, either laparoscopically or ultrasonically, with cytologic examination of the fluid, is no longer favored because cystadenomas or cystadenocarcinomas may be misdiagnosed.[8]

Prenatal

More than 90% of cysts that occur in pregnancy are nonneoplastic.[9] Corpus luteum cysts usually begin to regress after 12 weeks.[10] Asymptomatic ovarian cysts with benign sonographic features may be followed closely by serial scanning into the second trimester, when surgery can be planned, if necessary.[11,12] However, if the cyst is not enlarging, conservative management may be preferred. Surgery, even in the second trimester, may result in premature delivery in approximately 9% of cases.[6]

If ultrasound examination of an ovarian cyst larger than 5 cm shows echogenic features, surgery may be indicated.[11] Although laparotomy is the preferred management option, experienced gynecologists remove persistent smaller cysts laparoscopically without increased risk to the pregnancy.[13]

Torsion of ovarian cysts is treated by surgery.[14] Progestogen support, such as with medroxyprogesterone acetate 20 mg twice daily, may be advised.[15] There is no evidence that untwisting of an ovary that has undergone torsion increases the risk of venous embolism.[14] The use

of tocolysis to reduce the risk of preterm delivery is controversial, and there are no reported trials to help to resolve this issue.[16]

Evacuation by puncture is not well evaluated and is not recommended during pregnancy.[8] If intervention is necessary, laparoscopy is the preferred method.

Labor and Delivery

If an ovarian cyst causes obstruction in labor, delivery is by cesarean section.[3] The ovarian mass is managed in the usual manner at the same time. Aspiration is not advisable because the chance of malignancy is approximately 2%.[8]

PROCEDURE

OVARIAN CYSTECTOMY IN PREGNANCY

Indications

Cystectomy is performed in patients with a symptomatic cyst (e.g., torsion, hemorrhage, rupture) and in those with an asymptomatic cyst that is recognized ultrasonically, but does not regress by 16 weeks. Other indications include echogenic material that suggests a dermoid or has a septate or multilocular appearance.

Gestation

The procedure should be performed ideally at 18 to 20 weeks' gestation. A cyst noted earlier in gestation may be corpus luteum.

Description

Preoperative and perioperative measures include antithromboembolic stockings and the use of subcutaneous heparin postoperatively.

Anesthesia

A general anesthetic agent is used.

Incision

A longitudinal midline incision is used. The incision extends from below the umbilicus to just above the pubic bone. The actual size of the incision depends on the size of the cyst.

Method

The uterus is retracted gently to one side. The ovary with the cyst is usually very mobile, unless the cyst is associated with infection, endometriosis, or malignancy. The ovary and cyst are gently drawn through the incision. The mesenteric border is identified. Two Allis forceps are placed on the antimesenteric border near each pole of the ovary (Fig. 58–1A).

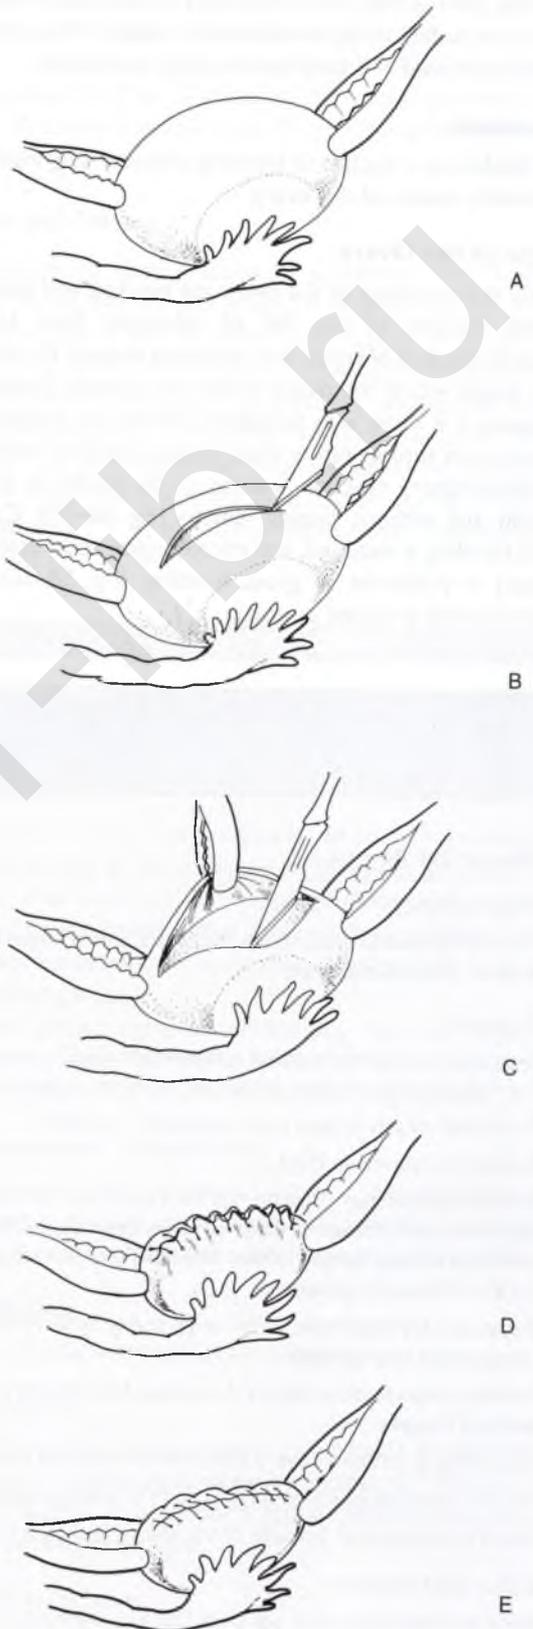
The ovarian capsule only (not the cyst) is incised along the antimesenteric border, between the two forceps (taking care not to puncture the cysts) [Fig. 58–1B].


FIGURE 58–1
Ovarian cystectomy.

The handle of the scalpel or closed scissor blades is used to bluntly dissect the capsule away from the cyst, using tissue forceps on the margin of the capsule as counteraction (Fig. 58–1C). The blunt dissection is continued close to the cyst, including along the mesenteric aspect. The cyst can then be removed and sent for histologic evaluation.

Hemostasis

Spot diathermy is applied to bleeding points arising from the mesenteric aspect of the ovary.

Repair of the Ovary

Usually the cut edges of the ovary are everted, and repair is advised because of the risk of adhesions from bowel. However, the goal of repair is to minimize damage to the vascular supply within the ovary and to the capsule. If repair is necessary, it is done with polyglactic (Vicryl) or polyglycolic (Dexon) acid sutures rather than catgut sutures to minimize the inflammatory reaction. Sutures (3–0) should be placed carefully and without causing tension (Fig. 58–1D). Careful tissue handling is required, and microsurgical technique (i.e., forceps) is preferred to gross handling (Fig. 58–1E). The abdominal wall is closed as usual.

Postoperative Management

Narcotic analgesia is used. The use of prophylactic tocolysis is debatable. The fetal heart rate is monitored, and histologic studies are performed.

Complications

The major complication of ovarian cystectomy in pregnancy is miscarriage or premature labor; the risk probably depends on the amount of inflammation caused by the operation.

Tubal adhesions of the fimbria to the incision in the ovarian capsule may occur and impair future fertility. This complication is not usually recognized until subsequent laparoscopic examination.

If the lesion does not appear to be a dermoid and could be a mucinous or serous cystadenoma, ovarian cystectomy rather than oophorectomy is probably the treatment of choice, because malignancy is rare. In young women, it is probably better to repeat the laparotomy to remove the ovary later rather than remove an ovary for what may be a benign condition.

Rarely, ileus may occur, but because there is usually no need to handle bowel, the risk is low.

SUMMARY OF MANAGEMENT OPTIONS			
Ovarian Cysts			
Management Options	**Quality of Evidence**	**Strength of Recommendation**	**References**
Prepregnancy			
Treat symptomatic cysts, sonolucent cysts, and echogenic cysts 8 cm or more in diameter.	III	B	7
Prenatal			
Treat ovarian hyperstimulation symptomatically. Do not aspirate cysts, but thoracentesis or paracentesis for effusions or ascites may be necessary.	–	GPP	–
Functional corpus luteum cysts regress by 16 weeks.	III	B	10,16
Remove symptomatic cysts.	–	GPP	–
Perform laparoscopy (laparotomy) for cysts 8 cm or more in diameter and those with echogenic features. Leave cysts caused by endometriosis and tuberculosis; remove others. The ideal time for surgery is 18 to 20 weeks' gestation.	III	B	13,17
If cysts are asymptomatic, with benign sonographic features, conservative management is acceptable.	III	B	11
Provide progesterone support if a corpus luteum cyst is removed before 10 weeks.	III	B	15
Untwisting a torsioned ovary does not increase the risk of embolism.	III	B	14
Provide tocolysis to cover surgery and the postoperative period.	III	B	16
Avoid cyst aspiration because of the risk of missing a malignancy.	III	B	8
Labor and Delivery			
For cysts impacted in the pouch of Douglas, perform LSCS and ovarian cystectomy rather than cyst aspiration.	III	B	3

LSCS, lower segment cesarean section.

FIBROIDS (See Chapter 57)

Introduction

Fibroids are more common in primiparous women than in multiparous women.[17] Fibroids are usually asymptomatic and may be seen in up to 80% of women of reproductive age, although only approximately 4% of pregnant women have ultrasonographically visible uterine fibroids.[18] They may interfere with conception and maintenance of pregnancy.[19]

Risks

Although it was believed that fibroids increase in size during pregnancy, those that are initially less than 5 cm in diameter usually involute completely during pregnancy. Larger fibroids may undergo hemorrhagic infarction and can cause pain of varying severity associated with nausea, vomiting, and mild pyrexia.[20] Classically, this complication occurs at approximately 20 to 22 weeks' gestation.

Other risks of fibroids in pregnancy relate to their size and position. These risks include recurrent pregnancy loss, preterm labor, fetal malposition, obstructed labor, retained placenta, and postpartum hemorrhage.[18,21–23] The need for cesarean delivery is at least doubled in patients with fibroids in the lower uterine segment and those larger than 5 cm.[18]

Management Options

Prepregnancy

Because most complications of pregnancy are associated with submucosal fibroids, their removal is advised before pregnancy,[23] usually hysteroscopically, with or without the use of goserelin.[24] The appropriate interval from surgery to conception is not known.

Intramural or subserosal fibroids should be removed only if they are large, distorting the uterine cavity, or are symptomatic, and then only after careful patient counseling,[25] because hysterectomy may become necessary if excessive bleeding occurs. Preoperative gonadotropin-releasing hormone analogue therapy may reduce the risk of hemorrhage.[24]

Prenatal

Most fibroids are asymptomatic during pregnancy and are diagnosed on routine ultrasound examination. If degeneration occurs and causes pain, then analgesia is necessary. Application of local heat or ice packs to the abdomen may provide relief.[26] Prostaglandin inhibitors may also be useful, but should be prescribed for only a few days because of their possible adverse fetal effects.[27] Rarely, the degree of maternal discomfort indicates the need to remove a large subserosal pedunculated fibroid

during pregnancy. A subserosal fibroid that becomes impacted in the pouch of Douglas and interferes with micturition may be managed conservatively by catheterization. The patient should be encouraged to spend time resting prone in the head-down position.[28]

If a fibroid (usually a lower-segment fibroid) causes an abnormal lie of the fetus after 36 weeks' gestation, elective abdominal delivery at 38 to 39 weeks' gestation is advised.[29]

Labor and Delivery

Management during labor of a patient with a fibroid depends on whether the fibroid is obstructing delivery. If a lower-segment fibroid causes obstruction, cesarean delivery is indicated.[30] If it is not, then problems associated with poor uterine contractility, particularly postpartum hemorrhage, should be anticipated. Adequate oxytocic therapy should be prescribed and blood transfusion anticipated. Blood should be typed and held in case urgent crossmatch is required.[21–23] A wide-bore intravenous cannula should be in situ.

PROCEDURE

CESAREAN DELIVERY WITH A LOWER-SEGMENT FIBROID

Indication

Cesarean delivery is indicated when a lower-segment fibroid causes an abnormal lie at 38 weeks' gestation or is larger than 6 cm at 38 weeks' gestation and is palpable below the fetal head, either abdominally or vaginally. Smaller fibroids are usually soft and "drawn" or "pressed" out of the way during labor.

The ultrasonographic dimensions may not accurately reflect the true size of the fibroid, so clinical evaluation is more important than ultrasonographic assessment.

Preoperative Preparation

In preparation for cesarean delivery, crossmatched blood should be available. In addition, the patient is given antibiotics. Antithromboembolic stockings are used as well.

Anesthetic

Spinal or epidural anesthesia is used.

Skin Incision

A midline subumbilical incision is advisable if the fibroid is large or if a classic procedure is anticipated. However, if the fibroid is small or posterior, a routine lower transverse incision may be performed.

Uterine Incision

The type of incision used depends on the observed site of the fibroid. If the lower segment is well formed around the

fibroid and a transverse lower-segment incision can be made, allowing a 2- to 3-cm margin with the fibroid, then a lower-segment approach is used. If access through the lower segment with a 2- to 3-cm margin is not possible, then a classic cesarean section should be performed, again ensuring a 2- to 3-cm safety margin with the fibroid. Concurrent myomectomy should be avoided because of the high risk of hemorrhage.

Complications and Postnatal Care

There are no complications, other than the usual complications of cesarean delivery. As a result of the hypoestrogenic state that occurs in the puerperium, the fibroid normally regresses and degenerates, possibly causing pain. Occasionally, this involution does not occur in the puerperium, and med-ical therapy, such as gonadotropin-releasing hormone analogues or embolization, can be used to induce regression. If myomectomy is indicated, bleeding may be reduced.

Previous Myomectomy

If the patient had a previous myomectomy in which the endometrial cavity was opened, then the standard advice is to perform elective cesarean delivery, especially if the implantation site is likely to be over the previous myomectomy incision scar. However, if myomectomy was performed for subserosal fibroids only, there is less risk of uterine rupture during labor. In this case, conservative management is usually advised, although labor should be managed as in a patient with a previous cesarean delivery.

SUMMARY OF MANAGEMENT OPTIONS
Fibroids

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Remove endometrial or submucosal fibroids hysteroscopically, with or without the use of a gonadotropin-releasing hormone analogue, if the patient has a history of subfertility.	III	B	24
Most women with fibroids have no problem conceiving or with pregnancy.	Ia	A	19
Consider myomectomy for other fibroids if they are symptomatic, and only after careful counseling.	Ia	A	19
Prenatal			
Red degeneration is treated with bed rest, analgesics, local heat, ice	III	B	26
Prostaglandin synthetase inhibitors may be used with caution.	IIb	B	27
Removal of a pedunculated serosal fibroid producing severe symptoms is rare.	–	GPP	–
Ligate and avulse cervical fibroid polyps.	–	GPP	–
Consider elective LSCS if: • Lower segment or cervical fibroids cause unstable lie or failure of engagement of the fetal head • The patient had a previous myomectomy for intramural fibroids	III	B	29
Labor and Delivery			
LSCS if a fibroid leads to obstructed labor	III	B	30
Vigilance for postpartum hemorrhage	III	B	21–23
Do not remove fibroids at LSCS	–	GPP	–
For cesarean delivery, consider a classic or upper-segment approach if access through the lower segment with 2 to 3 cm normal tissue is not possible.	III	B	29
Postnatal			
Analgesia for excessive pain (GnRH analogue in extreme cases)	–	GPP	–

LSCS, lower segment cesarean section.

SUBFERTILITY

Introduction

One in six couples of reproductive age needs specialist help because of inability to conceive (primary infertility) or inability to conceive the number of children they wanted (secondary infertility).[30] This figure may increase in the future as more women delay having children until an age when natural fertility is in decline because of increased aneuploidy of oocytes.[31,32] The problem is compounded by the fact that most couples who seek treatment are not sterile, but have decreased fertility, and many eventually conceive spontaneously.

A male factor is the dominant cause of subfertility in 20% to 25% of couples.[33,34] Female causes of subfertility include problems with ovulation, defects in sperm–mucus interaction, and tubo-peritoneal disorders. In 25% to 30% of couples who undergo evaluation, inability to conceive is unexplained.[33] Endometriosis causes subfertility in approximately 5% of women through any of these mechanisms.

Treatments to assist conception include ovulatory drugs, tubal or ovarian microsurgery, and assisted reproductive technology. This technology may include intrauterine insemination; in vitro fertilization, with or without intracytoplasmic sperm injection; or donor insemination.

Risks Associated with Pregnancies Conceived Using Fertility Treatments

Ovarian stimulation is associated with a risk of theca lutein cysts in the ovary; these cysts are more common with gonadotropin (6%) than with clomiphene therapy (3%).[35] When cysts are associated with ascites, pleural effusions, hemoconcentration, or hypoalbuminemia, the syndrome is called ovarian hyperstimulation syndrome.

Clomiphene or gonadotropin therapy is associated with spontaneous miscarriage rates of approximately 25%.[36]

Women with polycystic ovary syndrome who conceive spontaneously or with the use of drugs also have an increased risk of impaired glucose tolerance and pregnancy-induced hypertension. This risk is independent of body mass index, although women with polycystic ovary disease generally have a higher body mass index than other women.[37] In a case–control study, pregnant women with polycystic ovary syndrome had a much higher incidence of pregnancy-induced hypertension, 31.8%, versus women without polycystic ovary syndrome, who had a pregnancy-induced hypertension incidence of 3.7%.[38]

Multiple pregnancy is a major risk factor associated with ovulation induction, intrauterine insemination, and assisted reproductive technology, including in vitro fertilization, gamete intrafallopian transfer, and zygote intrafallopian transfer. The maternal morbidity rate is sevenfold greater in multiple pregnancy than in singleton pregnancy. In addition, perinatal mortality rates are fourfold higher for twins and sixfold higher for triplets, and cerebral palsy rates are 1% to 1.5% in twin and 7% to 8% in triplet pregnancies.[39] Restricting the number of embryos transferred to one or two[40] can reduce this risk.

Compound heterozygosity for the cystic fibrosis transmembrane regulator (CFTR) mutation for cystic fibrosis is increased in patients with infertility associated with azoospermia and congenital bilateral absence of the vas deferens.[41] The frequency of mutations differs significantly from that in the general population (2% vs. 40%, respectively).[42]

Management Options

Prepregnancy

When a couple seeks treatment for infertility, the woman must undergo an assessment that includes a thorough history and examination to ensure that she does not have a medical problem that must be treated or controlled before conception to minimize subsequent risks during pregnancy. All women with infertility should be tested for rubella. Those who are not immune should be vaccinated at least 3 months before pregnancy.[43]

More than half of patients who undergo in vitro fertilization are of advanced reproductive age and at risk for producing offspring with age-related aneuploidies, which contribute significantly to the risk of spontaneous abortion and implantation failure. Aneuploidy rates of greater than 50% are reported. These patients must be informed about the availability of preimplantation genetic diagnosis. They can use this option to improve their relatively poor chances of becoming pregnant, especially with the current tendency to limit the number of transferred embryos to avoid the complications of multiple pregnancy.[44]

For all women contemplating pregnancy, folic acid supplementation should be initiated.[45]

Preventive strategies for ovarian hyperstimulation attempt to identify women who are at increased risk (using ultrasound and serum estradiol measurements). The lowest possible dose of gonadotropin is used to reduce the granulosa and luteal mass. In patients with a large number of follicles (>20) and an increasing serum estradiol level, the most widely used and most cost-effective approach is to withhold gonadotropin stimulation (coasting) while continuing down-regulation.[46] Other methods include early unilateral ovarian follicular aspiration; administration of glucocorticoids, macromolecules, and progesterone; cryopreservation of all embryos; and electrocautery or laser vaporization of one or both ovaries.[47]

Identification of the CFTR gene mutation in couples with subfertility associated with oligospermia would assist in the selection of the most suitable method of assisted reproduction.[41]

Prenatal

The first, and probably most important, management step is to confirm that the missed period is associated with at least one viable intrauterine pregnancy and to identify multiple pregnancy, if present.

All caregivers should recognize the likelihood of anxiety and the need for supportive counseling in patients who conceive after in vitro fertilization.[48]

Vigilance for ectopic pregnancy should be maintained in women with a history of tubal disease.[49]

If pregnancy is associated with the use of hyperstimulatory drugs, corpus luteum cysts are commonly seen until 12 weeks.[10,16] Surgical therapy or aspiration should be avoided. Sometimes the need for stimulation of ovulation is associated with an endocrine dysfunction, such as a progesterone defect, in early pregnancy. High-dose progestogen therapy has been advocated, but should be initiated only in women whose progesterone levels are lower than the fifth percentile for their gestation.[14] Interestingly, only half of women with low serum progesterone levels miscarry, suggesting that the endometrial and myometrial roles of progesterone are uncertain.

Prenatal screening should be discussed, especially with older women. As the value of first-trimester screening becomes more evident and practical, and if the risk of chorionic villus sampling becomes an acceptable norm, a select patient population will reach the second trimester of pregnancy, and few patients will need second-trimester screening and invasive testing.[50]

Women with polycystic ovary disease should be screened for gestational diabetes during pregnancy, with frequent surveillance of blood pressure.[37]

Ultrasound is frequently performed to evaluate fetal growth and well-being, especially to allay the anxiety of the couple and the physician.[48]

The prenatal management of multiple pregnancy is discussed in Chapter 60. However, if there are three or more fetuses, the risk of prematurity is high and selective reduction may need to be considered.

Ideally, the number of people caring for these patients should be restricted, especially so that consistent information and advice can be given to the couple, who may be anxious. The couple may believe that their only difficulty was in conceiving and that once this goal has been achieved, the pregnancy is not at additional risk. Counseling may be necessary.[48]

Labor and Delivery

The "preciousness" of these pregnancies, with the associated anxiety and stress, results in an increased rate of operative deliveries. In addition, catecholamines released as a result of anxiety may theoretically inhibit labor or affect the fetus, leading to increased numbers of cesarean deliveries because of failure to progress or fetal distress. Continuous fetal heart monitoring is advisable and may be demanded by the patient. Immediate measurement of fetal scalp pH is important when fetal heart irregularities occur. Otherwise, physician or midwife anxiety may lead to unnecessary cesarean delivery.

Postnatal

Contraception is not usually an issue in these couples, but must be discussed. The usual contraindications to the use of intrauterine devices in women with a recent history of tubal disease apply. Contraceptives that may delay the return of ovulation (progesterone-only preparations) should be avoided in couples who may want another pregnancy soon.

SUMMARY OF MANAGEMENT OPTIONS			
Subfertility			
Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Check for underlying medical disease (e.g., hypertension, diabetes, renal disease, chlamydial infection).	–	GPP	–
Counsel women undergoing assisted reproduction about the rates of multiple pregnancy.	III	B	39,40
Use preconceptual and periconceptual folate supplementation.	Ia	A	45
Discuss the preimplantation genetic diagnosis.	III	B	44
Ensure that the patient is immune to rubella.	III	B	43
Follow protocols to avoid hyperstimulation and multiple pregnancy.	III	B	46,47
If the male partner has obstructive azoospermia, the couple should be screened for cystic fibrosis carrier status. Males should also be screened for Y chromosome deletions.	III	B	41

Subfertility (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal			
Check the viability and number of intrauterine pregnancies.	III	B	39
Diagnose ectopic pregnancy early.	–	GPP	–
Check progesterone levels until 12 weeks in patients who undergo clomiphene (Clomid) or gonadotropin therapy	–	GPP	–
Screen for hypertension and gestational diabetes in women with polycystic ovary syndrome.	III	B	37
Check fetal growth and development in pregnancies achieved through in vitro fertilization.	–	GPP	–
For multiple pregnancies, see Chapter 60.			
Provide reassurance.	IIb	B	48
Labor and Delivery			
Provide continuous fetal heart rate monitoring for psychological reasons.	IIb	B	48
Postnatal			
Contraception is not usually an issue.	–	GPP	–
Avoid IUCD use in patients with a history of tubal disease.	–	GPP	–
Avoid progestogens in patients with a history of ovulatory disorders.	–	GPP	–

IUCD, intra-uterine contraceptive device.

OTHER GYNECOLOGIC DISEASES AND PROBLEMS

Congenital Disorders

Some women have congenital abnormalities of the genital tract that affect pregnancy or labor and delivery. Most uterine abnormalities are diagnosed by hysterosalpingogram. Bicornuate uterus, uterus didelphys, and septate uterus constitute 80% of cases.[51] These conditions are associated with preterm delivery (29%), spontaneous first-trimester miscarriage (24%), ectopic pregnancy (3%), fetal malpresentation (23%), and a high cesarean delivery rate (27.5%). Cervical cerclage improved obstetric outcomes in patients with cervical incompetence.[52] In patients with other abnormalities, fetal survival rates improved from 13% to 91% after hysteroscopic metroplasty and from 3% to 86% after an abdominal procedure.[52] The other disorder of the lower tract is a vaginal septum. A septum that is fenestrated superiorly may obstruct labor. This complication can usually be managed acutely simply by dividing the septum in the second stage under epidural or pudendal anesthesia. Hemostatic measures are not usually required.

CERVICAL STENOSIS OR INCOMPETENCE AS A RESULT OF PREVIOUS CONE BIOPSY

Cone biopsy may affect conception because the destruction of mucus-producing glands may cause cervical stenosis or incompetence. The overall rate of normal term vaginal delivery is reported as 46.6% and is inversely proportional to cone size. The incidence of both spontaneous midtrimester abortion and prematurity is increased in direct proportion to cone size. Cervical stenosis necessitating cesarean delivery is associated with small rather than large cones.[53] The role of cervical cerclage is uncertain.[54]

PREGNANCY AFTER PREVIOUS ENDOMETRIAL ABLATIVE THERAPY

Endometrial ablation by numerous methods is used in women with dysfunctional menstrual bleeding and usually is performed only in women who do not wish to retain reproductive capacity. Pregnancy is rare, presumably because of incomplete endometrial resection or regrowth of the endometrium. The risks of pregnancy may be comparable to those in women with Asherman's

syndrome.[55] In one series, only 17 of 43 pregnancies had progressed beyond 20 weeks.[56]

VULVAL VARICOSITY

Vulval varicosities are common during pregnancy, especially in multipara. This familial condition is slight during a first pregnancy, but varicosities develop earlier and are larger as the number of pregnancies increases. They cause discomfort, heaviness in the pubic region, and sometimes pruritus or even pain, which is most often relieved by lying flat. They usually disappear completely postpartum. Bed rest and support may provide symptomatic relief. They are also significantly relieved by sclerosing agents.[57]

SUMMARY OF MANAGEMENT OPTIONS
Other Gynecologic Diseases and Problems

Management Options	Quality of Evidence	Strength of Recommendation	References
Congenital Anatomic Defects			
Evaluate and treat prepregnancy.	III	B	51
Evaluate prenatally and plan delivery.	III	B	51,52
Divide vaginal septa.	III	B	51
Cervical Stenosis or Incompetence			
Evaluate prenatally and plan delivery.	III	B	53
Cervical suture	Ia	A	54
Vigilance for dystocia in labor and the need for LSCS	–	GPP	–

Provide symptomatic treatment prenatally (bed rest, support).	–	GPP	–
Sclerosing therapy may be used.	IV	C	56
Avoid trauma during delivery.	–	GPP	–

LSCS, lower segment cesarean section.

CONCLUSIONS

OVARIAN CYSTS
- Ovarian cysts are common in pregnancy. Most are benign and regress spontaneously.
- An ultrasound scan is useful in assessing the nature of the cyst.
- When surgical treatment is required, laparoscopy is the preferred method, but the risk of preterm labor should be discussed.

FIBROIDS
- Fibroids are common in pregnancy. Small fibroids usually cause no problems.
- Fibroids that distort the uterine cavity should be resected, preferably hysteroscopically, before conception. Gonadotropin-releasing hormone analogues have been used to reduce their size preoperatively.
- Pain during pregnancy can usually be managed conservatively, but care is required during labor for delay and postpartum hemorrhage.

SUBFERTILITY
- Assisted reproduction is being used with increasing frequency, and techniques to avoid ovarian hyperstimulation are becoming more refined.
- The risk of multiple pregnancy, with its associated risks, is still high. Even after conception, these pregnancies should be considered high risk. Counseling is essential.

Bleeding in Late Pregnancy

Justin C. Konje / David J. Taylor

INTRODUCTION

Bleeding in late pregnancy, or antepartum hemorrhage, is defined as bleeding from the genital tract after 20 weeks' gestation. This type of bleeding complicates 2% to 5% of all pregnancies[1] and has various causes (Table 59–1).

MANAGEMENT OF BLEEDING IN LATE PREGNANCY (See Chapter 79)

Antepartum hemorrhage is unpredictable, and the patient's condition may deteriorate rapidly before, during, or after presentation. Management starts with general measures to treat or prevent deterioration, followed by specific treatment measures. The general measures discussed in this chapter apply to all cases of antepartum hemorrhage, but they may be modified, depending on the severity of bleeding. The specific measures depend on the diagnosis and are discussed under the various causes of bleeding.

INITIAL ASSESSMENT (Fig. 59–1)

Management of the patient with antepartum hemorrhage must be in a hospital with adequate facilities for transfusion, cesarean delivery, and neonatal resuscitation and intensive care. In the patient with significant vaginal bleeding, immediate transfer to a hospital by ambulance is recommended.

Initial management includes a history, evaluation of the patient's general condition, and initiation of testing and treatment.

History

The history should identify initiating factors, such as trauma or coitus, the amount and character of bleeding, associated abdominal pain or regular uterine contractions, a history of ruptured membranes or previous vaginal bleeding, gestational age as determined by early ultrasound scan or the last menstrual period, information about the site of the placenta from previous scans, and information about fetal movements.

Physical Examination

Physical examination should assess both the maternal and the fetal condition, including the following features:

- Maternal pulse, blood pressure, and respiratory rate
- Clinical evidence of shock (restlessness; cold, clammy extremities; poor skin perfusion; piloerection response)
- Abdominal examination to determine whether the uterine fundus is compatible with the estimated gestational age and to assess the presence of tenderness, the number and viability of fetuses, the presence of uterine contractions, and the lie and presentation of the fetus or fetuses
- Vaginal examination. Traditionally, digital or speculum examination is considered inadvisable unless placenta previa has been excluded. However, despite this

TABLE 59–1

Causes of Bleeding in Late Pregnancy

Genital infection	0.5
Hematuria	0.5
Vasa praevia	0.5
Other	0.5

conventional guidance, in practice, careful vaginal examinations are undertaken by experienced clinicians when they are certain that the fetal head is engaged, making the diagnosis of placenta previa unlikely. In most cases, only an inspection of the vulva to quickly assess the amount of blood loss and to determine whether bleeding has stopped or is continuing is necessary. When placenta previa has been excluded, speculum examination may be performed.

Testing and Immediate Management

Initially, the patient with antepartum hemorrhage should be evaluated and managed as discussed later, but subsequent management is determined by gestational age and the severity and type of bleeding. Initial management includes the following:

- Insertion of an intravenous line with a wide-bore cannula (preferably size 14–16 French)
- Obtaining blood for immediate hemoglobin or hematocrit estimation, complete blood count and typing, and holding of serum for potential crossmatching. If bleeding is continuing or is heavy, then at least four units of blood must be crossmatched. When placental abruption is suspected, a coagulation profile and measurement of urea and electrolytes should be performed. Other tests that may be performed are the Kleihauer-Betke test on maternal blood and the Apt test on vaginal blood.
- Administration of intravenous fluids if bleeding is continuing or severe while crossmatched blood is awaited. Colloids are the most suitable fluids. Consideration should be given to transfusing type O, Rhesus-negative blood if crossmatching is delayed.
- Performing an ultrasound scan to exclude placenta previa if a scan has not been done previously or to exclude a major abruption with placental separation. However, a scan should be performed only if maternal and fetal conditions are stable.

After initial management, one of the following conditions is likely to be present:

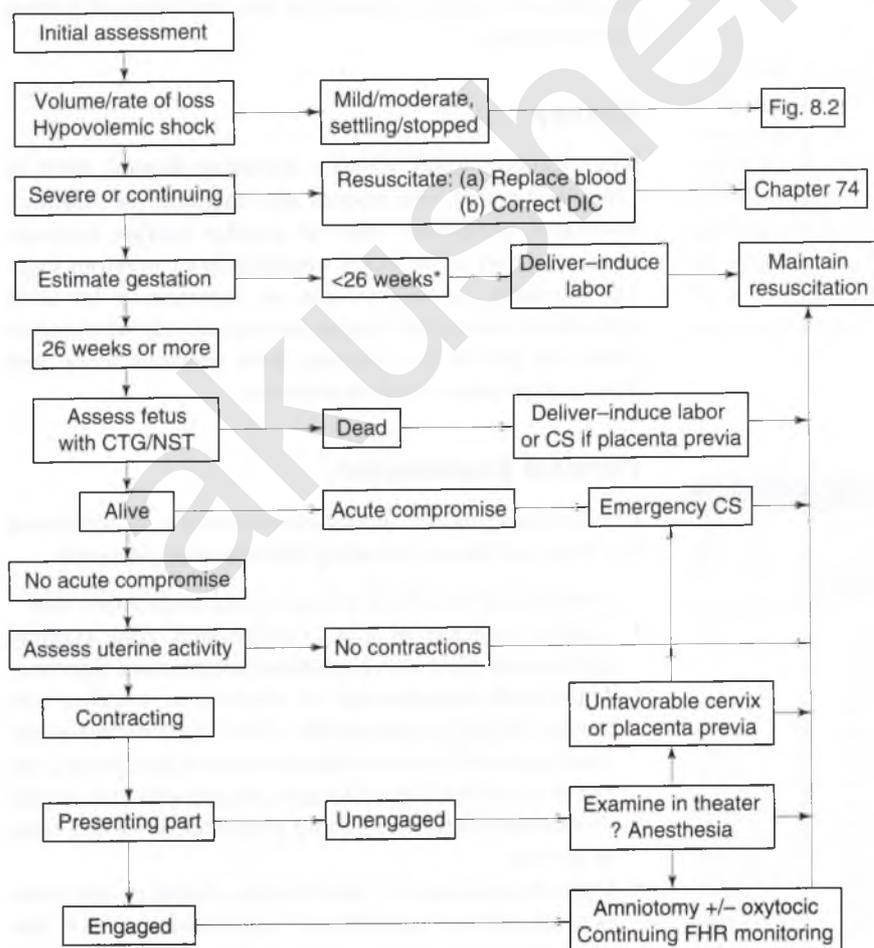
- Bleeding has stopped.
- Bleeding is continuing, and is mild to moderate and non-life-threatening.
- Bleeding is continuing and is severe and life-threatening.
- The fetus is in distress, regardless of the bleeding pattern.
- The fetus is dead, regardless of the bleeding pattern.


FIGURE 59–1
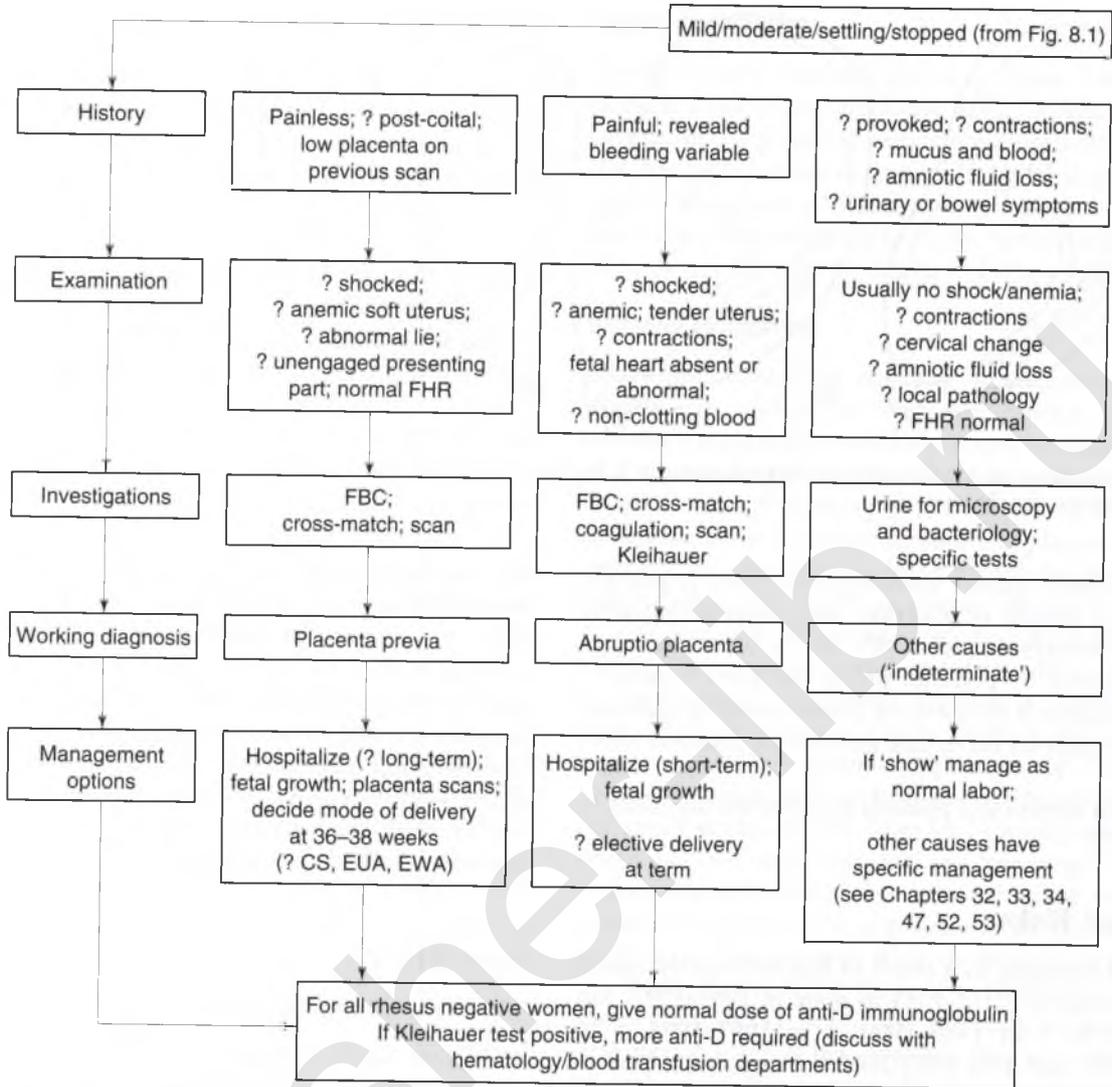
Management of bleeding in late pregnancy. Initial assessment and management of severe bleeding. (*The gestation after which survival rates are considered high enough to influence the mode of delivery of the preterm fetus varies in different centers from 24 to 28 weeks.)


FIGURE 59–2

Management of bleeding in late pregnancy. Subsequent assessment and specific management of mild bleeding. (EUA, EWA, examination in the theater with and without anesthesia, respectively.)

Subsequent management is determined by these circumstances. Options include immediate delivery and expectant management. These are discussed under the various types of antepartum hemorrhage. The flow charts in Figures 59–1 and 59–2 outline the steps in management.

PLACENTA PREVIA

In placenta previa, the placenta is inserted partially or entirely into the lower uterine segment. Four grades have been defined (Table 59–2 and Fig. 59–3). Figures 59–4 and 59–5 show two of these grades. This condition occurs in 0.4% to 0.8% of pregnancies,[2] although an incidence of 0.16% was recently reported in an unselected population in Finland.[3]

The etiology of placenta previa is unknown, but various associations have been identified. These include age, parity, and previous cesarean delivery.[4–7] A single cesarean delivery increases the risk by 0.65%, two increase the risk 1.5%, three increase the risk by 2.2%, and four or more increase the risk by 10%.[7] Other risk

TABLE 59–2

Grading of Placenta Previa

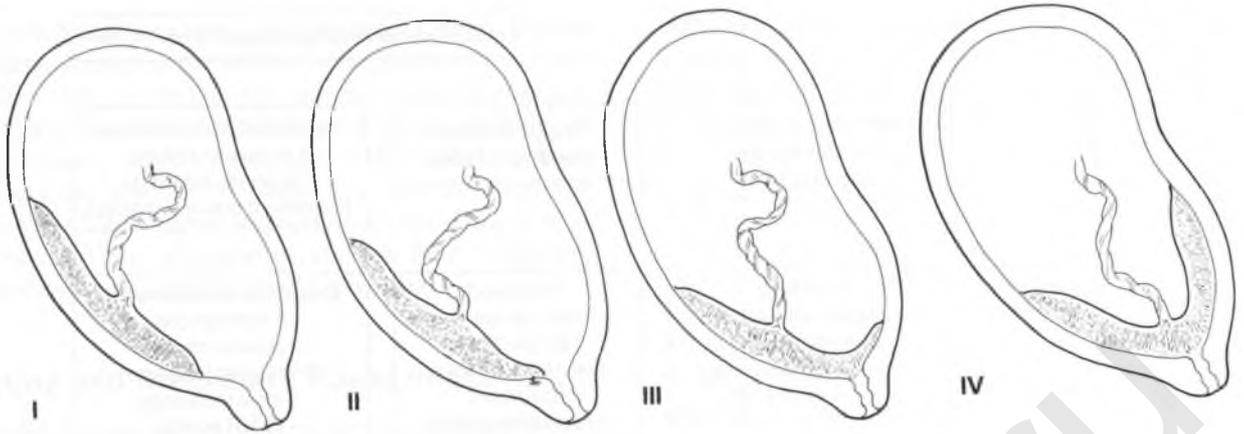
GRADE	DESCRIPTION
I	The placenta is in the lower segment, but the lower edge does not reach the internal os
II	The lower edge of the low-lying placenta reaches, but does not cover, the internal os
III	The placenta covers the internal os asymmetrically
IV	The placenta covers the internal os symmetrically


FIGURE 59–3
Grades of placenta previa. I, Encroaching on the lower segment; II, reaching the internal OS; III, asymmetrically covering the internal os; IV, symmetrically covering the internal os.

factors include cigarette smoking,[8] drug abuse (especially cocaine), a history of abortion, and previous placenta previa. A recurrence risk of 4% to 8% after one pregnancy affected by placenta previa has been reported.[9] The association with abortion (spontaneous or induced) is greater with an increasing number of previous abortions.[10,11]

Placenta accreta and placenta percreta are discussed in Chapter 77.

Maternal Risks

Maternal mortality as a result of hemorrhage decreased from 29 cases in 1952–1954 to none in 1985–1987, but increased to 5 in 1988–1990, 4 in 1991–1993, 3 in 1994–1996, and 4 in 2000–2002.[12] Postpartum hemorrhage is believed to be caused by inadequate occlusion of

the sinuses in the lower segment after delivery. Anesthetic and surgical complications may occur, especially in women with major placenta previa who have emergency cesarean delivery with suboptimal preparation for surgery. Air embolism occurs when the sinuses in the placental bed are torn. Postpartum sepsis is caused by ascending infection of the raw placental bed. Placenta accreta occurs in up to 15% of women with placenta previa. The risk of recurrence is approximately 4% to 8% after one previous placenta previa.

Fetal Risks

The fetal risks of placenta previa include the following:

- Preterm birth. Cotton and colleagues[13] reported a perinatal mortality rate of 100% at less than 27 weeks,

FIGURE 59–4
Grade II posterior placenta previa. The placenta extends to the cervical os, but does not cover it.

FIGURE 59–5
Grade IV placenta previa. The placenta covers the os symmetrically.

19.7% at 27 to 32 weeks, 6.4% at 33 to 36 weeks, and 2.6% after 36 weeks. These figures, however, represent the outcome nearly 23 years ago. In recent years, the overall perinatal mortality rate has dropped from 126 per 1000[12] to 42 to 81 per 1000[4] as a result of conservative management and improved neonatal care.

- Fetal growth restriction, which may occur in up to 16% of cases. The incidence is higher in patients with multiple episodes of antepartum hemorrhage.[14]
- Placenta previa. The incidence of serious malformations is doubled in women with placenta previa. The most common malformations are those of the central nervous system and the cardiovascular, respiratory, and gastrointestinal systems.[3]
- Other risks. Additional fetal risks include umbilical cord complications, such as prolapse and compression,[10] malpresentation, fetal anemia, and unexpected intrauterine death (e.g., rupture of vasa previa, severe maternal hypovolemic shock).

Presentation

Placenta previa characteristically causes unprovoked painless vaginal bleeding. Occasionally, it is caused by sexual intercourse. Threatened second-trimester miscarriage may precede placenta previa,[15] although bleeding may be minor and in some cases unreported. The initial episode of bleeding has a modal incidence at approximately 34 weeks and occurs before 36 weeks in more than 50% of cases. It occurs after 40 weeks in only 2% of cases.[4]

The absence of pain is often considered a significant distinguishing factor between placenta previa and placental abruption, but 10% of women with placenta previa have coexisting abruption.[10] These patients and those who seek care for the first time while in labor and are therefore experiencing painful uterine contractions (25% of women with placenta previa[16]) may present a diagnostic problem.

Because ultrasound scanning is performed in early pregnancy in most centers, some patients with a low-lying placenta may be identified before 20 weeks' gestation, but the diagnosis of placenta previa cannot be made because the lower segment has not formed at this time.

Abdominal findings in placenta previa include malpresentation, which is either breech or transverse in 35% of cases[13]; slight, but consistent deviation of the presenting part from the midline; and difficulty with palpating the presenting part.

Diagnosis

Various approaches have been used to diagnose placenta previa.

Vaginal Examination

Digital vaginal examination may cause hemorrhage. Because local causes are likely to be benign, speculum examination is probably best deferred until ultrasonography has excluded the diagnosis. If digital vaginal examination is necessary because of excessive bleeding, it should be performed only in an operating room, with full preparation for cesarean delivery (discussed later).

Placental Localization

Diagnostic ultrasound scanning is safe, accurate, and noninvasive, and is the diagnostic method of choice. Although routine placental localization is considered part of the anomaly scan at 20 to 22 weeks' gestation, several questions arise from this practice. For example, is a low-lying placenta at this stage predictive of placenta previa at delivery, and does this screening reduce the likelihood of adverse outcome? More important, should the scan be repeated at 32 to 34 weeks' gestation? Must the asymptomatic patient be admitted, and if so, when?

Unfortunately, the earlier the scan is performed, the more likely the placenta is to be found in the lower pole of the uterus. For example, approximately 28% of placentas in women who undergo transabdominal scanning before 24 weeks are "low," but by 24 weeks, this number drops to 18%, and only 3% are low-lying by term.[17] Conversely, a false-negative scan for a low placenta is found in as many as 7% of patients at 20 weeks.[18] These results are more common when the placenta is posterior, the bladder is overfilled, the fetal head obscures the margin of the placenta, or the operator does not scan the lateral uterine wall.[19] A low-lying placenta is more common in early pregnancy because the lower segment does not exist. The apparent placental migration is caused by enlargement of the upper segment and formation of the lower segment. Many apparently low placentas are found above the lower segment. Comeau and associates[20] and Ruparelia and Chapman[21] showed that the more advanced the pregnancy, the more accurate the diagnosis of placenta previa based on scanning findings.

When a transvaginal ultrasound scan is performed for placental localization and the distance between the lower edge of the placenta and the internal cervical os is measured, the persistence of a low-lying placenta at a later gestation is higher. Taipale and colleagues[22] observed that if a placenta overlapped the internal os by at least 25 mm at 18 to 23 weeks, the positive predictive value for placenta previa at delivery was 40%, with a sensitivity of 80%. Becker and associates[23] found that when the lower edge overlapped the os by at least 25 mm at 20 to 23 weeks, vaginal delivery was not possible at term (i.e., 100% positive predictive value).

Although no randomized controlled trials have been conducted, case studies advocate localization of the placenta at the routine anomaly scan. Practitioners must

recognize the limitations of this practice, and whenever possible, offer transvaginal ultrasound scans to improve the accuracy of localization and measure the distance from the os to the placental edge to help define the extent to which the placenta is low-lying.

Because there are no randomized controlled trials of the maternal and fetal effects of routine localization versus no localization, current practice must be governed by large cohort case studies. It is assumed that when there is a low-lying placenta, education of patients and careers enhances the chance of better maternal and fetal outcome but this is not always the case. Whether these patients should be admitted routinely at a later gestation is debatable. Most units do not routinely admit these patients, but repeat the scans at 32 to 34 weeks' gestation. Dasche and colleagues[24] observed that in 34% of cases, placenta previa that was diagnosed at 20 to 23 weeks was still present at delivery, whereas 73% of those present at 32 to 35 weeks persisted at delivery. A policy of routine scanning will reduce the false-positive rate, but at the expense of increasing workload and patient anxiety. Unfortunately, none of the studies reported the proportion of patients with low-lying placenta diagnosed at 32 to 34 weeks who had bleeding later in gestation. For units that do not routinely scan for placental site at 20 weeks, this 32 to 34 week scanning is indicated only in patients with an indication such as abnormal presentation, vaginal bleeding, or a chance finding when ultrasound was undertaken in late pregnancy for other reasons. In these cases, a transvaginal approach is recommended because it has better diagnostic accuracy, especially with posterior placenta previa.[25,26] This approach is safe and well tolerated. Placenta previa is diagnosed on transvaginal ultrasound scan when the placental edge is less than 3 cm from the internal os.

The findings on placenta previa can be summarized as follows:

- Routine location of the placental site at the 20-week transabdominal ultrasound has a low positive predictive value for placenta previa later in pregnancy.
- Transvaginal ultrasound is more accurate than transabdominal in diagnosing placenta previa.
- There is no evidence that either of these interventions or rescanning "at-risk" patients in the third trimester reduces adverse maternal or fetal outcomes from placenta previa, and randomized trials addressing these issues are needed.

Magnetic resonance imaging may be a diagnostic technique of the future, but its high cost limits its availability.[27,28]

Management Options (See Fig. 59–2)

General management options were discussed earlier (see Fig. 59–1). Specific measures include immediate delivery and expectant management.

Immediate Delivery

If bleeding continues, but is neither profuse nor life-threatening and the gestation is more than 34 weeks, delivery is preferred after resuscitation is initiated. The mode of delivery depends on the grade of placenta previa and the state of the cervix. Occasionally, placental localization leads to inaccurate grading of placenta previa. In addition, some units do not have facilities for emergency placental localization. Options include immediate cesarean section and examination in an operating room, with or without anesthesia ("double setup"). Cesarean section is the only option in patients with profuse, life-threatening bleeding.

<div style="text-align:center">**PROCEDURE**</div>

EXAMINATION IN AN OPERATING ROOM (DOUBLE SETUP)

Indications

Examination in an operating room provides the most accurate assessment of the relationship between the lower edge of the placenta and the cervical os. It should be done only when delivery will be undertaken. This approach is contraindicated by active, profuse hemorrhage mandating immediate delivery; fetal malposition or malpresentation precluding vaginal delivery; fetal heart rate abnormality; and clear ultrasonographic evidence of major placenta previa. It may be considered when ultrasonographic evidence of placenta previa is inconclusive or when grade I or II anterior previa is suspected in patients with ongoing, but not life-threatening, uterine bleeding in active labor.

Preparation

Before this procedure is undertaken, crossmatched blood must be available. An anesthetist must be present, a midwife or operating room nurse must be scrubbed and gowned, and a cesarean section tray prepared. A second obstetrician should be scrubbed and ready to operate. The procedure must be performed by an experienced obstetrician, and a pediatrician must be present. Opinions vary as to whether the procedure should be carried out under general anesthesia. A survey of anesthetic management of cesarean section for placenta previa in the United Kingdom showed that 86% of anesthetists were willing to use regional anesthesia for a minor degree of placenta previa, but only 15% were prepared to offer these techniques for all degrees of placenta previa.[29] One advantage of general anesthesia is proper relaxation of the patient, which makes examination easier and allows rapid progression to cesarean section, if necessary. The main disadvantage is the need to wake the patient from anesthesia before inducing labor if vaginal delivery is possible. In addition, if cesarean section becomes necessary, a second anesthetic increases the risks. Performing the procedure under epidural anesthesia is an alternative, but this approach causes peripheral vasodilation

and may worsen the effects of hypovolemia if hemorrhage is severe. A compromise appears to be drawing the drugs for induction of general anesthesia and preparing the anesthetic machine and instruments before the procedure. With such precautions, and in experienced hands, the interval between examination and delivery can be short.

Procedure

The patient is placed in the lithotomy position and draped with sterile towels after the vulva, but not the vagina, is cleaned. The bladder is catheterized, and two fingers are gently introduced into the vagina, with care taken to avoid the cervical os. Each vaginal fornix is palpated in turn to feel whether there is placenta between the presenting part and the finger. If placental tissue is present, a sensation of "bogginess" is felt. If the four fornices are empty, the index finger is gently introduced into the cervical os and the surroundings felt for the placental edge. If the cervix is closed, it should not be forced open and cesarean section should be performed. If the cervix admits a finger and no placental tissue is felt, the fetal membranes should be ruptured. An organized blood clot in the cervix may be mistaken for placental tissue. Persistent bright red bleeding after membrane rupture is an indication for cesarean delivery. If the placental edge is felt anteriorly but does not extend to the os and no bleeding is provoked, the decision may be made to rupture the membranes in preparation for vaginal delivery. If brisk vaginal bleeding occurs at any stage during the procedure, the procedure should be abandoned immediately and cesarean section performed.

Expectant Management

The perinatal mortality rate in placenta previa is directly related to gestational age at delivery.[13,30–32] Macafee and associates[30] and Johnson and colleagues[32] introduced expectant management of placenta previa to achieve the maximum fetal maturity possible while minimizing maternal and fetal risks. The overall objective is to reduce perinatal and maternal mortality. The basis of this approach is that most episodes of bleeding are small and self-limited and are not fatal to the fetus or mother in the absence of provoking trauma (e.g., intercourse, vaginal examination) or labor. A major advantage of expectant management is that in some patients, particularly those presenting early with lesser degrees of previa, the condition may resolve to permit vaginal delivery. More recently, several groups reported an improvement in perinatal mortality rates that was attributed mainly to prolongation of pregnancy.[33,34]

Macafee and associates[30] recommended treating the patient as an inpatient in a fully equipped, fully staffed maternity hospital from initial diagnosis to delivery. Permitting some women to return home is advocated[35] as part of expectant management. This practice is controversial because reports from some units have been conflicting. Cotton and colleagues[13] reported no difference in perinatal and maternal mortality rates in those sent home and those managed in hospitals, whereas D'Angelo and Irwin[36] suggested that keeping the mother in the hospital until delivery was justified because neonatal mortality and morbidity rates and treatment costs were reduced. Kaunitz and colleagues,[37] in a review of 355 patients who were managed at home, however, reported one intrapartum death as a result of placenta previa. This controversy is more evident when asymptomatic placenta previa is diagnosed on ultrasonography. It is becoming increasingly acceptable to manage these patients at home.[38,39] Love and Wallace,[40] in a review of 15,930 deliveries in Edinburgh, concluded that although clinical outcomes were variable and could not be predicted from antenatal events, most patients with or without bleeding, regardless of the degree of previa, could be managed on an outpatient basis. Randomized controlled trials are needed to justify the merits of this conservative approach.

Severe hemorrhage (heavy vaginal bleeding that causes maternal hypovolemia) was originally considered a contraindication to expectant management.[40] However, in one study in which approximately 20% of the women lost more than 500 mL blood, half were managed expectantly, with a mean gain in gestation of 16.8 days.[11] Crenshaw and colleagues[31] managed only 43% to 46% of patients successfully with an aggressive expectant approach, whereas Cotton and associates[13] successfully managed 66% of women expectantly with an aggressive approach.

During expectant management, preterm labor is a problem. Brenner and associates[41] found that 40% of women with placenta previa had rupture of the membranes, spontaneous labor, or other problems that resulted in delivery before 37 weeks' gestation. Inhibiting contractions in those with preterm labor seems logical, but some consider antepartum hemorrhage a contraindication to the use of tocolytics.[42] With vaginal bleeding and uterine contractions, placental abruption, which is widely considered a contraindication to tocolysis, cannot be excluded. In addition, placental abruption may coexist with placenta previa in 10% of cases. Further, tocolytics cause maternal tachycardia and palpitations, features that may be confused with hypovolemia. Sampson and associates[43] advocate the use of tocolytics in cases of placenta previa and uterine contractions after 21 weeks and reported a reduction in the perinatal mortality rate from 126 to 41 per 1000.

The perinatal mortality rate is also directly related to the total amount of blood lost antepartum. Liberal use of blood transfusions may nullify this effect.[13] There is no limit to the number of blood transfusions a patient can have. To optimize the oxygen supply to the fetus and protect the mother against anticipated blood loss, the aim of transfusion is to maintain hemoglobin of at least 10 g/dL or hematocrit of 30%.

Despite expectant management, 20% of women with placenta previa are delivered earlier than 32 weeks.

These cases account for 73% of perinatal deaths.[13] These premature deliveries are a major problem, and although cervical cerclage has been advocated, it is not normally used. Neonatal mortality and morbidity rates are reduced in this group by maternal corticosteroid administration. The use of thyroid-releasing hormones[44] should be limited to randomized controlled trials until more evidence is available.

The main disadvantages of continuous hospitalization are the cost and the psychological effect of separation on families. For many families, hospitalization means prolonged separation, and in some extreme cases, the breakup of marriages. Advantages include easy access to resuscitation and prompt delivery and ensuring bed rest (which may decrease the occurrence of hemorrhage) and limitation of activities. With improvement in transportation facilities and ambulance services, highly motivated women who clearly understand the need for restriction of activity and are within approximately 15 to 30 minutes of the hospital may be monitored at home. This approach applies only to women with grade I to III placenta previa or asymptomatic grade IV placenta previa. In all cases of expectant management, two units of crossmatched blood must be available at all times.

Method of Delivery

In general, the diagnosis of placenta previa means cesarean delivery. When the degree of placenta previa is minor (grade I or II anterior) and the fetal head is engaged, pregnancy may be allowed to continue beyond 37 to 38 weeks and vaginal delivery anticipated. In these patients, amniotomy followed by oxytocin (Syntocinon) administration can be considered. In those with more severe placenta previa, emergency or elective cesarean delivery is commonly used. Elective delivery is ideal because emergency delivery has a negative effect on perinatal mortality and morbidity rates, independent of gestational age. Cotton and associates[13] found that 27.7% of infants delivered emergently had anemia compared with 2.9% delivered electively. Cesarean section for placenta previa poses several problems. It should never be left to an inexperienced obstetrician. The Royal College of Obstetricians and Gynaecologists in the United Kingdom recommends that such cesarean sections be performed by senior obstetricians (consultants in the U.K.). Although general anesthesia was preferred to regional anesthesia in the past, there is an increasing tendency to use the latter, and Frederiksen and colleagues[45] showed its safety and a reduction in intrapartum blood loss compared with general anesthesia.

PROCEDURE

Although epidural anesthetic is increasingly advocated for cesarean delivery, Moir[46] described placenta previa as an absolute contraindication to epidural anesthesia. Epidural anesthesia, by lowering blood pressure, may critically reduce uterine and placental perfusion. Crawford,[47] however, believes that in experienced hands, an epidural is safe. An increasing number of anesthetists offer regional anesthesia to these patients.[28] When the patient's condition is stable and there is no active bleeding, epidural or spinal anesthesia should not be regarded as contraindicated, provided an experienced anesthetist is available. Because patients and their partners may experience severe anxiety in the presence of profuse bleeding during cesarean delivery, careful consideration should be given to the decision to allow partners in the operating room.

A transverse incision of the lower segment of the uterus is commonly used, provided there is a lower segment. When the lower segment is nonexistent or is very vascular, some obstetricians advocate a classical or De Lee's incision. Scott,[48] however, believes that such incisions are rarely justified because of their consequences and long-term disadvantages. When difficulties occur with transverse incisions of the lower segment, the incision may be converted to an inverted T-, J-, or U-shaped incision.

If the incision in the uterus is transverse and the placenta is anterior, two approaches are available: going through the placenta or defining its edge and going through the membranes above or below the placenta. The former approach requires speed and may cause significant fetal blood loss.[49] The latter approach, however, may be associated with undue delay in the delivery of the fetus, more troublesome bleeding from a partially separated placenta, and resultant fetal blood loss and anoxia. Myerscough[49] advises against cutting or tearing through the placenta because of the inevitable fetal blood loss that occurs as fetal vessels are torn. Because the lower segment is less muscular, contraction and retraction cause inadequate occlusion of the sinuses of the placental bed, and intraoperative hemorrhage is not uncommon.[50] When hemostasis is difficult, bleeding sinuses can be oversewn with atraumatic sutures.[48] If this approach is unsuccessful, the uterus can be packed, but if the pack is left in situ during closure of the uterus, bleeding may continue but remain concealed for some time. Intramyometrial injection of prostaglandin $F_{2\alpha}$ is useful in these cases.[49] When bleeding is uncontrollable, ligation of the internal iliac artery or even hysterectomy may be necessary as a last resort.

PLACENTAL ABRUPTION

Placental abruption is bleeding after premature separation of a normally situated placenta. The reported incidence varies from 0.49% to 1.8%.[51] The wide variation in reported incidence is believed to be caused by variations in diagnosis. Fox[52] found evidence of abruption in 4.5% of placentas examined routinely, suggesting that small episodes of placental abruption are more common than those diagnosed clinically. Placental abruption is concealed in 20% to 35% of cases and revealed in 65%

to 80% of cases.[26,28] The concealed type is more dangerous, with more severe complications. Four grades of placental abruption have been described (Table 59–3). The most severe type (grade 3) occurs in approximately 0.2% of pregnancies.[26]

The etiology of placental abruption is unknown in most cases. In a few, however, the cause is obvious, such as in direct trauma to the uterus. Various risk factors are associated with placental abruption. The risk of recurrence in subsequent pregnancies is significant, varying from 6%[51] to 16.7%[53–55] It is more common in older women, but this increase has been attributed to parity and is independent of age.[54] Cigarette smoking increases the incidence of placental abruption.[56] Naeye[4] reported an incidence of 1.69% in nonsmokers, 2.46% in smokers, and 1.87% in smokers who had quit. In the smokers, evidence of decidual necrosis at the edge of the placenta was found. This finding may represent the effect of smoking on uteroplacental blood flow[57,58] and decidual integrity.

Other etiologic factors include sudden decompression of the uterus after membrane rupture in patients with polyhydramnios and multiple pregnancy, external cephalic version,[59] placental abnormalities (especially circumvallate placenta),[60,61] abdominal trauma,[62] and increased levels of α-fetoprotein.[63,64] Although maternal hypertension is considered a risk factor, there is no consensus on whether hypertension precedes abruption or vice versa. Naeye and colleagues[65] found no evidence of placental abruption in patients with hypertension, but Abdella and associates[66] observed that the incidence of placental abruption in patients with preeclampsia was twice that in those without preeclampsia. In a meta-analysis, Ananth and associates[67] concluded that chronic hypertension was associated with a threefold increased risk of abruption compared with normotensive patients, whereas the odds ratio for patients with preeclampsia was 1.73. The suggestion that folic acid deficiency may have an etiologic role in placental abruption has not been confirmed. Large prospective studies[68,69] have not shown an association between placental abruption and folate supplementation. More recently, hyperhomocysteinemia

and protein C deficiency[70] and other thrombophilias were reported to be more common in women with placental abruption.[71] Although inferior vena caval compression and the use of lupus anticoagulant have been suggested as possible etiologic factors, there is no convincing evidence.

Maternal Risks

- The maternal mortality rate is approximately 1%. In the last confidential enquiry into maternal deaths in the United Kingdom (2000–2002),[12] four maternal deaths were caused by placental abruption. The maternal mortality rate decreased from 8% in 1919 to less than 1% in 1995.[72] Although severe hemorrhage is usually the major cause of other complications that lead to mortality, disseminated intravascular coagulation may cause severe hemorrhage, renal failure, and death.

- The recurrence rate is generally reported as 6% to 17% after one episode and increases to 25% after two episodes. Approximately 7% of women with abruption severe enough to kill the fetus have the same outcome in subsequent pregnancies, and 30% of all future pregnancies of women who have a placental abruption do not produce a living child.[1]

- Hypovolemic shock. Blood loss may be underestimated in placental abruption because concealed bleeding into the myometrium may be difficult to quantify.

- Acute renal failure can result from hypovolemia or disseminated intravascular coagulation.

- Disseminated intravascular coagulation

- Postpartum hemorrhage can result from coagulation failure or from a Couvelaire uterus, in which severe bleeding occurs into the myometrium and impairs the ability to contract.

- Fetomaternal hemorrhage can lead to severe Rhesus sensitization in Rhesus-negative patients. All Rhesus-negative patients must undergo a Kleihauer-Betke test and have anti-D immunoglobulin administered to prevent immunization.

Fetal Risks

Fetal risks include the following:

- The perinatal mortality rate varies from 4.4% to 67.3%, depending on neonatal facilities.[73] More than 50% of the perinatal deaths are stillbirths.[9] Of the infants delivered alive, Abdella and associates[66] reported a 16% mortality rate within 4 weeks, with most infants weighing less than 2500 g. The perinatal mortality rate is closely related to gestational age. Paterson[54] reported survival rates varying from 23% at 28 to 32 weeks to 87.6% at 37 to 40 weeks. However, survival rates today are probably higher than these figures suggest because they were reported before the advances that have occurred in modern

TABLE 59–3

Grading of Placental Abruption

GRADE	DESCRIPTION
0	Asymptomatic patient with a small retroplacental clot
1	Vaginal bleeding; uterine tetany and tenderness may be present; no signs of maternal shock or fetal distress
2	External vaginal bleeding possible; no signs of maternal shock; signs of fetal distress
3	External bleeding possible; marked uterine tetany, yielding a boardlike consistency on palpation; persistent abdominal pain, with maternal shock and fetal demise; coagulopathy may be evident in 30% of cases

neonatal care. For example, in Norway, the rate decreased from 2.5 per 1000 to 0.9 per 1000 between 1967 and 1991.[51] The higher incidence of fetal malformations[72] and intrauterine growth restriction[1] contributes to the high perinatal mortality rate. For babies weighing more than 2500 g, the reported survival rate is 98%.[74] In the presence of associated complications, such as hypertension, the fetal mortality rate increases threefold.[66]

- Fetal growth restriction is reported in up to 80% of infants born before 36 weeks' gestation.
- The rate of congenital malformations may be as high as 4.4% (twice that in the general population[75]). The rate of major malformations is increased threefold. Most involve the central nervous system, and these can occur at five times the normal incidence.[72]
- The neonatal hematologic findings may be abnormal. Anemia results from significant fetal bleeding.[68]

Diagnosis

The diagnosis is usually made on clinical grounds, but ultrasonography is helpful in some cases (e.g., when there is a large retroplacental hematoma, although this is uncommon, even in severe cases). The symptoms and signs are diagnostic in moderate to severe cases. In mild forms, the diagnosis may not be obvious until after delivery, when a retroplacental clot is identified.

Placental abruption causes vaginal bleeding, abdominal pain, uterine contractions, and tenderness. Vaginal bleeding occurs in no more than 70% to 80% of cases.[26] This bleeding is characteristically dark and nonclotting. It occurs after 36 weeks' gestation in approximately 50% of cases.[26] In a study of 193 cases, Paterson[54] found that 18% occurred before 32 weeks, 40% occurred between 34 and 37 weeks, and 42% occurred after 37 weeks. Because labor is the most common factor precipitating placental separation,[9] nearly 50% of patients with placental abruption are in established labor. Uterine contractions may be difficult to distinguish from the abdominal pain of abruption. When this distinction is possible, the contractions are characteristically very frequent, often with more than five occurring in 10 minutes.[76]

Although abdominal pain is common, it is not invariable and is less common in posteriorly sited placentas. This is evidenced by unsuspected, or silent, abruption described by Notelovitz and colleagues[77] and the higher pathologic incidence of placental abruption reported by Fox.[52] Pain probably indicates extravasation of blood into the myometrium. In severe cases (grade 3), the pain is sharp, severe, and sudden in onset. In addition, some patients may have nausea, anxiety, thirst, restlessness, and a feeling of faintness, whereas others report absent or reduced fetal movements.

If blood loss is significant, the patient may have signs of shock (tachycardia predominates; blood pressure is poorly correlated with blood volume in this condition).

Hypertension may mask true hypovolemia, but increasing abdominal girth or fundal height suggests significant concealed hemorrhage. The uterus is typically described as "woody hard" in severe placental abruption. In such cases, the fetus is difficult to palpate, and a continuous fetal heart rate monitor or real-time ultrasonography must be used to identify the fetal heartbeat. The fetus may be "distressed," with fetal heart rate abnormalities, or may be dead. Fetal distress occurs in grade 1 to 2 abruption, but in grade 3 abruption, fetal death is inevitable, by definition.[78] In severe cases complicated by disseminated intravascular coagulation, there may be no clotting in the vaginal blood, which is dark. The incidence of coagulopathy is 35% to 38%,[53,79] and it occurs mainly in the severe forms.

Typically, blood clots are found in the vagina, except if the blood is nonclotting. Serous fluid from a retroplacental clot may be confused with liquor. The cervix may be dilating because 50% of patients are in labor. If the membranes are ruptured, blood-stained liquor is seen.

Ultrasonography is not a sensitive method of diagnosing placental abruption, but it is useful in excluding coincident placenta previa, which is present in 10% of cases. When the retroplacental clot is large, ultrasonography identifies it as hyperechogenic or isoechogenic compared with the placenta. This echogenicity may be misinterpreted as a thick placenta.[80] Resolving retroplacental clots appear hyperechogenic within 1 week and sonolucent within 2 weeks. Although ultrasonography is not an accurate diagnostic tool, it is useful in monitoring cases managed expectantly, and Rivera-Alxima and colleagues[81] used it to determine the time of delivery. The size of the hematoma, its location and change in size over time, and fetal growth are monitored by ultrasound scan. The Kleihauer-Betke test may be useful in making the diagnosis when a patient has abdominal pain without vaginal bleeding and in cases of unsuspected (silent) abruption.

The differential diagnosis of placental abruption includes conditions that can be broadly classified into two groups. These are other causes of vaginal bleeding and causes of abdominal pain. The former groups are discussed elsewhere in this chapter. The latter groups are discussed in Chapter 57.

Management Options (See Fig. 59–2)

Once the diagnosis of placental abruption has been made, management depends on its severity, associated complications, the condition of the mother and the fetus, and gestational age. Management is divided into general and specific measures. For management, Sher and Statland[82] divided placental abruption into three degrees of severity. These are summarized in Table 59–3.

The general management options were discussed earlier (see Fig. 59–1). Specific measures to be considered are the following:

- Immediate delivery
- Expectant management
- Management of complications

Immediate Delivery

The need for immediate delivery depends on the severity of abruption and whether the fetus is alive or dead. If the fetus is dead, vaginal delivery is the goal. Maternal resuscitation is emphasized because fetal death is common in severe placental abruption, often with coagulopathy. Once resuscitation has been initiated, the fetal membranes should be ruptured to hasten the onset of labor. This approach is effective in most cases, but in a few, augmentation with oxytocin is needed. This drug must be administered cautiously because uterine rupture may be caused by an overstimulated uterus. Barron[83] reported that membrane rupture should be reserved for dead fetuses and patients who are in advanced labor.

If the fetus is alive, the decision as to how best to achieve delivery is not always easy. In addition, the outlook for the fetus is poor not only in terms of immediate survival but also because studies show that as many as 15.4% of liveborn infants do not survive.[66] However, when the mortality rate associated with vaginal delivery is compared with that of cesarean section in nonrandomized controlled trials (52% vs. 16%, Okonofua and Olatubosun[73]; 20% vs. 15%, Hurd and associates[76]), cesarean delivery has advantages. Hibbard[9] stated that many of the poor results associated with cesarean section are largely the result of indecision and delay in the last quarter of pregnancy. He stated that cesarean delivery must be considered when the fetus is alive, particularly if there is evidence of fetal distress. However, coagulopathy adds considerable maternal risk, and the likelihood of injury or death may be increased by surgery.

If the decision is made to deliver and the fetus is alive, the degree of abruption and the state of the fetus are important determining factors. When abruption is severe, cesarean section must be performed once resuscitation has started. Delivery should be performed promptly, especially because most postadmission fetal deaths occur in fetuses delivered more than 2 hours after admission.

In mild to moderate cases of abruption, the mode of delivery is determined by the condition of the fetus, its presentation, and the state of the cervix. Abnormal fetal heart rate patterns are an indication for immediate cesarean delivery. However, if the decision is made to deliver vaginally, continuous fetal monitoring must be available to identify early abnormal fetal heart rate patterns. Golditch and Boyce,[68] Lunan,[74] and Okonofua and Olatubosun[73] showed that the perinatal mortality rate is higher with vaginal delivery in the absence of electronic fetal monitoring. Prostaglandins are used to ripen the cervix in women with mild abruption, but the danger of inducing tetanic contractions must be remembered. When feasible, amniotomy often hastens delivery, but when it is not possible, oxytocin can be used. However, vigilance must be maintained for the development of hyperstimulation.

Expectant Management

The goal of expectant management is to prolong pregnancy, with the hope of improving fetal maturity and survival. Expectant management is usually considered in cases of mild placental abruption occurring before 37 weeks' gestation. Vaginal bleeding is slight, abdominal pain is mild and usually localized, and the patient is cardiovascularly stable. Once conservative management has been chosen, the fetal condition must be monitored closely. No evidence supports the routine admission of patients who are being managed expectantly, especially when there is no evidence of maternal or fetal compromise or uterine contractions. Fetal growth restriction is a common finding in association with placental abruption. The timing of delivery depends on the finding of further vaginal bleeding, the fetal condition, gestational age, and the availability of neonatal care facilities. If bleeding episodes are recurrent, induction at 37 to 38 weeks is usually undertaken if fetal indices of health (e.g., biophysical parameters and growth; see Chapters 11 and 12) are satisfactory. When the initial episode is small and self-limiting and there is no acute (abnormal cardiotocographic findings or biophysical profile score) or chronic (growth restriction, oligohydramnios, or abnormal umbilical artery Doppler recording) fetal compromise, no evidence supports the induction of labor. Despite this lack of evidence, induction of labor at term is often advocated in such patients using the speculative argument that undetected damage might have occurred to the integrity and function of the placenta, and in the face of uncertainty, delivery at term confers more advantages.

If the initial ultrasound scan showed a retroplacental clot, the clot may be monitored by serial ultrasound scans. If the fetal condition deteriorates, delivery is expedited, with the speed and urgency determined by whether fetal compromise is acute or chronic.

Some cases of mild abruption may be complicated by labor. In such cases, it is difficult to establish which came first. Many consider tocolytics contraindicated in the presence of placental abruption because they may worsen abruption.[42] Sholl[84] stated that a trial of tocolytics in mild abruptio placentae and labor may successfully prolong pregnancy without jeopardizing the mother and fetus. There have been no large trials to confirm this statement.

Management of Complications

The major complications of placental abruption are hemorrhagic shock, disseminated intravascular coagulation,

ischemic necrosis of the distal organs (especially the kidneys and brain), and postpartum hemorrhage. These are discussed in Chapters 50, 77, 79, and 80.

Rhesus Isoimmunization

Fetomaternal hemorrhage during abruption can be significant.[85] All Rhesus-negative women with abruption must undergo a Kleihauer-Betke test and receive an appropriate dose of anti-D immunoglobulin to prevent immunization. Repeated doses depend on the amount of fetomaternal hemorrhage, as determined by the Kleihauer-Betke test. This treatment must be given within 72 hours of the onset of abruption. When management is expectant in a patient with intermittent recurrent bleeding, regular Kleihauer-Betke testing and assays of therapeutic anti-D immunoglobulin levels can be performed to guide further anti-D administration. Collaboration with the hematologist and blood bank is advisable to determine the correct dose when the Kleihauer-Betke test result is positive.

UNCLASSIFIED BLEEDING

The exact cause of bleeding in late pregnancy is unknown in 47% of patients. The reported incidence varies from 38% to 74%.[86-90] The cause of bleeding may become apparent later, but in most cases, no cause is seen.[28] When causes are identified, they include marginal sinus rupture (60%), "show" (20%), cervicitis (18%), trauma (5%), vulvovaricosities (2%), genital tumors, hematuria, genital infections, and vasa previa (0.5% each). Although this group of causes is referred to as unclassified bleeding, it invariably includes unrecognized cases of minor abruption or placenta previa. Marginal sinus rupture is the most common source of bleeding in antepartum hemorrhage of unknown cause.[60]

Risks

The risks of unclassified bleeding depend on the cause. More serious causes are discussed in the relevant chapters. This type of bleeding is associated with a higher perinatal mortality rate, which varies from 3.5% to 15.7%.[86-88] This rate is higher than that associated with placenta previa (4.2%–8.1%), suggesting some degree of placental dysfunction. Preterm labor is more common in these patients and is a contributor to the higher perinatal mortality rate.

In vasa previa, fetal exsanguination after rupture or compromise of placental circulation as a result of compression of the abnormal vessels may cause fetal death. Seventy-five percent of deaths in vasa previa are caused by exsanguination. Other fetal risks include increased incidence of intrauterine growth restriction and congenital malformations. The main risk to the mother is bleeding, but often, maternal blood loss is mild and therefore not life-threatening.

Diagnosis

There are usually no signs and symptoms diagnostic of either placenta previa or placental abruption. In most cases, bleeding is mild and resolves spontaneously. Approximately 60% of cases occur after 37 weeks, and of these, 15% of patients are delivered within 10 days of the initial hemorrhage.[88] When marginal bleeding occurs with clot formation, serum separated from the clot may be confused with liquor after spontaneous rupture of fetal membranes.[91]

The diagnosis of unclassified bleeding is often made after placental abruption and placenta previa are excluded. An ultrasound scan is necessary to exclude placenta previa because minor grades may present in a similar manner.

Speculum examination should be performed in patients with unclassified bleeding. Opinions differ about the timing of this examination. Some believe that it should be delayed until bleeding has stopped, whereas others advocate immediate examination once placenta previa has been excluded. Some advocate immediate examination because they want to exclude advanced labor and local causes of bleeding. Others advocate delayed examination because they believe that a delay does not affect management and that other local causes of bleeding are usually benign and need no immediate action. No controlled trials have compared these different types of management.

Management Options

If placenta previa and abruption have been excluded, further management depends on gestational age, the nature of the bleeding (severity and persistence or recurrence), the state of the fetus (abnormal fetal heart rate patterns), and the presumed cause of bleeding.

Options for further management include delivery and an expectant approach. At or beyond 37 weeks' gestation, when bleeding is recurrent or significant or associated fetal factors (e.g., growth restriction, abnormal heart rate patterns) are present, delivery is the management option of choice. Vaginal delivery is not contraindicated if there is no fetal compromise. Before 37 weeks' gestation, if bleeding is recurrent and significant, immediate delivery may be needed. The mode of delivery is determined by the state of the fetus, its lie, and other associated factors, such as the state of the cervix.

If expectant management is chosen, the patient may be monitored at home or in the hospital. Most units monitor patients in the hospital until bleeding has stopped for at least 24 hours. Watson,[88] in a retrospective review, showed no significant advantage in admitting patients to the hospital. A randomized controlled trial comparing

inpatient versus outpatient care in these cases is needed, especially with the current emphasis on community-based care for pregnancy. Regardless of where the patient is managed, fetal surveillance should be implemented because of the increased risk of perinatal death (discussed earlier). Where awaiting the spontaneous onset of labor is the practice,[87] the perinatal mortality rate is not increased. Some advocate induction at 38 weeks[87,90] because any bleeding carries a theoretical risk of disrupting placental function and should be considered an indication for delivery at 38 weeks' gestation.[92] We recommend awaiting the spontaneous onset of labor if fetal growth and welfare are satisfactory (because no evidence supports the proposition of placental disruption) and use induction only when there is evidence of fetal compromise.

One potential hazard of vaginal bleeding in late pregnancy is fetal exsanguination as a result of vasa previa. This complication usually occurs at amniotomy or when fetal membranes rupture spontaneously. Classically, profuse vaginal bleeding follows amniotomy, with subsequent fetal bradycardia. The diagnosis of this condition before these events occur is difficult, but an experienced observer may be able to feel vessels coursing over the membranes. Speculum examination may also show the vessels. In some cases, when mild bleeding occurs after amniotomy but the fetal heart rate is normal, this diagnosis cannot be excluded. An Apt[93] test (discussed earlier) must be performed. If fetal blood is found, the infant should be delivered immediately by cesarean section.

CONCLUSIONS

GENERAL

- Bleeding in late pregnancy is an important cause of fetal and maternal morbidity and mortality.
- The etiology of the various types of bleeding is poorly understood.
- The principles are initial assessment of the patient's condition and subsequent planned management aimed at resuscitation and prolongation of pregnancy, if possible, or immediate delivery for either fetal or maternal indications.

PLACENTA PREVIA

- Previous cesarean delivery increases the risk of occurrence from 0.65% after one cesarean delivery to 10% after four or more.
- Transvaginal ultrasound provides the most reliable diagnosis and poses no maternal risk.
- Routine anomaly scans at 20 to 22 weeks' gestation have a high false-positive rate of 40% to 70% and a 7% false-negative rate for diagnosis, depending on whether transabdominal or transvaginal scanning is performed.
- Management depends on presentation, gestational age, and the degree of previa. When the mother's life is not at risk, expectant management (with or without blood transfusion) will improve neonatal outcome.
- When major placenta previa is present, delivery is by cesarean section, preferably under regional anesthesia (provided by an experienced anesthetist) and performed by an experienced obstetrician.

PLACENTAL ABRUPTION

- Risk factors include age, parity, smoking, thrombophilia, hyperhomocysteinemia, and increased maternal serum levels of α-fetoprotein.
- The diagnosis is made clinically rather than radiologically.
- Major risks include intrauterine fetal death, maternal disseminated intravascular coagulation, and renal failure.
- Management depends on the grade. If the fetus is alive and is not distressed or is dead, vaginal delivery should be offered; otherwise, cesarean delivery should be performed. Correction of a coagulopathy is essential before embarking on delivery; however, when correction is not possible, adequate blood products must be available.
- The recurrence risk is 6% to 17% after one episode and 25% after two episodes.

UNCLASSIFIED BLEEDING

- The diagnosis is one of exclusion.
- Vasa previa must be considered as part of the differential diagnosis.
- Unclassified bleeding increases the risk of an adverse perinatal outcome and is an indication for ongoing fetal monitoring.

Multiple Pregnancy

Caroline Anne Crowther / Jodie Michele Dodd

INTRODUCTION

Multiple pregnancy rates vary worldwide. The lowest prevalence for twin births is reported in Japan (6.7 per 1000 deliveries), with intermediate prevalence reported in North America and Europe (11 per 1000 deliveries), and the highest prevalence reported in Africa, particularly Nigeria (40 per 1000 deliveries). The frequency of twin births in tertiary centers ranges from 1 in 25 to 1 in 100, with the highest rate reflecting the hospital referral population rather than the true rate for the population. The incidence of monozygous twinning is relatively constant worldwide, at 3.5 per 1000 births.[1] Dizygous twinning rates and higher-order birth rates vary widely and are affected by age, parity, racial background, and the use of assisted reproductive techniques. This chapter discusses the general and obstetric risks and problems associated with multiple pregnancy. Specific fetal problems (e.g., poor fetal growth, single fetal death in twins, congenital anomaly in one twin, twin reversed arterial perfusion sequence, monoamniotic twins, twin–twin transfusion syndrome [TTTS]) in multiple pregnancy are discussed in Chapter 24.

RISKS

Multiple pregnancy is associated with greater maternal and fetal risks than singleton pregnancy.

Maternal Risks (Table 60–1)

Increased Symptoms of Early Pregnancy

Nausea and vomiting are common and may arouse the suspicion of a multiple pregnancy. Higher levels of pregnancy hormones are implicated.[2]

Increased Risk of Miscarriage

Miscarriage is more common in multiple pregnancy than in singleton pregnancy. The rate of missed abortion is approximately twice as high as the 2% rate seen in singletons at 10 to 14 weeks' gestation. The risk of miscarriage with one missed abortion is ten times that of a normal twin pregnancy.[3]

Vanishing Twin Syndrome

Twins and higher-order multiple gestations are more often conceived than born. During the first trimester, arrest of development and subsequent reabsorption of one or more of the fetuses may occur. This event can be seen ultrasonographically and is known as the "vanishing twin" phenomenon.[4] First-trimester vaginal bleeding may be related to this syndrome. The prognosis for the

---

TABLE 60–1

Maternal Risks Associated with Multiple Pregnancy

Increased symptoms of early pregnancy
Increased risk of miscarriage
Vanishing twin syndrome
Minor disorders of pregnancy
Anemia
Preterm labor and delivery
Hypertension
Antepartum hemorrhage
Hydramnios
Possible need for prenatal hospitalization
Single fetal death in twins
Increased risk of an operative vaginal birth
Increased likelihood of cesarean birth
Postpartum hemorrhage
Postnatal problems
Maternal mortality

remaining fetus after loss of a cotwin at this early stage of pregnancy is good.[4]

Minor Disorders of Pregnancy

The extra weight carried with a multiple pregnancy exaggerates the minor symptoms of pregnancy. Backache, breathlessness, difficulty walking (especially toward the end of pregnancy), and pressure problems (e.g., varicose veins) are more common in multiple pregnancy.

Anemia

Anemia is more frequent in multiple than in singleton pregnancy. The greater increase in blood volume compared with the red cell mass decreases the hemoglobin concentration, producing a more pronounced decrease in hemoglobin compared with singleton pregnancy.[5] However, mean corpuscular hemoglobin concentration, used as a measure of anemia, does not differ in multiple versus singleton pregnancy. In a retrospective case–control study comparing hemoglobin concentration in twin and singleton gestations matched for parity, no statistically significant differences in third-trimester hemoglobin levels were identified between the two groups.[6] The lower levels identified in the first and second trimesters of pregnancy in twins compared with singletons reflected lower values in multiparous women with a twin pregnancy. Fetal demands in a multiple pregnancy are greater, particularly for folate, and megaloblastic anemia has been reported.

Preterm Labor and Delivery

Preterm birth (birth <37 weeks) occurred in 43.6% of all twin pregnancies compared with 5.6% of singleton pregnancies in the Scottish Twin Study.[7] In the United States, there has been an increase in the preterm birth rate for twins, from 40.9% in 1981 to 55.0% in 1996.[8] Very preterm birth (birth <32 weeks) occurred in 6% of women with a twin pregnancy in South Australia in 1995.[9] The mean duration of pregnancy decreases as the number of fetuses in utero increases. The risks to the mother of a preterm birth relate to the need for hospitalization and the possible use of tocolytic therapy, with potential side effects. Premature rupture of the membranes occurs more frequently in multiple gestations, and preterm labor and birth are frequent sequelae.

Hypertension

The incidence of pregnancy-induced hypertension, preeclampsia, and eclampsia is increased in multiple pregnancy.[10–12] A primigravida with a twin pregnancy has a five times greater risk of severe preeclampsia than a primigravida with a singleton pregnancy, and for a multigravida, the risk is 10 times greater.[13] Some report a higher risk of hypertension with monozygotic twins,[10,14] but others do not.[15,16]

Antepartum Hemorrhage

Antepartum hemorrhage as a result of placenta previa[17] and placental abruption[18] is increased in multiple gestations.

Hydramnios

Hydramnios is suspected clinically in up to 12% of multiple pregnancies[19] and is associated with an increased risk of preterm labor. Acute polyhydramnios may occur, particularly with monoamniotic twins, and may cause significant abdominal discomfort for the mother. Hydramnios may be associated with TTTS (see Chapter 24).

Possible Need for Prenatal Hospitalization

With the increased risk of threatened preterm labor, hypertension, fetal growth restriction, and minor disorders of pregnancy, women with a multiple pregnancy often require hospital admission, sometimes for prolonged periods, during the prenatal period. For the mother, prolonged separation from her family is often a disruptive and stressful experience. Specific complications of twinning, such as TTTS or single fetal death, may require hospitalization.

Single Fetal Death in Twins

The risk of single fetal death in a multiple pregnancy is 2% to 6%. Psychological trauma may be considerable and is enhanced by concerns about the health of the surviving fetus or fetuses. The mother who experiences fetal death of one twin during the antepartum period must adjust to a future without one of the twins while developing a bond with the surviving twin. The mother also must adjust to the additional risk of death and morbidity from cerebral and renal lesions for the surviving twin (see Chapter 24).

Risk of Operative Vaginal Birth

Compared with a vaginal singleton birth, there is an increased likelihood of operative delivery for one or both twins, with the associated maternal risks of trauma, infection, and hemorrhage.

Increased Likelihood of Cesarean Birth

Twins are more frequently born by cesarean section than singletons, either as an elective procedure or as an emergency procedure before or after the birth of the first twin. Presentation and gestational age influence this likelihood.[20] The higher the order of multiple birth, the higher the likelihood of cesarean birth.[21]

Postpartum Hemorrhage

The risk of postpartum hemorrhage is greater in multiple pregnancy because of the increased placental site,

uterine overdistention, and a greater tendency to uterine atony.[11]

Postnatal Problems

Learning to cope with the demands of two or more infants can be stressful. A higher percentage of depression is reported in mothers of twins.[22] Given the increased perinatal mortality rate among higher-order multiple pregnancies, the problems of coping with the loss of one or more infants may be an added burden in the postnatal period.

Maternal Mortality

Women with a multiple pregnancy have a twofold increase in the risk of death compared with women with a singleton gestation.[11]

Fetal Risks (Table 60–2)

Stillbirth and Neonatal Death

In reports from Australia, the United Kingdom, the United States, Scandinavia, and Zimbabwe, multiple pregnancy contributed up to 10% of perinatal mortality.[7,23–27] The perinatal mortality rate in twins is up to 10 times that in singletons,[7,19,23,28,29] and if a broader concept of loss is used to include late abortion, late neonatal death, and infant death related to perinatal causes, the mortality risk is further doubled. Cause-specific mortality among twins is considerably higher for every major cause of death.[30] At all weeks of gestation, the risk of stillbirth and neonatal death is increased compared with singletons.[31] Same-sex twins have a poorer prognosis than opposite-sex twins.[29,32]

Higher mortality rates are reported for monochorionic compared with dichorionic twins,[33] although not by all.[34] For dichorionic twins, the risk of death increased

Twin entrapment
Cerebral palsy

throughout gestation, whereas the risk for monochorionic twins reached a maximum at 28 weeks' gestation and then remained constant.[34] In a review of 1051 twin pairs, factors associated with one or both twins dying in utero related to monochorionicity (odds ratio [OR], 2.0; 95% confidence interval [CI], 1.2–3.4) and discordant birth weight (OR, 4.3; 95% CI, 2.5–7.3), after correcting for gestational age at birth.[35]

Single Fetal Death in Twins (See Chapter 24)

Preterm Labor and Birth

Preterm birth (<37 completed weeks) is the main reason for the poor perinatal outcome in multiple pregnancy. All studies of perinatal mortality in multiple pregnancy agree that preterm birth is the greatest single threat to infants. The preterm birth rate in twin pregnancy varies among populations from 30%[36] to 50%.[37] Triplets have a higher risk of preterm birth than twins, up to 80%.[38,39]

The median gestational age at birth for monochorionic twins is 36 weeks compared with 37 weeks for dichorionic twins. However, 9.2% of monochorionic twins are born before 32 weeks' gestation compared with 5.5% of dichorionic twins (Fig. 60–1).[3]

Intrauterine Growth Restriction

The incidence of small-for-gestational-age infants (birthweight <10th percentile for gestational age standards in pregnancy) is common in multiple pregnancy. Rates vary between populations from 25%[37] to 33%.[40] These infants are at increased risk for perinatal mortality and morbidity. The risk of low birth weight is increased in monochorionic twin pregnancies.[41–43]

Fetal Problems Specific to Multiple Pregnancy

Major congenital abnormalities are more common in multiple pregnancies compared with singletons, with rates reported as 4.9%.[44] Several fetal problems are specific to multiple pregnancy, including conjoined twins (discussed later), twin reversed arterial perfusion sequence, monoamniotic twins, and TTTS (see Chapter 24).

Conjoined Twins

Conjoined twins is a congenital abnormality that occurs only in multiple pregnancy and affects 1 in 200 monozygotic twins.[45]

Cord Accident

Preterm birth, preterm prelabor rupture of the membranes, hydramnios, malposition, and malpresentation are more likely to increase the risk of a cord accident in multiple pregnancies than in singleton pregnancies.

FIGURE 60–1
Gestational age at birth for monochorionic and dichorionic twin pregnancies. (From Sebire N, Thornton S, Hughes K, et al: The prevalence and consequence of missed abortion in twin pregnancies at 10–14 weeks of gestation. BJOG 1997;104:847–848.)

Chorionicity

Chorionicity has an important effect on pregnancy outcome. Two thirds of monozygous twins are monochorionic and are at increased risk for mortality and morbidity compared with dichorionic twins. Risk factors include increased risk of TTTS, congenital anomalies, single fetal death in utero, and acute hydramnios (see Chapter 24).

Hydramnios

Hydramnios may occur in one gestational sac in both TTTS and the "stuck twin" phenomenon (see Chapter 24). It may be caused by fetal anomalies such as upper gastrointestinal tract atresias and hydrops fetalis, possibly as a result of congenital heart anomalies. In some cases of gross hydramnios in both sacs, no causal factor is evident. Hydramnios is a major cause of preterm birth because of increased intrauterine volume. The associated perinatal mortality rate is high.[46]

Risk of Asphyxia

The risk of mortality as a result of asphyxia in a twin is four to five times that in a singleton.[30] Important risk factors include the increased occurrence of intrauterine growth restriction, cord prolapse, and hydramnios.

Operative Vaginal Birth, Especially for the Second Twin

The likelihood of operative birth is increased, especially for the second twin, who may require internal podalic version. Operative birth is associated with an increased risk of birth trauma, low Apgar scores, and hyperbilirubinemia compared with a normal vaginal birth.

Twin Entrapment

Twin entrapment is rare and is reported to occur in 1 in 817 twin pregnancies.[47] The risk of fetal death of the first twin is high, as is the risk of fetal hypoxia in both twins. Twin entrapment is associated with monoamniotic twins.

Cerebral Palsy

The prevalence of cerebral palsy in triplets is 47 times that in singletons. The risk in twins is eight times that in singletons.[48] Lower gestational age at birth is associated with a greater risk of cerebral palsy.[49]

MANAGEMENT OPTIONS

Prepregnancy

The risk of multiple pregnancy for women undergoing ovulation induction is increased to 20% to 40%. After the use of clomiphene, the twinning rate is 5% to 10%.[50] Appropriate counseling about this increased risk should be provided to women who are offered this treatment. The risk of multiple pregnancy as a result of the use of assisted reproductive techniques correlates directly with the number of embryos or zygotes transferred, increasing from 1.4% when a single embryo is transferred with in vitro fertilization, to 17.9% after transfer of two embryos, and

24.1% after transfer of four embryos.[51] Similarly, the risk of multiple pregnancy after gamete intrafallopian transfer correlates with the number of oocytes transferred, with a risk of 18.7% after transfer of two oocytes and 25.8% after transfer of three oocytes.[51] The rate of multiple pregnancy at 20 weeks' gestation after zygote intrafallopian transfer with three zygotes is 27%.[52]

When deciding how many embryos, zygotes, or oocytes to transfer, a compromise between a wanted high conception rate and an acceptable risk of multiple pregnancy is necessary. The best way to reduce the risk of multiple pregnancy is to reduce the number of embryos, zygotes, or oocytes transferred after full discussion of the risks and benefits with the couple. Two randomized controlled trials compared single versus double embryo transfer,[53,54] and another compared double embryo transfer with transfer of four embryos.[55] In a meta-analysis of these trials, when single embryo transfer was compared with double embryo transfer, fewer women became pregnant (relative risk [RR], 0.69; 95% CI, 0.51–0.93), but the risks of twin pregnancy (RR, 0.12; 95% CI, 0.03–0.48) and low birth weight (RR, 0.17; 95% CI, 0.04–0.79) were markedly reduced.[56] No statistically significant differences were identified for outcomes relating to singleton pregnancy, pregnancy loss at less than 20 weeks' gestation, extrauterine pregnancy, or preterm birth at less than 37 weeks.[56] When the transfer of two embryos was compared with the transfer of four embryos, no statistically significant differences were seen in the number of women who became pregnant with a multiple or singleton pregnancy or the risk of pregnancy loss.[55] However, these trials were significantly underpowered to be able to detect all but large differences, and they did not report other important clinical outcomes.

Periconceptual folate supplementation is recommended as a general measure for all women to reduce the risk of neural tube defects.[57]

Prenatal

Overall Care

Regular antenatal attendance for pregnancy care is accepted practice. Most clinicians increase the number of times women with a multiple pregnancy are seen during the prenatal period. Many forms of care are practiced, ranging from modified shared care, with a general practitioner seeing the woman at the hospital for alternate prenatal visits, to seeing her weekly at the hospital prenatal clinic from 20 weeks' gestation. Specialized multidisciplinary twin clinics have been advocated, and some nonrandomized cohort data suggest that perinatal outcome can be improved by intensive preterm birth education, continuity of care providers, and individualized care.[58–60] Prospective randomized data are lacking.

Frequent prenatal visits permit extra vigilance in the early detection of pregnancy-induced hypertension.[61]

Routine screening for gestational diabetes is often performed, although evidence to support this practice is conflicting, with some reports suggesting an increased risk in twins and others suggesting no increased risk.[62,63]

Antepartum hemorrhage can be neither predicted nor prevented by additional prenatal visits or any other strategy. In addition, iron and folate supplementation is frequently advised from the beginning of the second trimester for women with multiple pregnancy, although the evidence to support this practice is limited.[5,6]

Diagnosis of Chorionicity by Early Ultrasound

Amnionicity and chorionicity can be determined by ultrasound.[64] Hazards for monochorionic twins include TTTS, and for monoamniotic twins, cord entanglement. Knowledge of amnionicity and chorionicity may be useful in predicting which pregnancies are at greater risk for TTTS or to differentiate TTTS from a twin pregnancy complicated by growth restriction. Similarly, this knowledge may be useful in the management of twin pregnancy when one twin has a major congenital malformation and selective termination is considered, or in the management of pregnancy after a single fetal death.[65] Screening for amnionicity and chorionicity is best performed in the first trimester, although it is not always easy, even for a skilled ultrasonographer.[66]

Monochorionic twins are the same sex and have one placental mass, with a thin dividing membrane (two amnions, no chorions) and a T insertion.[35,67] Because the dividing membrane is so thin, it is often difficult to identify, and the pregnancy may be misidentified as monoamniotic. Visualization of the dividing membrane is facilitated by searching over the fetal chin or away from the fetal body and around the limbs. A dichorionic placenta essentially eliminates the diagnosis of TTTS.

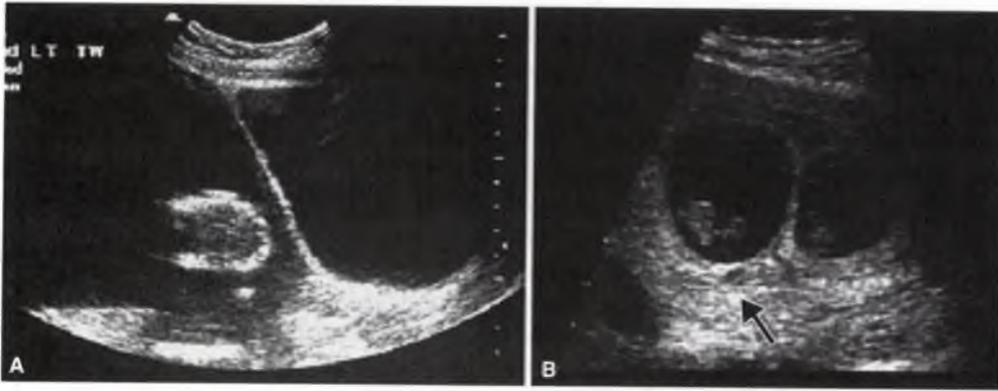
The dividing membrane is thicker in dichorionic twins than in monochorionic twins (contains two layers of amnion and two layers of chorion). Measuring the membrane thickness by ultrasound, using a cutoff of 2 mm to characterize a dichorionic or monochorionic placenta,[68] has been described as a good, but suboptimal, test for determining chorionicity.[66] High interobserver and intraobserver variation, together with differences related to gestational age and sampling site, lead to suboptimal accuracy of the determination of chorionicity.[67] Ultrasonic detection of the lambda sign[69] (an echogenic V-shaped chorionic projection of tissue between the dividing membranes in dichorionic placentation) is reported as more reliable, especially if the scan is performed at 10 to 14 weeks' gestation (Fig. 60–2).[70] As gestational age increases, the lambda sign is more difficult to see, and after 20 weeks, it may disappear. The lambda sign is also known as the twin peak sign.[71] Given the prognostic value for later risks of pregnancy, attempting to establish the chorionicity of the placenta between 10 and 14 weeks' gestation may be appropriate.


FIGURE 60–2
Ultrasonography to establish chorionicity. *A,* Monochorionic twin pregnancy. *B,* Dichorionic twin pregnancy showing the lambda sign (*arrow*).

Accuracy rates for determining chorionicity with first-trimester ultrasound, determined by subsequent pathologic examination, are reported as up to 96% with transabdominal sonography[72] and up to 100% with transvaginal sonography.[73]

No prospective clinical studies show that knowledge of chorionicity should alter subsequent clinical management or whether pregnancy outcome can be improved by changes in clinical care.

Nuchal Translucency Screening

The use of nuchal translucency screening for trisomy 21 and aneuploidy in singleton gestation is widespread, and it has been used to screen women with twin pregnancy. In a study of 448 women with twin pregnancy, nuchal translucency was measured for each fetus and combined with maternal age to derive a risk estimate. The detected nuchal translucency was greater than the 95th percentile for gestational age (using crown–rump length derived from singletons) in 7.3% of fetuses, including 88% of those with trisomy 21. These findings suggest that in dichorionic twin pregnancies, the sensitivity and false-positive rate of fetal nuchal translucency as a screening tool for trisomy 21 are similar to those reported for singleton pregnancies.[74] In monochorionic twin pregnancies, the false-positive rate of screening is higher than that reported in singleton pregnancies, and discordance in nuchal translucency measurements raise the possibility of early-onset TTTS.[75]

Pregnancy Reduction

Couples who are faced with the dilemma of a triplet or higher-order multiple pregnancy have several options. Termination of the entire pregnancy generally is not acceptable to women, particularly those with a history of infertility. Attempting to continue the pregnancy with all of the fetuses is associated with inherent problems related to preterm birth, survival, and long-term morbidity. Reduction in the number of fetuses by selective termination has been advocated in an attempt to reduce the risk of adverse obstetric and perinatal outcomes.[76] This practice involves intracardiac injection of potassium chloride (see Chapter 24). Many prospective nonrandomized studies have compared pregnancy outcome after multifetal pregnancy reduction in twins conceived spontaneously or after assisted reproduction[77–79] with multifetal pregnancy reduction in expectantly managed triplet pregnancies.[79–82] A systematic review assessed the effects of multifetal pregnancy reduction on fetal loss, preterm birth, and perinatal and infant mortality and morbidity rates in women with triplet and higher-order multiple pregnancies. This review included prospective nonrandomized studies, but excluded[83,84] case series, retrospective studies, and prospective studies that used historical controls as well as those in which selective fetal reduction was performed because of fetal anomaly. The overall quality of the included studies was poor, with inconsistent allocation of patients to treatment groups. However, when pregnancy was reduced to twins, the reported outcomes appeared comparable to those in twins conceived spontaneously or those conceived with assisted reproductive techniques (Table 60–3). Counseling these patients is further complicated by the varying preterm delivery rates and their consequences (Table 60–4). No randomized controlled trials have assessed multifetal reduction. The available nonrandomized studies provide limited insight into the benefits and risks associated with fetal reduction procedures.[84] Although a randomized controlled trial would provide the most reliable evidence, selective termination may not be acceptable to couples, particularly those with a history of infertility, and consequently, recruitment to such a trial may be exceptionally difficult.

Fetal Anomaly Scanning

A complete abdominal ultrasound scan performed by an operator with expertise in obstetric anomaly scanning is essential. The goals of midtrimester sonographic examination are to document fetal biometric discordance, seek evidence of discordant fetal anomalies or infection, and localize the placenta. The likelihood of a chromosomal

abnormality is increased greatly in the presence of a structural malformation.

Given the increased risk of congenital abnormalities, an anomaly scan of each fetus is suggested, usually between 18 and 20 weeks' gestation. In centers offering routine ultrasound scanning at this stage of pregnancy, undetected multiple pregnancy should be diagnosed. Early diagnosis allows appropriate counseling and planning for future care and has been reported to reduce perinatal loss related to twin pregnancy.[85] Conjoined twins can be diagnosed if an ultrasound scan is performed at this stage.

In one series, prenatal ultrasonography, including cardiac screening limited to the four-chamber view, resulted in the detection of up to 39% of all major congenital anomalies in twins.[86] However, none of the cardiac lesions were detected. Of major noncardiac anomalies, 55% were detected, as were 69% of major anomalies that could alter prenatal management.[86] In a retrospective study of 245 women with twin pregnancy, ultrasound screening for fetal anomalies identified a 4.9% prevalence of congenital malformations. For the detection of each individual anomaly, sensitivity was 82%, specificity was 100%, positive predictive value was 100%, and negative predictive value was 98%.[44]

Conjoined Twins

Conjoined twins are usually diagnosed antenatally.[87] Determination of the conjoined site permits multidisciplinary discussion before birth as to the prognosis and the possibility of surgical correction and allows full involvement of the parents. Unless birth is necessary for other reasons, preterm cesarean section is recommended. The use of steroids to stimulate fetal lung maturity is advisable. Some test for fetal lung maturity before birth. Many obstetricians recommend elective cesarean delivery at 38 weeks; however, this procedure can be difficult technically. Some recommend a classic incision, but this approach seems to offer little fetal benefit over a lower-segment incision and increases the maternal risks, particularly of uterine scar rupture in subsequent pregnancy. At delivery, two neonatal teams should be available, with the neonatal surgical team and operating room on standby.

Preterm Labor

Preterm labor and subsequent birth presents the greatest risk for fetal morbidity and mortality. Patient counseling as to the signs and symptoms of preterm labor may be of value, and parents should be given a written information

TABLE 60-4

Likelihood of Preterm Delivery and Subsequent Preterm Mortality and Neurodevelopmental Morbidity (NDM) Rates in Unreduced Triplets (URT) and Triplets Reduced to Twins (TWN)

sheet. If uterine activity is noted, the woman should go to the hospital promptly.

It is difficult to predict which patients will have preterm labor. Cervical assessment by either digital[88–90] or ultrasound examination[91–94] has been suggested as a useful way to evaluate the risk of preterm delivery. How frequently such an assessment should be made (e.g., weekly, every 2 weeks, monthly) is uncertain, and whether such assessment is more beneficial than harmful is not known. Cervical assessment allows calculation of the cervical score (cervical length [in centimeters]—cervical dilation [in centimeters]). A cervical score of 2 or less at or before 34 weeks' gestation has a positive predictive value of 75% for preterm birth,[89] with other authors reporting that a cervical score of 0 or less has a positive predictive value of 75% for preterm birth.[90] As part of a study of the prediction of preterm delivery, cervical length was prospectively assessed by ultrasound in 147 women with a twin pregnancy. A short cervix (<25 mm) was consistently associated with spontaneous preterm birth at less than 32 weeks' gestation (OR, 6.9; 95% CI, 2.0–24.2), less than 35 weeks' gestation (OR, 3.2; 95% CI, 1.3–7.9), and less than 37 weeks' gestation (OR, 2.8; 95% CI, 1.1–7.7).[91]

The presence of fetal fibronectin in cervical secretions has been used to predict preterm birth.[91,92] In multiple pregnancy, a positive fetal fibronectin test result at 28 to 30 weeks was associated with preterm birth before 32 weeks' gestation.[91] A positive fetal fibronectin test result at 28 weeks' gestation predicted birth before 35 weeks, with sensitivity, specificity, positive predictive value, and negative predictive value of 50.0%, 92.0%, 62.5%, and 87.3%, respectively.[92] The ability of fetal fibronectin to predict very preterm birth requires ongoing prospective evaluation to determine whether such prediction can lead to effective interventions that would reduce the risk of preterm birth.

If cervical change is noted, hospital admission is the most generally accepted management. Routine hospital admission and subsequent rest, however, seem to offer little benefit in delaying labor.[95,96] It is unknown whether prophylactic tocolysis is of value in this identifiable group at high risk for preterm birth.

Several prenatal interventions have been tried to reduce the risk of preterm birth in multiple pregnancies and have been evaluated by randomized clinical trials. These include prophylactic cervical cerclage,[97,98] prophylactic β-mimetic agents,[99,100] bed rest in the hospital,[95] and home uterine activity monitoring.[101,102] However, none of these have proven to be of value in reducing the incidence of preterm birth and the associated high perinatal mortality rate in multiple pregnancy.

Prophylactic cervical cerclage in twin pregnancy does not show benefit when the results of randomized trials are reviewed.[103] It seems prudent to reserve the insertion of a cervical suture for women with evidence of cervical incompetence. Prophylactic tocolytic agents are occa-

sionally used in multiple pregnancy. Systematic review of randomized trials of prophylactic β-mimetics does not show a benefit in the incidence of preterm labor,[104] and their use cannot be recommended.

Admission of women with an uncomplicated twin pregnancy to the hospital for rest does not reduce the risk of preterm birth. The Cochrane systematic review of randomized trials of routine hospitalization for rest shows an increased likelihood of preterm birth in women who were admitted, compared with control subjects who continued normal activity at home.[105] Hospital admission for rest in an uncomplicated twin pregnancy should be considered only if the woman requests admission. Women may request hospital admission for several reasons, including discomfort, difficulty coping at home, or living a significant distance from the hospital.

The value of hospital admission for rest in triplet or higher-order multiple pregnancy is uncertain. Only one small randomized study has been done. In this study, hospitalization for rest showed a beneficial trend in reducing the incidence of preterm delivery in 19 triplet pregnancies. In addition, the hospitalized group had infants with higher birth weight.[106] All of these benefits are also compatible with chance variation. A multicenter trial is needed to evaluate further the effects of hospital admission for rest in triplet pregnancy.

Home uterine activity monitoring (HUAM) has been suggested to permit the diagnosis of preterm labor at an early stage, allowing successful tocolysis and fewer preterm births. A small randomized trial of 45 women reported these benefits.[101] However, in subgroup analysis of the 844 twin gestations in a multicenter trial comparing HUAM with weekly or daily nursing contact, HUAM did not reduce the risk of preterm birth.[102] HUAM, when combined with daily nursing contact, resulted in more unscheduled visits and increased use of tocolytics.

A course of prenatal corticosteroids should be given to improve fetal outcome in women with multiple pregnancy who are considered at risk for preterm birth at less than 34 weeks, if birth is planned or if there is a high risk of birth within the next 48 hours.[107] Whether a larger dose of corticosteroids than that given in singleton pregnancies would be more beneficial in twin gestations has been suggested but not adequately assessed.[107] The efficacy of repeat doses of steroids is uncertain in women with multiple pregnancy who have not been delivered 7 or more days after a first course of steroids but are still at high risk for preterm birth. This issue is being addressed by ongoing randomized trials in Australia, New Zealand, Canada, the United States, and Scandinavia.

Fetal Assessment

Fetal assessment during pregnancy includes regular ultrasound to determine fetal growth and well-being. The recommended frequency of scanning varies (e.g.,

from every 2 weeks from 24 weeks' gestation to every 3 to 4 weeks from 20 weeks' gestation). Umbilical artery Doppler improves pregnancy outcome in high risk pregnancy, and is often included as part of routine fetal assessment.[108] Some centers suggest obtaining biophysical profiles from 30 weeks' gestation, although the evidence to support this strategy is not strong.

The use of umbilical artery Doppler studies in the assessment of twin pregnancy was evaluated in three randomized controlled trials.[109–111] Giles and colleagues[111] randomly allocated 526 women with a twin pregnancy at 25 weeks' gestation to biometry only or to biometry and umbilical artery Doppler waveform at 25, 30, and 35 weeks' gestation. This study of close antenatal surveillance identified a lower than expected fetal mortality rate from 25 weeks' gestation in both the biometry alone and combined biometry and Doppler groups.

Maternal Education and Support

During the prenatal period, the couple will need specific information and support to help prepare for the birth and care of their infants.[25] The most likely mode of birth, care in labor, and the use of analgesia, especially epidural, should be discussed.[112] Many countries have multiple pregnancy support groups. The opportunity to contact a local group during the prenatal period, attend meetings, and make personal contact with other families who have had a multiple birth is recommended.

Labor and Delivery

Birth in a hospital is accepted practice,[113] with many advising birth in a tertiary unit, when possible. Induction of labor may be indicated for complications such as preeclampsia or growth restriction. The benefit of elective birth at 37 weeks' gestation to reduce the risk of antepartum stillbirth as a result of intrauterine growth restriction is controversial.

Retrospective data suggest that the lowest rate of perinatal mortality and morbidity in twin pregnancies occurs at 36 to 38 weeks' gestation, with the risk of adverse outcome increasing as gestation advances.[31,114–118] A recent Cochrane systematic review of the role of elective birth in twin pregnancy from 37 weeks' gestation[119] identified a single small randomized controlled trial from Japan[120] assessing elective birth with continued expectant management. This study identified no statistically significant differences. However, the sample size was underpowered to detect meaningful differences, and insufficient data are available to support the practice of elective birth from 37 weeks' gestation in women with an otherwise uncomplicated twin pregnancy. A multicenter randomized controlled trial is in progress, coordinated by the Maternal Perinatal Clinical Trials Unit at the University of Adelaide, to assess the optimal timing of birth in women with twin pregnancy at term.

Intrapartum blood loss is greater in multiple pregnancy, as is the risk of postpartum hemorrhage. An intravenous access line should be inserted early in labor and blood obtained to estimate maternal hemoglobin or hematocrit and to hold serum for crossmatching, if needed later.

For a vaginal birth, both twins should be monitored continuously.[113] Initially, only external fetal monitoring will be possible. When feasible, a scalp electrode should be placed on the first twin, with continuation of external monitoring of the second twin. The use of a twin fetal heart rate monitor allows simultaneous recording of the two fetal heart rate tracings. If continuous monitoring of the second twin is impossible, some recommend cesarean section because of the higher risk of fetal asphyxia in twins, which may go undetected without adequate monitoring.

Epidural analgesia is widely used, providing the mother with adequate pain relief, and minimizes the risk that she will push before full dilation occurs.[113] In addition, adequate analgesia is provided in the event that operative birth, internal podalic version of the second twin, or cesarean delivery is needed. The widespread use of epidural anesthesia often negates the need for emergency general anesthesia with the complications discussed earlier, although it may still be needed for emergency cesarean section for fetal distress.

The optimal mode of birth in multiple pregnancy is controversial.[121] For triplets and higher-order multiple gestations, the most frequent mode of delivery is cesarean section,[122–124] although no randomized studies are available to support this mode of birth over vaginal birth. Reports suggest that the risk of lower Apgar scores in higher-order multiple gestations is reduced with cesarean delivery[38,125]; in addition, there are fewer perinatal deaths.[38]

Neonatal respiratory disease was more common in twins born by cesarean section at 36 to 38 weeks than in those born vaginally at 38 to 40 weeks.[126] A more recent report suggested higher perinatal mortality rates with cesarean delivery, primarily as a result of respiratory distress syndrome.[127]

The Cochrane systematic review of the mode of birth for the second twin[128] identified a single randomized trial[129] comparing planned vaginal birth with planned cesarean birth for the second, nonvertex twin. This study highlighted the need for further evidence from randomized controlled trials to inform practice. To provide more reliable information about the optimal mode of birth for women with twin pregnancy, a randomized controlled trial (Twin Birth Study) is in progress, coordinated by the University of Toronto, Maternal, Infant and Reproductive Health Research Unit, at the Centre for Research in Women's Health.

Based on the literature on twin pregnancy, some recommendations can be made. The mode of birth is often affected by the presentation of the twins, which may be divided into the following three groups:

- First twin vertex, second twin vertex
- First twin vertex, second twin nonvertex
- First twin nonvertex

First Twin Vertex, Second Twin Vertex

The most common presentation of twins is vertex–vertex. In this case, most obstetricians recommend vaginal birth,[130–133] and the literature supports vaginal birth, even of very low-birth-weight infants (<1500 g).[131,134,135]

First Twin Vertex, Second Twin Nonvertex

For twins presenting as first twin vertex, second twin nonvertex, opinion is divided as to the optimal mode of birth. Some recommend elective cesarean delivery,[132,136] reporting reduced neonatal mortality and morbidity rates for the second twin. Others suggest that there is no increase in neonatal risk associated with vaginal birth of the second twin weighing 1500 g or more, either as breech presentation after internal podalic version if the fetus does not have a longitudinal lie, or as cephalic presentation after external cephalic version.[137–142] The only randomized study found no difference in neonatal outcome in 60 nonvertex second twins at 35 weeks' gestation or more. Study subjects were randomly allocated to either vaginal delivery or cesarean section.[129,143] Assessment of whether vaginal breech delivery is appropriate is necessary using the standard criteria for singleton birth. These include exclusion of cephalopelvic disproportion, estimated fetal weight of less than approximately 3500 g, and the finding of a flexed fetal head on ultrasound.

For a nonvertex second twin of very low birth weight (<1500 g), the mode of birth is controversial. Some recent reports recommend cesarean delivery to minimize birth trauma to the preterm infant,[131,137,139,140,144] whereas others show no neonatal benefit and emphasize that vaginal delivery has reduced risks for the mother.[134] No randomized studies have compared vaginal and cesarean birth in these infants.

First Twin Nonvertex

When the first twin is nonvertex, cesarean delivery is often preferred[121,133] and advised,[131] although no series suggests that vaginal birth is inappropriate. It is likely that this approach is influenced by the data on the optimum mode of delivery in singleton breech presentations (see Chapter 64). By following such a policy, the risk of twin entrapment by interlocking chins or heads can be avoided.

PROCEDURE

TWIN BIRTH

For a vaginal twin birth, at least one experienced obstetrician, anesthetist, pediatrician, and neonatal nurse should be in attendance. Depending on gestational age (e.g., if preterm) and circumstances (e.g., operative birth, abnormal CTG findings), a double pediatric team (two pediatricians and two neonatal nurses) may be appropriate. For higher-order multiple births, one pediatric team should be present for each infant. Some recommend having a nurse scrubbed and the operating room prepared for emergency cesarean section.

For a vaginal birth, delivery of the first twin should be as for a singleton. After the birth of the first twin, an experienced obstetrician assesses the lie and presentation of the second twin. This assessment can be done by vaginal examination, abdominal palpation, or transabdominal ultrasound examination. The lie should be corrected to longitudinal by external version or internal podalic version.[145] External version (Fig. 60–3) gently turns the fetus so that the vertex lies above the pelvic brim. Amniotomy can be performed if there are uterine contractions (discussed later), and then delivery is completed. Version is more likely to be successful with epidural anesthesia and when the twins are of similar weight (difference of <500 g).[138]

In two series, external version was less likely than breech extraction to result in a vaginal birth.[140,146] Emergency cesarean section and complications such as cord prolapse and fetal distress were more frequent in the external version group. Although these were not randomized studies, in view of these findings, internal podalic version, if necessary, and breech delivery are recommended by some obstetricians if the lie is nonlongitudinal or the breech is presenting. However, others prefer to use external cephalic version and perform amniotomy once the lie is longitudinal and there are regular uterine contractions. They advocate cesarean delivery if the lie remains nonlongitudinal. Oxytocin (Syntocinon) infusion is mandatory if there is uterine inertia, and it is normal practice in many units to

FIGURE 60–3
Modified external version for delivery of the second twin.

have an infusion ready at the onset of the second stage of labor. Once there are contractions and the lie is longitudinal, amniotomy is performed and birth proceeds with maternal effort during contractions. A scalp electrode can be applied after amniotomy to permit continuous fetal heart rate monitoring, or an external monitor can be used. Most authors advise continuous monitoring of the second twin throughout the second stage of labor, given the increased risk of intrapartum asphyxia. The risk of fetal distress and acidosis is increased if the twin–twin delivery interval exceeds 30 minutes.[147] If fetal distress develops and birth cannot be achieved safely, or if the second twin does not descend into the pelvis, emergency cesarean delivery is necessary.

After birth of the second infant, active management of the third stage of labor is recommended with an oxytocic agent.[148] To prevent uterine atony, in many units, infusion of oxytocin is continued for 3 to 4 hours.

Internal podalic version with vaginal breech delivery remains an option for birth of the second twin when a non-longitudinal lie persists and the membranes are intact (Fig. 60–4). This approach involves the following steps:

- Use adequate analgesia, usually epidural, but possibly a general anesthetic.
- Place the patient in the lithotomy position.
- Provide continuous fetal heart rate monitoring.
- Use aseptic technique, and catheterize the patient.
- Ensure that a pediatrician is present.
- Determine the lie of the second twin by abdominal palpation, internal examination, or transabdominal ultrasound examination.
- Locate a fetal foot. Confirm that the structure is a foot rather than a wrist by palpating the heel.
- Perform an amniotomy.
- Grasp the foot, and pull down into the vagina. Grasp both feet, if possible.
- With maternal effort during contractions, deliver the fetus as an assisted breech.

Complications

Complications include the following:
- Fetal anoxia
- Difficulty with delivery of the head with breech presentation
- Fetal trauma as a result of breech delivery (e.g., dislocated hips)
- Inadvertent delivery of a hand with shoulder presentation
- Placental abruption
- Cord accident
- Endometritis
- Maternal trauma (e.g., ruptured uterus)

Twin Entrapment

Twin entrapment may occur if the first twin is delivered as a breech and the second twin is cephalic and the head of the second twin enters the pelvis before the head of the leading

FIGURE 60–4
Internal podalic version.

twin. Some maintain that the risk of twin entrapment can be avoided by performing elective cesarean section if the first twin is breech and the second twin is cephalic. In an emergency, an attempt may be made to separate the locked twins by passing a hand vaginally between the chins of the fetuses and pushing the second twin upward. If this attempt fails,

emergency cesarean section is necessary. Alternatively, an attempt may be made to push back the first twin, presenting as a breech, and allow the "second" twin, presenting cephalically, to deliver first. Again, if this attempt fails, emergency cesarean delivery is necessary.

During cesarean section, the head of the first twin is maneuvered upward, enabling birth of the second twin's head and body. The "first" twin may then be delivered. Some recommend having a second obstetrician available to manipulate the infants vaginally, if necessary.

If the first twin is already dead, rather than cesarean birth, there is the option of decapitation of the first twin, vaginal delivery of the second twin, and delivery of the head of the first twin. Such a destructive procedure should be performed under general anesthesia to protect the mother from seeing it. Many believe that this option should not be used in modern obstetrics, and some would argue that abdominal delivery may be associated with a lower incidence of perinatal asphyxia for the second twin.

Complications

In twin entrapment, the risk of fetal death of the first twin is high, as is the risk of fetal hypoxia for both twins. Maternal risks relate to the need for emergency cesarean section, endometritis, and the possible need for general anesthesia.

Postnatal

After the birth of twins, the mother may require a prolonged hospital stay. Breastfeeding should be encouraged, and additional support is important. The provision of adequate contraception is necessary and should be discussed. Coordinated support to help the parents care for their infants should be available.[25]

Before discharge, if extra help is not available at home, additional community support may need to be arranged. Maintaining contact with the local multiple birth support group during the puerperium is important.

CONCLUSIONS

- Multiple pregnancy is associated with maternal and fetal risks.
- Prepregnancy care centers on avoiding multiple conceptions in women who undergo assisted reproductive techniques.
- Early prenatal care focuses on determining chorionicity and diagnosing fetal anomalies.
- Later prenatal care is directed toward the prevention, prediction, and detection of preterm birth and intrauterine growth restriction.
- The optimal timing and mode of delivery in twins are not clear, and the results of ongoing multicenter randomized trials are awaited.

SUMMARY OF MANAGEMENT OPTIONS
Multiple Pregnancy

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy			
Counsel women who are undergoing assisted conception techniques about the risks of multiple pregnancy.	III	B	32, 52
No data are available to guide the "ideal" number of embryos or oocytes to replace.	Ia	A	56
Preconceptual and periconceptual folate supplementation	Ia	A	57
Prenatal			
Specialized twin clinics may lessen adverse outcomes. Little evidence supports other forms of prenatal care.	III	B	58–60
Documentation of zygosity or chorionicity at 10 to 14 weeks	III	B	70

Continued

Multiple Pregnancy *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
No prospective data on whether this documentation improves outcome			
Increased surveillance if twins are monozygous or monochorionic	IIb	B	41
Monochorionic twins are at increased risk for adverse outcome.			
No prosopective data on whether increased surveillance improves outcome			
Iron and folate supplementation from the second trimester	IIb	B	6
Screening for hypertension	IIa	B	61
Conflicting evidence of the value of screening for gestational diabetes	IIa	B	62, 63
Nuchal translucency measurement of each fetus identifies fetuses at risk for trisomy 21, cardiothoracic abnormalities, and twin–twin transfusion syndrome	III	B	74
Routine anomaly ultrasound scan at 18 to 20 weeks	III	B	44
Conjoined twins:	III	B	87
• Careful ultrasonographic evaluation of anatomy			
• Interdisciplinary discussion of therapeutic options			
Vigilance for early symptoms of preterm labor; prompt self-referral if it is suspected	Ib	A	101
Possible ultrasound assessment of cervical changes and fetal fibronectin as part of preterm delivery screening	IIa	B	91
Prenatal corticosteroids preterm birth before 34 weeks is possible	Ia	A	107
No evidence that hospitalization to prevent preterm labor and delivery is effective	Ia	A	105
No evidence that prophylactic cervical cerclage is effective to prevent preterm labor and delivery	Ia	A	103
Regular fetal ultrasound assessment of growth and umbilical artery Doppler	Ib	A	111
Hospitalization at the woman's request or if complications are detected	Ia	A	105
Consider therapeutic amniocentesis (repeated if necessary) for extreme hydramnios and maternal distress.	IIb	B	46
Prenatal education about the possible modes of delivery, analgesia, and care in labor	IV	C	112
Labor and Delivery			
Hospital delivery	III	B	113
Experienced obstetrician and other health professionals	III	B	113
Await spontaneous labor if no complications occur.	Ia	A	119
Pediatrician neonatal nurse, and anesthetist available at delivery, with one pediatrician per infant present if preterm or operative delivery or fetal problems are anticipated	—	GPP	—
Continuous monitoring of all fetuses during labor	III	B	113
IV access	—	GPP	—
Epidural analgesia recommended	III	B	113
Aim for vaginal delivery unless the leading twin has a nonlongitudinal lie.	III	B	126, 134
Some advocate elective cesarean delivery if the first twin is not cephalic.	III	B	126, 134
Vaginal delivery of the first twin, if appropriate	III	B	134
Synthetic oxytocin infusion for uterine inertia, especially after the first twin is delivered	—	GPP	—

SUMMARY OF MANAGEMENT OPTIONS
Multiple Pregnancy (Continued)

Management Options	Quality of Evidence	Strength of Recommendation	References
If the second twin has a longitudinal lie, amniotomy and delivery	III	B	145
If an infant has a nonlongitudinal lie, convert to a longitudinal lie by external version or internal podalic version.	III	B	145
Prophylactic oxytocin infusion after delivery to reduce the risk of postpartum hemorrhage	Ia	A	147
Some advocate elective cesarean delivery for triplets and higher-order births	IIb	B	127
Postnatal			
Extra support while in the hospital to assist with infant care	—	GPP	—
Offer longer in-patient stay.	—	GPP	—
Arrange support at home.	—	GPP	—
Provide adequate contraceptive advice.	—	GPP	—

Screening for Spontaneous Preterm Labor and Delivery

Robert Ogle / Jonathan Hyett

INTRODUCTION

Preterm birth is associated with significant perinatal morbidity and mortality rates. Adverse outcomes from preterm birth include cerebral palsy, developmental delay, chronic lung disease, and visual and hearing loss. About 40% of preterm births follow idiopathic preterm labor, 35% follow preterm prelabor rupture of membranes, and the remainder are iatrogenic because of obstetric or medical indications.[1] The early detection of preterm labor or preterm rupture of membranes in traditional antenatal care is often problematic because symptoms or signs may vary only a little from the normal physiologic symptoms and signs of pregnancy. The criteria for diagnosis of preterm labor, defined by the onset of increasingly frequent and painful uterine contractions with progressive effacement and dilation of the cervix, can be assessed most accurately once contractions occur at least once every 10 minutes, there is 80% cervical effacement, and the cervix is at least 3 cm dilated.[2,3] However, the patient may frequently present with relatively mild symptoms and signs suggestive of labor, which may be features of normal pregnancy.[4] Using lower thresholds for contraction frequency and cervical change will therefore affect the sensitivity and positive predictive value of clinical assessment for detection of preterm labor.

Prediction of preterm birth would ideally involve a screening test with high sensitivity and high negative predictive value. It should also enable effective intervention if the test gives a positive result. The screening tools and interventions that are currently available have not enabled obstetricians to decrease the incidence of preterm birth and do not satisfy the requirements of an optimal screening test. However, they may allow time for transfer of a pregnancy at risk to an appropriate tertiary referral center, as well as the administration of glucocorticoids to enhance fetal lung maturity and antibiotic prophylaxis to reduce the risk of neonatal sepsis.

A wide variety of screening tools have been evaluated in research, and those most extensively evaluated fall into four groups:

- Monitoring of uterine activity
- Assessment of cervical length
- Measurement of cervical fetal fibronectin
- Presence of bacterial vaginosis in early pregnancy

Other forms of screening have been looked at in small series and include estimation of estriol, interleukins, ferritin, and corticotropin-releasing hormone, but findings in relation to these measures have not been consistently associated with preterm labor. This chapter will review the four major areas of screening and evaluate their effectiveness in screening for preterm labor and preterm rupture of membranes.

MONITORING UTERINE ACTIVITY

If the onset of increasingly frequent and painful uterine contractions precedes effacement and dilation of the cervix, then assessment of uterine activity may identify pregnancies at risk of preterm delivery at an early stage of preterm labor, allowing effective intervention.

The simplest method for assessing uterine activity relies on teaching the patient to palpate and record her own contractions. Increased uterine activity appears to precede a clinical diagnosis of preterm labor by less than 24 hours.[5] Most obstetricians using this technique would therefore advise the patient to monitor her own contractions for an hour twice a day. Although this technique has the advantage that it does not involve any expensive equipment, it is completely subjective and has been shown to have poor sensitivity, with 89% of women palpating less than 50% of their contractions.[6] In addition, the process of monitoring is time-consuming, is generally limited to high risk groups, and potentially increases patient anxiety, which is itself associated with an increased risk of preterm delivery. This issue applies equally to other forms of uterine activity monitoring; indeed, these techniques require intense patient support through a process of education, analysis of results, and encouragement to continue monitoring on a regular

basis, and it has frequently been suggested that it is this support that leads to an improvement in outcome more often than the process of monitoring itself.[7]

A more objective approach to uterine activity monitoring involves tocography, monitoring activity indirectly via a pressure transducer attached to a recording device and placed against the maternal abdominal wall. Early studies with this technique demonstrated that normal uterine activity increases with advancing gestation and is more pronounced at night. Uterine activity was monitored in a series of 109 low risk pregnancies that delivered at term; the 95th percentile was 1.3 contractions per hour at 21 to 24 weeks, 2.9 contractions per hour at 28 to 32 weeks, and 4.9 contractions per hour at 38 to 40 weeks.[8] It was found that 96% of recordings had less than 4 contractions per hour, and this threshold is often used to define a risk of preterm labor. An early case control study recruited 76 women at high risk of preterm labor to assess whether daily ambulatory home uterine monitoring could facilitate an early diagnosis of preterm labor and compared them to 76 matched control subjects.[9] The rates of threatened preterm labor were similar in the study and control groups (51% vs. 45%), but the cervix was significantly less effaced and dilated and there were no cases of ruptured membranes at the time of diagnosis in the monitored group. Consequently, all cases were considered suitable for long-term tocolytic therapy, and the preterm delivery rate was lower in the monitored group (22%) than in the control group (41%).

Although this initial series appeared to give encouraging results, there are several problems with this technique. Few studies have validated the instrumentation used in home monitoring. Those that have been performed suggest that patients are readily able to use the machines, that home machines appear to be of similar sensitivity as hospital machines, and that they detect more than 90% of contractions recorded by an intrauterine pressure catheter during normal term labor.[10–12] However, the sensitivity and specificity of the tocometer vary according to its position, the tension on the belt, and the thickness of the maternal abdominal wall, so the amplitude of the waveform seen on a tocogram cannot be related to the strength of uterine activity. Data interpretation is also subject to observational error, with one study finding that the results were interpreted reliably in only 70% of cases by a single observer.[13]

Perhaps more important, monitoring uterine activity does not lend itself to screening a low risk population; the equipment is relatively expensive, monitoring is time-consuming, studies need to be repeated regularly for many weeks of pregnancy, and data analysis requires a skilled health care professional. The technique is, therefore, suitable only for pregnancies deemed to be at high risk for preterm labor. Many randomized controlled trials have evaluated the use of home uterine activity monitoring in such high risk pregnancies. The first six series were reviewed in a meta-analysis that accessed previously unpublished data from the study groups and defined four outcome measures: incidence of preterm birth, incidence of preterm labor with a cervical dilation of over 2 cm at diagnosis, neonatal admission to intensive care, and mean birth weight.[7,14–19] The meta-analysis, presenting data from six studies on a total of only 697 pregnancies, concluded that home uterine monitoring in singleton pregnancies was associated with a 24% reduction in preterm birth, a 52% reduction in "late presentation" with cervical dilation greater than 2 cm, and a significant mean increase in birth weight of 126 g. There was, however, no difference in the admission rate to neonatal intensive care.[20] This analysis was controversial, however, as a previous analysis had suggested serious methodologic deficiencies in some of the studies, had found no significant benefit of monitoring, and concluded that it should not be used clinically without further validation.[21]

One of the criticisms of early trials of home uterine monitoring was that the increased level of support that the monitored patients received may have been responsible for any improvement seen in the outcome. Three trials addressed this possibility, one using a sham monitor but offering all patients nursing support, the second offering monitoring without any nursing support, and the third randomly assigning patients to both nursing support and home monitoring.[22–24] The first of these studies randomized 1992 women, 1165 of whom used home monitoring devices, but only 842 (72.3%) of them completed the study, suggesting that there may be difficulties with compliance when home monitoring devices are used for wider indications. The study concluded that there was no evidence that either home uterine activity monitoring or daily nursing contact improved early diagnosis of preterm labor or reduced the rates of preterm birth or neonatal morbidity.[22] In contrast, the second, smaller study ($n = 218$), which also had a significant dropout rate in monitoring (15% did not complete the monitoring), found that the diagnosis of preterm labor could be made significantly earlier and that this affected the outcome, measured in terms of the interval between the diagnosis of labor and delivery, and was independent of nursing support.[23] However, the third study, which randomly assigned 2422 women to combinations of nurse contact and home monitoring concluded that neither daily contact nor home monitoring improved pregnancy outcome beyond that seen with weekly nurse contact.[24]

Because little evidence indicates that home uterine monitoring is a useful screening tool for preterm labor, the number of studies examining its role has dropped significantly over the last few years. During this time, interest in other markers for preterm delivery, such as sonographic assessment of the cervix and measurement of fetal fibronectin has grown. Consequently, the recent data sets that review home uterine monitoring are often acquired in trials primarily designed to assess other screening tests or a combination of screening tools.

Although most of the original trials defined preterm delivery before 37 weeks as their end point, most recent data sets are concerned with delivery before 34 weeks' gestation. Morrison and associates assessed 85 asymptomatic women at high risk of preterm labor with both serial fetal fibronectin measurement and home uterine monitoring.[25] They reported that 14 (16.5%) of the 85 women delivered before 34 weeks and the sensitivity and specificity of fetal fibronectin and home uterine monitoring alone were 43% and 89% (fetal fibronectin) and 64% and 85% (home uterine monitoring alone). When the two tests were combined, the specificity improved substantially but the sensitivity of a double positive result was poor (3 of 14 cases: 21%), so they are not usefully combined in this manner.

Most recently, home uterine monitoring was used to assess the risk of preterm labor in 306 high risk singleton pregnancies.[26] These patients were also seen regularly at the hospital for serial assessment of fetal fibronectin and for sonographic assessment of the cervix. All three investigations had a low sensitivity and poor positive predictive value for preterm delivery. The authors concluded that although the likelihood of preterm delivery is associated with an increased frequency of uterine contractions, assessment is not clinically useful for predicting preterm delivery.

CERVICAL SCREENING

Ultrasound assessment of the cervix in normal pregnancy shows that cervical effacement starts around 32 weeks. In pregnancies affected by preterm labor, the process may begin between 16 and 24 weeks. Effacement begins at the internal os and can be visualized as cervical shortening and funneling, a process that occurs before dilation of the external cervical os. Ultrasound assessment potentially allows changes other than cervical dilation to be assessed with a higher degree of accuracy, and using a transvaginal route, assessment is possible in virtually all cases.[27,28]

Ultrasound assessment of the cervix has been used in a variety of situations to improve the accuracy of a diagnosis of preterm labor and to predict the likelihood of a woman going into preterm labor. Screening has been studied in both high and low risk populations, and because the prevalence of preterm labor varies in these groups, these data sets are considered separately. A variety of techniques have been used to assess the cervix with ultrasound, and the multitude of studies describing the use of this test are heterogeneous in design, assessing the cervix at different stages of pregnancy, using either single or serial examinations, and choosing varying gestational ages at delivery to report the sensitivity and specificity of the test. A recent meta-analysis of antenatal transvaginal ultrasound assessment of the cervix identified 46 studies involving 31,577 pregnancies describing the effectiveness of this screening technique.[29] The review concluded that assessment of both cervical length and funneling, either alone or in combination, appeared to be useful in predicting spontaneous preterm birth in asymptomatic women, although there was less data available to assess the usefulness of this technique in symptomatic patients.

Ultrasound Measurement of the Cervix

One of the problems with comparison of studies measuring cervical change is a lack of standardization of the investigational technique. Most sonographers assess the cervix using a transvaginal scan, but transabdominal and transperineal routes can also be used. The cervix may be curved, and there may evidence of funneling; it is important to establish a method that allows for these differences in a consistent manner. The cervix is a dynamic structure, and measurements are affected by factors such as bladder filling and abdominal pressure.

A standardized technique for transvaginal cervical assessment has been described.[30] After the patient has emptied her bladder, a transvaginal probe (5–7 MHz) is introduced into the anterior fornix of the vagina, taking care to optimize image quality while avoiding undue pressure on the cervix that will distort anatomy. The whole length of the sonolucent endocervical mucosa is identified in a sagittal section, and the image is magnified so that this occupies 75% of the screen. Calipers are placed from the triangular echodense area marking the external os to the V-shaped indentation marking the internal os, and this distance is measured in a straight line. Three measurements are made over a period of 3 minutes to allow for any change in the state of the cervix, and the shortest measurement is reported. This technique allows clear views of the cervix and lower uterine segment and is acceptable to the majority of patients.

For women who do not find transvaginal sonography acceptable, or in circumstances in which vaginal examination ideally would be avoided (such as preterm prelabor rupture of membranes), alternative techniques such as transabdominal or transperineal/translabial assessment may be used. The limitations of these techniques, however, must be recognized. Transabdominal cervical assessment in 149 low risk singleton pregnancies at 23 weeks' gestation demonstrated that it was harder to visualize the cervix as it became shorter: a cervical length of less than 20 mm could be identified only 13% of the time, while a cervical length greater than 40 mm could be identified 51% of the time. In addition, the cervix was significantly easier to visualize when the bladder was fuller, but this state is associated with an artificial increase in the length of the cervix.[31] Visualization can also be difficult using a transperineal/translabial approach, and there is some evidence that the "operator learning curve" with this technique is substantial, making it a less appropriate test for screening.[32] Many authors have reported a poor correlation between transvaginal and transperineal/translabial techniques, making interpretation of data more difficult.[32-34] Cervical length in a low risk population is

normally distributed, with a mean length at 23 weeks' gestation of 35 to 38 mm; the 10th and 90th percentiles are approximately 25 mm and 45 mm, respectively.

Other cervical parameters have also been investigated. In many circumstances, a sagittal section of the entire length of the endocervical canal shows that it is in fact curved, and direct measurement from the internal to external os does not take this curvature into account. In these circumstances, cervical length would be undermeasured, and there would be a potential for false-positive screening results. To and associates investigated this in a prospective series of 300 singleton pregnancies undergoing transvaginal cervical assessment at 23 weeks' gestation.[35] A curved cervix was seen in 48% of patients: in 51% of those with cervical length of 26 mm or more, 25% of those with cervical length of 16 to 25 mm, but 0% in those with cervical length of 15 mm or less. This group had previously defined that pregnancies with cervical length less than 15 mm should be considered to have a positive test result, and in these circumstances, the effect of cervical curvature would not be important.

Early studies of transvaginal cervical screening suggested that cervical funneling could also be reported, and that this finding had an independent predictive role for preterm delivery.[36] Funneling can be assessed in a number of ways; subjectively, describing presence or absence, by measuring dilation at the internal os and the length of the endocervical canal that is involved, or by combining these features to give a cervical index.[37] In a series of 469 high risk pregnancies assessed longitudinally, funneling, determined in terms of width and length and the percentage of the cervix involved, was not found to give any additional information about risk if the cervical length was less than a screen-positive cutoff of 25 mm.[38] This was also the case in a series of 6819 low risk pregnancies screened at 23 weeks' gestation, in which funneling was defined as being present if the width at the internal cervical os was greater than 5 mm.[39] In this series, funneling appeared to be almost universally associated with a short cervix, and there was no apparent advantage to its inclusion as a screening criterion.

Cervical Assessment in Asymptomatic Patients at High Risk of Preterm Labor

Women with a previous history of preterm labor or preterm prelabor rupture of membranes together with women who have previously had cervical surgery or have a known uterine anomaly are considered to be at high risk of preterm labor. Other inclusion criteria have included extreme maternal age, in utero exposure to diethylstilbestrol, and maternal genetic anomalies such as Elhers-Danlos syndrome. The rationale for screening in this group is to allow early intervention that would prevent the onset of preterm delivery of preterm prelabor rupture of membranes.[40–42] It is not currently clear what the optimum gestation for screening is, what cervical cut-

off should be used to define a screen-positive group, or whether serial scans would be more appropriate than a single scan.

There is a strong association between a short cervix and preterm delivery in high risk pregnancies. Cook and associates showed that cervical length less than 21 mm at less than 20 weeks' gestation was associated with 95% delivery by 34 weeks' gestation.[43] Guzman and associates examined 469 women at high risk of preterm delivery with singleton pregnancies serially (mean of three occasions) between 15 and 24 weeks' gestation.[37] The cervix was 25 mm or less in length in 23.4% of women, including 76% of those delivering before 34 weeks' gestation. The negative predictive value of this cutoff was 96%. Similarly, Owen and associates demonstrated that a single examination at 16 to 19 weeks' gestation with a cervix 25 mm or less in length increased the risk of preterm delivery by 35 weeks' gestation 3.3 times (95% confidence interval [CI]: 2.1–5.0) and found that if serial examinations up to 24 weeks' gestation were performed, a single cervical length of less than 25 mm increased the risk of preterm labor 4.5 times (95% CI: 2.7–7.6).[33] Only limited data are available about the value of serial screening beyond 24 weeks' gestation, but in one small study (n = 69) of high risk pregnancies examined every fortnight from 16 to 30 weeks' gestation, cervical length and funneling were found to be significant at evaluations performed at 20 to 24 weeks as well as 25 to 29 weeks.[44]

Cervical Assessment in Asymptomatic Patients at Low Risk of Preterm Labor

The rationale for screening in a general, low risk population is that a significant proportion of preterm deliveries occur in pregnancies with no historical risk factors. The apparent effectiveness of screening high risk populations has lead many groups to examine screening in a low risk group, and evaluation of cervical length seems to be of similar predictive value in this setting.[45–49] Iams and associates reported a multicenter study of 2915 pregnancies recruited through 10 university perinatal centers in the United States.[45] Investigators used a clearly described method to assess cervical length; the process involved initial training, a period of standardization of technique, and continuing audit of the quality of examinations. Both cervical length and funneling were examined, but although funneling seemed to be equally predictive of outcome, the authors noted that determination of this sign was less consistent, with a prevalence of 0% to 12.7% across centers. The predictive value of cervical assessment was reported in terms of the proportion of spontaneous preterm deliveries that occurred before 35 weeks of gestation; this occurred in 126 (4.3%) of the pregnancies enrolled. A cervical length less than 20 mm was found in less than 5% of women, and this group included 23% of preterm births. The relative risk of preterm labor associated

with various cervical lengths was also reported. These data were calculated relative to the risk of preterm delivery in the top quartile rather than relative to the background population as a whole. This approach demonstrated that there is a significant association between the risk of preterm labor and a short cervix. It also demonstrated that there was a continuum of risk and the authors suggested that this challenged the traditional concept that the cervix is either competent or incompetent and provided evidence that cervical competence should be considered as a continuous variable.

There are four other studies that have examined large (>500 pregnancies) groups of low risk singleton pregnancies.[46–49] Although they are not directly comparable with the study of Iams described earlier, a review of their results demonstrates similar findings, i.e., the risk of spontaneous preterm birth is inversely related to cervical length (Table 61-1).

Unfortunately, there is little evidence to suggest that screening a low risk population is useful, as an effective intervention to improve pregnancy outcome has not yet been demonstrated. Therefore, it could be argued that such a screening policy is not appropriate or that such a policy is relevant only in units with an active interest in interventions for preterm labor where screen-positive patients would be recruited for further research.

Cervical Assessment in Patients Symptomatic of Preterm Labor

Early diagnosis of preterm labor potentially allows early intervention to reduce the risk of preterm delivery or to optimize conditions for the premature neonate. The clinical diagnosis of labor is dependent on the presence of uterine activity with cervical effacement and dilation, and accurate cervical assessment is therefore important. Traditional, digital examination tends to be imprecise, with large margins of inter- and intraoperator error. The rationale for using ultrasound to assess the cervix in women presenting with symptoms of preterm labor is that cervical assessment will be more precise, allowing earlier treatment of women with evidence of cervical change, but reducing the proportion of women who are not in preterm labor and have unnecessary treatment.

Cervical effacement has many potential causes. This process may be biologic or may represent a mechanical weakness that is revealed as the uterus becomes distended. Alternatively, it may be secondary to the onset of uterine contraction or to inflammation and the release of local hormones—frequently a response to infection or hemorrhage. It is unlikely that a single form of therapy will resolve all the etiologies underlying cervical effacement and dilation, and this may explain why most randomized controlled trials of cervical cerclage have not shown this to be an effective method of preventing preterm birth.

Cervical Screening in Twin Pregnancies

The incidence of preterm delivery is significantly higher in multiple pregnancies, with a consequent effect on perinatal mortality and morbidity rates in these infants. From 5% to 10% of twins deliver before 33 weeks' gestation, a sixfold increase over the rate of preterm delivery in singleton pregnancies by this gestation.[50] Despite this, fewer studies have assessed the use of cervical screening in twin pregnancies, and it is less clear whether ultrasound assessment is useful or at what week of gestation ultrasound should be performed.

A prospective cohort of 177 pregnancies was used to evaluate cervical length in normal twin pregnancies.[51] Of these 177, 28 (16.3%) pregnancies delivered before 34 weeks' gestation and were excluded from further analysis. In the remainder, the mean cervical length decreased from 47 mm at 13 weeks' gestation to 32 mm at 32 weeks' gestation in a linear fashion. The rate of cervical shortening was 0.8 mm per week.

Ong and associates suggested that, from a clinical perspective, it is not the estimation of risk per se that is important, but the prediction of preterm labor within a limited time frame, allowing admission, preparative treatment (such as steroid therapy), and transfer to a unit with appropriate neonatal facilities.[52] Cervical length was assessed every 2 weeks in 46 twin pregnancies between 24 weeks' gestation and delivery. Only data from pregnancies that labored spontaneously were subsequently included in the analysis. There was no difference in the rate of shortening between pregnancies delivering before and after 37 weeks' gestation. An absolute threshold for cervical length was, however, more useful: cervical lengths of less than 20 mm and less than 25 mm had relative risks of delivery within 1 week of 11.67 (95th CI: 4.23–32.17) and 4.12 (95th CI: 1.10–15.47), respectively. A similar longitudinal study of only 20 twin pregnancies suggested a difference in the rate of cervical shortening between women delivering preterm (<36 weeks' gestation) and those delivering at term. After excluding one preterm delivery that had a short cervix at the time of the first scan (10 mm at 24 weeks' gestation), the rate of shortening was found to be 2.9 mm/week and 1.8 mm/week in preterm and term pregnancies, respectively. This difference was not statistically significant, but this may have been due to the relatively low numbers enrolled.[53]

Skentou and associates also examined various thresholds for cervical length to predict the risk of preterm delivery.[54] This prospective study of 464 twin pregnancies involved a single transvaginal ultrasound assessment at 23 (22–24) weeks' gestation. This study included 313 (67.5%) dichorionic and 151 (32.5%) monochorionic twin pregnancies and found no significant difference in the rate of preterm delivery (defined as before 34 weeks' gestation) in these two groups. A significant inverse relationship was found between cervical length and the risk of preterm birth (risk = 26.48 × cervical length − 1.688)

such that thresholds of 15 mm, 20 mm, and 25 mm detected 17.6%, 39.1%, and 46.4% of twin pregnancies delivering before 34 weeks, respectively. The corresponding screen-positive rates were higher than those seen in singleton pregnancies: 2.1%, 4.7%, and 9.6%.

In addition to assessing cervical length, Guzman and associates looked at cervical funneling and the effect of transfundal pressure during the examination.[55] A series of 131 pregnancies were examined serially between 15 and 28 weeks' gestation. The effectiveness of assessments at 15 to 20, 21 to 24, and 25 to 28 weeks' gestation for the prediction of preterm delivery by 28, 30, 32, and 34 weeks' gestation were evaluated. Although the cervix was significantly shorter with transfundal pressure, this application did not improve the investigators' ability to predict preterm labor. A cervical length of less than 20 mm was found to be at least as good as any other characteristic at predicting spontaneous preterm delivery.

These data differ slightly from the findings of another group, who investigated the associations between preterm delivery and a short cervix and cervical funneling in a series of 251 twin pregnancies, examined at 22 and 27 weeks' gestation.[56] A receiver operating characteristic curve showed no clear best cutoff point for cervical length at 22 weeks' gestation, although a cutoff of 25 mm appeared best at 27 weeks' gestation. Using this cutoff at 22 weeks (for comparison to other data sets) gave a sensitivity of 38% and specificity of 97% for preterm delivery before 32 weeks' gestation. Cervical funneling, considered to be present when the lateral border of the funnel was more than 3 mm in length, was present in 12.4% of pregnancies at 22 weeks' gestation, and this finding had a sensitivity of 54% and a specificity of 89% as an indicator of preterm birth by 32 weeks' gestation. The authors concluded that cervical length and funneling both predict very preterm birth and that although cervical length is the method of choice at 27 weeks' gestation,

at 22 weeks the diagnostic characteristics of both parameters are close.

CERVICOVAGINAL FETAL FIBRONECTIN

Fetal fibronectin is a glycoprotein found in amniotic fluid, placental tissue, and the decidua basalis.[57] It is normally found in cervicovaginal secretions before 16 to 18 weeks' gestation, before fusion of the fetal membranes and the decidua is complete. Similarly, it is found at the end of pregnancy, prior to the onset of labor, but it is not normally present in cervicovaginal secretions between 22 and 37 weeks. It has been suggested that the presence of fetal fibronectin in cervicovaginal secretions in the later part of the second trimester and in the third trimester of pregnancy is due to disruption of the chorionic-decidual interface and is often secondary to infection.[58]

Initial studies establishing the presence of fetal fibronectin in cervicovaginal secretions involved extensive laboratory analysis that delayed the availability of results. More recently, an enzyme-linked immunosorbant assay containing the FDC-6 monoclonal antibody has been developed that can be used at the bedside, potentially making this test a much stronger clinical tool.[59]

A large systematic review of 64 primary articles reporting the effectiveness of screening for preterm delivery by the detection of cervicovaginal fetal fibronectin in a total of 26,876 women has recently been published.[60] There were two large subsets of women, asymptomatic and symptomatic of preterm labor. Among asymptomatic women, the likelihood ratio for predicting preterm delivery before 34 weeks was 4.01 (95% CI 2.93–5.49) with a likelihood ratio for negative results of 0.78 (95% CI 0.72–0.84). Among those women who were symptomatic, the likelihood ratio for positive results was 5.42 (95% CI

4.36–6.74) for predicting birth between 7 and 10 days of testing, with a corresponding negative likelihood ratio of 0.25 (95% CI 0.20–0.31).

Another meta-analysis, confined to reports in the English language, found that fetal fibronectin was useful in the prediction of delivery before 34 weeks, with an overall sensitivity of 53% and specificity of 89%.[61] The sensitivities for prediction of delivery within 7, 14, and 21 days were 71%, 67%, and 59%, respectively. The corresponding specificities were 89%, 89%, and 92%. Further analysis of studies in asymptomatic women who could be divided into low risk and high risk showed that for a single sampling of fibronectin, sensitivity for detection of delivery prior to 34 weeks was 41% (21%–59%) for low risk women with a specificity of 94% (91%–96%). For high risk women the sensitivity was considerably lower at 23% (14%–32%) but with a comparable specificity of 94% (93%–96%). The studies of serial sampling of cervical fibronectin showed a higher sensitivity of prediction of delivery prior to 34 weeks with low risk and high risk groups showing a sensitivity of 68% (52%–83%) and 92% (62%–100%), respectively. Predictably the specificities in each group of serial sampling were significantly reduced (there is an independent chance of a false-positive result every time the test is done, so the specificity falls as the number of samples, and hence false positives, increases). The few studies looking at multiple pregnancies have small numbers and result in sensitivities and specificities with such broad confidence intervals that a meaningful conclusion cannot be drawn.

Subgroup analysis of symptomatic and asymptomatic pregnancies demonstrated that this test was most sensitive in women with symptoms of preterm labor, but its usefulness as a screening test for decisions about hospital admission and the administration of glucocorticoids is reduced by the fact that the speci-

ficity is significantly lower than in asymptomatic women. The authors concluded that fetal fibronectin is a reasonably effective marker in predicting preterm delivery in the short term, particularly if there are symptoms of preterm labor.

Combined Cervical Screening and Fibronectin

The combined use of ultrasound and fibronectin has been evaluated in only a few studies, and in symptomatic women. Rizzo and associates found that combining cervical sonography with fibronectin screening improved diagnostic accuracy and allowed better prediction of the admission to delivery time.[62] Other investigators have found that fibronectin and cervical length had comparable ability to distinguish those at high and low risk of preterm delivery, but that their combination provides little added benefit.[63] Hincz and associates proposed a two-step test only when the cervical length was in an immediate range of 21 to 31 mm. This form of testing had an overall sensitivity of 86% with a specificity of 90% for predicting delivery within 28 days.[64]

SCREENING FOR BACTERIAL VAGINOSIS IN EARLY PREGNANCY

Bacterial vaginosis (BV) is characterized by an overgrowth of a mixture of organisms (*Gardnerella vaginalis*, *Mobiluncus*, *Bacteroides* spp., and *Mycoplasma hominis*), is often asymptomatic, and may resolve spontaneously. Although the role of BV in preterm labor is poorly understood, several reports[65,66] found that the relative risk of preterm labor is doubled if the mother has BV. The hypothesis is that the organisms found in BV ascend into and colonize the chorionic-decidual space, resulting

in preterm labor or preterm rupture of membranes. This increase in invasion of the genital tract may be due to the rise in pH, which is a key feature of BV, allowing vaginal bacteria to proliferate relatively unchecked. Two studies[67,68] suggest that infection in early pregnancy may be a greater risk factor than BV infection in the late second trimester and early third trimester of pregnancy.

Leitich and associates[69] performed a meta-analysis to evaluate the risk of preterm delivery associated with BV; 20,232 patients in 18 studies were included. They found that BV increased the risk of early delivery (less than 37 weeks' gestation) with an odds ratio of 2.19 (95% CI 1.54–3.12). A subgroup analysis showed that if BV was identified prior to 16 weeks, then the risk of preterm birth was further increased with an odds ratio of 7.55 (95% CI 1.80–31.65). Even at less than 20 weeks, a finding of BV was associated with an odds ratio of 4.20 (95% CI 2.11–8.39) for preterm birth. This analysis found no particular association of BV with delivery prior to 34 weeks; however, few studies used that gestation time as an outcome and the studies that used early screening used less than 37 weeks as their criteria for preterm delivery. There is little evidence that screening for BV in specific subgroups, particularly in women with a prior preterm delivery and in multiple gestations, improves its sensitivity or specificity.

Despite this reasonably convincing evidence of a link between early infection with BV and preterm delivery, screening and subsequently treatment of BV remain controversial. The recent review of the Cochrane Collaboration[70] of 10 trials of 4249 women showed that antibiotic therapy successfully treated BV but failed to reduce the risk of preterm birth before 37 weeks, with odds ratio 0.95 (95% CI 0.82–1.10); at 34 weeks, with odds ratio 1.20 (95% CI 0.69–2.07); or 32 weeks, with odds ratio 1.08 (95% CI 0.70–1.68). In those women who had a previous preterm birth, treatment of BV did not decrease the risk of a subsequent preterm birth, odds ratio 0.83 (95% CI 0.59–1.17), but did decrease the risk of preterm premature rupture of membranes, odds ratio 0.14 (95% CI 0.05–0.38). Similarly, Carey and associates[71] failed to show oral metronidazole therapy to be useful in prevention of preterm labor in a mixed population.

At present the role of screening for BV and then treating it is not clear in a low risk population. It possibly has benefit in a high risk population, but further controlled studies are required.

CONCLUSIONS

- The successful prediction of preterm labor potentially allows interventions to reduce preterm delivery rates and improve perinatal outcome.
- Four screening methods have been extensively evaluated.
- Uterine contraction monitoring has poor sensitivity as a screening tool and is of limited clinical value.
- Assessment of cervical length and cervical fibronectin may have a role in screening for preterm labor, particularly in high risk populations.
- Although there is limited evidence of successful intervention to prevent preterm labor, it is possible to improve perinatal outcome by arranging delivery in an appropriate setting and by giving steroids.
- An additional use of fetal fibronectin and cervical length assessment is the value of a negative result. The prediction that delivery is not imminent has practical applications, such as a reduction in inpatient admission, a reduction in unnecessary interventions such as cervical cerclage, and a reduction in the number of courses of steroids given to promote fetal maturity.[72]
- It remains unclear whether the presence of bacterial vaginosis is predictive of preterm labor, and further studies are needed to assess the effectiveness of antibiotic treatment in early pregnancy in reducing of rate of preterm labor and preterm rupture of membranes.
- To take full advantage of these screening tests, clinicians should aim to use the findings to focus interventions in those truly at high risk and to reduce interventions in other pregnancies.

SUMMARY OF MANAGEMENT OPTIONS
Screening for Spontaneous Preterm Labor and Delivery

Management Options	Quality of Evidence	Strength of Recommendation	References
Uterine Activity Monitoring			
Self-monitoring applies to whole population but has a poor sensitivity.	IIb	B	6
Any improved outcome reported in monitored pregnancies may represent the benefits of increased education and support inherent in the studies.	Ib	A	7

Screening for Spontaneous Preterm Labor and Delivery

Management Options	Quality of Evidence	Strength of Recommendation	References
Uterine Activity Monitoring—Continued			
Tocography is only practically applicable to high risk groups rather than whole populations.	–	GPP	–
Two meta-analyses of the same 6 studies in 697 high risk pregnancies have reached opposite conflicting conclusions; further studies are needed.	Ia	A	20,21
The addition of fetal fibronectin testing to uterine activity monitoring does not confer any benefit in practice.	IIb	B	25
Cervical Ultrasound			
It is important to use a standardized technique.	IV	C	30
Transvaginal route is significantly better than translabial/transperineal or transabdominal approaches.	IIa	B	31–34

Threatened and Actual Preterm Labor Including Mode of Delivery

John M. Svigos / Jeffrey S. Robinson / Rasniah Vigneswaran

INTRODUCTION, DEFINITION, AND INCIDENCE

Preterm labor refers to the onset of labor after the gestation of viability (20–28 weeks, depending on definition) and before 37 completed weeks or 259 days of pregnancy. The onset of labor may be determined by documented uterine contractions (at least one every 10 minutes) and ruptured fetal membranes or documented cervical change with an estimated length of less than 1 cm or cervical dilation of more than 2 cm. Threatened preterm labor may be diagnosed when there are documented uterine contractions but no evidence of cervical change.

Despite these apparently clearly defined entities, and because of the need for early management of suspected preterm labor, it is common for clinicians to make the diagnosis before the foregoing criteria are met. Hence, the reported incidence of threatened preterm labor is likely to be considerably greater than the incidence of actual preterm labor. For example, O'Driscoll[1] suggested that the pregnant woman's own diagnosis of preterm labor, based on her perception of uterine contractions, may be incorrect in as up to 80% of instances. Kragt and Keirse[2] demonstrated that 33% of women presenting with contractions could safely be discharged home in 48 hours without needing treatment.

Amon and Petrie[3] suggest that 50% of women presenting with uterine contractions do not need tocolytics, and Gonik and Creasy[4] in their review found that only 18% to 20% of women presenting with possible preterm labor were candidates for long-term tocolytic agents. Even more sobering was Gonik and Creasy's assessment of a 20% to 45% efficacy rate of placebo treatment for suspected preterm labor.

In South Australia in 2001,[5] the overall preterm delivery (PTD) rate was 8.1%. Since 1981, the percentage of babies born preterm has increased from 5.5% to 8.1%; however, in recent years this rate has remained stable. If we assume that about 50% of women who present in threatened preterm labor eventually deliver at term, then the proportion of the obstetric population presenting for diagnosis will be approximately 16.2%. As in previous years, two thirds of cases were associated with preterm premature rupture of the membranes (PPROM) and only one third (or 2.7% overall) were due to preterm labor (PTL) without PPROM.

The incidence of preterm delivery in most developed countries has remained frustratingly constant over the past 3 decades at about 5% to 10%, with some regions, including our own, noticing a small increase above the usual incidence over the last 5 years. In institutions serving as referral centers the rate, as would be expected, is much higher. In South Australia, the major tertiary center, the Women's and Children's Hospital, Adelaide, had a 14.3% rate of PTD in 2002.[6] There are a number of explanations to account for this lack of success.

First, doubts have been expressed about the comparability of current estimates of the incidence of preterm delivery with previous years, as they increasingly reflect the increased survival of the extremely preterm, very low birth weight infants, who would previously have been regarded as "nonviable." Registration practices can alter so that some babies are registered as births when previously they would have been regarded as midtrimester miscarriages. Change in requirements for registrations and increased ascertainment may account for some of the increase in preterm births in South Australia since 1981.[5]

Additionally, there is only a relatively limited window of opportunity during which the presently available tocolytic agents can be used, and because of their poor efficacy they prolong pregnancy only marginally. Thus, they should not be expected to impact substantially on the actual preterm delivery rate.

Tucker and associates' study[7] (1991) of 13,119 consecutive singleton births demonstrated this problem. There were 1445 (11%) preterm births in the study group, but 630 (44%) of them were at more than 34 weeks' gestation, and consequently treatment to prevent labor was not attempted. Another 241 (16.6%) of women had PPROM, and hence, tocolysis was withheld. A total of 238 women (16.5%) had medical or obstetric indications for delivery (vaginal bleeding, hypertension, intrauterine fetal death, intrauterine fetal growth restriction), and 189 (13%) were too far advanced in labor (cervical dilation >3 cm) to be considered for tocolytic therapy. Thus, in only 147 women (10.2% of the subgroup; 5% of women presenting at <35 weeks' gestation, and only 1% of the total obstetric population studied) was it appropriate to use a tocolytic agent. Therefore, the opportunity to make a significant impact on the incidence of PTD was limited.

In Project 27/28 in the United Kingdom, 3522 babies born between 27[0] and 28[6] weeks of gestation were reported to The Confidential Enquiry into Stillbirths and Deaths in Infancy (CESDI) in 1 year. A 2-year follow-up of 761 babies showed that major placental bleeding (18%), pregnancy-induced hypertension (21%), prelabor rupture of the membranes (31%), clinical chorioamnionitis (11%), preterm labor (55%), cervical incompetence (5%), bacteriuria (7%), and maternal smoking remain important antecedents of preterm birth. Thus, the strategies that would be required to prevent them are many and varied. In the CESDI report, emphasis was given to reduction of smoking as being the cause of preterm delivery most amenable to intervention.[8]

MATERNAL RISKS

General Risks

Consideration of preterm birth makes it clear that many of its causes have their origins in maternal pathology, which carries a risk for the mother as well as the fetus. Excluding PPROM and "idiopathic" PTL,[9] which together constitute approximately 66% of cases, the two most common maternal conditions associated with preterm birth are pregnancy-induced hypertension and antepartum hemorrhage.[4] These two conditions may either precipitate PTL spontaneously or prompt the deliberate induction of PTL as a way to resolve the problem or to deliver the fetus from an adverse environment. Induction of labor may of itself carry risks for the mother (see Chapter 68). Additionally, if "idiopathic" PTL is studied in detail, the following associations have been recognized: intrauterine infection (47%), placental abruption or previa (40%), uterine factors (anomalies, polyhydramnios 20%), cervical incompetence (17%), immunologic factors (33%), maternal factors (systemic infection, preeclampsia 10%), fetal anomalies (7%), trauma (surgical, others 3%), and true "idiopathic" PTL (1%). Often more than one factor may be present and will contribute to the maternal risks associated with PTL.

Risks of Tocolytic Agents

Beta-Sympathomimetics

Another area of significant risk to the pregnant woman with threatened or actual PTL is the risk from the treatment regimens currently employed. Although beta-sympathomimetic agents, mainly ritodrine, have been studied in randomized controlled trials to determine their efficacy in the treatment of PTL, unfortunately the total number of women studied is not able to provide meaningful information regarding the incidence of serious maternal hazards associated with such therapy. However, a systematic review by Gyetvai and associates[10] demonstrated the following adverse maternal effects when compared to no treatment or placebo: palpitations (48% with beta-sympathomimetic vs. 5% with no treatement or placebo), tremor (39% vs. 4%), nausea (20% vs. 12%), headache (23% vs. 6%), and chest pain (10% vs. 1%). Rare but serious and potentially life-threatening adverse effects have been reported following beta-sympathomimetic use. Pulmonary edema has become increasingly recognized as a serious maternal hazard, with many but not all cases being due to fluid overload. The actual incidence of this problem is difficult to estimate from the literature but varies from 5% of treated women[11] to "a few cases." Women receiving associated corticosteroid therapy for fetal lung maturity enhancement, women receiving combinations of tocolytic agents (e.g., beta-sympathomimetics and magnesium sulfate), those with unrecognized chorioamnionitis, and women with multiple pregnancies are reported to be at increased risk of pulmonary edema.[10] Myocardial ischemia, possibly as a result of diffuse myocardial micronecrosis, has been reported in women receiving beta-sympathomimetic tocolytic therapy and constitutes an infrequent but serious maternal hazard.[10,11] A number of maternal biochemical effects occur with these agents, but they rarely cause serious problems unless there are underlying maternal diseases such as diabetes, thyrotoxicosis, or cardiac disease. Blood sugar levels increase in approximately 40% of women receiving beta-sympathomimetic agents, particularly if combined with corticosteroid administration, and may occasionally result in severe ketoacidosis in pregnant diabetic women.[9,11] Serum potassium levels generally fall, owing to a net influx of potassium from the maternal extracellular fluid into the intracellular fluid compartments as a result of the changes in carbohydrate metabolism. The resulting hypokalemia, however, is usually transient and unlikely to be of serious concern.[10,12]

Although beta-sympathomimetic tocolytic agents have been the mainstay of regimens for the treatment of PTL, other agents are now being used increasingly, as they appear to have fewer adverse effects with comparable effectiveness. However, none of these agents are without risk for the mother.

Nonsteroidal Anti-inflammatory Agents

Nonsteroidal anti-inflammatory drugs (NSAIDs) are inhibitors of the cyclooxygenase enzyme (prostaglandin synthetase), which plays an integral role in the initiation and maintenance of labor. Indomethacin has been the most commonly used NSAID for tocolysis over the past 20 years. The most likely maternal side effects of treatment include peptic ulceration, gastrointestinal bleeding, thrombocytopenia, and allergic reactions that can occur irrespective of the mode of administration. Less common complications include the risk of postpartum hemorrhage, renal function impairment, particularly if aminoglycoside antibiotics are used, and severe hypertension if beta-blocking agents are used. Long-term use has been associated with depression, dizziness, psychosis, and frequent headaches. It is believed that some of these unwanted side effects may be mediated through the constitutive type 1 isoform of cyclooxygenase (COX-1), as this enzyme is responsible for the unwanted renal and gastric side effects in nonpregnant subjects.[13] It has been shown that labor is associated with up-regulation of the expression of COX-2 and not COX-1 within the uterus,[14] and therefore, there is increasing interest in the newer COX-2 selective NSAIDs. Trials evaluating the safety of these drugs is awaited.

Magnesium Sulfate

A recent systematic review of more than 2000 women in 23 trials failed to find support for use of magnesium sulfate because it did not delay birth or prevent preterm birth.[15]

However, surprisingly, despite this apparently complete lack of effectiveness, magnesium sulfate has been the most popular parenteral drug used for tocolysis in North America. Elliott's study[16] of maternal side effects found that side effects occurred in 7% of patients and necessitated stopping treatment in 2%. Cutaneous vasodilation, flushing, nausea, vomiting, palpitations, and headaches are common side effects. Less frequent but troublesome problems are maternal hypothermia, bone demineralization, and paralytic ileus. The most significant maternal side effect is the development of pulmonary edema and an adult respiratory distress–like syndrome in approximately 1% of patients. This appears to be less frequent than that seen with the use of beta-sympathomimetic tocolytic agents. Hypermagnesemia may lead to maternal respiratory depression, cardiac arrest, and even death on rare occasions. Because of these significant side effects, and the complete lack of efficacy of this medication, it is difficult to see how its use for tocolysis can continue to be justified.

Calcium-Channel Blockers

Following the early favorable report of Read and Wellby[17] regarding the use of calcium-channel blockers for tocolysis, nifedipine has been increasingly used in the management of preterm labor. Analysis of adverse maternal effects is limited due to inconsistent reporting in individual trials. One review[18] reported fewer interruptions of treatment due to adverse effects with nifedipine compared to beta-sympathomimetics (0% vs. 7%). Fewer adverse effects were reported among women allocated nifedipine rather than ritodrine. However, there have been reports of pulmonary edema, maternal hypotension, and hepatotoxicity, which justify caution with their use.

Oxytocin Receptor Antagonist (Atosiban)

The oxytocin receptor antagonist atosiban has been compared with three different beta-sympathomimetics (ritodrine, salbutamol, and terbulaline) in a large multicenter study.[19] When compared with beta-sympathomimetics, atosiban was associated with fewer maternal adverse effects such as chest pain (1% vs. 5%), palpitations (2% vs. 16%), tachycardia (6% vs. 76%), hypertension (3% vs. 6%), (dyspnea (0.3% vs. 7%), nausea (12% vs. 16%), vomiting (7% vs. 22%), and headache (10% vs. 19%). There was one case of pulmonary edema in the atosiban group and two in the beta-sympathomimetic group. Atosiban has recently been licensed in Europe and the United Kingdom for use as a tocolytic, and evaluation of its more widespread use is awaited, although its high cost may prove to be a significant factor limiting its use.

Nitric Oxide Donors

There have been reports of some small observational studies of the use of nitric oxide donors (e.g., glyceryl trinitrate) for tocolysis.[20] The reported side effects have been few, but clearly, randomized evaluation in studies of sufficient size and with sufficient power to test efficacy and to note rare adverse effects is necessary before any meaningful comments can be made with regard to maternal safety.[21]

Risks Associated with the Mode of Delivery in Preterm Labor

Cesarean section as the preferred mode of delivery for the very preterm infant is a practice that did not receive adequate scrutiny before it came into common use. With it came significant maternal morbidity related to a poorly formed lower uterine segment, increased operative hemorrhage, infection, and compromised future uterine function—all this without documented improvement in perinatal mortality or morbidity rates.[22-24]

A survey of members of the Society of Perinatal Obstetricians (SPO)[22] demonstrated a doubling over a 5-year period of the elective cesarean section rate for infants born between 24 and 28 weeks' gestation. However, Sanchez-Ramos and associates[23] were able to demonstrate that a significant decrease in the cesarean section rate over the same 5-year period for very low birth weight

infants did not alter the neonatal mortality rate, the incidence of low Apgar scores, or cord blood gas values, intraventricular hemorrhage, or the median length of stay in the neonatal intensive care unit. Grant and associates'[24] systematic review of six trials of elective versus selective cesarean delivery for infants less than 37 weeks' gestation not only demonstrated the difficulty of randomization of mode of delivery in this clinical situation, with only 122 women recruited, but concluded that decision making on an individual case-by-case basis, taking into account parental preference, was all that could be recommended from the available data.

The use of classical cesarean section for gestations less than 30 weeks, although often suggested, carries more risk of morbidity than the lower segment procedure and has very little data to recommend it. Unpublished data from Stacey and Steer[25] suggest that it confers no particular benefit, with 8 of 17 babies dying when delivered by the classic route before 30 weeks' gestation, compared to none of 21 babies of similar gestation delivered by lower segment cesarean section.

Assessing the psychosocial trauma experienced by the patient, her partner, and her family in relation to the management of threatened or actual PTL is difficult, and this short paragraph cannot do justice to the importance and magnitude of the problem. The physical restrictions imposed by the use of intravenous tocolytics, the impersonality of the multidisciplinary approach, the geographic dislocation that is commonly necessary, the uncertainty of the perinatal outcome, and delayed maternal-infant bonding are probably the major conflicts experienced. These factors need to be kept in mind as we attempt to further reduce the maternal risk associated with threatened and actual preterm labor.

FETAL AND NEONATAL RISKS

Risks of Associated Pathology

Compromised fetal health is often the precipitating factor in threatened or actual PTL. Hence, intrauterine fetal death, intrauterine growth restriction, major congenital anomalies, unrecognized intrauterine infection, and complicated multiple pregnancy will all contribute to the perinatal mortality and morbidity rates associated with PTL.

Risks of Prematurity

The gestational age at which threatened or actual PTL presents, together with the birth weight, influences both the management and the outcome (Fig. 62–1). In women presenting between 20 and 24 weeks' gestation, the management decision after discussion with the parents may be to allow delivery to occur because of the maternal risks from treatment and the likely poor prognosis for the baby if, as is often the case, delivery can be postponed only for a few hours or days.

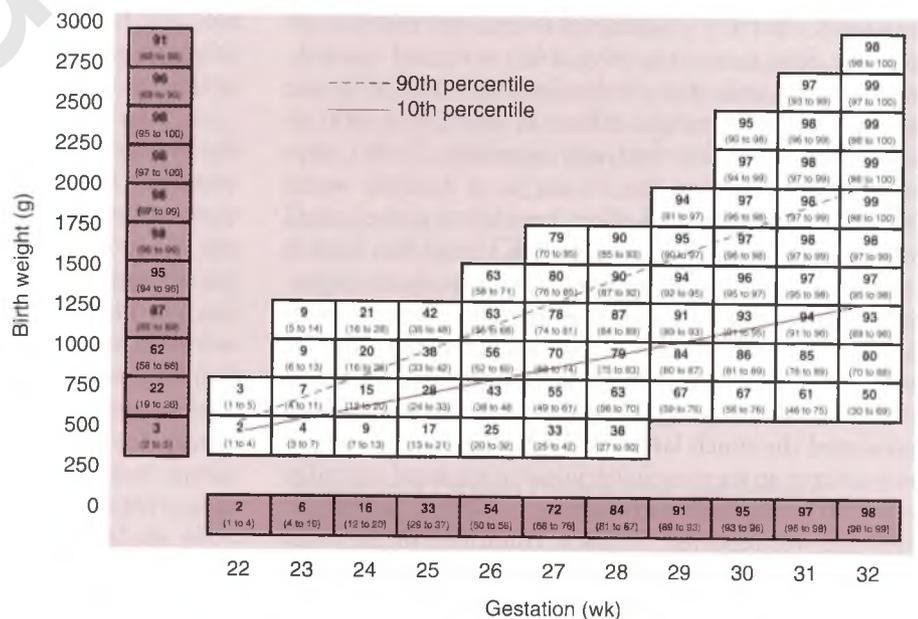
Fetal intrapartum hypoxia and birth trauma associated with PTL involving the very low birth weight infant, whether birth is by the vaginal or abdominal route, will contribute to the perinatal risk. The risks in the neonatal period are those of congenital malformation, the sequelae of intrauterine growth restriction, respiratory distress syndrome, necrotizing enterocolitis, intracranial hemorrhage, convulsions, and septicemia. The fetal and neonatal risks associated with the medical management of PTL have not been accurately quantified, but certainly they require consideration in the overall management.


Figure 62–1
Median (95% confidence interval) predicted survival rates for European infants known to be alive at onset of labor. Values above 90th percentile represent infants large for gestational age; values below 10th percentile represent infants small for gestational age (see reference source for other ethnic groups). (From Draper ES, Manktelow B, Field DJ, James D: Prediction of survival for preterm births by weight and gestational age: Retrospective population based study. BMJ 1999;319:1093–1097.)

Risks of Tocolytic Agents

Beta-sympathomimetic tocolytic agents cross the placenta and may cause fetal tachycardia and occasionally other adverse fetal cardiac effects, which may be significant in an already compromised fetus.[10,26] The maternal hyperglycemia commonly associated with the use of these agents may result in neonatal hypoglycemia. There is a suggestion that neonatal intraventricular hemorrhage may be associated with the use of oral beta-sympathomimetic drugs, although the data are preliminary.[27] There have been only a few small studies of possible long-term ill effects for the neonate, and currently it appears there is no difference in developmental outcome if all confounding factors are taken into account.

Prostaglandin synthetase inhibitors (NSAIDs) cross from the mother to the fetus, potentially resulting in prolonged bleeding time, cardiopulmonary effects (predominantly premature closure or constriction of the ductus arteriosus and persistent fetal circulation), renal dysfunction, and reduced urinary output. Necrotizing enterocolitis and neonatal intraventricular hemorrhage have also been recorded in association with the use of these agents.[28–30] Most studies have limited the use of prostaglandin synthetase inhibitors to short-term therapy (48–72 hours) before 32 to 34 weeks' gestation. Newer and possibly more specific prostaglandin synthetase inhibitors such as sulindac,[31] ketorolac,[32] and the COX-2 selective agents (e.g., nimesulide) are currently being evaluated, as there is some evidence that they have fewer fetal side effects.

Magnesium sulfate also readily crosses the placenta and may compromise fetal cardiac activity, with reduced baseline variability of the fetal heart rate demonstrated by cardiotocography being a common association, which in turn may lead to unnecessary intervention. The neonate may exhibit hypotonia and hypocalcemia as a consequence of the hypermagnesemia.[33] The more controversial aspects of magnesium sulfate are related to its possible fetal neuroprotective role, as several observational studies indicated a reduction in cerebral palsy rate in very low birth weight infants in association with its use. However, Mitterdorf and associates,[34] who were originally enthusiasts for its use as a tocolytic agent because of this presumed effect, have found in their small randomized controlled trial (MagNET trial) that there is a highly significant association between tocolytic magnesium sulfate exposure and total neonatal mortality rates as well as a trend toward worse outcomes in relation to intraventricular hemorrhage, periventricular leukomalacia, and cerebral palsy. Crowther and associates (2003) presented the much larger ACTO MgSO$_4$ trial and did not observe an increase in perinatal or neonatal mortality rate.[35] A nonsignificant reduction of adverse neurologic sequelae was reported. If this is confirmed in the other large trials which are under way, then there may be a role for magnesium sulfate before very preterm birth.

Calcium-channel blockers[18] have not been adequately evaluated with regard to fetal or neonatal effects, and the Cochrane reviewers recommended the assessment of different dose and formulations on maternal and neonatal outcomes. Some animal studies have demonstrated profound metabolic alterations in the fetus, but to date these changes have not been confirmed in the fetuses of pregnant women.[4]

Newer tocolytic agents such as nitric oxide donors and oxytocin receptor antagonists have not been sufficiently assessed for us to be able to make meaningful comments at this stage.[19,21]

The maternal administration of thyrotropin-releasing hormone (TRH) in association with corticosteroids was thought, from preliminary studies, to enhance the development of fetal lung maturity, but the ACTOBAT Study[36] demonstrated results to the contrary (see later discussion), and hence, its use is now discouraged.[37]

Maternal corticosteroid administration to enhance fetal lung maturity is beneficial for the preterm neonate but may carry a number of risks, including infection, although the latest available data do not confirm this potential complication.[38,39] These potential risks must be balanced against the proven beneficial effect on neonatal pulmonary function and the possible reduction in intraventricular hemorrhage and necrotizing enterocolitis.[34] The Dutch trial,[40] which studied the effects of maternal prenatal corticosteroid administration, suggested a long-term increase in the incidence of pharyngeal and ear infections in infants of treated mothers but reported no clear evidence of significant fetal or neonatal infection in PTL associated with intact membranes.

The former practice of repeated maternal corticosteroid administration encouraged by the NIH Consensus Statement (1994)[38] for pregnancies at risk for preterm delivery between 24 and 34 weeks' gestation raised the question of whether long-term studies were advisable to detect any adverse effects on the fetus and neonate. Crowley and associates,[39] in an early overview of three studies, suggested that there was little evidence of adverse long-term outcomes with repeated maternal corticosteroid administration and questioned the need for further long-term studies. Walfisch and colleagues[41] reviewed 280 articles on this topic and concluded that there are no well-designed randomized controlled trials (RCTs) in humans that support the advantages of multiple courses over a single course of antenatal corticosteroids. They also commented that an increasing body of evidence raises the concern of adverse consequences from the use of repeated courses. This conclusion is consistent with the current Cochrane systematic review of three trials, which included 551 women. However, fewer infants required surfactant and there were fewer cases of severe respiratory distress syndrome (RDS).[42]

In the randomized trial conducted by the NICHD MFMU Network it was planned to recruit 2200 women, which has been reported in abstract form).[43] However,

the trial was stopped after an interim analysis when only 495 women had been entered. There was no difference in the primary outcome, the respiratory distress syndrome, but infants delivered before 32 weeks may benefit with less use of surfactant, mechanical ventilation, and hypotension. There was a reduction in birth weight, particularly if four or more courses of steroids had been given.[43]

While awaiting full publication of the NICHD MFMU trial and results from RCTs in progress (such as the Australasian Collaborative Trial of Repeat Doses of Corticosteroids for the Prevention of Neonatal Respiratory Disease Study [ACTORDS] coordinated by Crowther and associates at the Women's and Children's Hospital, South Australia), it is recommended that only a single course of antenatal corticosteroids be given to all women at risk for preterm birth at 24 to 34 weeks' gestation.[41] (For a more detailed discussion of this topic, see Chapter 67.)

MANAGEMENT OPTIONS

Prepregnancy

The prevention and treatment of preterm birth has been the subject of extensive study. Risk-scoring strategies have been used to assess individual potential for preterm birth based on socioeconomic status, clinical history, lifestyle, and past obstetric and current prenatal complications. Unfortunately, there is little evidence from randomized trials of preterm preventive programs based on prospective risk scoring, whether they be hospital-based or require local social intervention, to suggest that there has been an overall reduction in the incidence of preterm delivery.[44] This failure is due both to a low sensitivity (generally below 50%) and a poor predictive value (17%–34%), particularly in primigravid women (previous pregnancy history is consistently reported to be one of the most important predictors). In addition, the value of prediction is limited when there are few, if any, effective treatments to alter the outcome.[45]

Hewitt and Newnham's study[46] of very low birth weight infants (weighing less than 1500 g) illustrates the limitations of preterm preventive programs. For infants born without major congenital anomalies, only 24% of the mothers had a history of a previous preterm birth. A total of 48% of the women were in their first pregnancy, and therefore, by definition they had no risk factors related to past obstetric history; of the multiparous women, 38% had no factors in their previous pregnancies indicating high risk. Another important feature revealed by this study was that idiopathic PTL was once again shown not to be the major factor in delivery at early gestations, occurring in only 17% of women studied, with PPROM in 30%, hypertension in 19%, antenatal hemorrhage in 17%, major anomalies in 8%, and fetal death in utero in 5%.

Thus, blanket preventive programs aimed indiscriminately at preterm delivery would not appear to be logical, other than as part of a scientific trial. With the assistance of the perinatal pathologist,[47] a significant proportion of women with "idiopathic" PTL can be demonstrated to have specific etiologic factors, and knowledge of these factors may be of assistance in the counseling and management of individual women with a previous preterm birth. In the situation of preterm birth without known causation, it is useful in prepregnancy counseling to estimate the likely recurrence risk. In their prospective study of preterm deliveries without uterine anomalies or medical problems, Ashmead and associates[48] determined that women with one previous preterm delivery had a 15% chance and those with two previous preterm births a 41% chance of another preterm delivery. These statistics may be useful in counseling patients who live in an area remote from a perinatal center, as it can be suggested that they move to a more convenient location during the critical period of a subsequent pregnancy in order to enhance the outcome.

More general advice with regard to daily work activity (avoidance of heavy manual labor or mental stress when family economics permit) and specific habits such as alcohol, smoking, and chemical dependency should be given, as there is some evidence that these factors may play a role in preterm birth.[49–51]

Hence, at the present time specific prepregnancy preventive measures for PTL might be considered for multiparous patients, but for nulliparous patients, apart from those with a known genital tract anomaly for which surgical correction might be possible, there do not appear to be any proven strategies to prevent PTL.

Prenatal

Assessment of Risk

At the first prenatal visit, assessing the risk of preterm delivery based on the history and examination may be useful as an initial screen to identify women at particularly high risk. The risk can be updated during the pregnancy if complications develop. An adaptation of the score devised by Creasy and associates[52] combines socioeconomic factors, previous medical history, daily habits, and aspects of the current pregnancy and is probably the most acceptable system, but its predictive value overall is only 17% to 34% owing to the multifactorial nature of PTL. In all women, but particularly those at risk of PTL, it is preferable that gestational age be confirmed by an early ultrasound scan.

Women with Previous Preterm Labor and Delivery: Cervical Problems

If cervical incompetence is suspected on the basis of a previous midtrimester miscarriage or known physical

damage to the cervix (e.g., following surgery), then cervical cerclage (ideally as a planned procedure) can be performed at 12 to 14 weeks' gestation. It has been calculated, from the evidence of randomized trials, that 1 woman in 30 will benefit from a cervical suture.[53] Systematic review of randomized trials does not support use of cervical cerclage in women at low or medium risk of midtrimester loss, and its use for a short cervix remains uncertain.[54] Placement of a cervical stitch is usually a vaginal procedure, but on rare occasions it may have to be performed by the abdominal route (see Chapters 6 and 7). Late cervical cerclage in the face of cervical dilation is a less successful procedure and should only be considered under certain circumstances, preferably using a scoring system as an aid to prognosis.[55]

The Role of Infection

In acknowledgment of the increasing emphasis of the role of subclinical infection in PTL, particularly if an infective etiology is suspected from a previous preterm birth, it seems reasonable to take vaginal and cervical microbiologic swabs electively in high risk women at 20 to 24 weeks' gestation.[56] Even if the patient is not subjected to prophylactic antibiotic therapy (see later discussion), knowledge of the potential microbiologic milieu at the time of PTL will assist both the obstetrician in the management of maternal pyrexia and the neonatologist in the management of suspected infection in the preterm infant. Identification of group B streptococcus carriers is of particular value, as it enables appropriate intrapartum treatment with intravenous penicillin in nonallergic women.

Patient Education

Education of the patient with a previous preterm birth about the signs and symptoms of PTL is a useful option to consider. The perception of contractions, menstrual-like cramps, pelvic pressure sensations, low, dull backache, abdominal cramping with or without diarrhea, an increase or change in vaginal discharge, and a "show" may all prove to be significant, but are, individually, not particularly predictive.[57] Nonetheless, if they occur in any women at risk of PTL, then a thorough cervical assessment should be performed, whether this be by digital examination or by ultrasonography.

Antenatal Care

In those women suspected of being at increased risk of PTL, more frequent antenatal assessment, particularly in the latter half of pregnancy, is a common option employed. The rationale for this form of management is based on indirect evidence that absent or delayed onset of prenatal care is associated with an increased rate of preterm birth and low birth weight infants. Of course, it is possible that those patients who are suffi-ciently motivated to seek early and regular prenatal care are intrinsically healthier and better motivated than those who do not. However, prenatal care does provide the opportunity to detect (and possibly treat) some of the maternal and fetal conditions (for example, anemia, hypertension, and bacteriuria) that can lead to preterm birth. Although multiple pregnancy and fetal anomalies cannot be treated, early warning may allow for decisions to be made regarding the place, the timing, and the route of delivery, which in turn may enhance the outcome.[58] Bowes[59] perhaps best summarized the contributions of prenatal care in preterm birth management by suggesting that success is related to the continuity of care, time available for patients to talk about their problems, ready access to ancillary services when needed, and a prenatal record that provides fail-safe reminders of critical procedures and screening tests.[59] Enhanced prenatal care may have the potential to become more effective as better predictive tests for PTL and more selective prophylactic agents are developed to deal with women at risk of preterm birth. This must be balanced by current evidence from the Cochrane overview that social support does not appear to reduce the risk of preterm birth.

Prediction of Preterm Labor

Prediction of PTL (see Chapter 61) has dominated research efforts for the past decade or more. Outpatient and home monitoring of uterine contractions, regular cervical assessment both clinically and ultrasonographically, the use of biochemical markers such as placental corticotropin-releasing hormone (CRH) and its binding protein, salivary estriol, the inflammatory cytokines and prostaglandins, fetal fibronectin (FFN), cervical ferritin, and most recently noninvasive cutaneous cardiovascular dynamics (CVD) have either come and gone or are being evaluated or reevaluated in the hope that we might obtain a reliable predictor with high sensitivity and specificity in order to judiciously manage patients at increased risk of preterm delivery.

Strategies for Prevention

A number of strategies involving the prophylactic use of oral tocolytics, antibiotics, and corticosteroids have been used in the prenatal management of women at high risk of PTL and are worthy of further discussion.

TOCOLYTICS

Several controlled trials of the prophylactic administration of beta-sympathomimetic drugs for the prevention of PTL have been reported in the literature.[10] Detailed analysis gives no indication that these agents decrease the incidence of PTD or low birth weight in multiple or singleton pregnancies, with odds ratios for both being 1.17 and 1.02, respectively. Hence, their use in the preventive management of PTL cannot be recommended.

ANTIBIOTICS

In some obstetric populations 40% to 50% of preterm labors have an infective basis that, through the inflammatory process, triggers the cytokine cascade, which is responsible for PTL and membrane rupture. Vaginal colonization with *Bacteroides, Trichomonas vaginalis, Ureaplasma urealyticum, Mycoplasma hominis, Gardnerella vaginalis, Neisseria gonorrhoeae*, or hemolytic streptococcus group B or asymptomatic bacteriuria appears to increase the risk of PTL, PPROM, and PTD.[60] Once labor has begun under these circumstances, then it is almost certainly too late for antibiotics to have any effect in delaying birth (see later discussion), and it would seem more logical to treat biologically relevant microorganisms early in pregnancy in order to prevent activation of the cytokine cascade. The current data suggest that bacterial vaginosis (BV) is the most closely associated with the foregoing outcomes, and Morales and associates[61] were able to demonstrate a significant reduction in the incidence of PTL, PTD, low birth weight (<2500 g), and PPROM using oral metronidazole compared to placebo. Subsequently, McGregor and associates[62] performed a randomized placebo-controlled trial using 2% clindamycin vaginal cream, but were unable to demonstrate a significant change in pregnancy outcome with locally administered antibiotics, and this was confirmed by a similar multicenter trial.[63] This led to the conclusion that systemic therapy may be required to reduce the incidence of PTD through the eradication of upper genital tract organisms. Hauth and associates[64] helped to clarify this question in a randomized study, from which they concluded that treatment with systemic therapy (specifically metronidazole and erythromycin) reduced the rate of preterm delivery in a high risk group with known BV. More recently, work by McDonald and associates[65] has shown in a subgroup analysis that in women with a history of PTD, treatment of BV-positive women with oral metronidazole during the second trimester reduces the incidence of preterm birth, but this benefit of treatment did not extend to all women with heavy growth of *Gardnerella vaginalis*. Further study of broad-based screening and treatment of asymptomatic carriers of BV, both at high risk and low risk for PTL, is necessary in order to evaluate the efficacy of this potential form of prophylaxis for PTL.

Fetal fibronectin (FFN) may offer some assistance in this regard, as preliminary studies have demonstrated that a positive FFN test at 24 weeks' gestation is associated with a twofold risk of BV, which in turn is predictive (20-fold increased risk) of subsequent chorioamnionitis and neonatal sepsis (6-fold increased risk) 6 to 8 weeks later.[66] Gibbs[67] did not support the prenatal treatment of BV as being effective in the prevention of intrauterine infection and PTD, and this view was supported by the large study of Carey and associates.[68] However, their conclusions continue to be challenged by the NICHD MFMU Network Study[69] and the previously mentioned authors Morales and associates, McDonald and associates, Hauth

and associates, and McGregor and associates and by the separate appraisals of Lamont[70] and Vigneswaran.[71] With regard to asymptomatic bacteriuria, Romero and associates[72] in their meta-analysis demonstrated that antibiotic therapy led to a significant reduction in low birth weight, although a similar effect on the rate of PTD was not seen.

The ORACLE trials,[73-75] although not directly answering the question of the use of prophylactic antibiotics for the prevention of PTL in women with intact membranes, nevertheless gave some important insights into the use of antibiotics in the management of PTL and PPROM. ORACLE II[75] confirmed the generally held view that antibiotics should not be prescribed routinely for women in spontaneous preterm labor without evidence of clinical infection, and ORACLE I considered the issue of antibiotic prophylaxis for PPROM (see Chapter 63). The explanation of a lack of beneficial effect may be that the population studied had a much lower incidence of asymptomatic vaginal infection and colonization than anticipated, and hence the sample size would be inadequate to show a positive effect. Additionally it is possible that once labor is established, then the cascade effect of cytokine/prostaglandin release would render antibiotics useless, and antibiotics might well aggravate the situation and contribute to neonatal morbidity by increasing the release of inflammatory cytokines.

CORTICOSTEROIDS

The use of "prophylactic" maternal corticosteroids to enhance fetal lung maturity in women at risk for PTD has currently been restricted to situations of threatened PTL and established PPROM during the immediate episode if it occurs before 34 weeks' gestation. A repeat course of corticosteroids may be given at 32 weeks' gestation should delivery be imminent more than 4 weeks since the last dose of corticosteroids. As mentioned previously, the results of the NICHD MFMU Network and ACTORDS trials are awaited with interest in view of experimental studies[76] and retrospective human studies, which have suggested caution with regard to the former practice of repeated maternal corticosteroid administration in high risk women because of possible fetal intrauterine growth restriction and neonatal neurodevelopmental impairment.[77]

PROGESTERONE

Supplemental progesterone to prevent PTD has been revisited with studies by da Fonseca and associates[78] and Meis[79] showing encouraging results with improvements in intermediate endpoints for prematurity reduction but with the sample size being insufficient to demonstrate a reduction in perinatal morbidity rate.

Management of Women Presenting with Threatened or Acute Preterm Labor

Once the diagnosis of threatened or actual PTL is established, then parenteral tocolytic therapy should be

considered. After a careful clinical appraisal of the maternal and fetal condition, preliminary investigations should be performed. Ultrasonography can be used to ascertain fetal number, estimate fetal weight, check fetal morphology and presentation, measure the volume of amniotic fluid, and identify the placental site. It can also be used to assess fetal well-being. Fetal breathing movements may also be visualized during this evaluation, and although suppression of fetal breathing movements was found in preliminary studies to predict the likelihood of PTL,[80] it has never been incorporated into routine management.

Testing for an infective etiology is important in the initial assessment and includes culture of vaginal and cervical secretions and a midstream specimen of urine, a complete blood count (including a white blood cell count), and C reactive protein estimation. Amniocentesis with Gram stain and culture and, more recently, interleukin 6 (IL-6) estimation, may be considered if infection is suspected. At the same time fetal lung maturity can be assessed by lecithin/sphingomyelin ratio or phosphotidyl glycerol measurement. If indicated by an abnormal fetal morphology, fetal karyotype determination, possibly using fluorescent labeled in situ hybridization (FISH) or rapid techniques for diagnosis of aneuploidy, should be considered. Not all obstetricians would perform amniocentesis routinely in this situation both because of the possibility of inducing further uterine activity and because of the lack of randomized data to guide management decisions based on the findings.

Determination of the presence or absence of PPROM by clinical and, if necessary, additional investigations is essential to the management.

Although acknowledging that positive FFN tests in symptomatic women have only a 29.3% predictability of delivery before 34 weeks' gestation, a large body of evidence now exists of a greater than 95% accuracy of a negative FFN test predicting that preterm delivery will not occur before 34 weeks[81] and should probably be utilized to stop unnecessary and potentially dangerous intervention in women presenting with threatened preterm labor, particularly in remote areas where unnecessary and costly maternal-fetal transfer may also be avoided. A number of noninterventional studies have confirmed the usefulness of fetal fibronectin testing in this situation, and its use merits consideration in regionalized perinatal networks.

Once gestational age is established, the universally poor immediate and longer-term fetal outcomes of infants born between 20 and 24 weeks' gestation require considerable discussion between the parents, the obstetrician, and the neonatologist either before or shortly after the initiation of tocolytic therapy.[22,82] In cases of extreme fetal immaturity the parents may well choose to allow delivery to occur rather than to invoke risky, uncomfortable, and expensive delaying tactics of poor efficacy, but caution must be exercized because fetal weight and gestational estimates are subject to significant variation between 20 and 24 weeks. Perhaps a more prag-

matic method of dealing with this dilemma is to transfer the patient to a tertiary center and allow her to deliver vaginally without intervention but with a neonatologist present at delivery to assess the delivered neonate with regard to the potential need for further neonatal support.

Whether continuous electronic fetal monitoring should be carried out during such a labor is a matter of dispute. Some argue that recording a potentially abnormal fetal heart rate while prescribing nonintervention is distressing for parents and staff, whereas others argue that the normality or otherwise of the fetal heart rate may be important for the neonatologist in deciding whether or not to resuscitate or support the neonate.

The use of tocolytic therapy between 24 and 34 weeks' gestation is not only to facilitate the in utero transfer of the fetus to a tertiary referral center[83] but also to enable sufficient time to enhance fetal lung maturity by the concomitant use of maternal corticosteroid therapy. The systematic review of 17 trials[10] with a total of 2284 women comparing tocolytics with no treatment or placebo and including some women with ruptured membranes found that ritodrine was the most frequently evaluated drug, but other agents were also used including isoxsuprine, terbutaline, magnesium sulfate, indomethacin, and atosiban. Overall, tocolytics were associated with a significant reduction in the odds of delivery within 24 hours (OR [odds ratio] 0.47; 95% CI [confidence interval] 0.29–0.77), 48 hours (OR 0.57, CI 0.38–0.83), and 7 days (OR 0.60; CI 0.38–0.95). For beta-sympathomimetics, indomethacin, and atosiban these effects were statistically significant, but for magnesium sulfate they were not. However, there was no statistically significant reduction in births before 30 weeks (OR 1.33; CI 0.53–3.33) or before 32 weeks (OR 0.81, CI 0.61–1.07) or before 37 weeks (OR 0.17; CI 0.02–1.62). Tocolysis was not associated with any clear effects on perinatal death (OR 1.22, CI 0.84–1.78) or on any measure of neonatal morbidity such as respiratory distress (OR 0.82; CI 0.61–1.07) or intraventricular hemorrhage (OR 0.73; CI 0.46–1.15). Trials for glyceryl trinitrate[21,84] have been too small to make any firm conclusions, and there are no placebo-controlled trials of calcium-channel blockers despite their increasing popularity as tocolytic agents. However, the latest Cochrane review did report on 11 randomized trials involving 870 women, comparing nifedipine with other tocolytics, and concluded that nifedipine was more effective than beta-mimetics and had fewer side effects.[18]

There are a number of explanations for the apparent negative (although not significantly so) effect of tocolysis on the perinatal mortality rate. Perhaps too many women in the trials were at an advanced gestation when prolongation of the pregnancy would have had little potential benefit for their babies; the time gained by tocolysis may not have been used productively (i.e., administration of corticosteroids, transfer to a tertiary unit), and there may have been direct or indirect adverse effects of the tocolytic

agents used which outweighed the benefits of pregnancy prolongation (e.g., their use in the presence of abruptio, severe hypertension, and intrauterine growth restriction).

Currently there appears to be a trend away from the use of beta-sympathomimetics as first-line tocolytics, with a swing toward nifedipine or, particularly in the United Kingdom, atosiban, because of their fewer side effects. Nifedipine does have the advantages of cheapness, ease of administration, and availability. However, there continues to be a lack of consensus in administration regimens. The lack of any trials that show an advantage against placebo means that we should continue to be intolerant of any harmful short- or long-term side effects.

Tocolytic therapy should be continued if possible for 48 hours to try to maximize the enhancement of fetal lung maturity by maternally administered corticosteroids. Data from the 12 controlled trials reviewed by Crowley and associates,[85] and later by the NIH Consensus group,[38] demonstrate that corticosteroids not only reduce the occurrence of neonatal respiratory distress, but are also associated with reductions in the risk of neonatal intraventricular hemorrhage, necrotizing enterocolitis, and neonatal death, particularly in extremely preterm infants (less than 28 weeks' gestation).

The place of other maternally administered agents to enhance fetal outcome requires further discussion in the light of completed studies. The Australian collaborative trial of antenatal thyrotropin-releasing hormone (TRH) for the prevention of neonatal respiratory disease in women at high risk of preterm delivery who also received corticosteroids (the ACTOBAT study)[36] concluded that the increased maternal side effects and the increased ventilatory requirements of the treated neonates could not justify the widespread use of TRH. This finding is supported in a systematic review of 11 trials that included more than 4500 women. The subsequent 12-month follow-up study of ACTOBAT,[86] which suggests the additional possibility of abnormal neurodevelopment, should alert clinicians to be cautious in their use of TRH unless it is under the strict conditions of a clinical trial.

The prophylactic use of maternally administered vitamin K and phenobarbitone to reduce the incidence of neonatal intracerebral hemorrhage has not been validated scientifically in clinical trials[87] and, similarly, cannot be recommended as part of the routine management of PTL.[88]

If the initially selected tocolytic agent is unsuccessful, or is not tolerated in the suppression of PTL, then an alternative agent may be considered. This agent can be given alone or in combination with the initial tocolytic agent. Any such strategy should only be instituted after a careful reappraisal of maternal and fetal well-being. In particular, intrauterine infection should be excluded as far as possible, because it is notorious for producing a "failure" of tocolysis and is potentially dangerous not only to the fetus but also to the mother. The results of the ORACLE trial[74] should discourage the routine use of

antibiotic therapy as an adjunct to tocolysis unless there is clinical evidence of maternal infection or when the mother is known to be a group B streptococcus carrier.

After an initial 48 hours of labor suppression by intravenous tocolysis, some workers have continued oral tocolytic agents until 34 to 37 weeks' gestation in an effort to prolong gestation. Although a trial[89] using a sustained-release oral tocolytic agent suggested benefit, continuing oral tocolysis has not been commonly employed by many perinatal centers, nor is it currently widely used.

More recently the role of cervical cerclage has been expanded to include women with nonreassuring sonographic cervical findings in the midtrimester.[90] Results of both retrospective cohort series and randomized trials of cerclage in women with shortened cervical length are inconclusive at this time. So-called rescue cerclage should therefore only be performed under the conditions of a randomized trial.[54,91,92]

Treatment of PTL after 34 weeks' gestation has little to recommend it because the additional expense and the maternal risks of tocolysis are not justified in view of the minimal neonatal morbidity potentially avoided between 34 and 37 weeks' gestation.[93]

Labor and Delivery

Once preterm delivery seems inevitable, the mode of delivery and the neonatal outcome should be discussed with the parents. The parents should discuss the further management with an obstetrician and a neonatologist as well as with an experienced obstetric anesthetist.[94] They play an essential part in establishing management guidelines that will be acceptable to all parties. The other central person in the management team in some countries is the midwife, who should also be included in discussions concerning the management of labor and the delivery.

In general, before 24 completed gestational weeks, vaginal delivery should be the accepted route, with expert neonatal evaluation at delivery to determine if further neonatal supportive care is warranted. Between 24 and 34 weeks the management of labor should not differ significantly from that beyond 34 weeks.[22] Continuous electronic fetal monitoring and a preference for regional analgesia are of unproven benefit but are commonly used in the contemporary management of established PTL.

Once labor is established, maternal antibiotic therapy should be commenced if signs of intrauterine infection are present. Earlier reservations regarding the possibility of inducing superinfection with resistant bacteria and complicating the diagnosis of infection in the neonate have not been borne out in clinical practice.[95,96] A reduction in maternal infectious morbidity rate has been shown in most studies, and although the authors currently favor the use of intravenous ampicillin 2 g every 8 hours and gentamicin 80 g every 8 hours during labor, this combination of antibiotics is currently under review

in the light of new evidence suggesting that beta-lactam antibiotics may have deleterious effects on the neonate as a result of the sudden release of cytokines and aggravation of the fetal inflammatory response syndrome (FIRS).[97]

Evaluation of the available randomized trials would suggest that "prophylactic" outlet forceps or "elective" episiotomy does not contribute significantly to the neonatal outcome and hence should only be performed for standard obstetric indications.[98] Early cord clamping has not been proved to confer an advantage to the neonate and so cannot be recommended in the routine management of a preterm birth.[98] Standard management of the third stage is recommended in PTL.

From the neonatal aspect, the significantly higher risk of morbidity and fatality of infants born outside a tertiary perinatal center makes a compelling argument for maternal-fetal transport (preferably with the baby in utero) to a tertiary perinatal center with neonatal intensive care facilities, providing such transport does not jeopardize the safety of the mother.[99,100] When transport is not possible (in some series up to 50% of cases), then specifically trained and equipped obstetric and neonatal retrieval teams with appropriate nursing and medical personnel should attend the birth. They can supervise or perform the delivery of the neonate and then stabilize the mother and her premature infant prior to their respective transfers to the tertiary perinatal center if this is deemed necessary.[99,100]

Postnatal

Maternal Considerations

Encouragement of parent-infant bonding is a major consideration in postnatal management. Continuous access by the parents to the neonatal nursery should be encouraged to facilitate the bonding process. Breastfeeding should be encouraged in a compassionate and pragmatic manner.

Continuing psychosocial support is important, utilizing the services of a domiciliary midwife, a social worker, and if indicated, a psychiatrist. This staff support is likely to be essential if there is significant neonatal morbidity or a perinatal death.

An early postnatal evaluation of possible etiologic factors related to the PTL should be considered by the perinatal team, which should include an obstetrician, neonatologist, perinatal pathologist, and where indicated, input from an obstetric physician, pediatric surgeon, geneticist, and ultrasonologist in order to construct a rational plan of management for further pregnancies.

Neonatal Considerations

Premature birth requires adaptation to extrauterine life while the different organ systems undergo continued structural and functional development and maturation. Thus, premature infants can be expected to have a variety of problems in the neonatal period with the risk of complications being proportional to the degree of prematurity.

Premature infants are likely to have difficulties in maintaining body temperature and in oral feeding, as well as having a greater risk of infection. Lung maturity of premature infants is proportional to their gestation and is the major cause of respiratory distress syndrome in these infants. Poorly developed respiratory control may lead to recurrent apnea in premature infants.[101]

Congestive cardiac failure may occur as a result of a patent ductus arteriosus associated with prematurity. Liver immaturity is likely to be associated with severe neonatal jaundice, and the baby is more vulnerable to the neurotoxic effects of unconjugated bilirubin. There is also an increased risk of intracranial hemorrhage and necrotizing enterocolitis in these infants, and in the extremely premature infant, chronic lung disease, retinopathy, cerebral palsy, and developmental delay are more likely in the longer term.[101]

Maturity of organ systems, particularly the lung, is the key factor determining the ultimate prognosis of the premature infant. Minimizing the incidence and severity of respiratory distress has been the major factor in the substantial improvement in neonatal morbidity and mortality rates over the past 2 decades. Previously mentioned strategies of regionalization of perinatal care, selective use of tocolytic agents, and the antenatal administration of corticosteroids to enhance fetal lung maturity have all been positive contributing factors.

Evaluation of the "prophylactic use" of exogenous surfactant has demonstrated a favorable outcome with a significant reduction in the incidence of respiratory distress syndrome.[102–104] Additionally, the course of established respiratory distress can be significantly modified by the administration of surfactant "rescue" therapy in association with mechanical respiratory support.[105] It cannot be emphasized too strongly that the antenatal administration of corticosteroids to the mother is equally as important as exogenous surfactant in minimizing respiratory morbidity.

Although there has been a significant increase in neonatal survival rates at 24 to 27 weeks' gestation over the past decade,[106] it appears that prematurity per se has a deleterious effect on neonatal growth and development, which contributes to a poorer outcome. This must be taken into account, particularly when assessing survival rates in premature infants in the less than 24 weeks' gestational ("previable") age group.[107]

Despite the very substantial medical advances in neonatal intensive care, it must be emphasized that not every premature newborn infant can be salvaged, and on some occasions survival will be accompanied by severe handicap, either physical or mental. Prolonging life in these circumstances may not be beneficial to the infant and may be unacceptably burdensome to the parents. Consideration of

withdrawing life support in such tragic circumstances should be undertaken after detailed and extensive consultation and counseling of the parents.[108,109]

In addition to these medical and ethical challenges confronting the neonatologist are the immediate and delayed financial costs of neonatal intensive care. Economic constraint applies a brake to the tendency of the specialist to attempt to overcome all these medical and ethical challenges, as neonatologists are increasingly being required to apply evidence-based medical practice in an environment of cost containment.

The final measure of the quality of a tertiary neonatal service is the dedication and commitment of its long-term follow-up program. All perinatal centers must be prepared continuously to maintain and even upgrade this essential service in order to practice early intervention so as to reduce to the minimum possible the physical and mental handicaps inevitable in very premature infants, and provide crucial information to obstetricians and subspecialists in maternal-fetal medicine of the potential outcome of infants of all gestational ages and birth weight groups. They must promulgate appropriate and relevant advice and support, reassure, and counsel the parents who will continue to bear the brunt of the care for the infant who is born prematurely.

CONCLUSIONS

- Since the last edition of this text in 1999 there have been numerous efforts made on many fronts not only to try to reduce the incidence of preterm delivery and the neonatal mortality rate associated with such an event but also to reduce the neonatal morbidity rate.
- Sadly, we have not reduced the incidence of preterm delivery, and indeed, in some centers there has been a small but significant increase in the incidence of preterm delivery. This rise may be due to expanding indications for obstetric intervention before term (in consultation with our neonatology colleagues) rather than a true increase in spontaneous preterm labor.
- Much effort continues in the quest to find accurate markers of preterm labor (see Chapter 61) to allow the use of interventions such as prophylactic progesterone therapy and cerclage after sonographic cervical evaluation. These possible interventions require further evaluation in large, well-conducted clinical trials.
- Our attempts to reduce neonatal morbidity rate may come to fruition with our rapidly increasing knowledge of the role of cytokines in the fetal inflammatory response syndrome, leading to the development of nonantibiotic anti-inflammatory agents that may play a significant role in the future management of preterm labor.

SUMMARY OF MANAGEMENT OPTIONS
Threatened and Actual Preterm Labor

Management Options	Quality of Evidence	Grade of Recommendation	References
Prepregnancy (Previous Preterm Delivery)			
Establish cause/precipitating factors; estimate risk of recurrence; be honest about the value of preventive measures.	III	B	44,47,48
Give advice about lifestyle, work, place of residence at critical phase of pregnancy, diet, smoking, alcohol and drug abuse.	III	B	49–51
Prenatal—Assessment of Risk			
Careful history taking for presence of specific risks (e.g., previous preterm birth), but value of formal risk scoring systems uncertain.	III	B	44,47,48, 52
Establish gestational age early and accurately.	–	GPP	–

Prelabor Rupture of the Membranes

John Michael Svigos / Jeffrey S. Robinson / Rasniah Vigneswaran

DEFINITIONS AND INCIDENCE

Prelabor rupture of the membranes (PROM) is an obstetric conundrum; it has been poorly defined with an obscure etiology, difficult to diagnose, and associated with significant maternal, fetal, and neonatal risks and management strategies that are often diverse and controversial. It may be defined as rupture of the fetal membranes with a latent period before the onset of spontaneous uterine activity. The length of this latent period varies in different definitions from not being specified to up to 8 hours.

It is generally accepted that PROM occurs in 10% of all pregnancies,[1] with the majority of cases occurring after 37 completed weeks of gestation. If PROM occurs before 37 completed weeks of gestation, then the condition is referred to as preterm prelabor rupture of the membranes (PPROM). PPROM occurs in approximately 2% of all pregnancies.[2–4] These statistics refer to the general obstetric population, but clearly, the incidence of PPROM recorded for any particular hospital will be determined by the level of perinatal care provided, and hence in a hospital accepting fetal-maternal transfers the incidence of PPROM may be recorded as 5% of all pregnancies delivering there.[5]

RISKS

Maternal Risks

Significant maternal risks are associated with PROM, especially PPROM, and these problems can occur antepartum, intrapartum, and postpartum. Although the incidence of subclinical chorioamnionitis may be as high as 30% with PPROM,[6,7] serious maternal systemic infection is rare if treatment is initiated promptly.

The use of a number of therapeutic agents such as corticosteroids, antibiotics, and tocolytic agents, particularly with PPROM, may pose some additional maternal risk, which must be considered in the overall management. Abruptio placentae is evident in 4% to 7% of women with PPROM, and hence vaginal bleeding in the presence of PROM must be regarded seriously and managed accordingly.[8–11]

The undoubted psychosocial sequelae, particularly related to PPROM, with the disruption created by maternal hospitalization and continued observation associated with the uncertain fetal/neonatal prognosis, should never be underestimated and should be addressed on an individual basis within the overall management strategy.

The maternal intrapartum consequences of PROM are predominantly related to the induction of labor. The latent phase of labor under these circumstances may be as long as 16 to 20 hours, and thus unrealistic limits must not be set regarding the duration of labor when counseling the patient and attendant staff. The increased likelihood of operative delivery associated with induction of labor will increase the chance of maternal complications.[12]

Pathologic examination of placentas associated with PROM demonstrates an increased incidence of marginal cord insertion and battledore placentae, which may account for the increased incidence of retained placenta in this condition.[13] This in turn may be associated with the known increase in the incidence of primary and secondary postpartum hemorrhage. The latter complication is also probably associated with the 10% incidence of endometritis and myometritis that occur with PROM.

The complications described here account for a significant proportion of puerperal maternal morbidity, and the impaired maternal-infant bonding, particularly seen with PPROM, and which results in maternal psychological and lactation problems, will contribute to the remainder.

Fetal and Neonatal Risks

Prematurity is the most significant factor in the increased perinatal morbidity and mortality associated with preterm rupture of the membranes, because delivery occurs within 7 days of PPROM in over 80% of cases.[14,15]

Although the incidence of chorioamnionitis is 30%, the reported incidence of neonatal sepsis is only 2% to 4%.[16–18] Gestational age at the time of rupture of the membranes will have some influence on the incidence of neonatal sepsis (the earlier the gestation, the greater the chance of infection), as will the length of the latent period (the longer the latent period, the smaller the chance of infection). A growing body of epidemiologic data has demonstrated a relationship between intrauterine infection and the development of neonatal intraventricular hemorrhage, periventricular leukomalacia, and the subsequent occurrence of cerebral palsy.[19] Recent evidence suggests this damage is the result of the fetal inflammatory response syndrome (FIRS)[20] initiated by placental inflammation rather than infection with the local generation of arachidonic acid and the proinflammatory cytokines (i.e., interleukin 1 [IL-1], interleukin 6 [IL-6], and tumour necrosis factor-α [TNF-α]) thought to be responsible.

Oligohydramnios, particularly if there is prolonged PPROM, may result in the neonatal "oligohydramnios tetrad" of facial anomalies, limb position defects, pulmonary hypoplasia, and impaired fetal growth, all of which will add to neonatal morbidity.[13]

Fetal hypoxia is also more likely, due to the greater possibility of cord prolapse, cord compression, and abruptio placentae associated with PROM, particularly with PPROM. Neonatal morbidity will also be increased because of the mechanical difficulties encountered with delivery, either by the vaginal or abdominal route, as a result of the increased incidence of malpresentations and reduced volume of amniotic fluid.

MANAGEMENT OPTIONS

Prepregnancy

Prepregnancy counseling has only a limited role in the management of PROM, particularly PPROM, because in the vast majority of cases the cause is unknown.

The recurrence risk for PPROM has not been extensively studied, but Naeye's original observations[21] of a recurrence rate of 21% to 32% were subsequently confirmed by Asrat and associates.[22] More recently, a somewhat lower recurrence rate of 16.7% has been reported by Lee and associates,[23] but in this study, after one pregnancy complicated by PPROM, the subsequent overall preterm delivery rate in the next pregnancy was 34.2%.

A detailed examination of etiologic associations of PPROM by Harger and associates[24] suggested that the only independent risk factor that might be amenable to prepregnancy intervention was cigarette smoking, and the risk appeared to be dose-related.

Other less constant associations that might be amenable to intervention include cocaine abuse, intrauterine diethylstilbestrol (DES) exposed women, and possibly nutritional deficiencies of ascorbic acid, copper, zinc, and iron.[25–28] However, evidence that implementing intervention strategies improves outcomes is lacking.

There is substantial direct and indirect evidence that reproductive tract infections and associated inflammatory changes are responsible for many instances of PPROM.[27] Group B streptococci, chlamydia, gonorrhea, syphilis, *Mycoplasma hominis*, and *Ureaplasma urealyticum* have all been variously incriminated, but good evidence that prophylactic treatment is effective at reducing the incidence of PPROM is lacking. The prophylactic antimicrobial treatment of bacterial vaginosis during pregnancy in high risk women was reported in three studies to show a 66% to 70% reduction in the expected incidence of PPROM.[28] However, the study by Gibbs[29] did not support the value of such prophylactic treatment, and the much larger study by Carey and associates[30] would tend to confirm his view. Despite the lack of consistent evidence, two recent separate appraisals by Lamont[31] and Vigneswaran[32] were supportive of the treatment of bacterial vaginosis as an effective preventive measure for PPROM. The Cochrane Systematic Review concludes that antibiotics are associated with delay in delivery and reduction in markers of neonatal morbidity,[33] but largely on the basis of the large multinational ORACLE trial, which showed a benefit only for the use of erythromycin in the presence of ruptured membranes (see later discussion).

In light of the foregoing information, prepregnancy vaginal cultures would appear to be a useful investigation in women with a past history of PPROM, especially in relation to the detection of group B streptococcus and bacterial vaginosis.

Antimicrobial treatment of the sexual partner is more controversial, but the avoidance of coital activity during the course of further pregnancies appears to be unnecessarily restrictive given the available evidence. If there is concern on the part of the woman that infection might be introduced by the male partner, then this risk might be reduced by the use of condoms.

Prenatal

Diagnosis and Further Assessment

The diagnosis of PROM requires a judicious assessment of the history, clinical findings, and specialized testing. Whenever the history is suggestive of PROM, a sterile vaginal speculum examination should be performed. Visualization of amniotic fluid draining through the cervix provides the most reliable diagnosis. In cases of doubt, demonstration that vaginal fluid has an alkaline

pH on nitrazine yellow testing (the pH indicator turning black) is suggestive, but not conclusive evidence of PROM. The normal vaginal pH is acid, and becomes neutral or alkaline due to the presence of amniotic fluid; however, such loss of acidity can also be due to vaginal infections, urine, or even bathwater. Ferning on microscopy is also a useful sign that the fluid is of amniotic origin and this simple test, which is easy to perform, should be more widely used in the diagnosis of PROM. However, both pH tests and ferning are less reliable with increasing prematurity.

When the diagnosis is in doubt, then further investigations, including the use of a modified vaginal pouch to collect the amniotic fluid,[34] ultrasound evaluation of amniotic fluid volume, and intra-amniotic dye injections, may be required. However, ultrasonographic diagnosis of oligohydramnios is often possible only with a large fluid loss that is clinically obvious. Furthermore, intra-amniotic injection of dyes is not without risk and is not widely practiced.[35,36] Alternatively, if conservative management is deemed appropriate, a "wait and see" policy may be adopted. Repeatedly dry pads and a normal amniotic fluid volume on scan make the diagnosis less likely, and the converse is also true.

Fetal fibronectin immunoenzyme testing has been utilized in the more precise diagnosis of PROM and may become a useful confirmatory test when the diagnosis is in doubt.[37]

The initial clinical assessment of the patient with PROM will determine the further management. All efforts must be directed initially at the exclusion of overt chorioamnionitis with attention to the detection of maternal tachycardia, pyrexia, uterine tenderness, purulent vaginal discharge, and fetal tachycardia (see also Chapter 27). Thereafter, there should be an evaluation of the fetal gestational age (from the history, clinical examination, and ultrasonographic assessment), immediate assessment of fetal well-being (clinical examination and fetal cardiotocography), and the exclusion of abruptio placentae and preterm labor.

The subsequent management of the patient will depend very heavily on the particular combination of the abovementioned features. The management alternatives that can be considered are discussed in the following sections.

Expectant Management

Expectant management consists of hospitalization and continued clinical observation of the mother and fetus. The role of bed rest is controversial but may aid diagnosis by allowing a pool of amniotic fluid to collect in the posterior fornix. Maternal activity also seems sometimes to increase the rate of fluid leakage, perhaps by dislodging the presenting part. Specialized assessments of continued fetal well-being using cardiotocography (nonstressed testing, NST) and biophysical profiles have been advocated,[38]

and obstetric ultrasonographic evaluation of fetal growth is usually performed every 2 weeks.

The detection of covert chorioamnionitis using serial white blood cell differential counts and C-reactive protein estimates, in association with an initial and then weekly vaginal microbiologic cultures, has been advocated. The use of amniocentesis in clarifying the possibility of covert chorioamnionitis is more controversial and has yet to be tested adequately.[39] A number of small clinical trials have studied the relationship of proinflammatory cytokines (IL-6, IL-8, LL-18) and microbial invasion of the amniotic cavity in PPROM, but these have yet to be validated as markers for obstetric intervention[40] and may not be better than clinical findings or fetal fibronectin.[41]

Of recent interest are the observations that early intrauterine infection appears to be associated with disturbances in neurobehavioral physiology.[40] Abnormalities of the fetal heart rate (NST) and the biophysical profile score (BPS) correlate closely with proven intrauterine sepsis. These noninvasive tests have obvious advantages over amniocentesis. However, at present, it is not known whether the use of these tests will be helpful in determining the appropriate management and improving fetal outcome.

Active Management

Active management may be defined as the expectant management plus the use of one or more of the following pharmacologic agents:

- Maternal corticosteroids
- Tocolytics
- Prophylactic antibiotic administration.

In the contemporary management of PPROM, there is good evidence to recommend corticosteroids before 34 weeks' gestation to enhance fetal lung maturity.[42] However, the repeated use of corticosteroids in women with a prolonged latent phase after PPROM is currently in question, awaiting the results of large multicenter trials (including NICHD MFMU trial[43] and ACTORDS[44]) to determine neonatal safety, particularly in relation to intrauterine growth, pulmonary structural development, and neurodevelopment despite the reassuring original work by Liggins and Howie[45] (see Chapters 62 and 67).

With regard to tocolytic agents, it would seem logical that if maternal corticosteroids are advocated, then tocolysis for at least 48 hours should be acceptable (again, provided there is no overt evidence of infection). However, there is no good evidence available to support this view, and a high index of suspicion of intrauterine infection must be maintained if tocolytic therapy is to be instituted under these circumstances. The use of tocolytics to facilitate maternal-fetal transfer to an appropriate tertiary center has been supported, but on the basis of limited evidence.[46,47]

It is believed that membrane rupture is preceded by structural weakness associated with extracellular matrix degradation and cellular apoptosis[46–48] with a considerable number being associated with covert chorioamnionitis. Microorganisms appear to degrade the fetal membranes either directly with proteases or phospholipases or indirectly by the activation of collagenases such as the matrix metalloproteinases (MMPs).[49]

Administration of antibiotics to the mother should improve neonatal outcome by preventing infectious morbidity in the fetus and perhaps by prolonging the latency period. The latest Cochrane review of antibiotics for PPROM[50] demonstrated a reduction in maternal infection, delay in delivery, reduction in neonatal infection, and a reduction in the number of neonates requiring surfactant or oxygen therapy at 28 days. However, there did not appear to be a reduction in necrotizing enterocolitis, major cerebral abnormality, respiratory distress syndrome, stillbirth, or neonatal death rates. Co-amoxiclav (ampicillin and clavulanic acid) should be avoided as it was associated with an increased risk of necrotizing enterocolitis.

The ORACLE II[51] randomized trial attempted to answer the question of the value of prophylactic antibiotics by randomly assigning women with PPROM to the following groups: oral erythromycin (n = 1197), oral augmentin (n = 1212), both (n = 1192), or placebo (n = 1225). The primary outcome measure was a composite of neonatal death, chronic lung disease, or major cerebral abnormality on ultrasound before discharge from the hospital. Analysis was by intention to treat. Among the 2415 infants born to women allocated erythromycin only or placebo, fewer in the erythromycin only group had the primary composite outcome. Co-amoxiclav alone and co-amoxiclav plus erythromycin groups had no benefit over the placebo group. Use of erythromycin was also associated with prolongation of pregnancy, reductions in the need for neonatal treatment with surfactant, decreases in oxygen dependence at 28 days of age and older, fewer major cerebral abnormalities on ultrasound, and fewer positive blood cultures. Although the co-amoxiclav alone group and the co-amoxiclav plus erythromycin group were associated with a greater chance of prolongation of the pregnancy, they were also associated with a significantly higher rate of neonatal necrotizing enterocolitis. The authors concluded that treatment with erythromycin was associated with the best range of health benefits for the neonate and suggested that there might be a reduction in childhood disability. This view was challenged in an accompanying leading article.[52]

With our increased understanding of the role of proinflammatory cytokines and their undesirable intestinal, pulmonary, and neurologic effects on the fetus, the choice of antibiotics used in PPROM may well be critical.[19] Macrolide antibiotics such as erythromycin, clindamycin, aminoglycosides, and metronidazole tend to shut down bacterial virulence factor production, exert antiprotease activity, and stabilize activated inflammatory cells. Beta-lactam antibiotics such as penicillins and cephalosporins act primarily by impairing cell wall synthesis with the release of endotoxins, which promote proinflammatory cytokine release and increase the potential for deleterious effects on the neonate. These views would appear to be supported by the ORACLE I trial, but much longer neonatal follow-up is required before definite conclusions can be drawn.

The ORACLE I trial utilized oral antibiotic therapy four times daily for 10 days or until delivery, but earlier evidence suggested that initial aggressive broad-spectrum intravenous antibiotic therapy was desirable,[51] even though it was not clear if extended antibiotic therapy was necessary. More recent trials suggest that 72 hours of antibiotic therapy after PPROM is sufficient to gain benefit.

Currently the authors favor the use of intravenous ampicillin 2 g every 8 hours and gentamicin 80 mg every 8 hours for 48 hours followed by oral therapy with amoxicillin every 8 hours for 5 days, as suggested by Mercer and Arheart,[53] but this regimen is under review in light of the ORACLE trial.

Aggressive Management

Aggressive management is employed when delivery is deemed necessary as a result of obstetric indications, such as fetal distress, maternal sepsis, or abruptio placentae, or is requested by the parents in the face of marked fetal immaturity (<24 weeks) or of demonstrated fetal maturity (after 34 weeks). This form of management implies an increased incidence of induction and augmentation of labor, operative delivery, and associated maternal and neonatal morbidity. We are presently fortunate to have the results of a prospective randomized trial to aid us in the management of PROM at term[54] (see following discussion). Unfortunately, prospective, randomized trials have yet to be done for PPROM at different gestational age groups, and this remains a challenge for contemporary perinatology.

Management Strategies

Generally, the recommended management of PROM has shifted from an expectant mode to a more active mode, with accurate assessment of fetal gestational age being crucial to the decision-making process. It is useful to consider prenatal management strategies in relation to five gestational periods.

PPROM AT LESS THAN 24 COMPLETED GESTATIONAL WEEKS

The most appropriate management at this gestation is not clear and must be individualized, the wishes of the parents being paramount. Aggressive management is almost always indicated if active labor, abruptio placentae, or clinical evidence of maternal-fetal infection are

present. It may also be requested by the parents if they fear delivery at a subsequent gestation (e.g., 25–26 weeks) when there is the possibility of survival, but also a high likelihood of serious neonatal complications and long-term handicap.

Expectant management is being increasingly considered, but with reported neonatal survival rates of less than 50% at gestations less than 24 weeks, even in the very latest and most optimistic studies[55–58] and with "normal" neonatal development in less than 40% after a 12-month follow-up period, care must be taken to ensure that parental counseling is thorough and cautious when there is PPROM at less than 24 weeks' gestation. The parents must be helped to understand that the neonatal prognosis is at best guarded and the likelihood of neonatal death and morbidity is significant. The prognosis for delivery at preterm gestations is also discussed in Chapter 62.

In view of the uncertainty of the outcome, an alternative management strategy has evolved for women who experience PPROM at less than 24 weeks' gestation. After initial hospitalization for 72 hours, the patient can be managed at home, restricting her physical activity, taking her own temperature, and reporting weekly for prenatal evaluation and microbiologic/hematologic surveillance. This management alternative has yet to be tested in randomized trials but would clearly have merit with regard to economic and psychosocial considerations.

PPROM AT 24 TO 31 COMPLETED GESTATIONAL WEEKS

At this gestation, the greatest risk to the fetus is still prematurity, and this risk currently outweighs any potential advantage in delivering a patient with occult intrauterine infection. Consequently, expectant management is the most favored option at this gestation.

The use of amniocentesis to detect the possibility of occult amniotic infection remains controversial at this gestation, particularly as fetal lung maturity is unlikely. It may be specifically indicated in certain circumstances, particularly if there are potential signs of chorioamnionitis, such as mild pyrexia, raised white blood cell count, and an elevated C-reactive protein.

A randomized study,[59] which assessed hospital versus home management after 72 hours of PPROM at 26 to 31 weeks' gestation, suggested that home management was a safe protocol to adopt, in terms of neonatal and maternal outcome, with significant savings in maternal hospital bed days. Hoffmann and associates[60] suggested that this form of management may be more appropriate for a subset of patients with PPROM characterized by the absence of labor or evidence of infection for 1 week, with adequate amniotic fluid volume demonstrated by ultrasonographic assessment. We await the outcome of similar larger randomized studies to determine the appropriate management of PPROM at this gestation.

Included in the prenatal management of PPROM at 24 to 31 weeks' gestation must be a discussion with the par-

ents regarding the likely mode of delivery, should expectant management not be appropriate. In this regard, some interesting trends in clinical practice have evolved. A survey of members of the Society of Perinatal Obstetricians conducted by Amon and associates (1992)[61] regarding the use of cesarean section for fetal indications, particularly at the limits of fetal viability, in women delivering between the years 1986 and 1992, showed a doubling of the cesarean section rate for infants delivered between 24 and 28 weeks' gestation. Sanchez-Ramos and associates,[62] however, were able to demonstrate that a significant decrease in the cesarean section rate from 55% to 40% ($P < 0.05$) for very low birth weight infants delivering between the years 1986 and 1990 did not alter the neonatal mortality rate, the incidence of low Apgar scores, cord blood gas values, the incidence of intraventricular hemorrhage, or the median length of stay in the neonatal intensive care unit. Weiner[63] specifically studied breech presentation before 32 weeks' gestation and concluded that cesarean section reduced the perinatal mortality rate by a reduction in the incidence of intraventricular hemorrhage, confirming the study by Olofsson and associates.[64]

On balance, it would appear that aiming for vaginal delivery of the very low birth weight infant would be a reasonable management option to put before the parents during counseling, with resort to cesarean section for standard obstetric indications, save perhaps for those infants presenting by the breech before 32 weeks' gestation (for a fuller description of the mode of delivery of the preterm breech, see Chapter 64).

PPROM AT 31 TO 33 COMPLETED GESTATIONAL WEEKS

At our institution, neonatal survival at this gestation exceeds 95%, and thus, the risk from prematurity is similar to the risk to the neonate from sepsis. Although the use of amniocentesis would appear to be an attractive refinement in the management of patients with PPROM at this gestation,[64–66] its value has never been adequately evaluated. Success rates in obtaining amniotic fluid at amniocentesis in women with PPROM have varied from 45% to 97%. If fluid is obtained successfully, then the lack of a "gold standard" for the diagnosis of occult intrauterine infection versus colonization makes interpretation of the results of Gram stain, fluid microbiologic culture, leukocyte esterase testing, and gas liquid chromatography studies particularly difficult.[67] Fisk's review[68] of six studies using culture or Gram staining to diagnose infection of the amniotic fluid revealed sensitivities of 55% to 100%, and specificities of 76% to 100%. The outcome studied is important in interpreting the sensitivity and specificity of tests designed to diagnose occult infection; for example, if the presence of pathogenic organisms is regarded as diagnostic of infection, then the sensitivity of demonstrating such organisms on Gram staining and culture of the amniotic fluid is by definition 100%, whereas if neonatal death from sepsis is used as the end-point, sensitivity will

be much lower and significant morbidity will be ignored. Fisk used histopathologic evidence of chorioamnionitis as definitive evidence of infection, but this has been disputed as an end-point by Ohlsson and Wang,[69] who accepted clinical chorioamnionitis and all its shortcomings; Dudley and associates,[39] who used neonatal sepsis (proven or suspected); and Vintzileos and associates,[38] who used both clinical chorioamnionitis and neonatal sepsis (proved or possible).

With regard to fetal lung maturity, Dudley and associates[39] demonstrated its presence in 58% of specimens obtained at amniocentesis at this gestation. This result was consistent with other studies,[64,66] which showed a 50% to 60% incidence of fetal lung maturity. With regard to neonatal respiratory distress with PPROM, pulmonary maturity testing (L/S ratio) had a positive predictive value of 68% and a negative predictive value of 79%. The specific situations of occult amniotic fluid infection but fetal lung immaturity, and fetal lung maturity but absent fluid infection, have not been adequately evaluated to determine the correct management option.

If amniocentesis is unsuccessful in obtaining an adequate amniotic fluid sample, then the management must be on a clinical basis with its inherent limitations, in association with the less precise hematologic parameters of serial C-reactive protein estimation and complete blood pictures to assess the presence of infection.[67–71] Although Yeast and associates[72] found no evidence that amniocentesis induces labor, the procedure is not entirely free of complications, and this must be considered when counseling the parents. It would appear that further evaluation of the role of amniocentesis in the management of PPROM, particularly at this gestation, requires a large prospective randomized trial before it can take its place as a legitimate management option.

PPROM AT 34 TO 36 COMPLETED GESTATIONAL WEEKS

Although an expectant management policy is commonly employed at this gestation, this is by no means the standard approach, with many favoring induction of labor as outlined by Olofsson and associates[64] in their review of the practice of Swedish obstetricians with regard to PPROM. The possibility of failed induction is more likely at this gestation than at term, but this has not been adequately evaluated to date.

Clearly, aggressive management is indicated if there is evidence of intrauterine infection, abruptio placentae, or fetal distress.

PPROM AFTER 36 COMPLETED GESTATIONAL WEEKS

In women with PROM after 36 completed gestational weeks, an expectant management policy may be justified initially because it can be anticipated that 75% to 85% of these women will enter labor within 24 hours. The controversial aspects of management at this gestation center around the risks of maternal and neonatal infection as the latency period lengthens, set against the risks of induc-

tion of labor and a possible increase in cesarean section rate. The study by Hannah and associates[54] in which 5041 women with PROM at term were randomly assigned to expectant management for up to 4 days or to induction of labor with intravenous oxytocin or vaginal prostaglandin E_2 gel has helped clarify this controversy. These authors found that the rates of neonatal infection and cesarean section were not significantly different among the study groups. The rates of neonatal infection were 2.0% for the induction with oxytocin group, 3.0% for the induction with prostaglandin group, 2.8% for the expectant management (with subsequent oxytocin) group, and 2.7% for the expectant management (with subsequent prostaglandin) group. Clinical chorioamnionitis and maternal colonization with group B streptococcus were important predictors of neonatal infection.[55] The rates of cesarean section ranged from 9.6% to 10.9% in the four groups. Hence, in PROM after 36 completed gestational weeks, induction of labor with oxytocin or prostaglandin E_2 and expectant management result in similar rates of neonatal infection and cesarean section. However, clinical chorioamnionitis was less likely to develop in the women in the induction with oxytocin group than in those in the expectant management (oxytocin) group (4.0% versus 8.6%, $P < 0.001$), as was postpartum fever (1.9% versus 3.6%, $P = 0.008$). Induction of labor with intravenous oxytocin therefore results in a lower risk of maternal infection than does expectant management. Hannah and associates[54] also found that the women viewed induction of labor more positively than expectant management and, although it is important to give women choices in their management, if the cost implications are also taken into account, then induction of labor with intravenous oxytocin would appear to be the most appropriate management in this clinical situation.

Special Circumstances

THE "HINDWATER" LEAK

This poorly defined clinical entity is of unknown frequency and is often a diagnosis of exclusion. The natural history of this phenomenon is unknown and awaits further evaluation.

RESEALED PROM

Once again this is a poorly defined clinical entity that may encompass a number of women with "hindwater" leak.[72,73] Mercer and associates,[53] in a study of 220 conservatively managed women with PPROM between 20 and 34 weeks' gestation, identified eight women (3.6%) in whom there was cessation of leakage. At approximately the same time Carlan and associates[74] reported on 349 women with PPROM of whom 14 (4%) apparently resealed after initial confirmation of PPROM. In both studies those women who resealed were of a younger age group, had PPROM at an earlier gestation, and had

larger pockets of residual amniotic fluid at the initial ultrasonographic examination than the women with PPROM who did not reseal. After resealing, the pregnancies proceeded normally without any increased likelihood of rerupture.

MULTIPLE PREGNANCY AND PROM

Currently there is little information regarding the latency period and perinatal outcome after PPROM in multiple gestations. Additionally, the relative risks of morbidity and mortality between presenting and nonpresenting infants have not been addressed. The study by Mercer and associates[75] showed only a brief latency period, regardless of gestational age, with no difference in infant survival between twins, but with a significant increase in respiratory morbidity in the nonpresenting infant. In their case-controlled study, Montgomery and associates[76] suggested that the natural history of PPROM in the twin gestation parallels that in the singleton pregnancy and that similar antepartum management strategies are appropriate for both groups.

Labor and Delivery

If labor occurs in the presence of PROM, then it should be monitored closely and augmented promptly if there is any delay, because of the increased risk of infection. The only exception to this rule is to allow transfer to a tertiary care center if labor is preterm and begins in a hospital without appropriate neonatal care facilities. Vaginal delivery should generally be the objective, with decisions regarding the mode of delivery and the need for cesarean section not differing substantially from other preterm deliveries with intact membranes.

Once labor is established, maternal antibiotic therapy is often commenced, particularly if signs of intrauterine infection are present. Although this policy has not been addressed specifically by controlled studies, earlier reservations regarding the possibility of inducing superinfection with resistant bacteria and complicating the diagnosis of infection in the neonate have not been borne out in clinical practice.

This has been demonstrated in particular by the controlled trials of antibiotic use in maternal group B hemolytic streptococcal colonization.[45] A documented reduction in anticipated maternal puerperal infectious complications has been confirmed in most studies advocating this approach.[72] The authors would favor the use of intravenous ampicillin 2 g, every 8 hour and gentamicin 80 mg, every 8 hour during labor. An alternative regimen to prevent neonatal group B sepsis is recommended particularly when two or more of the following are present: previous baby affected by group B streptococcus (GBS), GBS bacteriuria in the current pregnancy, preterm labor, prolonged rupture of the membranes, or fever in labor. Penicillin, initially 3 g is given intravenously, followed by 1.5 g (2.5 million units) intravenously at 4-hour intervals until delivery. If the woman is allergic to penicillin, then clindamycin 900 mg every 8 hours until delivery should be used instead. These regimens are currently recommended in the United Kingdom and most of Europe, where it is argued that it reduces GBS infection by more than 90%.[77] This regimen avoids use of ampicillin because of concerns about its association with an increase in the rate of gram-negative sepsis.

Labors following PROM carry an increased risk of fetal distress, often as a result of umbilical cord compression due to the associated oligohydramnios. The use of amnioinfusion to counter this complication has shown some promise in the controlled trial by Nageotte and associates[78] and in the prospective randomized study conducted by Schrimmer and associates[79] and can be used before 26 weeks' gestation with potential benefit.[80]

At the time of delivery, the presence of a neonatologist, with the backup of an appropriate neonatal support team, is essential to the optimization of perinatal outcome.

Postnatal

With regard to the woman delivering after PROM, an awareness of the risks associated with endometritis, not only postpartum genital sepsis/septicemia but also postpartum hemorrhage and venous thrombosis, is essential for effective management. Active promotion of maternal-infant bonding, particularly with PPROM, deserves special consideration.

All infants born after PROM should be thoroughly screened for sepsis, irrespective of the antepartum or intrapartum use of maternal antibiotic therapy. Screening investigations usually include neonatal blood culture, endotracheal aspirate culture, urinary latex particle agglutination testing, and a complete blood picture. Lumbar puncture and cerebrospinal fluid examination should be reserved for clinically septic neonates and for those with positive blood cultures. Initial antibiotic therapy using a combination of intravenous penicillin and gentamicin may be employed while awaiting the results of the screening investigations. Often the results are inconclusive or equivocal, and discontinuation of the antibiotic therapy may then have to be based on clinical judgment.

Prematurity remains the greatest hazard encountered with PROM, and hence, hyaline membrane disease requiring mechanical ventilation is common. This can be aggravated by pulmonary hypoplasia, which is usually only significant if PPROM occurs before 25 weeks' gestation, with a latent period of more than 5 weeks before delivery.[81] The outcome of PPROM at later gestations is more optimistic than is reported for other causes of oligohydramnios.

The other complications associated with prematurity and its management, including intracranial hemorrhage, jaundice, and feeding difficulties, must be

attended to in the usual fashion, and there should be provision made for long-term neonatal follow-up, particularly in view of preliminary data suggesting a higher risk of neurodevelopment impairment in preterm infants delivered after prolonged PPROM, compared to those born after spontaneous preterm labor (PTL) with intact membranes.[81] For example, placentas of infants that develop cerebral palsy are more likely to be infected with *Escherichia coli* and perhaps GBS than placentas from control cases.[82]

CONCLUSIONS

- A recent survey of perinatologists in the United States[83] has demonstrated national consensus in the use of steroids, antibiotics, and fetal monitoring, which represents a major change from 15 years ago, but beyond this, there continues to be little consensus regarding the optimal management of PPROM.
- Part of the problem continues to be our lack of progress in determining the etiology of PPROM and our inability to offer appropriate management options based on an understanding of the pathophysiology.
- The current interest in proinflammatory cytokines has shown that both PTL and PROM are associated with their overproduction, and increasing evidence suggests that TNF-α may represent the switch[84] between the PTL and PROM pathways because of its ability to engender MMP-9 activity and activate apoptosis in the fetal membranes. Nitric oxide synthetase inhibitors and *N*-methyl-D-aspartate receptor antagonists, which counter the effects of TNF-α, may represent a future sphere of activity for preventive therapy.[19]
- The ORACLE I trial,[50] which consolidated the place of antibiotic therapy in PPROM, has also opened up further areas for investigation. Not only has this study resulted in a reconsideration of the choice of antibiotic therapy, but it also has drawn attention to the potential deleterious effects of PPROM on fetal brain development. Murphy and associates[85] and Spinillo and associates[86] have suggested that the risk of neonatal neurologic handicap is related to the duration of membrane rupture. This in turn would suggest that FIRS with the elaboration of proinflammatory cytokines and the associated complications of intraventricular hemorrhage, periventricular leukomalacia, and cerebral palsy may not be prevented by antibiotic therapy alone. Animal experiments using anti-inflammatory agents and chemical agents to counteract the effects of IL-1 and IL-6 represent new areas, which may see them incorporated in a combined fashion with the current regimens employed to prevent or treat the fetal morbidity associated with intrauterine infection/inflammation related to PPROM.[19]

SUMMARY OF MANAGEMENT OPTIONS
Prelabor Rupture of the Membranes

Management Options	Quality of Evidence	Strength of Recommendation	References
Prepregnancy (Especially Previous Preterm PROM)			
Counsel about recurrence risks (21–32% for PROM; up to 34% for preterm delivery).	III	B	22, 23
Search for causes/precipitating factors has limited overall value.	—	GPP	—
Stress value of preventive measures, such as patient education and smoking cessation.	III	B	24
Note conflicting data on the value of vaginal bacteriologic screening and antimicrobial treatment of woman and partner.	Ib	A	28–32
Prenatal: Prevention			
There are conflicting data on the value of vaginal bacteriologic screening and antimicrobial treatment of woman and partner.	Ib	A	28–32
Cervical ultrasound assessment with fetal fibronectin (and similar biochemical screening tests) in women with previous history of PROM may be of benefit.	III	B	37

Prelabor Rupture of the Membranes *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal: Confirm Diagnosis			
Perform history and physical examination (especially sterile speculum) and collection of amniotic fluid; make repeated pad checks to confirm diagnosis.	–	GPP	–
Additional tests ("ferning," alkaline pH turning nitrazine blue/black, presence of vernix or meconium) all have limitations, especially being unreliable/inappropriate at preterm gestations.	–	GPP	–
Presence of fetal fibronectin (and other biochemical markers) may be useful confirmatory test indicating the likelihood of ensuing preterm labor—may allow intervention to reduce the likelihood of both complications.	III	B	37
Intraamniotic injection of dyes is not without risk and is not widely practiced.	IV	C	35, 36
Ultrasound diagnosis of oligohydramnios associated only with substantial fluid loss, which is usually clinically obvious.	–	GPP	–
Prenatal Management: General			
Maintain vigilance for chorioamnionitis (CA) (see also Chapter 27):	IIb	B	67–70
• Clinical: maternal fever, tachycardia, uterine pain/tenderness, purulent vaginal discharge, fetal tachycardia			
• Laboratory investigations (unreliable):			
– White blood cell count (and differential count)	–	GPP	–
– C-reactive protein	–	GPP	–
– Amniotic fluid Gram stain, white cells and culture (role of amniocentesis is uncertain).	IIa	B	38,39,64–66
– Gas chromatography	–	GPP	–
– Biophysical testing (NST and/or BPS)	III	B	38, 40
– Value of pro-cytokine testing is uncertain	IIb	B	40, 41
Delivery is indicated if chorioamnionitis is diagnosed or fetal "distress" occurs (NST/BPS)	–	GPP	–
Prenatal Management: <24 Weeks with No Evidence of CA or Fetal Distress			
Individualized management including: parental input.	–	GPP	–
Careful counseling of parents needed (see also Chapter 62).	–	GPP	–
If decision is to continue with pregnancy, then implement surveillance for sepsis (see above) (possibly at home).	IIb	B	67–70
Mode of delivery is usually vaginal.	IV	C	61, 62
Prenatal Management: 24–31 Weeks with No Evidence of CA or Fetal Distress			
The upper gestational age chosen will vary depending on local neonatal survival rates.	–	GPP	–
Expectant/conservative management (possibly at home after initial hospital assessment and exclusion of sepsis) is recommended.	Ib	A	59, 60
Counsel parents regarding prognosis (see Chapter 62).	–	GPP	–
Look for clinical evidence of chorioamnionitis (CA) (see above).	IIb	B	67–70

Prelabor Rupture of the Membranes *(Continued)*

Management Options	Quality of Evidence	Strength of Recommendation	References
Prenatal Management: 24–31 Weeks with No Evidence of CA or Fetal Distress—*Continued*			
Treatments:			
Steroid use is variable.	Ia	A	42–44
Many only use tocolysis for transfer to tertiary unit.	IV	C	46,47
Many give antibiotics (erythromycin common; *not* Co-amoxyclav).	Ia	A	50–52
Assessment of fetal pulmonary maturity is a variable practice and of uncertain value.	IIa	B	39,64,66
Aim for vaginal delivery if cephalic; most undertake cesarean section for breech (see also Chapter 64).	IV	C	61–64
Prenatal Management: 31–36 Weeks with No Evidence of CA or Fetal Distress			
Options used in practice:	–	GPP	–
Expectant/conservative (wait for 24–72 hours and if then not in labor, opt for induction)			
Aggressive (induce labor at presentation)			
Prenatal Management: After 36 Completed Weeks with No Evidence of CA or Fetal Distress			
Discuss options with patient:	Ib	A	54
Expectant/conservative (wait for 24–72 h and if not in labor, opt for induction)			
Aggressive (induce labor at presentation) (waiting up to 4 days increases maternal septic morbidity but no other outcome measures)			
Special Circumstances			
"Hindwater leak"—poorly defined, difficult to diagnose; if definite proof of PROM (irrespective of whether cervical membranes intact), then manage as any other PROM case.	–	GPP	–
Cessation of PROM—manage normally.	Ia	A	53, 74
Multiple pregnancy—manage as for singleton.	IIa	B	75, 76
Labor and Delivery			
Continue observing for evidence of infection.	–	GPP	–
Use of maternal antibiotics prophylactically during labor remains controversial (except with group B streptococcal colonization when antibiotics reduce maternal septic morbidity).	IIa	B	45
Consider amnioinfusion for fetal distress.	Ib	A	78, 79
Cesarean section for normal obstetric indications.	–	GPP	–

Breech Presentation

Zoë Penn

INTRODUCTION

The intense obstetric controversy that breech presentation has generated is drawing to an end. The place of external cephalic version for the preterm and term fetus (unnecessary and beneficial, respectively) has been largely resolved, as has the optimum mode of delivery. Vaginal delivery of the breech was the norm (and an essential manipulative skill to be acquired by all obstetricians) until the late 1950s, when cesarean section was first recommended on a routine basis. This opinion gained ground steadily, but it was not until the third millennium that a trial was published that finally convinced most of the world's obstetricians that it was evidence based.

However, another fundamental shift in opinion over the last 10 to 15 years has been the realization that breech presentation may well be a bad prognostic variable in itself.[1] Any studies, clinical trials, or proposed clinical management must take this into account.

INCIDENCE

The incidence of breech presentation varies with gestational age, being approximately 14% at 29 to 32 weeks and 2.2 to 3.7% at term (depending on the use of external cephalic version), giving an overall figure of 3% to 4%.[2,3]

ETIOLOGY

Although in many cases no specific underlying cause of breech presentation is apparent, in some cases a cause can be identified (Table 64–1).

Preterm Labor

A major reason for breech presentation is the preterm onset of labor (probably the chance lie of a highly mobile fetus in relatively copious liquor); most of these babies are structurally normal. It remains unclear whether breech presentation per se predisposes to preterm labor.

Fetal Abnormality

Lamont and associates[4] found that 18% of preterm breech infants were congenitally abnormal. Collea and associates[5] quoted a 5% incidence of congenital abnormality in term breech fetuses, two and a half times higher than in their vertex counterparts (2.1%). Central nervous system abnormalities are the most commonly noted; approximately 50% of all babies with hydrocephalus and myelomeningocele present by the breech, as do 50% of those with Prader-Willi syndrome and trisomy. Despite the association of breech presentation with preterm labor, labor at term is still most common and 90% of abnormal breech babies weigh more than 2000 g.

Breech presentation is also associated with fetal growth restriction and with abnormalities of amniotic fluid volume (either oligo- or polyhydramnios). The association between fetal growth restriction and breech presentation is particularly marked in the preterm fetus. Breech fetuses tend to have reduced fetal-placental ratios, to be small for gestational age, and to have an increased head circumference regardless of the mode of delivery. This difference in weight persists at 18 months of age but disappears by 4 years.[6] Breech presentation has also been linked with relatively short umbilical cords.

Maternal Abnormality

Uterine size or shape may also influence presentation. The narrower cephalic pole of the fetus usually fits better than the breech into the narrower lower segment, and the breech and legs into the wider upper segment, especially if the legs of the fetus are flexed at the knee. However, if the knees are extended, the hips flexed, and the uterine space limited, the head and feet may lie alongside each other, making the cephalic pole of the fetus larger and thus encouraging a breech presentation.

TABLE 64-1

Etiology of Breech Presentation

Preterm labor
Fetal abnormality (especially central nervous system)
Oligo- or polyhydramnios
Fetal growth restriction
Short umbilical cord
Extended legs in the fetus
Uterine abnormality (e.g., bicornuate uterus)
Placenta previa
Cornual placenta
Contracted pelvis
Multiple pregnancy
Maternal anticonvulsants
Maternal substance abuse

Uterine tone is greatest in nullipara, limiting the available space, and breech presentation is reported to be more common in nulliparous women. On the other hand, the relaxed uterus of the grand multipara encourages an unstable lie, so that the fetus enters labor by chance in a breech presentation.

Other less benign conditions may alter the uterine capacity or the intrauterine shape. Uterine anomaly, such as bicornuate uterus, is associated with breech presentation. Placenta previa is well recognized in association with breech presentation, as this changes the intrauterine shape and prevents engagement of the head. Cornual implantation of the placenta, an otherwise benign condition, is also strongly associated with breech presentation; only 5% of vertex-presenting fetuses have a cornual placenta in comparison to 73% of those presenting by the breech.

A contracted pelvis is also associated with breech presentation, probably by limiting uterine space in the lower segment.

Other Reasons for Breech Presentation

Women who have had a breech presentation at term are significantly more likely to have another in a subsequent pregnancy. This is usually associated with extended fetal legs and may indicate a genetic predisposition to this posture in the fetus.

Multiple pregnancy is strongly associated with breech presentation. The reader is referred to Chapter 60 for further discussion of management.

Medication with anticonvulsants in pregnancy also seems to be associated with breech presentation,[7] as does maternal alcohol abuse[8]; both substances have a profound influence on intrauterine fetal neurologic function. Fetal behavior in utero in fetuses with persistent breech presentation is also subtly different. They demonstrate more state transitions in fetal activity and heart rate patterns in utero than their cephalic presenting counterparts.[9]

RISKS AND SIGNIFICANCE

Although fetuses presenting by the breech have an increased perinatal mortality rate, it has proved difficult to separate and quantify the independent risks of the breech position itself and to distinguish the problems of the delivery from the problems of the fetus being abnormal. The perinatal mortality rate remains increased even when delivery is by cesarean section, and this is true even after correction for gestational age, congenital defects, and birth weight.

Many retrospective reviews of breech presentation and trials of antepartum and intrapartum management compare the breech-presenting infant with the vertex-presenting infant, and because of its associated problems, the breech-presenting infant is more likely to perform unfavorably, regardless of the mode of delivery. Nelson and Ellenberg[10] looked at all the obstetric factors that could be associated with the development of cerebral palsy using a multiple regression technique and found that breech presentation was an independent predictor for cerebral palsy. There were a number of small randomized controlled trials and meta-analyses studying the role of the mode of delivery of the term breech in relation to neonatal performance and long-term outcome, but they produced conflicting results.[5,11–15] (It should be noted that functional and behavioral outcomes by mode of delivery need to be considered independently of perinatal mortality; see the later section on mode of delivery.)

Some of the association of breech presentation with cerebral palsy can be accounted for by the excess of low birth weight in breech presentation, and this factor is independent of the mode of delivery.[16]

More subtle aspects of neuromotor development may also be manifest in breech-presenting fetuses. These may represent a continuum, with subtle differences in in utero fetal behavioral states being evident.[16] Bartlett and coworkers compared 90 morphologically normal term breech-presenting singletons having birth weights greater than 2500 g and delivered by cesarean section with similar cephalically presenting infants, matched for gender and mode of delivery. They prospectively collected data on neurologic status and motor performance over the first 18 months of life. They found that not only did breech-presenting infants have more open popliteal angles at birth (an unsurprising observation) but also they had significantly lower motor scores at 6 weeks and an excess of neurologic problems diagnosed at 18 months.[17]

The risks to the mother are easier to quantify. Breech presentation confers an increased likelihood of cesarean section with its attendant risks of morbidity and death.[5] It has been calculated by some that the risk of maternal fatality in cesarean section is up to 38 times that of a vaginal delivery.[18] However, others have suggested a relative risk as low as 7, decreasing to 5 after exclusion of women with medical or life-threatening complications.[19]

In the latter study, most of the surplus risk occurred in emergency cesarean sections, when the relative risk was 11, compared with elective cesarean sections when the risk was only 4. There is some evidence that breech presentation and cesarean section may reduce the subsequent pregnancy rate, probably because of the woman's decision not to reproduce again.[20]

DIAGNOSIS

Three clinical types of breech presentation are recognized. This classification is useful in that it may indicate the cause of the presentation and the complications to be anticipated. As with most clinical classifications, there is overlap of the associated factors between the groups:

- The frank (or extended) breech indicates that the legs of the fetus are flexed at the hip and extended at the knee. This type accounts for 60% to 70% of all breech presentations at term. The risks of fetal-pelvic disproportion and of cord prolapse are lowest in this group.
- The complete (or flexed) breech indicates that the hips and knees are flexed so that the feet are presenting in the pelvis.
- The incomplete (or footling) breech indicates that one leg is flexed and the other extended.

The woman with a breech presentation, especially towards term, may complain of subcostal discomfort and of feeling the baby kick in the lower part of the uterus. On palpation the hard round ballotable head is found at the fundus, and the softer breech is at the lower pole. The fetal heart sounds are more commonly heard above the umbilicus. One diagnostic pitfall is the confusion of a deeply engaged head and a breech presentation. The examiner thinks that the shoulders are above the pelvic brim when in fact the breech is over the pelvis.

At vaginal examination, if the cervix is sufficiently dilated, the fetal ischial tuberosities and the sacrum provide the bony landmarks. The anus and the genitalia may also be felt but are less useful in diagnosis due to their softness and compressibility. If the membranes are ruptured, the examining finger in the anus may produce meconium staining. The main diagnostic confusion is face presentation. Face presentation produces the characteristic bony landmarks of the malar eminences, mouth, and mentum that produce a bony triangle, whereas the ischial tuberosities and the sacrum are in line. The mouth, in contrast to the anus, has a firm unyielding margin of bone. Engagement of the breech implies that the bitrochanteric diameter has passed through the pelvic brim.

Because of the difficulties described earlier, approximately 45% of breech presentations are not diagnosed until after 38 weeks, and 30% remain undiagnosed until labor.[21] If there is any doubt about presentation, an ultrasound scan is mandatory if mistakes are to be avoided.

Some clinicians even advocate routine late third trimester ultrasonography to determine presentation and ensure time for external cephalic version (ECV) (thus decreasing the need for cesarean section).[21]

THE PRETERM BREECH PRESENTATION

The search for methods of preventing or suppressing preterm labor has proved disappointing, and obstetricians have been forced to look at other techniques for optimizing the condition of preterm infants at birth so as to minimize neonatal complications. This has focused predominantly on the mode of delivery and has led to an increase in the cesarean section rate. For breech-presenting fetuses at 23 weeks the cesarean section rate has risen approximately threefold between 1995 and 2002, reflecting the increasingly aggressive management policies for extremely preterm infants.

Risks

General

The proportion of babies delivered before 37 weeks' gestation in the United Kingdom has been remarkably constant over the years at about 7%. However, the mortality and morbidity rates of babies delivered between 33 and 36 weeks inclusive is now very low and not significantly influenced by mode of delivery, provided that cesarean section is undertaken for the usual clinical indications. Discussion is focused here on the gestation range of 26 to 32 weeks, when approximately 2% of all pregnant women with viable fetuses will deliver. About 25% of all babies delivered at these gestations are in breech presentation, probably due to the chance lie of a very mobile fetus in the relatively copious amniotic fluid. Thus, the overall incidence of very preterm (<33 weeks) breech presentation at delivery is 0.5%.

The premature baby in breech presentation shares many of the characteristics of the mature breech. The premature breech baby also has a higher rate of congenital abnormality than its vertex presenting counterpart, up to 18%.[22,23] The preterm breech has a higher antepartum stillbirth and neonatal death rate than babies presenting by the head, regardless of mode of delivery.[2] It is probably even more true of the preterm breech than the term infant that poor outcome in survivors, such as mild neurologic dysfunction, cannot safely be attributed solely to the fact of vaginal breech delivery but is often due to the abnormalities associated with breech presentation. The premature breech shows other differences from the premature cephalic-presenting infant; it is more commonly small for gestational age and has a lower fetal-placental ratio. It also tends to have a larger head circumference for a given birth weight than babies delivered in vertex presentation, probably due to the lack of the

compressive effect of the lower segment. It seems likely that in many cases of breech presentation at delivery, prematurity and poor fetal outcome are both determined by the same prenatal influences.

At Delivery

OCCIPITAL DIASTASIS AND CEREBELLAR INJURY

Experienced obstetricians have recognized that cesarean section is not always an atraumatic option for the fetus, and the preterm breech infant faces some formidable difficulties whichever route of delivery is employed. Wigglesworth and Husemeyer[24] have emphasized the vulnerability of the occipital bone to damage during vaginal breech delivery, due to its impact on the maternal pubis during descent of the fetal head into the pelvis during the second stage. These forces tend to separate the squamous part of the occipital bone from the lateral part (occipital diastasis). This produces a ridge in the posterior fossa and hence bruising or laceration of the cerebellum. The squamous part of the occipital bone is forced anteriorly to distort the foramen magnum and produce pressure on the spinal cord. Cerebellar bruising can be present in the absence of occipital diastasis, and although the fracture may be easily diagnosable after delivery with a lateral skull x-ray, the cerebellar bruising alone will not be diagnosable unless the cerebellum is scanned routinely by the neonatologist using ultrasound. The injury is commonly not discovered at postmortem examination if traditional dissection techniques have been used. The damage to the brain may not be clinically apparent until the age of approximately 2 years, when the child will manifest signs of clumsiness and poor coordination consequent upon its cerebellar damage (ataxic cerebral palsy).

INTRAVENTRICULAR AND PERIVENTRICULAR DAMAGE

In addition, the preterm infant is vulnerable to intraventricular and periventricular damage secondary to hemorrhage or ischemia, which can be due to hypoxic or acidotic insults in the antepartum, intrapartum, and neonatal periods. The premature breech may be still more susceptible to these as a consequence of the peculiar circumstances surrounding delivery. However, avoiding vaginal delivery will not necessarily prevent intracranial bleeding. Tejani and associates (1984) have shown that premature labor of itself can produce intracranial hemorrhage even if delivery is delayed or by cesarean section.[25]

GENERALIZED TRAUMA AND NERVE INJURIES

A traumatic breech delivery in which there is widespread limb and body bruising can produce gross skeletal muscle damage that results in large quantities of hemoglobin and myoglobin being liberated. This can lead to severe jaundice and damage to the kidneys in a premature infant whose hepatic capacity to deal with bilirubin is limited

and whose renal excretory capacity is poor. This can produce a form of "shock lung" in the neonate manifesting as severe respiratory distress syndrome.

The premature breech infant is also susceptible to damage to internal organs, transection of the spinal cord, and other nerve palsies consequent on traction, especially the brachial plexus and fractures of long bones similar to its more mature counterpart. Because the widest diameter of the fetus is the biparietal diameter and the discrepancy between the diameters of the head and the body is most pronounced in the premature fetus, it is possible for the body and limbs of the premature breech to slip through a cervix that is still incompletely dilated and the head will be unable to follow. This "entrapment" of the after-coming head is more likely in the mother who commences active pushing prior to second stage, with a footling presentation, especially with the preterm fetus in whom the subcutaneous fat has not yet been laid down and the liver is not of the large size reached in the mature fetus; hence, the abdominal circumference is relatively smaller. Recommended management is usually to incise the cervix with scissors at 4 and 8 o'clock, but inevitably there is delay in delivery and therefore an increase in the hypoxic stress to the fetus, together with a likely increase in traumatic morbidity to both mother and child. However, Robertson and associates,[26] after studying 132 consecutive preterm singleton breech deliveries, demonstrated that there did not seem to be a difference in the incidence of head entrapment by mode of delivery for breech infants at 28 to 36 weeks' gestation, and nor did there appear to be a difference in adverse neonatal outcomes after entrapment.

Injuries are not confined to babies delivered vaginally in breech presentation. Any very low birth weight baby is susceptible to trauma from a difficult delivery through a poorly formed lower segment. If the presentation is breech, a limited uterine incision can impede the delivery of the head to the same degree as a difficult vaginal delivery and is analogous in every way to the entrapment of the after-coming head that is such a feared complication of the premature breech delivered vaginally. To some extent this can be avoided by performing an anterior vertical uterine incision (ideally De Lee's incision, but often in a very small uterus it becomes a classical incision). However, this carries increased risks for the mother, particularly in respect to uterine rupture in a future pregnancy or labor, but occasionally also in terms of poor healing and postpartum hemorrhage. The incidence of intraventricular hemorrhage in the fetus and neonate is also closely related to the occurrence of preterm labor of itself, independent of the mode of delivery.[25]

Management Options for the Preterm Breech in Labor

Most elective deliveries of the preterm breech when the woman is not in labor are for fetal or maternal

indications when the preferred route of delivery is cesarean section. The controversy about management mainly centers on the preterm breech presentation in labor, in which the initial priorities are (1) the accurate diagnosis of premature labor, (2) the confirmation of presentation, and (3) the exclusion of fetal abnormality.

It is evident that in up to 80% of cases in which the mother thinks she is in premature labor, contractions cease spontaneously and the pregnancy continues. The definitive diagnosis of labor therefore rests on demonstrating progressive dilation of the cervix. Careful cervical assessment of all women in suspected premature labor is imperative to confirm or refute the diagnosis. In the presence of ruptured membranes this should be done using full aseptic technique and the number of examinations limited to minimize the risk of introducing infection, causing chorioamnionitis. Vaginal examination can confirm the presentation and can even reveal the presence of fetal abnormality (for example, imperforate anus!). In view of the recognized association of fetal abnormality with premature breech presentation, all previous ultrasound examinations should be carefully reviewed. A further detailed ultrasound scan should be performed if possible to confirm the normality of the fetus and check on placental position at the same time. An estimate of fetal weight may allow a more rational decision to be made about the optimum place and mode of delivery. Ultrasound fetal weight estimation is possible to ± 15% in skilled hands, although when performed by junior residents outside of normal hours, errors greater than 15% have been reported in over 40% of cases.[27] This has led some workers to suggest that the outcome for the infant is best predicted by accurate knowledge of gestational age.[21]

Administration of tocolytics may be appropriate in an effort to delay delivery long enough to administer steroids to promote surfactant production in the fetal lung prior to preterm delivery or to arrange delivery in a site with appropriate neonatal intensive care facilities. It is now clear that tocolytic therapy is ineffective in preventing premature delivery in the longer term and that its use beyond 48 to 72 hours is probably inappropriate.

The Optimum Mode of Delivery of the Preterm Breech

The preterm breech on the labor ward presents the obstetrician with a heterogeneous group of clinical problems. Some will present not in labor but with spontaneous rupture of the membranes only; others will present at 7 cm dilation in strong labor and deliver after only a short interval. As with all premature deliveries, premature vaginal breech delivery is sometimes precipitate and may therefore occur in the absence of skilled medical attendants. It is important to realize that, in common with all preterm labors, the antecedents are often pathologic, and therefore, a decision about the mode of delivery is uncontentious. If there has been a placental abruption or cord prolapse, then clearly cesarean section is indicated.

However, if the clinical situation is of "the uncomplicated preterm breech in labor," that is, if fetal and maternal condition are good, and labor is progressing at a normal rate, it is necessary to decide whether a vaginal delivery is to be allowed or a cesarean section should be undertaken.

One of the first suggestions that cesarean section should be undertaken routinely for the delivery of the preterm breech was in 1977 when Goldenberg and Nelson reviewed the outcome of 224 babies less than 1500 g delivered between 1965 and 1969.[28] They compared babies delivered vaginally in breech presentation with babies delivered vaginally in vertex presentation, and all those delivered by cesarean section. For reasons enumerated earlier (in particular, the differing incidence of congenital anomaly) their comparisons were not valid. The other problem highlighted by these authors was the noncomparability of the study groups in other respects. The authors reported that many fetuses below 1000 g were not monitored during labor as they were thought to be nonviable, or if they were monitored, when signs of fetal distress supervened surgical intervention was often not performed as the fetus was thought to be "too small to live." This approach resulted in infants being delivered vaginally who happened to survive despite nonintervention being compared with infants who were thought to be viable and not "too small to live" and who were therefore delivered electively by cesarean section, attended by senior and experienced members of staff. Such a comparison is inherently likely to show a better outcome for the latter group and therefore lead to the (potentially) erroneous conclusion that cesarean section improves the outcome for the preterm breech infant.

Further retrospective reviews of clinical practice were published over the next few years, some comparing the vertex with the breech,[29] some correctly comparing the vaginally delivered breech with the breech delivered by cesarean section, but then only stratifying by birth weight below and above 2500 g or in other similarly wide weight bands.[30] Some advocated cesarean section,[30] and some advised that selected preterm breeches should be allowed to deliver vaginally.[31] Most of these latter authors felt that outcome was more related to obstetric variables other than the mode of delivery. Other authors advised that all premature infants are best delivered by classical cesarean section.[32] Wolf and associates[33] observed the natural experiment of two adjacent maternity units both with different policies for the delivery of the preterm breech (26–31 weeks). One unit chose to deliver vaginally (17% cesarean section rate) and the other by cesarean section (85% cesarean section rate), but they did not observe any differences in survival rates.

Further evidence of the noncomparability of the vaginally delivered and cesarean delivered breeches is reported in a paper by Jain and associates.[34] He noted that even within the weight range of 1000 to 1499 g there was a marked difference in the average weight, with the babies

delivering vaginally being significantly lighter and at a lower gestation than those delivered by cesarean section, a difference likely to account for any differences in survival. A further series of retrospective and uncontrolled studies were then reported to show a better outcome after cesarean section for babies weighing 1000 to 1500 g, but no advantage to babies weighing less than this.[22,35,36]

In order to overcome the noncomparability of groups in these retrospective reviews of practice, there has been a series of attempts at using statistical techniques to determine the contribution that mode of delivery makes to outcome for the preterm breech.[37,38] Kitchen and associates[38] found that the mode of delivery was a significant factor in the likelihood of survival for the preterm breech. Rosen and associates,[37] on the other hand, found that variables such as gestational age or administration of steroids antenatally were more significantly associated with outcome.

Thus, all currently existing evidence has major methodologic flaws that make it unreliable as a guide to clinical decision making and have led to a number of calls for a randomized controlled trial to settle the question of optimum mode of delivery. Despite this, there has only been one such randomized trial which has actually been completed. Viegas and associates randomized 23 women, but unfortunately their analysis was fundamentally flawed by inappropriate withdrawals and no conclusions can be drawn from their results.[39] Two other randomized trials of the optimum mode of delivery of the preterm infant (both vertex and breech presenting) have been initiated, but both were terminated prematurely and produced no interpretable results.[40,41] Lumley and associates[40] randomized only 4 subjects out of a possible 33 who were eligible over a 5-month period and terminated the trial after drawing the conclusion that clinicians were unwilling to randomize their management. Wallace, Schifrin, and Paul[41] aborted their randomized trial of the optimum mode of delivery of the preterm infant because they found that an unacceptably high number of the babies (63%) were above the 1500-g upper weight limit for the trial. They concluded that a more accurate way of estimating fetal weight prior to delivery was needed before a further attempt was feasible. The subjects they did randomize were analyzed according to the eventual mode of delivery, not according to the randomized mode of delivery, thereby invalidating the randomizing process.

A prospective randomized multicenter trial to determine the best mode of delivery for the preterm breech (26–32 weeks) recruiting subjects in the United Kingdom was also abandoned.[42] The recruitment rate was disappointing, with only 10% of eligible subjects being randomized, despite large numbers of women consenting to take part in the trial antenatally and sufficient numbers of premature breeches presenting for randomization. No definitive conclusion was reached. The authors concluded that the failure of the trial did not mean obstetricians were insisting on cesarean delivery; 30% of preterm breeches not entered in the trial were allowed to deliver vaginally. Instead, they concluded that obstetricians were reluctant to abandon individualized decisions about management even in the presence of a high degree of scientific uncertainty about the basis on which their decisions were being made. Also, some evidence suggested that if the clinician was unsure of the optimum mode of delivery, then women wished to make a choice for themselves and withdrew from randomization. It therefore appears likely that the optimal mode of delivery of the preterm breech will remain uncertain for the foreseeable future. At gestations above 32 weeks but below 37 weeks and when the fetus weighs 1500 to 2500 g, current evidence does not suggest any advantage to routine cesarean section. Under this gestation and weight but at more than 26 weeks' gestation, the optimal mode of delivery remains uncertain in the absence of any clinical feature specifically indicating cesarean section. The advantage, if any, that routine section confers on the fetus is likely to be small, otherwise it would already be obvious in the multiplicity of published data already available. What is certain is that if a policy of routine cesarean section for the preterm breech fetus is followed, a number of cesarean sections will be performed unnecessarily for the fetus that is congenitally abnormal, for the fetus that is over 1500 g and therefore unlikely to benefit, for babies mistakenly thought to be in breech presentation (of which there were two in the U.K. study), and for some that will not actually be in established premature labor and were destined to deliver at a later gestation. A policy of routine cesarean section will also expose the mother to a definite risk of maternal mortality and morbidity.

PROCEDURE: CONDUCT OF DELIVERY

Vaginal delivery of the preterm breech should be supervised by an experienced obstetrician. An effective epidural anesthetic is preferable to prevent the woman from pushing prior to full dilation, to allow manipulation of the breech, or painless operative intervention either with forceps or rapid recourse to cesarean section. The anesthetist and pediatrician should be in attendance for the second stage. There is no clear evidence to favor the use of obstetric forceps to the after-coming head; the pelvis will be relatively capacious for the premature neonate, and it will not be subject to the rapid compression-decompression forces applied to the head of the mature infant in breech presentation. There is some evidence that delivery with intact membranes is an advantage.[29] Should the cervix clamp down over the head or the body be delivered through an incompletely dilated cervix, the head should be flexed abdominally and the finger of the vaginal hand should be inserted into the mouth of the fetus to flex the head and facilitate delivery. If this is not possible, then scissors with the intracervical blade guarded by a

finger should be introduced at 4 and 8 o'clock, and the cervix should be incised. The carefully flexed head should then deliver easily. The cervix is usually repaired easily provided analgesia is adequate.

If cesarean section is indicated, the abdominal incision used should be considered carefully. Although a Pfannenstiel will give good access for a lower segment uterine incision, if this needs to be extended in an emergency (for example, if the after-coming head becomes entrapped), then a vertical midline incision will be an advantage (it can be extended upward as far as is necessary). The advent of mass closure with nylon has reduced the morbidity of the midline approach so that it is now on a par with the Pfannenstiel, apart from the obvious cosmetic drawback of the midline scar. As well as providing improved access, it is also quicker. If a transverse uterine incision needs extending, then a J shape is to be preferred to an inverted T, as the latter leaves a point of marked scar weakness at its center, which may rupture in a future pregnancy. The De Lee or classical uterine incision appears to confer little benefit on the fetus in terms of reduced trauma, from 28 weeks onward (Patterson, Stacey, and Steer, unpublished data). On the other hand, neonatal mortality rates below 28 weeks can be high.[43] Because of the maternal morbidity involved, it is probably unwise to use the classical approach to try to salvage the preterm baby if its viability seems doubtful.

THE BREECH PRESENTATION AT TERM

Management Options

Version of the Breech

SPONTANEOUS VERSION

The fact that breech presentation is so uncommon at term implies that spontaneous version usually occurs in the weeks before term and so breech presentation becomes less common as the third trimester progresses. The incidence of spontaneous version after 32 weeks maybe as high as 57% and after 36 weeks' gestation may still be as high as 25%.[44] Spontaneous version is more likely in multiparas without a previous breech birth and is less likely in nulliparous women and in the breech with extended legs. Prior to cesarean section solely for breech presentation at term, the presentation should be checked immediately before surgery by ultrasound scanning, as the chances of spontaneous version even at this late stage are not insignificant.[44]

PROMOTION OF SPONTANEOUS VERSION

Techniques to promote spontaneous version have been investigated following Hofmeyr's observation that in some cases version from breech to cephalic occurred between the preliminary scan and the planned external cephalic version (ECV).[45] He postulated that the combination of disengagement of the breech and postural change might have promoted spontaneous version.

A variety of other techniques have been described including the knee chest position, with the buttocks higher than the torso and the chest lying on a flat surface for 10 minutes every day, and another technique describes elevation of the pelvis, and abduction of the thighs. The Cochrane review of five studies, including 392 women, of randomized or quasi-randomized controlled trials compared postural management of the breech with control subjects. There was no effect on the rate of noncephalic births, the rate of cesarean section, or the incidence of low Apgar scores.[46] Therefore, although there is likely to be no significant adverse effects from postural management, there is currently no evidence to support its efficacy.

EXTERNAL CEPHALIC VERSION

External cephalic version fell from favor in the mid-1970s. Prior to this time it was performed without medication (except occasionally sedation), without tocolysis, and usually prior to 36 weeks' gestation. It was thought that because ECV was easier to perform prior to 36 weeks, it must therefore be safer. Without tocolysis it was often unsuccessful after 36 weeks. Bradley-Watson in 1975 reported a 1% fetal mortality rate for ECV done prior to 36 weeks without tocolysis, which was considered unacceptably high.[47] As a result, the use of ECV declined and was almost abandoned in most institutions as cesarean section was seen as a safer alternative. Another significant disadvantage of preterm ECV is that fetal bradycardia may precipitate immediate delivery by cesarean section, with the risk of ensuing respiratory distress syndrome. To avoid this, it was traditional to manage acute bradycardia by reversion of the fetus to breech, which did not always work and in any case defeated the objective of the ECV. In addition, spontaneous reversion to breech occurred quite often prior to delivery. Thus, the effectiveness of ECV was controversial, especially as the fetal mortality rate was reported to be higher in the preterm than the term breech.

The Cochrane review included three randomized controlled trials of the use of ECV before term involving 899 women and showed no significant effect on noncephalic presentation, cesarean section, low Apgar scores, or perinatal mortality rate, and the practice cannot currently be recommended.[48] There are no published data on the use of ECV in the management of the preterm breech in labor. The antecedents of the preterm breech in labor are often abnormal, and ECV is therefore less relevant as a management strategy.

Any consideration of the efficacy and safety of the technique of external cephalic version should include a likelihood of spontaneous version, the effectiveness of ECV of producing a cephalic presentation at the time of birth, the risks to the mother and the baby, and the utility of cephalic presentation at birth to the mother and the baby (i.e., if some preexisting abnormality or fetal compromise determines the mode of delivery rather than the

presentation itself and also if the prognosis of the baby is determined by its condition rather than the mode of delivery, correction of the breech presentation will then not alter the outcome for the fetus).

The advantage of performing ECV at term is that it allows time for spontaneous version to occur and the clarification of conditions that of themselves may require delivery by cesarean section. This will result in fewer unecessary attempts being made. Also, should complications of ECV occur, then prompt recourse to cesarean section will result in the birth of a mature infant. It also appears that ECV at term results in fewer complications.

The Cochrane review[48] looked at six trials of a randomized or quasi-randomized nature and concluded that ECV at term was associated with a significant reduction in noncephalic births (relative risk 0.42) and a reduction in cesarean section (relative risk 0.52), although there was no significant effect on perinatal mortality rate. This review also concluded that there was insufficient evidence to assess any risks associated with ECV at term.

The implications of these data are that every 100 ECV attempts should prevent 34 breech births and 14 cesarean sections. A conservative estimate of the impact of performing ECV on 2% of the 750,000 pregnancies in the United Kingdom every year would be a reduction in the number of breech births by 5100 and a reduction in the number of cesarean sections by 2100.[48]

However, the impact of ECV on the rate of cesarean sections for this indication will depend on the success rate of ECV. There seems to be a wide variation in the reported success rate. Trials performed in Africa on black African women have much higher success rates. This success is probably due to the tendency of late engagement of the presenting part in the pelvis in black African women.[49] Success rates as high as 77% have been reported,[50] but in general, success rates of 50% or even less are acceptable.

Various methods of predicting the success of an attempted ECV have been devised. Most studies have found that nulliparity, increased uterine tone, a posterior fetal spine, the breech engaged in the pelvis, a frank breech, and gestations above 38 weeks are bad prognostic indicators for success.[51] One study found that if the presenting part in a nullipara was engaged and there was difficulty in palpating the fetal head, then no attempt at ECV was successful. On the other hand, if the presenting part was not engaged in a multipara and the fetal head was easily palpable, then 94% of attempts were successful.[52] ECV in the preterm breech tends to be more successful but does not promote more cephalic deliveries at term.[53]

Because of the observation that increased uterine tone decreases the chances of success of ECV, the use of tocolytics has been investigated. A variety of tocolytics have been used. The Cochrane database reviewed six trials of routine tocolysis and showed that its use was associated with fewer failures. Use of fetal acoustic stimulation (FAS) was also associated with fewer failures of ECV.

In a randomized controlled trial of the use of tocolysis in ECV, Marquette and associates[54] confirmed the efficacy of ritodrine in promoting success of ECV in nulliparous patients but not in parous patients. They found that ritodrine increased the success rate of ECV from 25% to 43% in nulliparous women. Fernandez and coworkers also assessed the efficacy of terbutaline (0.25 mg subcutaneously) in comparison with placebo for ECV and found a significant decrease in noncephalic presentations and cesarean sections because of increased chances of success with ECV.[55] There has been an evaluation of glyceryl trinitrate in a placebo-controlled randomized trial for women whose first attempt at ECV without tocolysis had failed, but no significant differences between groups were observed.[56]

Because one of the main reasons for the failure or abandonment of ECV is maternal discomfort, the use of epidural analgesia for the procedure has been suggested. There has been only one randomized controlled trial of the use of epidural anesthesia to improve the success of ECV. This trial had approximately 35 women randomized to epidural anesthesia versus no epidural and found that the success rate was significantly increased (risk ratio 2:12), and that the chances of success were not affected by an anterior placenta or oligohydramnios.[57] As reported earlier, observational studies suggest a doubling of the success rate for ECV using tocolysis. Two studies have examined the use of epidural anesthesia if initial attempts performed using tocolysis have failed. Both these studies reported fetal complications of the procedure and, although they reported favorable success rates, commented that the "safety of the procedure remains in question."

BENEFITS TO THE FETUS OF ECV

It is clear that ECV reduces the incidence of breech presentation at term and of breech delivery, whether vaginal or by cesarean section. It will therefore decrease the incidence of cord prolapse and unattended precipitate breech birth. Unattended or precipitate breech birth has been shown to be associated with an eightfold increase in the risk of poor condition at birth in comparison to women expertly attended and assessed for vaginal delivery ante partum.[58] It may be that the rate of cesarean section is higher than the average for cephalic presentations even after successful version, although not all studies have found this.[59,60] However, it would be a mistake to suppose that elective cesarean section eliminates all risks for the fetus: cesarean delivery of the preterm breech may still be traumatic, and the risk of pulmonary hypertension of the newborn may be increased.[61,62]

RISKS TO THE FETUS OF ECV

The risk to the fetus is difficult to quantify because there is at present no randomized controlled trial large enough to clarify the issue, and the authors of the Cochrane review were unable to draw any overall conclusions regarding risks. However, in a review of 979 reported

cases of ECV at term with neither inhalational analgesia nor general anesthesia, there were no fetal losses.[37] ECV has been associated with demonstrable changes in the fetal circulation.[63] An 8% incidence of fetal bradycardia has been reported in association with ECV.[64] If an ECV (whether successful or not) produces a fetal bradycardia, it is possible that subsequent labor is more likely to be complicated by fetal heart rate abnormality and result in cesarean section.[64] Lau and associates demonstrated changes in the fetal circulation, but not placental circulation, associated with attempted ECV. The pulsatility index was reduced in the middle cerebral artery, and these authors postulated that this was merely a physiologic response to manipulation of the fetal head.[63] Isolated cases of cord presentation and even fetal demise have also been reported. Kouam[65] followed up 116 children born after ECV. Developmental screening at 2 to 5 years of age showed no developmental delay. Although the short-term neonatal outcomes reported in the randomized controlled trials are essentially normal and compare favorably with control subjects, they are only surrogates for definitive follow-up studies of the effects of this procedure.

Fetal-maternal hemorrhage has been reported in association with ECV. The risk has been quoted at approximately 5% using tocolysis, whereas the risk without tocolysis has been reported to be as high as 28%. The experience of ECV prior to 36 to 37 weeks demonstrates that the risks to the fetus are related to gestational age and the use of general anesthesia. It may be that an anterior placenta also represents a risk. However, the risks of ECV set in the overall context of the risks of breech presentation in itself or of the risks of breech delivery vaginally or abdominally are small.

BENEFITS TO THE MOTHER OF ECV

There will be a decrease in the number of cesarean sections performed and possibly in the number of vaginal breech deliveries, which often entails episiotomy and forceps delivery. The maternal morbidity rate is usually higher after cesarean section than after vaginal delivery. Cesarean section may compromise future reproductive function,[66,20] and there may be adverse emotional sequelae for the mother and the maternal-infant pair.[67] All these aspects are aside from the higher maternal death rate associated with cesarean section.

Interestingly, although ECV has become much more widely used over the last decade and more pregnant women (and their clinicians) have become aware of the procedure, pregnant women may be less inclined to take up the option of ECV and opt for planned cesarean section instead.[68]

The contraindications for the performance of ECV are outlined in Table 64–2. The absolute contraindications are uncontroversial. However, the relative contraindications are more debatable. It may be that uterine anomalies and excessive maternal body weight should be regarded as

TABLE 64–2
Indications and Contraindications for External Cephalic Version (ECV)
Indications for ECV
Any breech presentation after 36/37 weeks' gestation
Suspected fetopelvic disproportion
Unengaged breech
Absolute Contraindications to ECV
Multiple pregnancy*
Antepartum hemorrhage
Placenta previa
Ruptured membranes
Significant fetal abnormality
Need for cesarean section for other indications
Relative Contraindications to ECV
Previous cesarean section
Intrauterine growth restriction
Severe proteinuric hypertension
Obesity
Rhesus isoimmunization
Evidence of macrosomia
(Grand multiparity)
(Anterior placenta)
("precious baby")
(previous antepartum hemorrhage)
Any suspected fetal compromise: unreactive cardiotocogram

*Apart from the second twin after the vaginal delivery of the first.
Note: If tocolysis is to be used, women with congenital or acquired heart disease, diabetes, or thyroid disease should be excluded because of possible adverse reactions.

relative contraindications. An amniotic fluid volume of less than 2 cm in depth in any pocket, the fetal back lying anteriorly, a tense uterus, difficulty palpating the fetal head, an engaged breech, and nulliparity will decrease the chance of success.[51] Chances of success are increased with increasing parity and a breech lying more in the iliac fossae than in the midline. Fetal abdominal circumference is related to the chances of success, whereas the biparietal diameter is not. Gestational age and estimated fetal weight, provided the attempt was after 37 weeks, had no relationship with the chances of success, as success rates were found to be the same at 37, 38, and 40 weeks.

Although previous cesarean section is a relative contraindication to ECV, there is a small series of 36 women who had one previous cesarean section and underwent an ECV, of which 66% were successful, and of these, 76% had a vaginal birth. There were no maternal or neonatal complications.[69] Maternal Rh negativity is a relative contradiction. If ECV is used, a Kleihauer test should be done and anti-D (Rhogam) administered.

PROCEDURE – EXTERNAL CEPHALIC VERSION

PREREQUISITES

1. Recent ultrasound to confirm a normal fetus and an adequate liquor volume
2. Reassuring fetal heart rate pattern

3. Informed consent-in which the mother is specifically advised of the risks of provoking labor, ruptured membranes, and cord and placental accidents
4. Facilities for the performance of a cesarean section

PROCEDURE

ECV may be performed in the labor room or the clinic room, if there is rapid access to delivery facilities. The woman is positioned either in steep or slight lateral tilt or in Trendelenburg position. It is sometimes recommended that a Kleihauer test be performed before and after the procedure. Some also recommend placing an intravenous line and cross matching blood for a possible cesarean section. If tocolysis is to be used, some practitioners perform an electrolyte and glucose estimation as well. A clinical pelvimetry should be judged as adequate. An ultrasound scan should be performed in order to assess the liquor volume, fetal attitude, and position of the fetal legs. The fetal heart rate pattern should be normal and reassuring prior to commencement. Some authorities recommend that a contraction stress test be performed prior to version. It has even been suggested that the maternal blood pressure be taken every 5 minutes throughout the procedure[53] and that the maternal heart rate be monitored electronically. This is probably unnecessary if the mother appears well throughout but could be important if tocolysis is used.

If tocolysis is employed, this can be given in a variety of ways: 10 μg of hexaprenaline given intravenously over 1 minute, terbutaline 0.25 mg subcutaneously or in 5 mL of normal saline over 5 minutes intravenously; terbutaline 0.5 μg/minute intravenously or terbutaline 0.5 μg/minute intravenously over 15 to 20 minutes; or ritodrine 0.2 mg/minute intravenously for 20 minutes. Some authors give the chosen tocolytic as a stat dose and commence the ECV almost immediately. Others increase the dose steadily or wait until adequate uterine relaxation is achieved, all contractions have ceased, or there is softening of the uterus and easy palpation of fetal parts.

The ECV should be performed as one episode by one operator, and continuous pressure on the uterus should be limited to 5 minutes. Many recommend that uterine manipulation should continue for only 10 minutes, although waiting for the fetus to be active spontaneously (helping to dislodge it from the pelvis) and then applying pressure may be advantageous. Others have recommended stimulating the fetus to move using a vibroacoustic stimulator.[70] Mohamed and associates[50] reported that 55% are successful after 1 minute and only 15% require up to 5 minutes continuous pressure on the abdomen. The increased incidence of fetal heart rate abnormalities with failed ECV suggests that persistence in an attempt beyond these suggested times may be counterproductive. The incidence of fetal heart rate abnormalities may be higher when the procedure is unsuccessful. Mohamed and associates[50] also report that 73% were deemed by the obstetricians to be easy versions with 90% of women reporting little or no discomfort.

A variety of techniques of ECV are also employed. A forward or backward somersault can be performed: the forward somersault is the classically described maneuver. A technique is described which involves placing the woman in a steep lateral tilt with her back against the wall behind the examination couch. A forward somersault is recommended if the fetal back is downward and a backward somersault if the fetal back is upward. If the breech is engaged, the breech must first be pushed out of the pelvis with the operator's right hand prior to correction of the presentation. There is a general consensus that vaginal disengagement should not be performed if the breech will not easily come out of the pelvis with abdominal pressure. Occasionally the fetal head is caught under the costal margin and this prevents the disengagement of the breech. In such a case the fetal head should be manipulated down and sideways prior to the disengagement of the breech and forward somersault. The actual version is accomplished using flexion of the fetal head and encouragement of a forward somersault by pressure on the uterus. Some practitioners pause as the breech is about to negotiate the transverse diameter of the uterus and apply acoustic stimulation. This may causes fetal kicking, which assists the version.[70]

If the fetal back is anterior, version is often impossible to achieve, either with a backward or forward somersault. Johnson and associates[70] suggest that fetal acoustic stimulation will convert the anterior to a lateral position in 90% of cases and thus make version possible.

After successful version, the attitude of the fetus should be maintained manually for a few minutes.

The fetal heart can be monitored continuously through the procedure or every 2 minutes. A repeat fetal heart rate tracing should be performed immediately after the ECV. If this is normal, the woman may go home. She should return within a few days so that the position of the fetus can be rechecked. Some practitioners perform a cesarean section if the breech presentation recurs, while others follow their protocol for selection for vaginal breech delivery. Others continue to correct the presentation repeatedly. There is some evidence that the latter approach does result in more vertex presentations at delivery.

Current evidence indicates that ECV performed at term, and particularly with tocolysis, is a safe procedure for carefully selected women. The short-term complications are negligible, and although the long-term complications are harder to determine, overall it seems likely that the benefits will outweigh the risks.

Assessment of the Fetus

The presentation of the fetus should be checked using ultrasound scanning. This should be possible in most cases even if the woman presents in labor. The fallibility of conventional abdominal palpation as a screening test for malpresentation has been demonstrated many times,

including personally by the author! Thorp and associates[71] showed that palpation only had a sensitivity of 28% and a specificity of 94% in the detection of breech presentation, using ultrasound scanning as the "gold standard."

X-ray erect lateral pelvimetry (see later discussion) to investigate pelvic capacity has been traditional but has been increasingly abandoned because of a possible long-term increased incidence of myelodysplasia.[72] If used, CT scanning is preferred because it reduces the radiation dosage. The presentation of the fetus can be confirmed at the same time. Radiologic exclusion of a nuchal arm, with an estimated incidence of 4%, has been suggested as a possible advantage, because this complication can produce delay and trauma during the second stage of labor. Magnetic resonance imaging is being used in some centers, but the same caveats about the value of the measurements apply.

As x-ray pelvimetry is abandoned, assessment of the fetus using ultrasound has become mandatory. If ECV is contemplated, then placental site, adequacy of fetal growth, and liquor volume are the minimum information required from ultrasound examination. More detailed information about the fetus should be obtained if vaginal delivery is being contemplated. Ultrasound examination will provide an estimate of fetal weight, which is crucial to the management of breech delivery. However, it should always be remembered that estimation of fetal weight has, at best, an error of ± 15%, which is ± 600 g in the 4-kg fetus. Chauhan and associates[73] have also demonstrated that fetal weight is less accurately estimated in the breech- than in the vertex-presenting infant. Placenta previa should also be excluded, as far as possible, prior to any decision about ECV or the mode of delivery. It has been suggested that, prior to attempts at ECV or vaginal breech delivery, a nuchal cord should be excluded on ultrasound examination. Successful detection of a nuchal cord has been reported but is unlikely to be practicable on a routine basis.

The validity of ultrasound measurement of fetal size measurements, especially the biparietal diameter, has long been debated. Bader and associates[74] performed ultrasound measurements in 450 fetuses in breech presentation and compared them with 1880 fetuses in cephalic presentation between 15 and 40 weeks' gestation. They found no difference between the biparietal diameter, head circumference, and the cephalic index (CI = BPD/occipital frontal distance × 100) in the two groups in uncomplicated pregnancy. However, in complicated pregnancies the CI was found to be lower in breech-presenting fetuses, indicating the dolichocephalic head shape that is commonly noted (the complications included premature rupture of the membranes, premature labor, intrauterine growth restriction, fetal anomaly, polyhydramnios or oligohydramnios, drug and alcohol abuse, maternal diabetes, and hypertension.) Neck hyperextension (the stargazing fetus) is an important condition that can cause spinal cord and brain injuries at delivery. Proposed etiologies are cord around the neck, fundal placenta, spasm of the fetal musculature, and fetal and uterine anomalies. It is of interest that most mammals

other than the human deliver their young with the neck of the fetus in a hyperextended position. Flexion of the neck in the human fetus is probably an adaptation to the necessity of delivering a large brain in a large fetal skull through a relatively small pelvis. Although the incidence of neck extension in the fetus has been quoted as 7.4%,[44] its significance is hard to ascertain. It is regarded as an unfavorable prognostic sign with regard to successful vaginal breech delivery, but few authors indicate how it is to be diagnosed ante partum. Rojansky and associates[75] have validated the ultrasound determination of fetal neck extension comparing ultrasound scans with the "gold standard" of x-rays and found a high correlation. They measured the craniospinal angle by obtaining a sagittal view of the fetus visualizing the orbital ridge and the occipital eminence along with the spine in the same plane. A line is drawn between the orbital ridge and occipital eminence and the angle formed with the second line, which passes through the cervical and thoracic vertebrae, is measured. Other adverse features if ECV or vaginal breech delivery are contemplated include intrauterine growth restriction and rhesus isoimmunization.

Choice of Mode of Delivery – Vaginal Breech Delivery

It was not until the late 1950s that the increasing safety of cesarean section led to it becoming the preferred mode of delivery, and elective cesarean section began to be recommended on a routine basis to minimize perinatal morbidity and mortality. In the 50 years that followed, the controversy continued until the frequent calls for a randomized controlled trial were finally answered.[76] Clinicians now have robust data on which to base their recommendations. These data strongly supports the view that elective cesarean section is the safest option for the baby, at a marginally increased risk to the mother.[77,78]

Risks of Vaginal Breech Delivery for the Fetus

The risks and benefits of vaginal breech delivery are shown in Table 64–3.

TABLE 64–3

Risks and Benefits of Vaginal Breech Delivery for the Fetus

Risks
Poor condition at birth
Intracranial hemorrhage
Medullary coning
Severance of the spinal cord
Brachial plexus injury
Occipital diastasis
Fracture of the long bones
Epiphyseal separation
Rupture of internal organs
Long-term neurologic damage
Genital damage in the male
Hypopituitarism
Damage to the mouth and pharynx
Benefits
Reduction in idiopathic pulmonary hypertension

SHORT-TERM NEONATAL/PERINATAL OUTCOME AND FOLLOW-UP
